GEOTHERMAL HEAT PUMPS

Ladislaus Rybach
Geowatt AG Zurich, Zurich, Switzerland

Definition

A geothermal heat pump (GHP) is a heating and/or cooling system that moves heat to or from the ground. It uses the earth as a heat source (in the winter) or a heat sink (in the summer). Geothermal heat pumps are also known by a variety of other names, including ground-source, geoexchange, earth-coupled, earth energy, or water-source heat pumps. They can be designed and installed in sizes from a few thermal kW to several MW capacity (the latter in modular assemblage). Currently GHPs represent the largest share in geothermal direct use and account mainly also for the global growth.

The resource

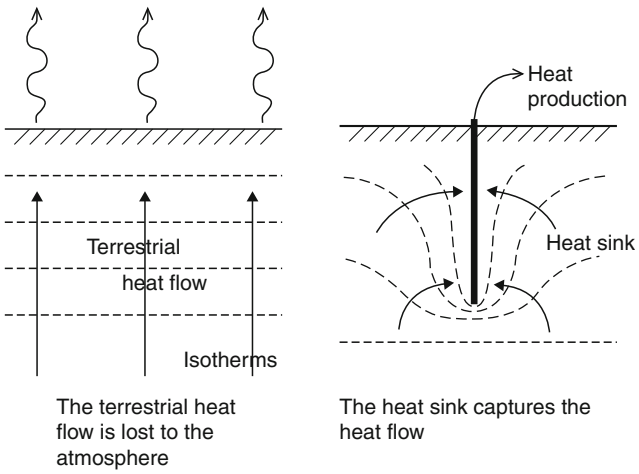
Shallow geothermal resources (the heat content of rocks in the top few meters of the continental crust) represent a major and ubiquitous energy source. The earth as planet can afford to give off heat by a thermal power of 40 million MW, without cooling down. Without utilization, the terrestrial heat flow is lost to the atmosphere. In this case, the isotherms run parallel to the earth's surface (i.e., horizontal in flat terrain) and the heat flow lines are perpendicular to them. If, instead, the heat flow can be captured, e.g., by a heat extraction device like

a borehole heat exchanger (BHE) (see later), the isotherms are deformed and the heat flow lines can be diverted toward heat sinks (Figure 1).

Geothermal heat pump (GHP) technology

A new chapter in the history of geothermal applications in buildings opened with the advent of geothermal heat pumps. This technology enables space heating, cooling, and domestic warm water production with the same installation. The GHP application is now in the focus of private, public, and municipal interest (Banks, 2008).

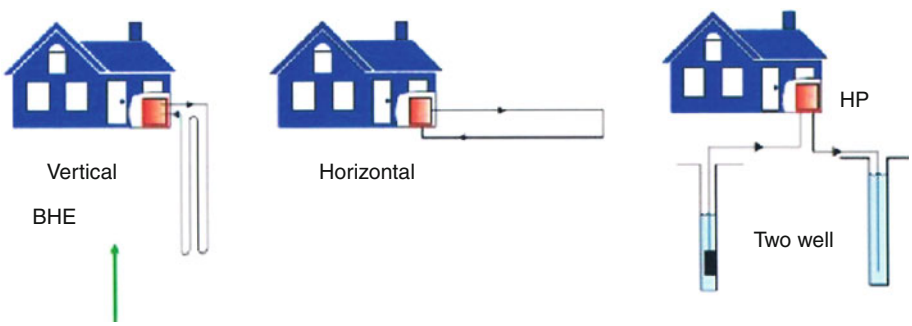
Geothermal heat pumps (GHPs) are one of the fastest growing applications of renewable energy in the world and definitely the fastest growing segment in geothermal technology, in an increasing number of countries (Rybach, 2005). GHP represent a rather new but already well-established technology, utilizing the immense renewable storage capacity of the ground. GHPs use the relatively constant temperature of the ground to provide space heating, cooling, and domestic hot water for homes, schools, factories, public buildings, and commercial buildings. The applicational size can vary from single-family homes with 1–2 borehole heat exchangers (BHEs) to large-scale complexes with hundreds of BHEs. The decentralized systems can be tailor-made, taking into account the local conditions. It is essential to employ proper installation design that takes into account meteorologic, ground property, and technical supply conditions. By these means, reliable long-term operation can be secured. Of the local conditions, the thermal conductivity of ground materials and the groundwater properties are of key importance.



Geothermal Heat Pumps, Figure 1 Principle of geothermal heat extraction and production.

There exist mainly two types of geothermal heat pumps (Figure 2). In ground-coupled systems, a *closed loop* of plastic pipe is placed in the ground, either horizontally at 1–2 m depth or vertically in a borehole down to 50–300 m depth. A water-antifreeze solution is circulated through the pipe. Thus, heat is collected from the ground in the winter and optionally heat is rejected to the ground in the summer. An *open loop* system uses groundwater or lake water directly as a heat source in a heat exchanger and then discharges it into another well, a stream, or lake, or even into the ground. The installation of horizontal coils needs relatively large surface area and extensive earthworks (digging the ground down to the level of coil layout); the prerequisite for extracting the heat of groundwater is the presence of a shallow water table. For these reasons, the most widespread technology of shallow heat extraction is by BHEs. Heat extraction is established by closed-circuit fluid circulation (a few m^3/h of pure water or with an antifreeze additive) through the BHE and the evaporator side of the heat pump.

Three basic components make up a GHP system: (1) the heat extraction/storage part in the ground, (2) the central heat pump, and (3) the heat distributor/collector in the building (e.g., floor panel). The key component is the heat pump. In essence, heat pumps are nothing more than refrigeration units that can be reversed. In the heating mode, the efficiency is described by the coefficient of

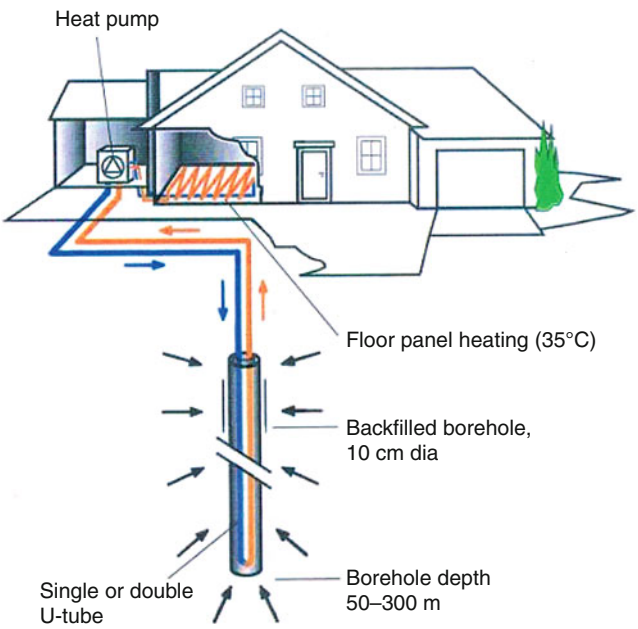


Geothermal Heat Pumps, Figure 2 Closed loop and open loop (groundwater) heat pump systems. The arrow indicates the most common system, with borehole heat exchangers (BHE). The heat pump (HP) is the red box in the house. (Modified from Lund et al., 2004).

performance (COP) which is the heat output divided by the electrical energy input for the heat pump. Typically, this value lies between 3 and 4 (Rybach, 2005). Except for larger, singular applications where gas-driven heat pumps are used, most heat pumps use electricity for their compressors. Therefore GHPs are electricity consumers. The source of electricity varies from country to country; it would be elegant if the electricity to drive the GHP heat pumps would originate from renewable sources like solar, wind, or even geothermal! The principal components of a BHE-based GHP system are depicted in Figure 3.

Heating and cooling with GHPs

As mentioned above, GHP systems can provide space cooling also. In moderate climate, the ground below about 15 m depth is significantly colder than outside air in summer. Thus, a large geothermal store with favorable heat capacity is available where the heat can be exchanged (extracted from the building and deposited in summer, extracted from the ground store and supplied to the building in winter). The thermal capacity of the system depends, besides the volume, on the thermal and hydrogeologic characteristics of the installation site; these must be carefully considered in system dimensioning. In summer, most of the time the heat pump can be bypassed and the heat carrier fluid circulated through the ground by the BHEs and through the heating/cooling distribution (e.g., floor panels). By these means, the heat is collected from the building and deposited in the ground for extraction in the next winter (Lund et al., 2003).



Geothermal Heat Pumps, Figure 3 Sketch of a GHP system with a single BHE. Horizontal/vertical arrows indicate circulation in the U-tube heat exchanger, oblique arrows indicate heat extraction from the ground (heating mode in winter). In summer the oblique arrows are reversed; heat is extracted from the building and stored in the ground.

Design, costs

BHEs can be installed in nearly all kinds of geologic material. Design and installation must consider numerous influence factors. The sizing must consider the demand characteristics of the object to be supplied (size, extension; heating alone, or heating + domestic water, combined heating/cooling) as well as the local site conditions (climate, ground properties). The key ground property is the thermal conductivity of the ground surrounding the BHE. The higher the rock thermal conductivity λ (W/m,K), the higher the specific heat extraction rate (W/m) and the energy yield (kWh/m,a) per unit BHE length (see Table 1).

The installation and operation of a BHE/HP system needs installation and running costs. BHE drilling and installation costs amount to about 50 US$ per meter in the USA and about 70 € per meter length in Europe. The operational cost is significantly less than with fossil-fueled systems. Currently, the price of heat and cold provided by GHP systems is comparable with conventional systems; GHP installation cost payback (the period of years before the savings in annual operating costs exceed the initial premium of an installation) ranges from 4 to 10 years, depending on the size and complexity of the system.

GHPs represent by far the fastest growing market in geothermal development. In the USA, over 100,000 systems are installed annually (IGSHPA, 2009a). Annual GHP sales reached 35,000 units in Germany in 2008, and 40,000 units in Sweden in 2007 (EGEC, 2009). In Switzerland, over 2,000 km borehole length was drilled in 2008 to install BHEs (Rybach and Signorelli, 2010).

Licensing, environmental benefits

In general, GHP installation needs permits. In most countries, the water protection agencies (local, regional, national) are providing permits. Regulation varies from country to country, in some cases even within the same

Geothermal Heat Pumps, Table 1 Borehole heat exchanger performance (single BHE, depth ~ 150 m) in different rock types. From Rybach (2001)

Rock type	Thermal conductivity ($W\,m^{-1}\,K^{-1}$)	Specific extraction rate (W per m)	Energy yield ($kWh\,m^{-1}\,a^{-1}$)
Hard rock	3.0	max. 70	100–120
Unconsolidated rock, saturated	2.0	45–50	90
Unconsolidated rock, dry	1.5	max. 25	50

country. Usually, some standard forms need to be filled and submitted. It is common practice that in groundwater protection areas the installation of GHP systems is limited or forbidden.

GHPs operate with little or no greenhouse gas (GHG) emissions since no burning processes are involved. GHPs driven by fossil-fueled electricity reduce the CO_2 emission by at least 50% compared with fossil-fuel-fired boilers. If the electricity that drives the geothermal heat pump is produced from a renewable energy source like hydropower or geothermal energy, the emission savings are up to 100%.

Reducing current CO_2 emissions is the central option in all the efforts to mitigate global warming. Here, a clear distinction must be made between actual emission reduction and merely avoidance of additional emission: by new GHPs only additional CO_2 emission can be avoided ("saving"), not a reduction of actual emissions. When GHPs are installed in refurbishment (to replace fossil-fueled systems), actual emission reduction can be achieved. Emission reduction is also evident when electric heater/cooler installations, driven by fossil-based electricity, are replaced by GHP systems.

Applications, development trends

There is a growing number of successful examples of GHP applications, for all kinds of buildings of highly varying sizes. The largest installation currently under construction is the geothermal store at the Bell State University (Indiana, USA) campus, with 4,100 BHEs, each 120 m deep (IGSHPA, 2009b). Several international organizations cover and/or promote the applications of GHPs. Here, only a few links are provided.

- International Ground Source Heat Pump Association (IGSPHA) http://www.igshpa.okstate.edu/
- Geothermal Heat Pump Consortium (GHPC) http://www.geothermalheatpumpconsortium.org/
- International Energy Agency Heat Pump Centre http://www.heatpumpcentre.org/
- European Heat Pump Association (EHPA) http://www.ehpa.org/

Besides, there are national associations active in many countries.

Most GHP systems operate with borehole heat exchangers (BHEs). In the early days of BHE applications, the boreholes have been drilled outside the objects to be served by the GHP installations. Nowadays, also dictated by the high prices of land, the boreholes are more and more located beneath of the buildings to be erected.

Energy piles are now becoming increasing popular. At many locations, the ground properties are such that load-bearing rock formations occur only at some depth. Therefore, foundation piles need to be placed to secure firm standing of buildings. These piles can be equipped with heat exchanger pipes; the assemblage is then called "energy pile." Special care must be taken to secure that the temperature changes caused by heat extraction and storage does not affect the pile/ground contact. A special handbook has been published in Switzerland that describes design, installation, and operation of energy pile systems (SIA, 2005).

Summary

Currently, geothermal heat pumps (GHPs) represent the fastest growing branch in the utilization of geothermal energy. There are various factors that can lead to the successful dissemination of the GHP technology. Promoting factors are manifold: technical, economic, environmental awareness, governmental support, etc. The most important driving force is simply knowledge and know-how. Besides, various applications and wide-scale realizations, high-level quality assurance and successful demonstration facilities are needed.

The use of GHP systems represents an important contribution of renewable energies to the mitigation of climatic warming: the increasing use of the environmentally friendly geothermal technology enables the saving of great amounts of fossil fuels, avoid corresponding CO_2 emissions and, in the case of the application of GHP systems in building renovation, it results in a significant emission reduction. It can be expected that GHP systems, along with other geothermal technologies (especially for power generation), will further increase the benefits to future generations.

GEOTHERMAL RECORD OF CLIMATE CHANGE

Michael G. Davis[1], David S. Chapman[1], Robert N. Harris[2]
[1]Department of Geology and Geophysics, The University of Utah, Salt Lake City, UT, USA
[2]College of Oceanic and Atmospheric Sciences, Oregon State University, Corvallis, OR, USA

Introduction

Because changes in temperature at the Earth's surface are transferred to the subsurface through the process of thermal diffusion, past changes in decadal and centennial surface temperature trends are now evident in subsurface temperatures. Thus, temperature-depth measurements in boreholes register not only the heat flowing out of the Earth but also transient departures from the background attributable to past surface temperature changes (e.g., Lachenbruch and Marshall, 1986; Pollack and Chapman, 1993; Pollack and Huang, 2000; Beltrami, 2002a; Harris and Chapman, 2005). Identifying and interpreting these transient departures in terms of the past few hundred years of surface temperature change is now known as the geothermal method of climate reconstruction. Because thermal diffusion behaves as a low-pass filter, such that high-frequency changes in surface temperature are attenuated more quickly and at shallower depths than longer-term changes, this method is most useful in identifying centennial scale climatic trends. The geothermal method of climate reconstruction has several benefits including (1) bypassing the empirical temperature calibration inherent with proxy records of climate change; (2) extending coverage to remote and widely dispersed continental sites where meteorological instrumental records are not available; and (3) establishing a surface baseline temperature prior to the industrial revolution when anthropogenic greenhouse gases started their unprecedented growth phase.

The geothermal method of temperature reconstruction

The geothermal method of temperature reconstruction is most easily understood in terms of the one-dimensional heat diffusion equation,

$$\frac{\partial T(z,t)}{\partial t} = \alpha \frac{\partial^2 T(z,t)}{\partial z^2}, \tag{1}$$

where T is temperature, z is depth, t is time, and α is thermal diffusivity. Time and depth are scaled nonlinearly through the thermal diffusivity such that a surface temperature change at time t prior to the present is largely captured within a depth, l, called the thermal length:

$$l = \sqrt{4\alpha t}. \tag{2}$$

Because the thermal diffusivity of rocks is about 1×10^{-6} m^2 s^{-1}, the majority of the past 100 years of surface temperature change is stored within the upper 150 m of the Earth; the majority of the last 1,000 years of surface temperature change is captured in the uppermost 500 m. Careful analysis of curvature in the upper few hundred meters of a temperature-depth profile, therefore, can be used to reconstruct surface temperature change over the past millennium (e.g., Huang et al., 2000; Harris and Chapman, 2001; Beltrami, 2002b; Pollack and Smerdon, 2004).

Useful analytical solutions to Equation 1 for a temperature-depth profile resulting from simple functional changes of temperature at the Earth's surface include the following (Carslaw and Jaeger, 1959; Lachenbruch and Marshall, 1986; Chisholm and Chapman, 1992):

(a) Single step ΔT change in surface temperature at time τ before present,

$$\Delta T(z) = \Delta T erfc\left(\frac{z}{\sqrt{4\alpha\tau}}\right), \tag{3}$$

(b) Multiple step ΔT_i changes in surface temperature at respective times τ_i before present,

$$\Delta T(z) = \sum_{i=1}^{n} \Delta T_i erfc\left(\frac{z}{\sqrt{4\alpha\tau_i}}\right), \tag{4}$$

and

(c) A single ramp change in surface temperature starting at time τ before present and with amplitude ΔT when the temperature log is obtained,

$$\Delta T(z) = 4\Delta T i^2 erfc\left(\frac{z}{\sqrt{4\alpha\tau}}\right), \tag{5}$$

where the complementary error function is denoted by *erfc* and $i^2 erfc$ indicates the second integral of the complementary error function.

Interpretations of surface temperature change from the geothermal method of climate reconstruction are most confident when curvature in the temperature-depth profile can be shown to be transient and fully attributable to a changing surface temperature in the past. Because the Earth is not homogeneous, phenomena and processes other than a changing surface temperature can also cause curvature in temperature-depth profiles. Steady-state source of curvature includes variations in subsurface thermal conductivity, radioactive heat production, heat refraction due to topography, and differential solar insolation due to variations in slope and azimuth. Transient sources of curvature include: changes in ground surface temperature (GST) in response to changes in surface air temperature (SAT), spatial changes in surface temperature around the borehole caused by temporal variations in albedo, non-isothermal groundwater flow, precipitation, and other microclimate effects (e.g., Beck, 1982; Chisholm and Chapman, 1992; Lewis and Wang, 1992; Harris and Chapman, 1995; Bartlett et al., 2004). Chisholm and Chapman (1992) and Harris and Chapman

(1995) explore the magnitude of many of these effects quantitatively. While most studies of climate change inferred from borehole temperature profiles attempt to select sites that minimize these non-climatic sources of borehole temperature profile curvature, it is often difficult to partition curvature between steady-state and transient sources of curvature. Repeated temperature measurements in the same borehole can help improve the confidence in separating and interpreting steady-state and transient sources of curvature (Davis et al., 2010).

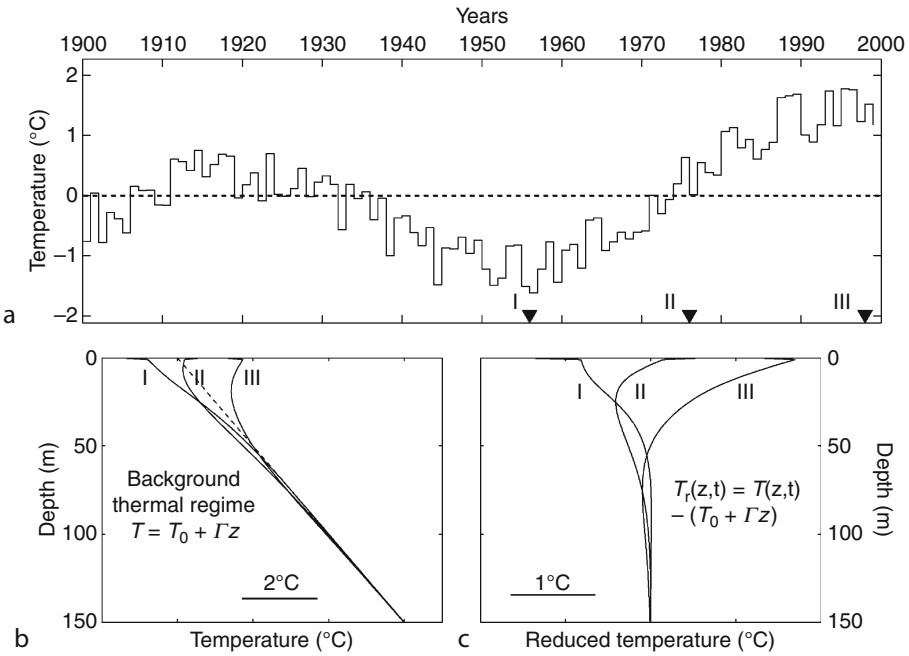
Tutorial

Important elements of the geothermal method of climate reconstruction are illustrated in Figure 1. First, consider a ground surface temperature (GST) that is essentially constant in time (dashed line; Figure 1a). In this case, the measured borehole profile has no transient curvature and the surface temperature intercept is equal to the GST (Figure 1b). However, if the GST is not constant, but fluctuating in some way such that there is a deviation from the mean GST, it will impart curvature to the subsurface according to Equation 1 (Figure 1b). For interpretations of climate change based on temperature profiles, one is interested in the departures from the background thermal regime. To highlight these departures, we compute reduced temperatures expressed as

$$T_r(z) = T_{obs}(z) - (T_o + \Gamma z), \tag{6}$$

where T_o is the reducing intercept and Γ is the reducing gradient. In Figure 1c, the background gradient has been removed, making the anomalous temperature strikingly apparent. The transient nature of the anomaly is illustrated by measuring the borehole temperatures at several times. The three temperature-depth profiles marked I, II, and III in Figures 1b and 1c were measured at three different times shown by the solid triangles in Figure 1a. Cooling from 1915 to 1955 creates a negative transient in the 1955 log I. Surface warming since 1955 results in warming features in the temperature-depth logs II and III that propagate deeper with time. This example also illustrates the low-pass smoothing of thermal diffusion. While trends in subsurface curvature can be related to trends in GST, individual annual means are not apparent. Further, the magnitude of GST change is much better resolved than the timing of the change, consistent with the physics of diffusion (Chisholm and Chapman, 1992).

Because SATs represent the gold standard of temperature change, and because climatic proxies such as tree rings are empirically calibrated to SATs, a final step is often taken whereby derived changes in GST are related to SATs. Many borehole temperature-depth profiles are located in areas where SAT records exist and the combination of datasets offer additional information about surface

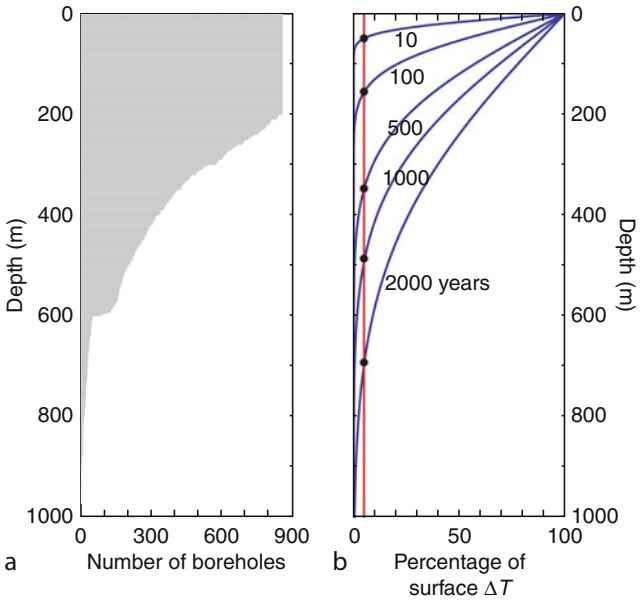


Geothermal Record of Climate Change, Figure 1 Basic aspects of the geothermal method of climate reconstruction. (**a**) An arbitrary time series of surface temperatures for the last century. Dashed line represents a climatic history with no temperature change. Triangles indicate times of borehole temperature logs illustrated in (**b**) and (**c**); log I in 1955, log II in 1975, and log III in 1998. The method asserts that changes in ground surface temperature (GST) are manifested as transient departures from the background, steady-state thermal regime. (**b**) Temperature-depth profiles for times I, II, and III. The linear profile results from the zero change scenario in (**a**) – dashed line. (**c**) Reduced temperature-depth profiles with background removed at times I, II, and III.

temperature change. Techniques to compare or use borehole temperatures with surface records include overlaying a GST reconstruction on an appropriate SAT curve (e.g., Huang et al., 2000) or using an appropriate SAT curve as a forcing function and comparing the resulting transient temperature-depth curve to a reduced temperature profile (e.g., Harris and Chapman, 2001). In this second technique, the best-fitting initial temperature, sometimes called the pre-observational mean (POM; Chisholm and Chapman, 1992; Harris, 2007), is found by minimizing the fit between the reduced temperatures and the synthetic transient calculated from the SAT time series. An obvious uncertainty in this step is the nature of coupling between air and ground temperatures. Regional comparisons at the centennial timescale generally show good agreement between changes in air and ground temperature (Huang et al., 2000; Harris and Chapman, 2001; Beltrami, 2002b; Pollack and Smerdon, 2004). Modeling studies using General Circulation Models allow comparisons between changes in air and ground temperatures at longer timescales and also suggest good agreement between these measures (Gonzalez-Rouco et al., 2003, 2006). Questions regarding changes in the relationship between air and ground temperatures have prompted detailed investigations often in combination with other meteorological parameters (e.g., Smerdon et al., 2003, 2004, 2006; Bartlett et al., 2006; Chudninova et al., 2006; Stieglitz and Smerdon, 2007). These studies have found that variations in air and ground temperatures generally track each other over the time period of study.

A global geothermal climate change database

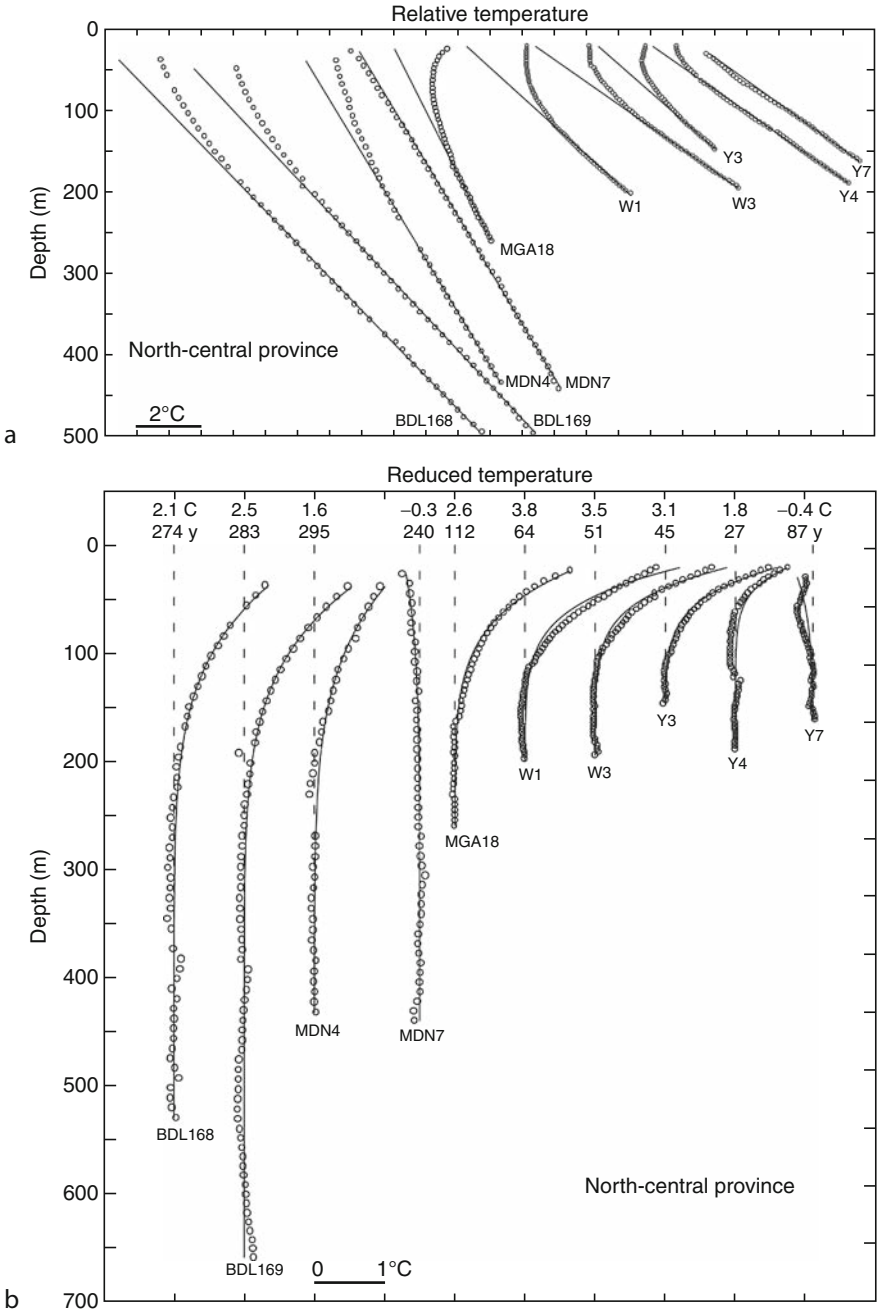
An archive of borehole temperature profiles at 862 sites (Huang et al., 2000) suitable for studying climate change has been compiled at the University of Michigan. Individually, the boreholes exhibit many characteristics of the meteorological record of climate change: hemispheric scale variation, regional variation, local effects, and noise. Collectively, however, borehole temperatures show clear evidence of significant twentieth century warming and a potential for inferring longer-term climate change (Huang et al., 2000). Figure 2a shows a histogram of the number of boreholes in the global climate borehole database with temperature observations to a given depth. Boreholes at all 862 sites extend to at least 200 m depth, one criteria for inclusion in the archive. Half of the boreholes are deeper than 350 m but fewer than 10% extend more than 600 m into the subsurface. The depth distribution of boreholes is important because the depth of borehole temperature anomalies is related to the timing of surface temperature changes (Equation 2), as shown in Figure 2b. The resolution of borehole temperature measurements can generally resolve a surface temperature signal that is greater than 5% of the surface temperature change. Figure 2b shows that to reconstruct past surface temperature adequately for the entirety of the last millennium, temperature-depth measurements must be collected over at least 500 m. In practice, these records must be deeper than 500 m so that the background thermal gradient and surface temperature intercept can be adequately estimated (Equation 6).



Geothermal Record of Climate Change, Figure 2 (**a**) The number of boreholes in the global climate borehole database with temperature observations to a given depth (*shaded*). (**b**) Temperature versus depth at times following a step change ΔT in surface temperature. Solid dots mark depths where the signal is 5% of the surface change.

Temperature-depth profiles

An ensemble of climatically perturbed temperature-depth profiles from India (Roy et al., 2002) is shown in Figure 3a. The boreholes are from the north-central climatic province of India. The first-order effect shown in these profiles is the general increase in temperature with depth, consistent with an upward flux of heat toward the Earth's surface. The deepest part of the borehole temperature profiles has a constant background thermal gradient. Figure 3b shows the reduced temperature profiles where the background gradient and surface temperature intercept have been removed (Equation 6), illustrating the transient temperature departures in the uppermost 200 m of the boreholes. The transient departure from a steady-state background signal is most consistent with a ramp change of amplitude −0.3–3.8°C starting 27–295 years ago. This example is notable because it shows the predominantly warming signal shown in ground temperatures consistent with surface temperature warming over the past two centuries, as well as the site-specific climatic conditions recorded in subsurface temperatures.



Geothermal Record of Climate Change, Figure 3 (**a**) Plots of temperature-depth data (*open circles*) obtained at 10 selected sites from the north-central climatic province of the Indian peninsula (Modified from Roy et al., 2002). The background temperature profiles (*solid lines*) are obtained by fitting a line just below the curved upper portion in each temperature-depth profile. Temperatures below 500 m are not displayed. (**b**) Reduced temperature profiles (*open circles*) for the 10 boreholes are shown in (**a**). Each profile is offset to avoid overlap and plotted relative to zero reduced temperature (*dashed line*). Solid lines show the best-fitting ramp models for the reduced temperature profiles. The magnitude and onset time of the ramp model are shown at the top of the profiles. See Roy et al. (2002) for more details.

Repeat temperature logs

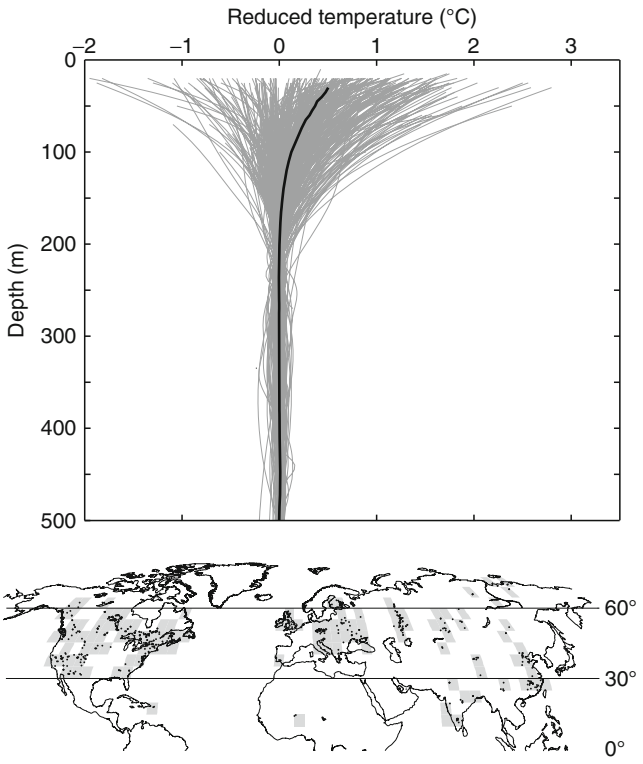
The regional analysis of Davis et al. (2010) employed multiple repeat temperature-depth profiles from three individual boreholes in northwestern Utah over nearly 30 years to provide observational constraints for understanding the relationship between ground and air temperatures. A key part of the study was to calculate and compare synthetic temperature profiles from nearby SAT records to the

observed temperature profiles. The synthetic profiles closely fit observed temperature-depth profiles and match both the amplitude and pattern of subsurface transient changes. Further, forward modeled ground temperatures and differences between temperature logs isolate transient variations and indicate that the observed profiles can be ascribed to changes in GST (Davis et al., 2010). Such observations of transient temperatures in boreholes offer strong support for using GST histories to complement SAT data and multi-proxy reconstructions in climate change studies.

Temperature reconstruction analysis

Several groups have used boreholes to analyze past temperatures on both regional (e.g., Lachenbruch and Marshall, 1986; Beltrami and Mareschal, 1991; Chisholm and Chapman, 1992; Harris and Chapman, 1995; Roy et al., 2002; Davis et al., 2010) and global (e.g., Huang et al., 2000; Harris and Chapman, 2001; Beltrami, 2002b) scales. The temperature reconstruction of Huang et al. (2000) utilized the global database and a Bayesian estimation technique, similar to the functional space inversion of Shen and Beck (1991). The method parameterized the reconstruction into century-long rates over the past 500 years, resulting in a 1.1°C increase over the entire period (Huang et al., 2000). Further analysis of this dataset partitioned the borehole into both hemisphere and continental reconstructions. Huang et al. (2000) found that warming was greatest in the Northern Hemisphere, and greatest in the twentieth century.

Another analysis used a Northern Hemisphere subset of the global database (Harris and Chapman, 2001) to obtain an average reduced temperature profile (Figure 4). The surface temperature record was then used as the forcing function, calculating the best-fitting synthetic profile. This process requires determination of a baseline or POM temperature prior to the beginning of the surface temperature record (Chisholm and Chapman, 1992; Harris, 2007). The result, which combined the POM and the instrumental surface temperature record, indicated that there was approximately 1°C of ground warming over the past 100–200 years (Harris and Chapman, 2001), consistent with proxy methods of paleoclimate reconstruction (e.g., National Research Council, 2006, and references therein) and comparable to other borehole analyses (Huang et al., 2000; Beltrami, 2002b).



Geothermal Record of Climate Change, Figure 4 (*Top*) Northern Hemisphere reduced temperature profiles from Harris and Chapman (2001) and Roy et al. (2002). Lines represent 509 profiles whose locations are shown on the map (*bottom*). Bold line shows average reduced temperature profile. Figure modified from Harris and Chapman (2001).

Summary

Temperature-depth profiles measured in boreholes can be an important record of surface temperature change and can be summarized as follows:

1. Thermal diffusion results in low-pass filtering of changes in surface temperature trends to be related to subsurface curvature. Unfortunately, annual means are not apparent. Further, the depth distribution of borehole temperature anomalies is related to the timing of surface temperature changes.
2. Both globally and regionally, ground temperatures show a predominantly warming signal consistent with surface temperature warming over the past two centuries.
3. Repeated temperature measurements in the same borehole can help improve the confidence in separating and interpreting steady-state and transient sources of curvature.
4. Geothermal climate change reconstruction techniques show approximately 1°C of ground warming over the past one to two centuries, consistent with proxy methods of paleoclimate reconstruction.

Definition

GPS, Global Positioning System, is a US satellite-based navigation system which can accurately determine position, velocity, and time in a common reference system, anywhere on or near the Earth on a continuous basis.

Satellite positioning

Point positioning

Satellite-based point positioning consists in determining the 3-dimensional position (X, Y, Z) of a receiver, using the radio signals emitted by a number of satellites with known position. The receiver, mostly located on the Earth, measures the travel time τ of the radio signal. Then it reconstructs the distance D between the receiver and the satellite by multiplying the travel time τ by its velocity. In the ideal case, neglecting the influence of the Earth's atmosphere, radio signals travel with the speed of light c (299,792,458 m/s) and the distance reads $D = \tau . c$.

Because the receiver and satellite clock are not perfectly synchronized, the measured travel time is corrupted with synchronization errors causing an error on the measured distance with respect to the true satellite-receiver distance. The unknown synchronization error dT between the satellite clock and the receiver clock becomes then the fourth unknown the receiver has to determine, next to the three-dimensional (X, Y, Z) receiver position.

Consequently, to solve this problem with four unknowns, at least four satellites have to be tracked simultaneously.

Relative positioning

Differential or relative satellite positioning is a technique developed to improve the accuracy of satellite point positioning by combining the measured travel time at different receivers. The basic principle consists in reducing the biases at a "remote receiver" using measured biases at a fixed "reference receiver" with known coordinates. This allows removing the errors common to the travel times measured at both stations. The position of the remote receiver (or the baseline vector) is then determined relative to the reference receiver. The corrections may be used in real time or later, using post-processing techniques. The remote receiver can be stationary or moving.

System description

Introduction

Development work on the NAVSTAR/GPS (Navigation by Timing And Ranging/Global Positioning System) started in 1973, when the US Department of Defense (DoD) applied its technical resources to develop a highly accurate, space-based navigation system to replace the TRANSIT system. For background to the development of the GPS system, the reader is referred to Parkinson (1994).

The first GPS satellite was launched on February 22, 1978, and GPS Full Operational Capability (FOC) was declared in July 1995 (US Coast Guard, 1995). FOC status means that the system meets all the requirements specified in a variety of formal performance and requirements documents. The system consists of three major segments: a space segment, satellites that transmit radio signals; a ground segment, ground-based equipment to monitor the satellites and update their signals; and a user segment, equipment which passively receives the satellite signals and converts satellites signals into position and navigation information.

Satellites, signals, and system time

The GPS is designed as a constellation of 24 satellites distributed among 6 orbital planes of which the inclination with respect to the equator is 55°. The orbital planes have a radius of 26,600 km. Each satellite makes two complete orbits each sidereal day. With this constellation, one can always see minimum four satellites from any point on the Earth. In the original GPS design, the satellite signal consists of

- The L1 and L2 carrier waves, with a respective wavelength of 19 and 24 cm
- Information, encoded in the form of binary bits on the carrier signals by a process known as phase modulation:
  - The Coarse/Acquisition code or C/A, which is freely available to the public, is a binary code sequence which repeats every 1 ms. It is transmitted on the L1 carrier at 1.023 Mbps (million bits per second) using a Binary-Phase Shift Keying (BPSK) modulation technique. The "chip length," or physical distance between binary transitions (between digits +1 and −1), is 293 m. Each satellite has a different C/A code, so that it can be uniquely identified.
  - The Precision code or P-code is transmitted on both the L1 and L2 frequencies at 10.23 Mbps with a chip length of 29.3 m and using the same BPSK modulation technique. The P-code repeats every 7 days, and like for the C/A code, each satellite has a unique P-code. Whereas C/A is a courser code appropriate for initially locking onto the signal, the P-code is designed for more precise positioning. The P-code is also not classified, but since January 31, 1994, a process called "Anti-Spoofing" encrypts the P-code in order to prevent an enemy to imitate the GPS signal. To that end, the P-code was modulated with the W-code, a special encryption sequence, to generate the Y-code.
  - The navigation message is modulated at 50 bit/s on the L1 wave on top of both ranging codes. It is sent in blocks of 1,500 bits (taking 30 s to transmit). One message block is subdivided in three parts or five subframes. The first part, or first subframe, contains GPS date and time, plus the satellite's status and an indication of its health. The second part, consisting of the second and third subframe, contains orbit parameters (often called the "broadcast ephemeris") and allows the receiver to calculate the position of the satellite in the earth-fixed WGS 84 system (ICD-GPS-200C, 2000). The last part, consisting of the fourth and fifth subframe, are partly for military use, but also contain information on the ionosphere (8 coefficients of the Klobuchar model, see Klobuchar (1986)), UTC data (Universal Time Coordinated), and the almanac data part. The almanac data contain information and status concerning all the satellites, their locations, and PRN numbers. The first and second parts are identical in all transmitted 30-s blocks. The third part differs as it contains only 1/25 of the entire almanac. Hence, to receive the almanac of the entire constellation, a total of 25 blocks must be received, which takes 12.5 min.

The GPS signal is transmitted with enough power to ensure a minimum signal power level of −160 dBW at the Earth's surface. The orientation of the satellites is always changing, such that the solar panels face the sun, and the antennas face the center of the Earth. More details on the GPS signals can be found in GPS Signal Specifications from the US Coast Guard (GPS-SPS, 1995). For a full description on the generation of the navigation message, we refer to the GPS Interface Specification (IS-GPS-200D, 2004).

New demands on the existing GPS system pushed for a gradual modernization. Within that frame, different

generations of GPS satellites have been developed, where the newer generations contain new satellite signals not present in the original design:

- Block I (no more operational): satellites launched between 1978 and 1985, with an average lifetime of 8–9 years.
- Block II and IIA: launched after 1985, these satellites are able to voluntary degrade the signals and have a typical lifetime of 7.3 years. They contain two cesium and two rubidium atomic clocks.
- Block IIR: launched after 1996, they have a lifetime of 10 years. They contain three rubidium atomic clocks.
- Block IIR-M: launched since 2005, these satellites transmit a second civil signal L2C on the L2 frequency and the military M signal on the L1 and L2 frequencies. The L2C signal aims at improving navigation accuracy, providing an easy to track signal, and acting as a redundant signal in case of localized interference. The satellites contain three rubidium atomic clocks.
- Block IIF: first launch scheduled for May 2010, the satellites will emit a new L5 civil signal providing a second safety-of-life signal that meets the technical requirements for enabling aircrafts to make precision landings in high multipath environments. Future launches of satellites with L5 capability will continue throughout the coming years until a full constellation of 24 satellites emitting L5 will be available by 2018. The satellites will carry four atomic clocks (cesium and rubidium).
- Block III: first launch scheduled for 2014, will carry a new L1C civil code which will be transmitted on L1 in addition to current signals. This seeks to maximize interoperability with Open Service signal of the European Galileo satellite navigation system. Further, Japan's Quazi-Zenith Satellite System (QZSS) will transmit a signal with virtually the same design as L1C. More background on the L1C signal can be found in Betz et al. (2007).

GPS system time is a paper clock based on the atomic clocks in the GPS ground control stations and the GPS satellites themselves. The GPS Control Segment maintains GPS system time to within 1 μs of UTC(USNO) (ICD-GPS-200C, 2000), which is the realization of the UTC kept by the USNO (United States Naval Observatory, Washington, USA). However, GPS system time is continuous and does not follow the UTC leap-seconds. UTC (USNO) itself is kept very close to the international benchmark UTC as maintained by the Bureau International des Poids et Mesures, in Paris.

GPS ground instrumentation

High-end GPS ground instrumentation generally consists of an antenna with hemispherical radiation pattern, connected to a receiver through a coaxial cable. GPS devices for the consumer market generally use small integrated antennas, resulting in a single portable device. For fixed GPS stations, portability is not an issue, but performance in terms of accuracy is. Consequently for this application, better, but larger, antennas and more complex, but more power consuming, receivers are used. Only the high-end instrumentation relevant for scientific use is discussed in this entry.

Antenna

Most GPS antennas in consumer electronics solely receive the primary L1 frequency. As a second frequency, however, allows for, e.g., correction of ionospheric delays which was already intended in the original system design (Spilker, 1978), antennas for high-precision positioning will receive on both L1 and L2. Typically, these high-precision antennas will be mounted on locations with clear sky view in order to be able to track as many satellites as possible. This implies that the cable connecting the antenna to the receiver, somewhere inside a building, will have a length of several meters. To compensate for the signal loss in this cable, most high-precision antennas have a built-in Low Noise Amplifier (LNA). In most cases, the LNA is fed by a dc voltage put on the antenna cable by the receiver.

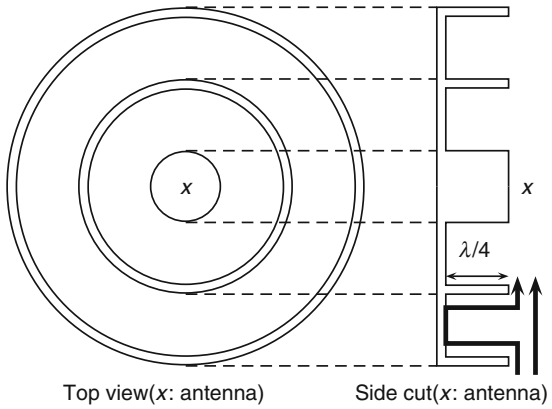
As the fields emitted by the satellites are Right Hand Circularly Polarized (RHCP) (IS-GPS-200D, 2004), any antenna capable of receiving this polarization is able to receive the GPS signals. This can be wire antennas, such as helix antennas or crossed dipoles (e.g., the Dorne Margolin antennas included by many manufacturers), or circular patches.

In many cases, choke rings are added to the antenna in order to suppress the reflections (also known as multipath). These choke rings are cavities with a depth of approximately a quarter of a wavelength. As a consequence, multipath waves, generally coming in from the back side of the antenna, will partly reflect in the cavities. These reflected waves will cancel out with the multipath waves which did not enter the cavity, thanks to a difference in path length of half a wavelength. This working principle is illustrated in Figure 1. The concept of choke rings was first introduced by Jet Propulsion Laboratory (Tranquilla et al., 1989).

As the choke ring is typically a narrow band design, its performance can never be perfect on both L1 and L2 frequencies. Therefore, many design improvements such as dual depth choke rings (Zhodziskhky et al., 1998) were proposed. Another problem linked with the antenna being multiband is the considerable variation of the phase center, which is the physical point where the signal is received. Fortunately, this can be measured and compensated for through an appropriate calibration procedure (Cohen and Parkinson, 1991).

Receiver

A generic GPS receiver consists of a Radio Frequency (RF) part that demodulates the messages transmitted by the GPS satellites, and a positioning part that, based



Gps, Data Acquisition and Analysis, Figure 1 Working principle of the choke ring ground plane.

on the information received from the RF part, determines the position of the user.

Most GPS receivers allow storage of some variables (such as position and speed), and status information (such as system errors), and observables (such as code and phase measurements) in log files for further processing, mostly on removable memory cards. In combination with battery feeding, this should allow for autonomous operation for several days.

The RF block in the receiver demodulates the radio signals of all satellites in view. These signals are received by a single antenna, meaning that the receiver essentially gets a signal from the antenna that is the sum of all satellite signals. The receiver will hence use Code Division Multiplexing (CDM) techniques to extract the messages from the different satellites out of the single received signal (Braasch and Van Dierendonck, 1999). To do so, the receiver duplicates the antenna signal into several identical copies. Each of the identical copies will be sent into a different channel of the receiver. In every single channel, a signature from a different GPS satellite will be sought for, and the navigation message and the propagation delay of this satellite will be extracted. For cost reasons, this duplication is performed after down conversion of the original signal to a lower Intermediate Frequency (IF) and digitization with an Analog to Digital Converter (ADC). Indeed, a digital signal can easily be copied to feed the distinct channels. Contemporary receivers have about 100 such channels.

Using a trial and error procedure by varying Doppler shift, carrier phase, and PRN time delays, the following steps are performed in each of the channels. The first step consists in removing the carrier by a numerical (digital) mixing of the IF signal with an internally generated carrier. The remaining signal only contains the PRN code and data bits. This signal is correlated with the satellite-specific PRN code generated by the receiver for varying time delays. In Figure 2 the correlation with the received signal as a function of the time shift of the internally generated PRN is shown. Once the correlation of the internally generated replica of the PRN and the received signal succeeds, the Doppler shift, carrier phase, and code time delay of a certain satellite signal is determined. The channel is then said to be locked on to that specific satellite. Else, another PRN is tried.

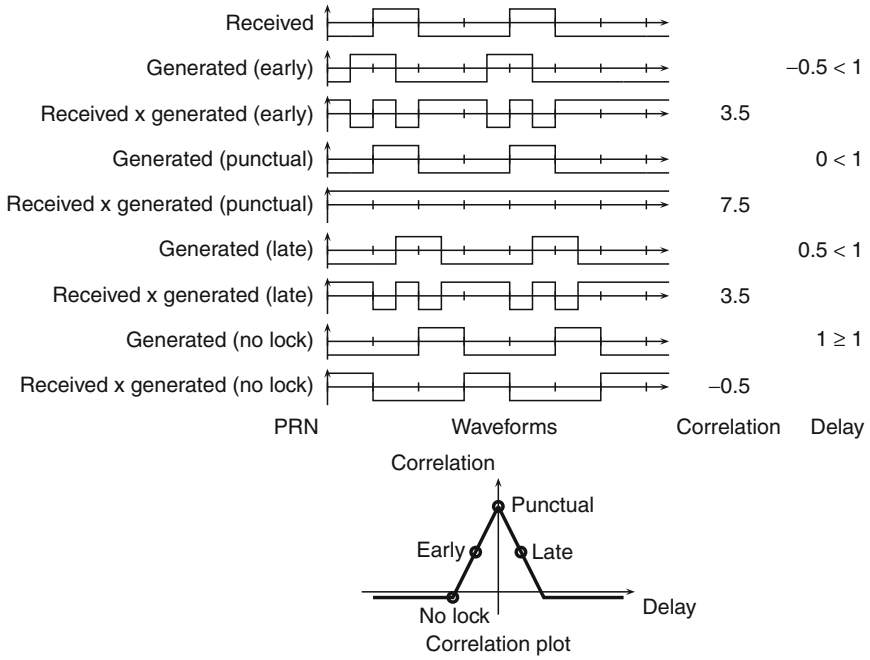
Obviously, the more stable the receiver internal clock (mostly a quartz crystal) is, the more accurately the Doppler shift, carrier phase, and code delay can be determined. However, due to systematic errors, the timescale of the receiver's clock deviates from the GPS timescale. If the difference between both approaches 1 ms, the receiver's time is resynchronized to the GPS timescale, resulting in a time jump, but assuring time correspondence of measurements from different receivers. In addition, signal noise and noise in the channel control loops will cause minor errors in the determination of these variables. These errors, referred to as measurement noise will limit the precision of the position determination.

Only the PRNs of the C/A code, sent on L1, are publicly known. The encrypted Y-code's PRNs cannot be generated by the civil GPS receivers. Consequently, the civil receivers cannot receive the messages that were encoded with the military CDM. However, as the Y-code is sent on both L1 and L2, techniques of cross-correlating the signals on both frequencies are used to still allow determination of difference in arrival time of the P-code ay both frequencies (Woo, 1999).

If the channel is locked to a satellite, the correlation between the received satellite and the internally generated PRN code sequence will be strong. Then, in order to decode the navigation message, the sign of this correlation is investigated. If the correlation is strongly positive, a 1 was sent by the satellite; if it is negative, a 0 was sent. This way, the bits sent by the satellite can be demodulated. The demodulated navigation message, together with the Doppler shift, carrier phase, and pseudo range of the channel are then passed to the positioning block that will combine all information from all channels to determine the receiver's position. Besides using the information from the RF block, the positioning block of most contemporary receivers can also take into account signals from correction streams from neighboring GPS receivers (see Sect. Positioning Modes) or inertia sensors.

Measurements

The basic principle of the GPS measurement is that the GPS receiver determines for each satellite the time shift between the signal emission time and the signal reception time (see the "Receiver" part for more details). By multiplying this time difference with the signal travel speed, the distance between the GPS receiver and emitting antenna of each locked satellite can be reconstructed. As will be shown later, this measured distance does not correspond with the geometric distance separating the receiver and satellite, and is therefore called "pseudo range." As already outlined in the Sect. Receiver, two main types of measurements can be done by the RF block of the GPS receiver:



Gps, Data Acquisition and Analysis, Figure 2 Correlation with the received PRN as a function of time shift of the internally generated PRN.

- Range observations, based on the time shift of the internally generated PRN codes, also called "pseudo-range" measurements.
- Carrier phase observations, based on the phase shift in the numerical IF mixing step in each receiving channel. They are more precise than the pseudo-range type measurements, but have a much higher degree of "ambiguity" than the code ranges.

Code pseudo-range model

The GPS code pseudo-range P_i^k measurement at receiver i to satellite k can be expressed according to the following simplified equation (Wells et al., 1987):

$$\rho_i^k = \rho_i^k + c.\left(dt_i - dt_i^k\right) + I_i^k + T_l^k + \varepsilon_{Pi}^k \tag{1}$$

where ρ_i^k is the geometric range from receiver i to satellite k, dt_i and dt_i^k are, respectively, the receiver and satellite clock offsets from GPS system time, while I_i^k and T_i^k take respectively into account the effect of the ionosphere and troposphere on the signal. Finally, ε_{Pi}^k stands for the measurement noise components, including multipath.

Using Pythagoras Theorem, we know that

$$\rho_i^k = \sqrt{\left(x^k - x_i\right)^2 + \left(y^k - y_i\right)^2 + \left(z^k - z_i\right)^2} \tag{2}$$

with $\overrightarrow{x_i} = (x_i, y_i, z_i)$ and $\overrightarrow{x^k} = \left(x^k, y^k, z^k\right)$ resp. the receiver and satellite positions (at signal transmission time).

For positioning or navigation purposes, the user wishes to determine the receiver position $\overrightarrow{x_i}$. As Equation 2 is a nonlinear equation, it is linearized around the a priori receiver position $\overrightarrow{x_{i0}} = (x_{i0}, y_{i0}, z_{i0})$:

$$\begin{aligned} P_i^k(t_i) = {} & \frac{\left(x_{i0} - x^k\right)}{\rho_{i0}^k} dx_i + \frac{\left(y_{i0} - y^k\right)}{\rho_{i0}^k} dy_i \\ & + \frac{\left(z_{i0} - x^k\right)}{\rho_{i0}^k} dz_i + c.\left(dt_i - dt_i^k\right) \\ & + I_i^k + T_i^k + \varepsilon_{\mathrm{Pi}}^k \end{aligned} \tag{3}$$

where (dx_i, dy_i, dz_i) denotes the deviation of the unknown receiver position with respect to its a priori value and ρ_{i0}^k denotes the geometric range from receiver i to satellite k computed using the a priori receiver position.

For most applications, the satellite position $\overrightarrow{x^k}$ and clock synchronization error dt_i^k can be considered as known. This leaves the following unknowns (dx_i, dy_i, dz_i, dt_i) in Equation 3. As previously mentioned, a minimum of four GPS satellites has to be observed simultaneously to solve for these four unknowns.

Carrier phase model

The GPS carrier phase φ_i^k measured at receiver i to satellite k can be modelled according the following simplified equation (expressed in [m]):

$$\phi_i^k = \rho_i^k + c.\left(dt_i - dt_i^k\right) + \lambda N_i^k - I_i^k + T_i^k + \varepsilon_{\phi i}^k \tag{4}$$

This equation differs from the pseudo-range (Equation 1) as follows:

N_i^k, the initial cycle ambiguity: an integer associated with the first measurement (fractional phase) of a satellite track (or after a tracking interruption). After the initial measurement (and as long as there is no tracking interruption), the receiver keeps track of the cumulative phase differences reflecting the changes in distance to the satellite.

λ, the wavelength of the carrier wave (L1, L2 or any of their linear combinations, see Dach et al., 2007).

$\varepsilon_{\phi i}^k$, the measurement noise of the phase observable, including phase multipath.

But this equation can be linearized in exactly the same way as the code pseudo-range equation (Equation 1).

Remarks

The following comments can be made with regard to Equations 1 and 4:

- These equations are generic and several of the terms in the equations differ depending on the observed code pseudo-range (C/A, P1, or P2) or carrier phase (L1 or L2) signal.
- High-end GPS receivers are programmed to measure GPS satellites simultaneously at the epoch $\mathbf{t_i}$ (e.g., at the full second). Even if the reception times are identical, respective signals leave the satellites at slightly different times because the satellite-receiver distances differ. The signal transmission time t_i^k corresponding to the reception time becomes thus receiver-dependent (hence the use of the double index).
- The receiver clock error is identical in all simultaneous measurements at receiver i from all satellites.
- Using simultaneous code pseudo-range measurements to at least four satellites, the absolute position of the receiver can be computed rather straightforward. This is not possible when using carrier phases as the initial cycle ambiguity is an additional satellite-receiver-dependent unknown which has to be dealt with.
- Note the different sign for the ionospheric effect in Equations 1 and 4. The ionosphere, being a dispersive medium, acts differently on the group velocity (code) than the phase velocity and is consequently delaying the code measurements while it advances the phases (Leick, 2004).

Single and double differences

For relative positioning between two stations (i, j), the observations made simultaneously to the same satellite k are differenced:

$$\begin{aligned}\Delta P_{ij}^k &\cong P_i^k - P_j^k \\ &= \Delta\rho_{ij}^k + c.\Delta dt_{ij} + \Delta I_{ij}^k + \Delta T_{ij}^k + \Delta\varepsilon_{\mathrm{p}ij}^k\end{aligned} \tag{5}$$

$$\begin{aligned}\Delta\varphi_{ij}^k &\cong \varphi_i^k - \varphi_j^k \\ &= \Delta\rho_{ij}^k + c.\Delta dt_{ij} - \Delta I_{ij}^k + \Delta T_{ij}^k + \lambda\Delta N_{ij}^k + \Delta\varepsilon_{\phi ij}^k\end{aligned} \tag{6}$$

$\Delta(.)_{ij}^k$ denotes the single difference. Note that the satellite clock difference errors are eliminated from Equations 5 and 6. If in addition, the difference between the single differences to two satellites k and l is taken, then the so-called double differences are constructed (indicated with $\Delta(.)_{ij}^{kl}$):

$$\Delta P_{ij}^{kl} \cong \Delta P_{ij}^k - \Delta P_{ij}^l = \Delta\rho_{ij}^{kl} + \Delta I_{ij}^{kl} + \Delta T_{ij}^{kl} + \Delta\varepsilon_{\mathrm{p}ij}^{kl} \tag{7}$$

$$\begin{aligned}\Delta\varphi_{ij}^k &\cong \Delta\varphi_{ij}^k - \Delta\varphi_{ij}^l \\ &= \Delta\rho_{ij}^{kl} - \Delta I_{ij}^{kl} + \Delta T_{ij}^{kl} + \lambda\Delta N_{ij}^{kl} + \Delta\varepsilon_{\varphi ij}^{kl}\end{aligned} \tag{8}$$

where the receiver clock difference errors, which are the same for both single differences, are also eliminated.

Although the use of single and double differences has many advantages (see Sect. Errors and Biases), the differencing process increases the measurement noise level by $\sqrt{2}$ for each difference and introduces correlations between the differenced equations. These correlations can, however, be taken into account using the procedure developed in Beutler et al. (1986).

The double difference integer ambiguity ΔN_{ij}^{kl} in Equation 8 plays an important role in accurate positioning, using carrier phase double differences. When the ambiguity is estimated together with the other parameters as a real number, a so-called "float solution" is obtained. If the estimated ambiguities can, however, be successfully constrained to their integer value, then an "ambiguity-fixed solution" is obtained. This process of estimating ambiguity parameters, and then selecting the likeliest integer values, is known as "ambiguity resolution." Once the L1 and L2 ambiguities are resolved, and can thus be removed from the Equation 8, the double differenced phase observations become precise pseudo-range observations.

Errors and biases

Introduction

GPS measurements are corrupted by biases (measurement errors that cause true ranges to be different from measured ranges by a "systematic amount") and errors (internal instrument noise or residual biases) which limit the positioning accuracy. Three groups of GPS errors and biases are generally distinguished: receiver-dependent, satellite-dependent, and signal propagation errors.

Receiver-dependent errors

Measurement noise

The measurement noise is included in the terms $\varepsilon_{\mathrm{P}i}^k$ and $\varepsilon_{\phi i}^k$ within the code pseudo-range (Equation 1) and carrier phase

(Equation 4) measurements. Without biases contaminating the measurements, low measurement noise is expected to result in high accuracy positioning. A "rule-of-thumb" (Wells et al., 1987) states that the measurement noise is at the level of 1%, or better of the wavelength (or chip length) of the signal. In the case of code pseudo ranges, this results in a measurement noise of 3 m for the C/A code and 0.3 m for the P-code. With their shorter wavelength, carrier phase measurements are less noisy implying millimeter noise for carrier phase measurements.

Receiver clock errors

GPS receivers are equipped with relatively inexpensive quartz crystal oscillators. The receiver clock error dt_i contaminates all satellite-receiver ranges. As mentioned in "The code pseudo-range model", the solution to this problem is to treat the clock error as an additional parameter in the code pseudo-range estimation procedure. This allows estimating the receiver clock error with a precision of 10^{-8} to 10^{-7} s which is in addition satisfactory to access the exact measurement epoch of both code and phase measurements. An alternative strategy uses single or double differences see (Equations 5–8) to eliminate the receiver clock errors dt_i.

Antenna-specific errors

The precise point whose position is measured by a GPS receiver is the electrical phase center of the GPS receiver's antenna which is not the physical center of the antenna. The phase center will change with the changing direction of the signal from a satellite. The a priori receiver position $\overrightarrow{x_{i0}}$ has to be corrected for this effect. This behavior is different for each antenna, and modelling it requires precise antenna calibrations (Mader, 2001; Görres et al., 2006; Schmid et al., 2007). GPS antenna calibrations consist of two parts: (1) an average phase center offset with respect to a physical feature of the antenna and (2) the phase center variation (PCV) with respect to the satellite elevation angle and azimuth. Ignoring these phase center variations can lead to serious (up to 10 cm) vertical positioning errors. Even if the antenna calibrations have submillimeter accuracy, the access to absolute high-precision positioning is still limited by site-specific near-field multipath errors (Elósegui et al., 1995) which can introduce systematic biases up to 1–2 cm, mostly in the estimated height component.

Multipath effects, included in terms $\varepsilon^k_{\mathrm{Pi}}$ and $\varepsilon^k_{\varphi i}$ in respectively Equations 1 and 4, are propagation errors arising from the interference of the direct signal by reflected signals from water or metallic surfaces or nearby buildings. The combined direct and reflected signals will give rise to incorrect pseudo-range or phase measurements. Low-elevation signals are more susceptible to multipath effects than those at high elevations. The size of pseudo-range multipath can reach 10–20 m on the C/A code (Evans, 1986), while for the carrier phases, it can have a maximum value of a quarter of a cycle (4.8 cm for L1) (El-Rabbany, 2002).

Using specific antenna design (see Sect. Ground Instrumentation), careful antenna mounting, and advanced signal processing to filter out multipath integrated in the receiver, can reduce the multipath errors. Using differenced code or phase observables will not remove the effect of multipath as the effect is receiver and satellite-dependent. However, when using stationary receivers, an appropriate multipath mitigation can be implemented by taking advantage of the multipath time correlation due to the repeating satellite ground tracks (Wu and Hsieh, 2010).

Cycle slips

If the receiver loses lock on a satellite signal, due to, e.g., obstructions or interference, then the carrier phase observables might suffer from cycle slips. These cycle slips are jumps in the carrier phase measurements caused by the fact that when signal lock is reacquired, the integer initial cycle ambiguity N^k_i of the phase observable will be re-initialized. Cycle slips can occur independently on L1 and L2.

The detection and repair of cycle slips (Kim and Langley, 2002) is an important carrier phase data preprocessing step. Each time the software will detect a cycle slip, the cycle slip will be repaired (to restore the continuity of carrier cycle count) or a new integer initial ambiguity N^k_i will be setup (Jonkman and De Jong, 2000 and Dach et al., 2007). If this is properly done, the cycle slips are not contributing to the error budget anymore.

Satellite-dependent biases

Orbit and satellite clock errors

Computing the a priori geometric range, ρ^k_{oi} (Equation 3) implies known satellite position. The navigation message broadcast by the GPS satellites provides the user in real-time information on the satellite position and clock error. Following the International GNSS Service (http://igscb.jpl.nasa.gov/), the accuracy of the broadcast orbits is at the 1-m level while the satellite clock error is given at the 5 ns level. The effect of the satellite orbit and clock errors (dt^k_i in Equations 4 and 6) propagates directly into the point position results and amplifies the positioning error.

In the case of relative positioning, the orbit errors dr (in m) propagate into errors db (in m) in the coordinates of a baseline of length b following the rule of thumb of Bauersima (1983): $\frac{|db|}{b} = \frac{|dr|}{r}$ where r is the receiver–satellite distance (in km), typically 20,000 km. So, for a receiver inter-distance (or baseline length) of 100 km and an orbit error of 1 m, the error on the baseline components will be of the order of 0.5 cm. Following Beutler (1996), the Bauersima rule is a bit too pessimistic and actually gives mainly an approximation for the propagation of the orbit errors on the estimated height component. For the horizontal component, the error can be divided by a factor of three.

Precise GPS positioning (see *GPS, Tectonic Geodesy*) requires orbits with a higher precision than the ones provided in the broadcast navigation message. For that purpose, the International GNSS Service (IGS, see *Geodesy, Networks and Reference Systems*) uses the tracking data

from a worldwide GPS network to generate the most precise satellite orbits and clocks related to the International Terrestrial Reference system (ITRS). Their accuracy depends on their latency (Dow et al., 2009) but typically varies between 2.5 and 5 cm for the orbits and ±75 to 150 ps for the satellite clocks.

Antenna-specific errors

Each GPS satellite has a transmitting antenna which, like the receiver antenna, also has a phase center which changes with elevation angle and is influenced by the local environment around each satellite. The scientific community, mainly driven by the International GNSS Service, has made considerable efforts to accurately determine the satellites antenna phase center offsets and variations (Schmid et al., 2007). The correct location of this phase center with respect to the satellite's center of mass is critical for accurate orbit determination.

Signal propagation biases

When travelling from the GPS satellites to the receiver on Earth, the radio signals cross and interact with the Earth's atmosphere. The two atmospheric layers that influence the most the propagation of the GPS signals are the troposphere and the ionosphere. The atmospheric refraction has consequently an ionospheric I_i^k and tropospheric T_i^k component, each with their own spatial and temporal characteristics.

Ionospheric refraction

The ionosphere is stretching from a height of about 50 km to more than 1,000 km over the surface of the Earth; it is named so because it is ionized by the Sun's ultraviolet light. When the GPS signals propagate through this medium dispersion occurs, bending the signal and changing its velocity (Klobuchar, 1991). The ionosphere speeds up the propagation of the carrier phase and slows down the PRN code (as can also be seen in Equations 1 and 4). The signal bending can be neglected for satellite elevations larger than 5°.

The ionospheric delay I_i^k is proportional to the number of free electrons along the GPS signal path, called the total electron content (TEC) which varies as a function of the latitude of the receiver, the season, the time of day, and solar activity (approximately 11-year cycle). At first order, the ionospheric delay on the carrier phases reads: $I_i^k = -\frac{1}{\cos z}\frac{40.3}{f^2}TEC$, with z the satellite's zenith distance. It ranges from about 50 m for signals at the zenith to as much as 150 m for low-elevation observations.

To reduce the ionospheric effect, a correction (using the Klobuchar model, Klobuchar, (1986)) is transmitted within the navigation message. However, it is generally conceded that the broadcast correction model corrects only 50–60% of the ionospheric delays, which is considered as the performance level of the model. For single frequency receivers, the use of the correction model parameters is often the only option for point positioning. Another source of information on the behavior of the ionosphere is provided by the IGS from their Global Ionospheric Maps (GIM) which consist of a global TEC grid (2,5° lon × 2.5° lat) available at 2-hourly intervals. The IGS GIM maps have a typical accuracy of 2–8 TEC units (Dow et al., 2009).

In relative positioning, it has been shown by Georgiadou and Kleusberg (1988) that the ionospheric error will induce a baseline shortening dependent of the baseline length. Following Santerre (1991), the estimated receiver positions will suffer from scale and orientation biases. For example, at a midlatitude site using an elevation cutoff angle of 20°, a horizontal scale bias of −0.63 ppm is incurred for each 1×10^{-7} m^{-2} of TEC not accounted for.

As the ionosphere acts as a dispersive medium, the ionospheric delay is frequency-dependent. Hence, if dual-frequency receivers are available a special combination of the L1 and L2 signals, called the ionosphere-free combination L3, can eliminate the first order of the ionospheric effect (Beutler et al., 1988a). The ionosphere-free carrier phase measurement is:

$$\phi_{L3} = \frac{f_1^2}{f_1^2 - f_2^2}\phi_{L1} - \frac{f_2^2}{f_1^2 - f_2^2}\phi_{L2} \tag{9}$$

with f_1 and f_2, respectively, the frequencies of the L1 and L2 signals, and ϕ_{L1} and ϕ_{L2} the carrier phase observables (converted in m) on L1 and L2. A similar equation can be derived to construct the ionosphere-free code measurements. Using the ionosphere-free combination removes 99% of the ionospheric error. For applications requiring the highest positioning precision, the usage of ionosphere-free differenced observables is the most effective way of mitigating the ionospheric effect.

Tropospheric refraction

The troposphere is the lower part of the Earth's atmosphere, and it is the seat of all meteorological phenomenas (clouds, rain, hydrometeors...). It contains approximately 75% of the atmosphere's mass and and 99% of its water vapor and aerosols. The troposphere extends from the surface of the Earth to less than 9 km over the poles to 16 km over the equator (Lutgens and Tarbuck, 1989). For radio frequencies below 15 GHz, it is a nondispersive medium meaning that it delays all GPS codes and carriers by the same amount so that the effect cannot be removed by combining observations made on two frequencies.

The tropospheric refraction delay T_i^k depends on atmospheric pressure, temperature, and water vapor pressure. In addition, it is the shortest in the zenith direction (2 m) and increases when going down to the horizon (about 20–28 m for signals at an 5° elevation angle) as the air mass traversed by the signal increases (Brunner and Welsch, 1993).

The tropospheric delay consists of a dry and wet component. The dry component, which depends on surface pressure and represents about 90% of the delay, can be

easily modelled. The most commonly used model is the Saastamoinen model (1972), which is also recommended by the IERS conventions (2003). Today, the necessary pressure values input to the Saastamoinen model can be derived from numerical weather model data from the European Centre for Medium-range Weather Forecasts (ECMWF), see Boehm et al. (2007). The wet component of the tropospheric delay accounts for the remaining 10% of the delay and depends on the amount of water vapor along the signal path; it is much more difficult to accurately model.

Two kinds of troposphere biases can affect relative positioning (Beutler et al., 1988b): relative and absolute tropospheric biases. Relative troposphere biases are caused by errors of (mismodelled) tropospheric refraction at one endpoint of a baseline relative to the other endpoint, while absolute ones are caused by errors common to both endpoints of a baseline. Relative troposphere biases primarily bias station heights. For example, a relative troposphere bias of only 1 cm leads to an error of approximately 3 cm in the estimated relative station height for an elevation cutoff angle of 20°. This error increases to 19 cm for an elevation cutoff angle of 3°. Absolute troposphere biases produce scale biases of the estimated baseline lengths. For example, an absolute troposphere bias of 10 cm induces a scale bias of 0.05 ppm for an elevation cutoff angle of 20° and of 0.3 ppm for a cutoff angle of 3°.

For high-precision applications where mm accuracy is desired, the tropospheric bias at zenith is parameterized in the final position solution (see IERS Conventions (2003)). For that purpose, different mapping functions (Niell, 2000; Boehm and Schuh, 2004; Boehm et al., 2006) are used to express the dependency between the tropospheric delay at zenith and the one experienced at satellite's zenith distance.

In addition, as with the ionospheric bias, the tropospheric bias is spatially correlated over distances up to several tens of kilometers meaning that differential positioning is an effective strategy for mitigating the effect of the tropospheric bias on positioning results.

Summary

As we have seen, all biases exceeding the measurement noise level have a high probability to degrade the accuracy of the positioning and should therefore be accounted for somehow. Various strategies have been developed to account for them:

- They can be estimated as explicit (additional) parameters, e.g., the receiver clock error and the tropospheric refraction.
- Common-mode biases can be eliminated or mitigated through combination of observables or datasets, e.g., by using of the ionosphere-free observable or relative positioning to mitigate the ionospheric and tropospheric refraction as well as satellite clock and orbit errors.
- The biases can be directly measured, e.g., by using antenna calibrations.
- The biases can be considered known or adequately modelled, e.g., by using precise satellite orbits and clocks from the IGS.
- They can be ignored, e.g., the phase multipath error at moving receivers.

Positioning modes

Two main methods of positioning with GPS exist: point positioning and relative positioning. In addition, the precision of the obtained positions depends on the observables used: code and/or carrier phase data, the interval over which the data are accumulated before being analyzed, and the sophistication of the error modelling.

Point positioning

GPS point positioning employs the data from a single GPS receiver.

Using code pseudo-ranges from at least four satellites, Equation 1 can be used to compute the instantaneous receiver position and receiver clock error. With the broadcast ephemeris and ionospheric correction, a typical position accuracy of 22 m (2D rms) can be achieved using C/A codes. Typically, code pseudo-range positioning is used for low-accuracy real-time land, sea, and air navigation. The distinguishing characteristic of navigation is the *urgency* with which positioning information is required.

A more sophisticated method of performing point positioning uses the ionosphere-free combination of dual-frequency code and carrier phase observables. It is known as Precise Point Positioning (PPP) and allows reaching centimeter-level precision when using long observation series. Kouba and Héroux (2001) show that to reach this precision, it is necessary to use the most precise satellite orbit and clock information (from the IGS) as well as a sophisticated error modelling. For that reason, PPP is at the moment mostly implemented in scientific GPS analysis software such as Bernese (Dach et al., 2007), and GISPY/OASIS (Zumberge et al., 1997). As PPP eliminates the need to acquire simultaneous tracking data from a reference station, it has given rise to centralized geodetic positioning services that require from the user a simple submission of a valid GPS observation file (see, e.g., Ghoddousi-Fard and Dare, 2005). As shown by Bisnath and Gao (2008), PPP has the potential to become a positioning technique that could replace the RTK positioning mode (see next section).

Relative positioning

Relative positioning employs two GPS receivers, a remote and a reference receiver, simultaneously tracking the same satellites (minimally four) to determine their relative coordinates (see Sect. Satellite Positioning). It is based on the ability to eliminate, or significantly reduce, the common measurement biases across observations made simultaneously by GPS receivers see (Equations 5–8 and Sect.

Errors and Biases). Depending on the accuracy requirements, code pseudo-range as well as carrier phase measurements can be used in relative GPS positioning. In addition, relative positioning can be implemented with different latencies varying from real-time to post-processing:

– Carrier-phase-based relative positioning

The basis of high-precision relative positioning is carrier phase measurements because of their low measurement noise. The problem of processing the "ambiguous" carrier phase data can be overcome by collecting sufficient epochs of data (up to 1 h or more) to ensure ambiguity resolution and strengthen the baseline solution. The reliability of the ambiguity resolution depends on:

- Baseline length
- The number of satellites (the more, the better)
- The satellite-receiver geometry
- Whether observations are made on both frequencies (it is much easier to resolve ambiguities when dual-frequency observations are available)
- The length of the observation session (the longer, the better)

Throughout time, GPS ambiguity resolution methods have become more and more sophisticated. The LAMBDA (Least-squares AMBiguity Decorrelation Adjustment method by Teunissen (1995)) allows now even on-the-fly ambiguity resolution using few observation epochs. This is typically necessary when the receiver is in motion.

At one extreme, static GPS surveying is the most precise positioning technique in use today. Observation times vary between 20 min to a day, depending on the expected precision, the distance between the two receivers, the number of visible satellites and the satellite geometry. Measurements are typically taken at intervals between 10 and 30 s. After completing the field measurements, the data are processed on a PC using different processing options depending on, e.g., observation time and baseline length. For long baselines (>20 km), typically ionosphere-free carrier phases will be processed. For very long baselines (>1,000 km), the user will process the data using high-precision scientific GPS analysis software, e.g., GAMIT (Herring et al., 2007) and Bernese (Dach et al., 2007). In this case, mm to cm precision can be reached over distances exceeding 1,000 km. Typical applications are the surveying of crustal or intraplate deformations (see *GPS, Tectonic Geodesy*).

At the other extreme, real-time-kinematic (RTK) GPS is the less precise relative GPS positioning method based on carrier phases. The main differences to static GPS surveying is the drastic reduction of the observation time and the fact that the position of the remote receiver is often computed in real-time. RTK can be carried out in real-time if an appropriate communications link (UHF radio modem, satellite link, cell phone, or other transmission media, cf. Langley, 1993; Weber et al., 2005) is provided over which the carrier phase data collected at the reference receiver can be made available to the remote receiver's onboard computer. In this way, the remote receiver can generate the double differences, resolve the initial ambiguities, and perform the position calculations. Typically, measurements are taken at a 1 Hz rate and initial ambiguities are determined on-the-fly. In order to mitigate as much as possible the error sources, baselines should not exceed 10–15 km to reach the expected positioning precision of the order of 2–5 cm. Cadastre surveying is one of the applications that uses RTK. More information on RTK can be found in Langley (1998).

Other relative positioning modes based on GPS carrier phases are rapid static positioning and stop-and-go surveying (cf. El-Rabbany, 2002). They are lying between the above-mentioned extremes.

– Code-based relative positioning is mostly known as real-time Differential GPS (DGPS). There are two ways to implement DGPS: (1) the fixed reference station broadcasts the differences between the measured pseudo-ranges and actual (internally computed) pseudo range so that it can correct its pseudo-ranges by the same amount before determining its position (method of range corrections); (2) the fixed reference station compares its known position with its computed position and sends the difference to the remote receiver which uses this difference to correct its computed position. The correction signal is broadcast using similar means as uses RTK. Range corrections are the preferred mode for real-time DGPS navigation. DGPS can deliver meter-level positioning that typically ranges between 0.5 and 5 m.

The standard format used to exchange GPS data in real-time is RTCM 104 (cf. RTCM104, 2009). For the exchange of GPS data targeting post-processing, the RINEX format (Gurtner and Estey, 2007) is used.

Conclusion and outlook

GPS positioning is based on measuring the travel times of radio signals emitted by satellites to a receiver mostly located on the ground. These travel times can be obtained by measuring on the precise, but ambiguous, GPS carrier phases or on the, less precise, GPS PRN codes. By multiplying the travel time by the speed of light, the distances receiver–satellites are reconstructed. Using minimally four satellites, the receiver can compute its position. Errors that influence GPS positioning are receiver-related (measurement noise, multipath, receiver clock errors, antenna phase center variation), satellite-related (satellite orbit and clock error, antenna phase center variation) or related to the signal propagation (ionospheric and tropospheric effect). As a lot of these errors are similar for GPS receivers distant of a few kilometers, relative GPS positioning was developed to improve the point positioning accuracy.

GPS is active since the mid-1980s. It has grown from a purely military navigation system to a scientific tool allowing today to measure deformations of the Earth's crust with millimeter-level precision. Within the next years, existing Global Navigation Satellite Systems (GNSS) like GPS and the Russian GLONASS will launch new types of satellites and provide additional signals to deliver better accuracy, reliability, and availability of positioning. Moreover, Europe and China are also developing their own GNSS, known as Galileo and Compass, respectively (Gibbons, 2009). All these signals have the potential to allow even more precise positioning.

Crustal deformation

Definition

Earthquake cycle. A conceptual model that explains the buildup of stress that causes earthquakes through a period of steady tectonic loading that culminates in sudden slip in an earthquake.
Slip deficit. The difference between the slip that has occurred over a period of time on a fault and the long-term fault slip rate; the slip deficit is a measure of the accumulated stress available to cause an earthquake on the fault.
Coseismic displacement. The final, static displacement of the surface caused by slip in an earthquake.
Postseismic displacement. Displacements caused by postseismic processes, which are transient deformation processes that follow large earthquakes.
Volcanic inflation. Dilatational deformation caused by pressurization of a volcanic system.
Glacial isostatic adjustment (GIA). The deformation, mainly uplift, that results from the removal of glacial surface loads.

Tectonic geodesy

Introduction

Tectonic geodesy uses measurements of changes in the position of a network of points on earth's surface to study motion and deformation of the earth. These motions mainly result from plate motions, slip on active faults (including earthquakes), and the pressurization or depressurization of magma systems beneath volcanoes, but significant deformation can also result from changes in surface loads such as glacial isostatic adjustment. It is one of the most important tools for the study of plate boundary zones, the regions of distributed deformation

that are commonly found at the boundaries of the major tectonic plates.

Measurements of change depend on a precise time series of positions in a stable terrestrial reference system (see *GPS, Data Acquisition and Analysis* and *Geodesy, Networks and Reference Systems*), and the principal measurement system today is the Global Positioning System (GPS). GPS is most commonly used because of the relatively low cost of the equipment and its ease of use in the field, but the same principles apply to positions measured by any space geodetic technique. Usually, GPS time series is dominated by steady, linear motion over time, so site velocities are frequently used to describe site motions. For sudden or large deformations, especially due to earthquake and volcanic activity, measurements of motion from Interferometric Synthetic Aperture Radar (InSAR) have also become very important and are complementary to GPS (see *SAR Interferometry*).

Although tectonic geodesy has become prominent over the last couple of decades, the field dates back more than a century and many of the important conceptual and mathematical models relating deformation measured at the surface to sources within the earth pre-date the availability of precise, modern geodetic data. During the last three decades, the focus of tectonic geodesy has changed from measuring motions, assumed to be steady in time, to a more general representation of time-dependent deformation. This evolution in theory and practice has resulted from the steady improvement in precision and accuracy of the measurements along with the realization that many processes are not steady in time.

History of tectonic geodesy

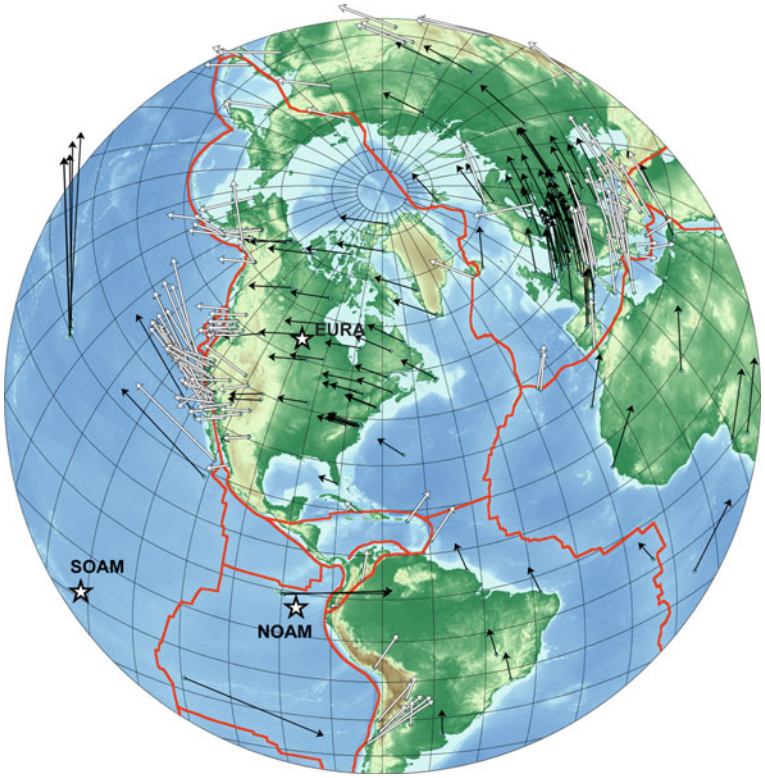
Early work in tectonic geodesy dates back more than a century. The Dutch surveyor J. J. A. Müller reported ground movements associated with the 1892 Tapanuli earthquake in Sumatra, which caused changes in observed angles (Bonafede et al., 1992). H. F. Reid used displacements computed from geodetic surveys conducted before and after the 1906 San Francisco earthquake as the basis for the elastic rebound hypothesis (Reid, 1910, 1911). These observations supported the hypothesis proposed by G. K. Gilbert a few decades earlier that earthquakes were the result of a sudden release of strain that had built up over a long period of time (Gilbert, 1884). Numerous studies over the succeeding decades used all kinds of terrestrial geodetic measurements to document both sudden displacements due to earthquakes and the slow, steady deformation between earthquakes. By the 1970s, the US Geological Survey had begun to make extensive and systematic terrestrial geodetic measurements for the purpose of measuring crustal deformation, and similar developments occurred in Japan and other countries that experienced active tectonics. Because of the limited spatial scale of the terrestrial measurements, these efforts generally focused on the deformation associated with individual faults or fault systems. Although restricted in spatial scale and coverage, these terrestrial data prompted the development of most of the conceptual and numerical models used in tectonic geodesy today.

Measurement of tectonic motions over large spatial scales began in the 1980s with NASA's Crustal Dynamics Project and related international efforts (e.g., the WEGENER project in Europe). This work used a network of fixed (and a few mobile) Very Long Baseline Interferometry (VLBI) and Satellite Laser Positioning, Ranging (SLR) stations (see *Very Long Baseline Interferometry* and *Satellite Laser Ranging*), and achieved its goals of comparing plate motions over a decadal timescale to geologic plate motions (e.g., Smith et al., 1990; Stein, 1993; Robbins et al., 1993; Robaudo and Harrison, 1993) and measuring deformation across broad plate boundary zones in North America and the Mediterranean (e.g., Ma et al., 1990; Gordon et al., 1993; Wilson and Reinhart, 1993; Gendt et al., 1993). Since the early 1990s, the tremendous expansion of GPS networks has resulted in a vast data set available to study plate motions (e.g., Sella et al., 2002) and active deformation of plate boundary zones (e.g., McCaffrey et al., 2007; Meade, 2007).

Today, data from thousands of GPS stations are available and used by researchers around the world. A growing number of these stations also record data from other Global Navigation Satellite Systems (GNSS), such as the Russian GLONASS or European Union's Galileo. These data come from global and regional networks of fixed instruments, as well as from survey markers measured episodically. High-accuracy GPS satellite orbits are available from the International GNSS Service (IGS), and the stations that contribute to the IGS tracking network form a reference network that any researcher can use to determine station positions in the International Terrestrial Reference Frame (ITRF) (Altamimi et al., 2007). Modern studies in tectonic geodesy are based on motions derived from time series of site positions expressed in the ITRF, on regional to global scales.

Plate motions

Plate tectonic theory holds that the surface of the earth can be divided into a set of rigid plates moving relative to each other (Figure 1), with tectonic activity concentrated on the boundaries of the plates and caused by the relative plate motions. The motion of a rigid plate on the surface of a sphere is a rotation about an axis passing through the geocenter, described by a single angular velocity vector. The surface projection of this axis of rotation is called the pole of rotation, or the Euler pole. Models of plate motions thus consist of angular velocities of plates relative to some reference frame, or angular velocities of relative plate motions. Magnetic anomalies at spreading centers and transform fault azimuths record the rates and directions of past relative plate motions, and estimates of current plate motions estimated from these data (averaged over periods of up to a few million years) can be compared



GPS, Tectonic Geodesy, Figure 1 Velocities of geodetic sites illustrate both rigid plate motion and plate boundary deformation. Velocities are from Argus et al. (2010), in the ITRF2005 reference frame. Black vectors are sites on plate interiors, and illustrate rigid rotational motion of the plates. White vectors are sites within plate boundary zones, and generally show motions intermediate between the rigid plates that bound the plate boundary zone. The stars show the poles of rotation (in ITRF) for the North American (NOAM), South American (SOAM), and Eurasian (EURA) plates, also derived from Argus et al. (2010). For all three of these plates, the plate rotation is counterclockwise about the pole. The main plate boundaries are shown in red, based on DeMets et al. (1990).

with geodetic estimates averaged over the last 2–3 decades (DeMets et al., 2010; Argus et al., 2010). The latest work shows that the approximation of rigid plates moving at a steady rate over millions of years is quite good, but there is evidence for small changes in plate motions over the last few million years, and evidence for small but significant internal deformation of the plates.

In the early history of tectonic geodesy, geodetic results were compared to models of geologically current plate motions, which were more precise at that time and whose level of accuracy was understood. Even at that time the geodetic data made a significant contribution. Robbins et al. (1993) compared rates of plate motion from SLR and VLBI to predictions of the geological plate model NUVEL-1 (DeMets et al., 1990), and found a very high correlation between the geodetic and geologic estimates based on magnetic anomalies at spreading centers and transform fault azimuths. However, the geodetic plate motion rates were systematically $6 \pm 1\%$ slower than geologic rates. This discrepancy resulted mainly from errors in the geomagnetic timescale; after recalibration based on the revised timescale, the NUVEL-1A plate motion model agreed with space geodetic estimates (DeMets et al., 1994). The conclusion of this work was that, with perhaps a few exceptions, plate motions averaged over the last ~3 million years and plate motions averaged over the last decade were the same within the measurement precision of the time.

The full capability of space geodesy to measure plate motions was not realized until long time series of GPS data were available, beginning in the mid to late 1990s. The spatial density and coverage of GPS data meant that more plates could be included and the measurements for each plate were more robust. The first global plate motion models based on GPS data alone were Argus and Heflin (1995) and Larson et al. (1997). Larson et al. (1997) found that the motion of the Nazca plate was significantly slower than predicted by NUVEL-1A, a result later confirmed by Norabuena et al. (1998, 1999), who found that the rate of subduction of the Nazca plate beneath South America has declined steadily over the last 20 million years. The GEODVEL model of Argus et al. (2010) is the most complete global geodetic plate motion model to date. GEODVEL combined GPS, VLBI, SLR, and DORIS site

velocities (Figure 1) and presented an estimate of relative plate angular velocities based on these data. The earlier REVEL model (Sella et al., 2002) presented the angular velocities of each plate in ITRF97, and although now somewhat dated it remains useful for realizing a reference frame fixed to a particular plate. Estimates of motions of the major plates in ITRF have also been included in the entries that describe the successive realizations of ITRF (e.g., Altamimi et al., 2007), although these estimates are based on smaller data sets than GEODVEL or REVEL.

The central results of these studies are that the present-day motions of the plate interiors are similar to plate motions averaged over the last ~3 million years, and outside of known regions of tectonic activity, the plate interiors are rigid to a level comparable to the measurement precision of GPS (Calais et al., 2006; Argus et al., 2010). However, for most plate pairs the small differences between GEODVEL and the NUVEL-1A (median difference of 0.063° Myr^{-1}) are nonetheless statistically significant (Argus et al., 2010). The comparison of GEODVEL and the most recent geological model MORVEL (DeMets et al., 2010) reveals smaller but still significant differences. This implies that changes in plate motions of a few to several percent have occurred over the last 3 million years, most notably the reduction in angular speed of the Nazca plate relative to South America. Calais et al. (2006) analyzed internal deformation of the eastern part of the North American plate, and found a weighted RMS residual horizontal velocity of 0.7 mm/year. However, horizontal residuals showed a systematic spatial pattern, interpreted to be the result of glacial isostatic adjustment (GIA). Horizontal deformation from GIA complicates the determination of the angular velocity of the plate itself, so Sella et al. (2007) used a set of 124 sites selected to minimize the effects of GIA and used these sites to determine an updated estimate of the North American plate. The unweighted RMS residuals for these sites were 0.6 mm/year, consistent with the estimated precision of the measurements. The Indian plate may be an exception. Banerjee et al. (2008) estimated 2 ± 1 mm/year of shortening across central India, which could reflect contraction driven by the collision of India with Eurasia.

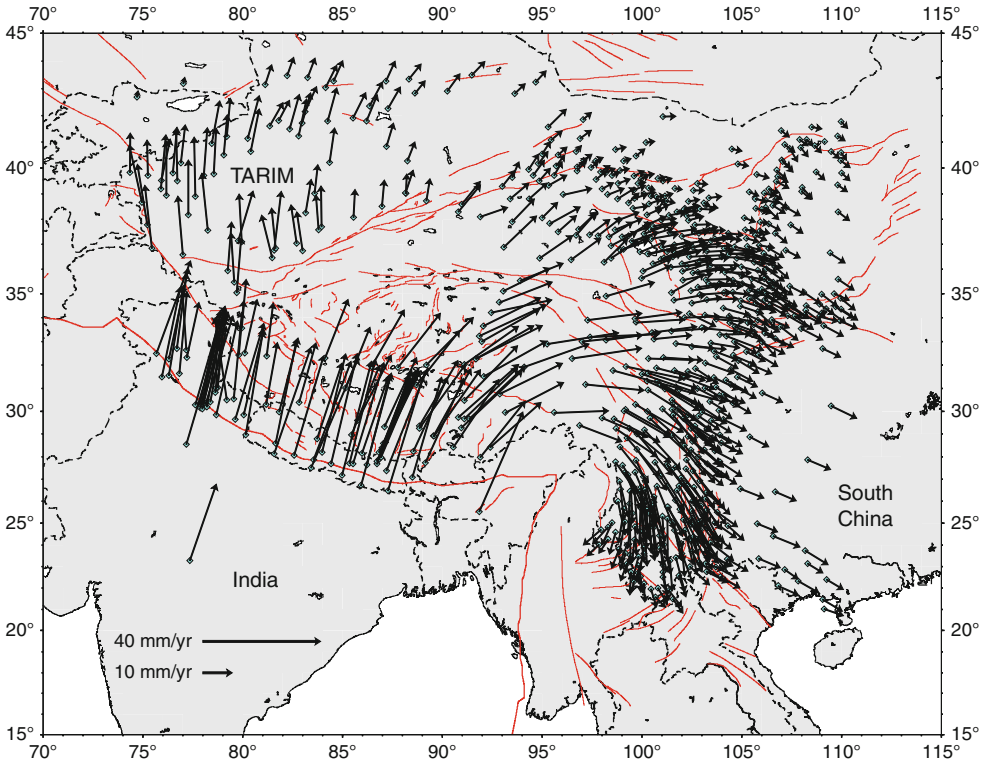
The estimated plate motions from tectonic geodesy are also important for studies of plate boundary zones, which are zones of distributed deformation on the boundary between two or more plates (Figures 1 and 2). The steady interseismic motions of areas within a plate boundary zone between two major plates must be understood in context of the motions of the major plates. Geodetic motions are understood most easily in terms of geologic structures when the velocities of sites are expressed relative to one of the major plates. Plate boundary zones can extend over hundreds or thousands of kilometers and involve many active structures, especially within the continental crust (Thatcher, 2003, 2009). Plate boundary zones typically include rigid blocks or microplates within them, such as Tarim and South China in the broad and complex India – Eurasia boundary zone (Figure 2). Plate boundary zone deformation in Asia and North America (Figure 1) has received a great deal of study, and work on these plate boundary zones requires an integration of the concepts of plate tectonics with the earthquake cycle and interseismic deformation, along with other causes of deformation detailed later in this entry.

Steady "Interseismic Deformation"

Time series of site positions is typically dominated by steady, quasi-linear motion with time, although periodic seasonal variations are also commonly observed (especially in the vertical). This is true not only for sites in the interiors of tectonic plates, but also for many sites within plate boundary zones. As a result, the time series of positions is commonly reduced to a site velocity based on a linear fit and velocities are then used to study the steady motions with time. Offsets in position due to earthquakes and time-dependent motions due to postseismic deformation and other effects will be discussed in later entries. For now, it is simply important to note that the linear fit for velocity needs to take account of any discontinuities or known time-dependent variations in the time series, whether due to motions of the earth or to changes in equipment.

The steady, linear motion of the tectonic plates leads to the concept of an "earthquake cycle," in which tectonic stresses increases linearly with time until a fault failure criterion is reached, at which point an earthquake occurs and the stored stresses are relieved by fault slip (e.g., Scholz, 1990). The basic concept goes back to Reid's elastic rebound hypothesis, in which he proposed that the strain accumulation pattern between earthquakes would be opposite to the strain release pattern during the earthquakes (Reid, 1910). The net result of one full cycle is a block-like offset along with fault, with no strain off the fault – much like what would be observed by geologists (Figure 3). Given linear stress accumulation and an elastic rheology for the earth, strain (deformation) should occur at a constant linear rate between earthquakes. Elastic earthquake cycle models thus imply a long "interseismic" period of linear deformation with time, punctuated by offsets at the times of large earthquakes. Although there is unambiguous observational evidence for transient postseismic deformation following earthquakes, the observed deformation prior to large earthquakes has generally been linear with time within measurement precision, and the concept of "interseismic deformation" remains useful.

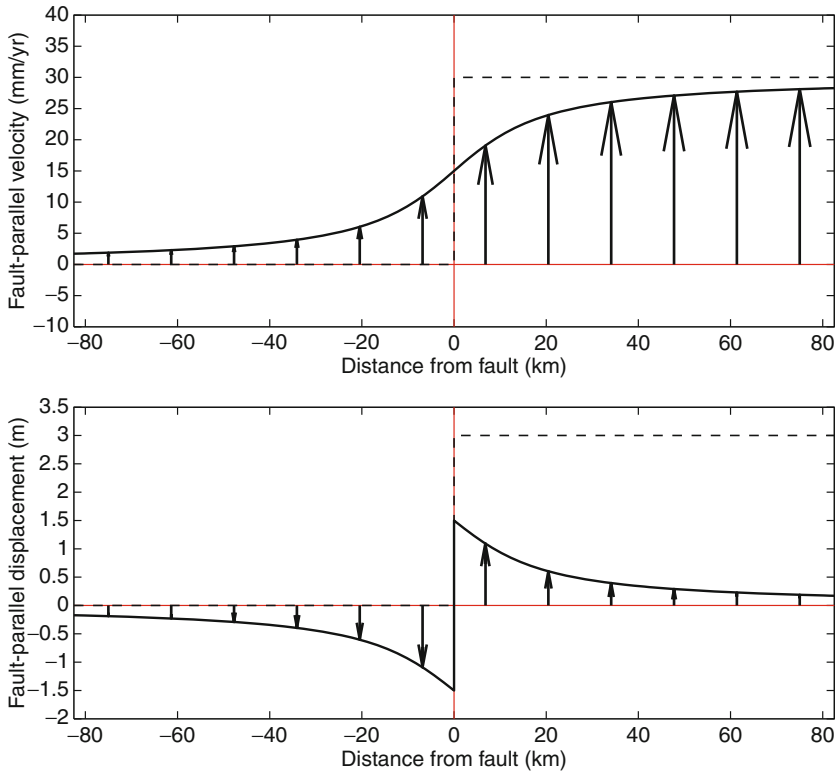
Numerical models for the interseismic period follow directly from the assumptions of the earthquake cycle model. Large earthquakes within continental crust rupture a limited range of depths, from at or near the surface to a lower depth limit that is usually no deeper than 10–20 km. Observations of exhumed deep fault zones show evidence for ductile shear, presumed to occur continuously with time (for a comprehensive summary, see



GPS, Tectonic Geodesy, Figure 2 Velocities of sites in the India-Eurasia plate boundary zone, relative to the Eurasian plate. GPS velocities are from Gan et al. (2007), and faults (*red lines*) are from Taylor and Yin (2009). Rigid rotation of two microplates or small plates, Tarim and South China, is clearly visible in the velocity field at this scale. Most of the motions shown here can be explained by a combination of rigid block motion, including a number of smaller blocks, and elastic deformation that results from the shallow locked zones of block-bounding faults.

Scholz, 1990). Savage and Burford (1970) proposed a simple interseismic model using elastic dislocation theory. In their model, the deeper part of the fault zone creeps continuously at the long-term fault slip rate, while the shallow part of the fault zone remains stuck by friction except in earthquakes. They represented this numerically by an elastic dislocation plane that slips steadily from a locking depth d to infinite depth. The dislocation is embedded in an elastic half-space, which represents the earth from its surface to infinite depth as an elastic body. Alternately, the slip on the fault as a function of depth can be represented by a linear superposition between uniform slip at all depths and backward slip or backslip on the shallow part of the fault. The backslip is a mathematical construct, one component of the linear superposition; the fault does not actually slip backwards. Backslip represents the *slip deficit*, or the difference between the slip that actually occurs over a period of time, and the slip expected from the long-term average rate of fault slip. Slip deficit is proportional to the accumulated stress. In the simplest earthquake cycle model, the accumulated slip deficit over the interval between earthquakes would be equal to the slip in an earthquake. In the two-dimensional case of an infinitely long strike-slip fault, the equations describing the dislocation model are very simple, with the velocity of a site located at a distance x from the fault $V = (s/\pi)$*arctan(x/d), where s is the average slip rate, and d is the locking depth (Figure 1). This velocity is expressed in a frame in which the velocity is zero at the fault and reaches plus or minus half the long-term fault slip rate far from the fault. When the locking depth is shallow, the interseismic strain is concentrated close to the fault, and when it is deep, the strain is distributed over a larger region.

This simple model has proven to be extremely successful in a wide variety of tectonic settings, and the same conceptual model has been applied to normal faulting and to subduction zones (Savage, 1983) in addition to strike-slip faults. In all cases, the critical step in describing interseismic deformation is a superposition between steady fault slip at the long-term fault slip rate, assumed to result in block-like or plate-like motion with all offset occurring as slip on the fault and no strain occurring in the surrounding rock, and the deformation associated with the accumulating slip deficit. When the locking depth varies along strike, the pattern of strain will also vary along strike; in the extreme limit of a locking depth of zero, the fault creeps at the surface at its long-term slip rate. Observations show a wide range of fault locking depths, generally in agreement with depths of maximum earthquake slip or depths of seismicity. Locking depths



GPS, Tectonic Geodesy, Figure 3 Velocities and coseismic displacements expected from a simple elastic earthquake cycle model. The fault in this model is an infinitely long strike-slip fault (*left-lateral*) with a slip rate of 30 mm/year, which has an earthquake after 100 years with 3 m slip. During the interseismic period, the fault is locked from the surface to 15 km depth and slipping steadily below that. The interseismic deformation pattern (*top panel*) is shown by the arrows and solid line, relative to the far field on the left side of the fault. Compared to the uniform block motion that would result if the fault slipped uniformly at all depths (*dashed line*), the elastic response of the earth spreads the fault shear over a broad area. The coseismic displacement (*bottom panel*) is antisymmetric about the fault, with maximum displacement at the fault (each side moves by half the coseismic slip, in opposite directions). The sum of 100 years of interseismic deformation and the coseismic displacement is a uniform block motion, shown by the dotted line.

sometimes vary abruptly in the along-strike direction. Examples of along-strike changes in fault locking behavior include variations in the rate of fault creep along the creeping section of the San Andreas fault in California (Titus et al., 2005), and variations in the extent of the locked zone along the subduction zone of the Aleutian and Sumatran arcs (Cross and Freymueller, 2008; Freymueller et al., 2008; McCaffrey, 2008; Chlieh et al., 2008). The parts of the fault determined (from geodetic data) to be locked by friction and accumulating slip deficit correspond well to the rupture areas of the last set of great earthquakes, and the along-strike boundaries between locked and creeping segments correspond to the limits of seismic slip or major seismic asperities of the last great earthquakes.

The elastic dislocation approach to modeling interseismic deformation has been extended to three dimensions using elastic block modeling (e.g., McCaffrey, 2002; Meade and Hager, 2005a). In this approach, which blends the description of plate motions in terms of angular velocities with an elastic interseismic model, the model domain is first broken up into a set of blocks or microplates, each of which is assumed to be rigid. The boundaries between adjacent blocks are thus the faults on which the relative block motion occurs. The velocity of a GPS site is the sum of two components, the rotation of the block it lies upon (described by the block angular velocity) and the elastic deformation caused by the slip deficit on all faults in the model. The elastic block model enforces self-consistency of block motions, fault slip rates, and elastic deformation, because the fault slip rates are computed from the block angular velocities and the elastic deformation is computed using dislocation theory from the fault slip rates and assumed fault locking depths. Thus, the only estimated parameters in an elastic block model are the block angular velocities, unless the fault locking depths or other geometric parameters are explicitly optimized as well. This approach has been successful in describing deformation in North America, Asia, the Mediterranean and Middle East, and other parts of the world, and has sometimes been combined with an assumption of uniform strain for some blocks rather than

rigidity (McCaffrey, 2002; Nyst and Thatcher, 2004; Meade and Hager, 2005a, b; Reilinger et al., 2006; McCaffrey et al., 2007; Meade, 2007, Loveless and Meade, 2010).

Despite the general success of this approach, there is no way to account for observed time dependence in postseismic deformation within this model, and there are some significant discrepancies between fault slip rates estimated from geodetic data and geologically estimated rates from dated fault offsets. A prominent example of this involves the Garlock Fault and Eastern California Shear Zone in the Mojave Desert of California. The Garlock fault is a left-lateral strike-slip fault that is in a conjugate orientation to the right-lateral San Andreas Fault and the faults of the Eastern California Shear zone. The present geodetic slip rate estimated for the Garlock fault (Meade and Hager, 2005a) is significantly lower than expected based on the recent geological slip rate (McGill et al., 2009), while the reverse is true for the adjacent Eastern California Shear Zone (Peltzer et al., 2001; Oskin et al., 2008). Dolan et al. (2007) and Oskin et al. (2008) suggested that time-dependent behavior of ductile shear zones in the deep crust may result in time-dependent fault slip, which in this case might result in switching between two modes: elevated slip rate on the Eastern California Shear Zone with low slip on the Garlock fault (the present), and elevated slip on the Garlock fault with low slip on the Eastern California Shear Zone (much of the geologically recent past). Time-dependent postseismic deformation not accounted for in the geodetic models might play a role in this discrepancy.

Coseismic deformation

Coseismic displacements are the sudden displacements caused by earthquakes. Coseismic displacements from large earthquakes can extend a long distance from the fault due to the elastic response of the earth (Figure 3). The earliest observations in tectonic geodesy were of the angle changes between triangulation stations caused by coseismic displacements. Today, GPS and InSAR displacements provide precise and spatially dense measurements of coseismic displacements, allowing detailed models of the distribution of slip in earthquakes to be determined. Very large earthquakes are followed by a period of postseismic deformation, during which the deformation pattern is very different from the pre-earthquake pattern (see next section).

One of the earliest important large earthquakes during the modern GPS era was the 1992 Landers earthquake in southern California. This M_W 7.4 strike-slip earthquake ruptured multiple faults with a complex surface rupture pattern (Sieh et al., 1993) and caused immediate displacements of five continuous GPS sites in the region, which had been installed a few years earlier. Displacements from these continuous GPS sites were used to develop slip models for the earthquake (Bock et al., 1993; Blewitt et al., 1993). Later, a much more extensive set of displacements determined from repeated GPS surveys of many survey marks in the region provided almost 100 displacement vectors for use in studying the distribution of slip during the earthquake (Hudnut et al., 1994; Freymueller et al., 1994). The pre-earthquake surveys were of variable precision and were made over a range of time before the earthquake. Many of the important near-field displacement vectors came from survey marks that had been surveyed originally by private land surveyors or by the California Department of Transportation. In addition, the post-earthquake surveys, while more uniform in precision, were carried out over a period of a few weeks to months during which postseismic deformation was occurring. Removing pre- and post-earthquake deformation from the coseismic displacements was, and still is, a significant challenge. Even in the era of dense continuous networks, the problem of separating coseismic and postseismic deformation has been pushed down to shorter timescales, as postseismic deformation is observed to begin immediately after the earthquake rupture terminates (Melbourne et al., 2002; Savage and Langbein, 2008).

The Landers earthquake and the studies that followed it provide several lessons that remain relevant today. Even a small number of geodetic displacements provide significant constraints on the total seismic moment of an earthquake. Six different geodetic studies for the Landers earthquake were published within the first 2 years after the event, and the total moment estimated in all cases was the same within 10% even though some studies used as few as four or five displacements and others used as many as 96. Determining the moment of the earthquake to within 10% means determining the magnitude to within ± 0.1, which is comparable to the best magnitude precision from seismology. More displacements allowed a more detailed model for the distribution of slip on the fault plane, but changed the total moment (proportional to slip times area) only incrementally. The GPS displacements were compatible with offset measurements made by geologists working on the surface rupture, but slip at the surface rupture was not always indicative of the typical slip at depth. In general, the maximum slip was located some distance beneath the surface. The slip distribution was highly variable in space even along parts of the rupture that were geometrically simple. Estimates of the slip distribution from geodesy and seismology were also compatible (Cohee and Beroza, 1994).

The recent sequence of great earthquakes along the Sumatra subduction zone provides a good picture of the present capabilities for studying earthquakes using geodesy (McCaffrey, 2008). Coseismic displacements from the 2004 Sumatra-Andaman earthquake, the first and largest of the sequence, were large enough to be measured more than 2,000 km from the fault, and probably as far as 4,000 km distant (Banerjee et al., 2005). Significant displacements, large enough to be informative about the earthquake slip distribution, were measured throughout Southeast Asia and across the Indian Ocean on the Indian subcontinent. By the time of the subsequent earthquakes in Sumatra, continuous GPS networks extended across

most of the area, and the coseismic displacement fields were measured rapidly and easily (e.g., Hsu et al., 2006; Kreemer et al., 2006). Additional GPS surveys in the affected areas provided additional displacements from a spatially dense network of sites.

The problem of estimating the earthquake slip distribution from surface displacement data is similar to that of modeling interseismic deformation. As in the interseismic case, elastic dislocation theory provides the mathematical basis for predicting surface displacements given slip on a fault and the inverse problem of estimating slip given surface displacement. Most studies have used the simplest elastic model, a uniform elastic half-space, although some studies have included the effect of elastic layering and/or sphericity of the earth. For the largest earthquakes, a model that treats the earth as a layered elastic sphere is necessary (Banerjee et al., 2005). As in the interseismic case, the fault geometry may or may not be known, and the detailed fault geometry must be estimated as part of the inverse problem if is not known from other sources. What is most different about the coseismic slip problem is that spatial variations in the slip always must be estimated and, because the displacements are larger than in the interseismic case, the data have the strength to resolve spatial variations in slip to a greater extent than in the interseismic case.

The most common approach to estimating the slip distribution is to segment the fault plane or planes into a grid of small elements, or subfaults. The slip on each subfault is estimated, subject to spatial smoothing or other regularization to make the problem invertible. As a general rule, it is necessary to discretize the fault into a grid that is small compared to the actual spatial resolution of the data; the weight given to smoothing is then optimized according to some criterion. The reason for this is that actual spatial variations in slip during earthquakes can be quite large over relatively short distances, and a grid that is too coarse can compromise fit to the data significantly by forcing the boundary between a high slip and low slip region to be in the wrong place. An alternate approach to spatial smoothing is to discretize the fault at a fine spacing first, and then use the model resolution matrix to lump together adjacent subfaults that are poorly resolved (Pritchard et al., 2002). In this approach, a single slip parameter refers to a large area of the fault where there are no nearby data that can resolve variations in slip, and where data are dense the ability to resolve short-wavelength variations in slip is retained. Earthquake slip inversions commonly use nonlinear optimization techniques, from least squares with inequality constraints (to constrain the slip direction) to full nonlinear inversions that are required when the fault geometry must be estimated.

Over time, the amount and accuracy of data used in coseismic slip inversions have increased, and improvements in the terrestrial reference frame have made it possible to use absolute displacements, even for distant sites. Studies of the Landers earthquake used nearly 100 displacements, the 2002 Denali earthquake more than 200, and the 2008 Wenchuan earthquake in China more than 400 GPS displacements. Early earthquake slip inversions using GPS data generally used displacements relative to a local site, because the site positions in an absolute frame were not accurate enough. The inversion for the 2002 Denali Fault Earthquake in Alaska (Hreinsdóttir et al., 2006) used absolute displacements in ITRF, even for sites as much as 800 km from the fault, and Banerjee et al. (2005) determined and modeled absolute displacements for the Sumatra-Andaman Earthquake up to 4,000 km away. The greater density and spatial distribution of data for more recent earthquakes allows estimation of the fault geometry along with the slip distribution as well as resolution of greater detail in the slip distribution. GPS displacements can be augmented with displacements from InSAR, surface offsets from geological measurements from correlation of remote sensing images, and seismic data.

Although GPS for tectonic geodesy is most often used in static mode, in which up to a day of data are used to determine a single daily position for each station, GPS can also be used in kinematic mode to measure the ground motions associated with earthquakes. Nikolaidis et al. (2001) first demonstrated that kinematic GPS could record displacements due to seismic waves, but they were limited by having only data recorded once every 30 s. Larson et al. (2003) measured the propagation of surface waves from the 2002 Denali fault earthquake using GPS data recorded at 1 Hz, which demonstrated the utility of kinematic GPS for "GPS Seismology." GPS displacement records are much less precise than records from seismometers, but can record large displacements faithfully, are not subject to distortion in the presence of tilts, and do not need external information to resolve integration constants because they provide a displacement record directly. Miyazaki et al. (2004a) determined a time-dependent slip model for the 2003 Hokkaido Tokachi-oki earthquake in Japan based entirely on kinematic GPS records. This model clearly showed the spatial evolution of slip on the fault, which propagated downdip and to the northwest from the hypocenter. The kinematic GPS records also showed a secondary slip peak to the northeast, which might represent triggered slip. The spatial and temporal resolution of slip models estimated from kinematic GPS data is superior to that of teleseismic recordings, and are comparable to models derived from near-field strong motion recordings (Ji et al., 2004).

Postseismic deformation

Postseismic deformation is the general term used for any kind of transient deformation that follows earthquakes. Because of the large stress changes associated with large earthquakes, the pattern and rate of strain around the fault is often quite different immediately after the earthquake compared to the pre-earthquake time period, and the time evolution of strain depends on the rheology of the crust

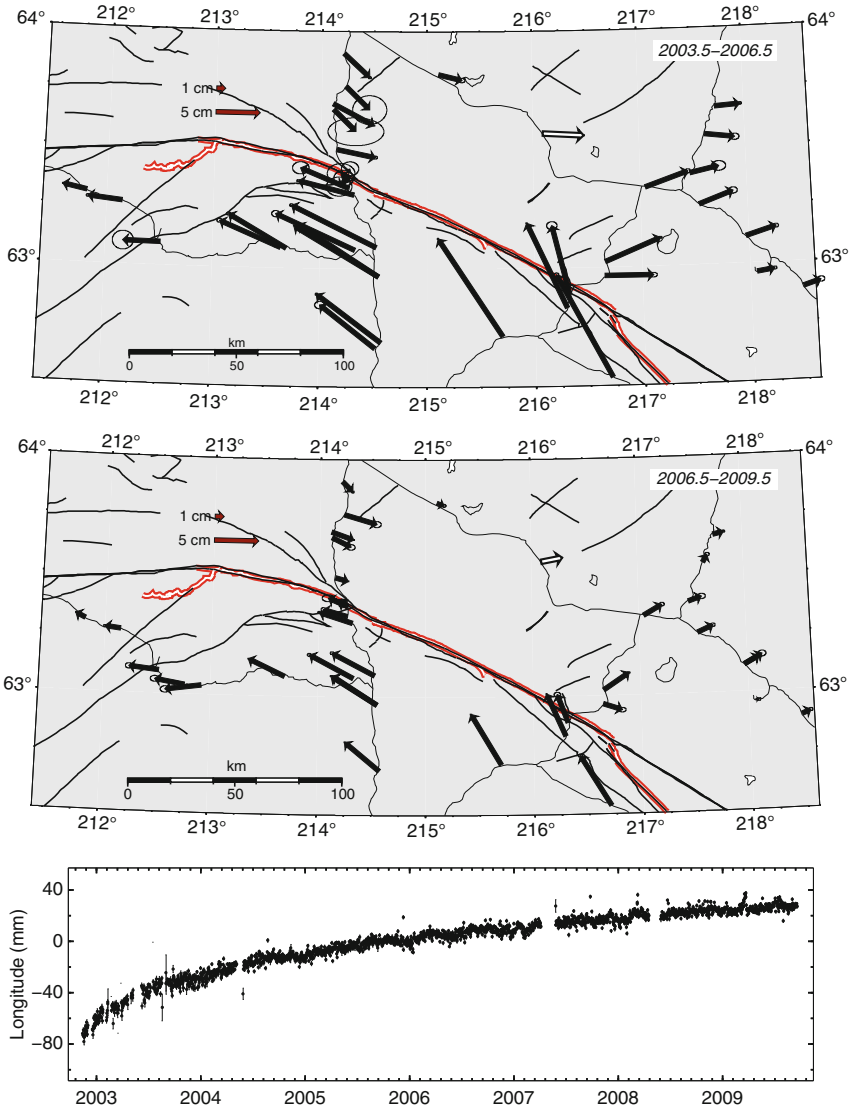
and upper mantle (Bürgmann and Dresen, 2008). Postseismic deformation provides an opportunity to study the dynamics of tectonic deformation and the rheology of the crust and upper mantle, whereas the linear motion in time observed for most of the time between earthquakes allows only a kinematic description. Postseismic deformation can be large and long lasting, although there is great variation from earthquake to earthquake.

Postseismic deformation is thought to result from a superposition of three main physical mechanisms, which cause deformation on different spatial and temporal scales: viscoelastic relaxation of the mantle and possibly lower crust, afterslip on the very shallow or deep parts of the fault zone, and poroelastic relaxation. Poroelastic relaxation, which is deformation driven by fluid flow that relieves pressure differences caused by the earthquake, is generally considered to be important only very close to the fault and near geometric complexities such as fault stepovers and bends, where the dilatational strain is the largest (and thus fluid flow changes will be most significant). Shallow afterslip is a frictional process, first observed after the 1966 Parkfield earthquakes (Smith and Wyss, 1968), and observed after many subsequent earthquakes, including subduction zone events (Hsu et al., 2006; Kreemer et al., 2006). Depending on the rheology of deep fault zones, deep afterslip may be a frictional process, a ductile shear process, or some combination of the two. Deep afterslip is generally found immediately downdip of the coseismic rupture zone. Close to the fault, postseismic displacements are usually significantly smaller than coseismic displacements, reflecting the smaller amount of slip involved and the generally deeper deformation source. The 2004 Parkfield earthquake was an exception to this rule, because coseismic slip at shallow depth was small, while shallow postseismic afterslip was large (Johanson et al., 2006). However, in the far field, the longer spatial wavelength of the postseismic signal that results from its deeper or spatially distributed source means that far-field postseismic displacements can be a significant fraction of, or even comparable to, the coseismic displacements.

The various mechanisms of postseismic deformation can produce similar deformation at the surface, especially in the horizontal components, and the predicted displacements from different mechanisms can be similar enough that controversy over postseismic deformation models can linger for years, even for well-studied earthquakes. The ambiguity between postseismic source models is enhanced because GPS data are always irregularly sampled in space, while InSAR data may be continuous in space, but do not measure 3D displacements. There is not yet a consensus regarding the physical model for afterslip that would allow accurate prediction of afterslip given only the coseismic slip model; this means that afterslip is usually estimated in a manner similar to the coseismic slip model, whereas viscoelastic relaxation is predicted from the coseismic slip distribution and an (estimated or inferred) earth model that describes the rheology. Unfortunately, the appropriate rheological model varies from place to place, and parameters such as mantle viscosity are both heterogeneous and poorly constrained in value (Bürgmann and Dresen, 2008). As a result of these factors, postseismic studies often make assumptions that certain displacements result from only the effect of one mechanism, or attempt to use the spatial or temporal character of the observed displacements to constrain the mechanisms separately.

The 2002 Denali fault earthquake provides a useful example. Ten continuous GPS sites were set up within a few weeks of the earthquake and nearly 100 sites were surveyed repeatedly over the next several years, providing a rich data set in space and time (Figure 4). Both the spatial and temporal variations in postseismic displacements require more than one mechanism to explain them. All sites show an initially rapid rate of deformation that decayed over time. In general, site velocities averaged over the first 1–2 years were ~20 times faster than the pre-earthquake rates. Even several years after the earthquake, average velocities remain several times higher than the pre-earthquake rates at many sites. No single simple relaxation function of time, such as an exponential or logarithmic relaxation, can explain the temporal variations of the time series to within the scatter in the measurements. However, a combination of relaxation functions can explain the temporal decay of the displacements quite well, as long as the model fit to the time series has both a short relaxation component (characteristic decay time of ~months) and a long relaxation component (characteristic decay time of a few years). In addition, several sites close to the fault (within a few tens of km) exhibited an initial phase of extremely rapid displacements, up to several millimeters per day, which decayed over a period of a few weeks with a characteristic decay time on the order of days. This component was not sampled uniformly enough to develop models for it.

Postseismic models for the 2002 Denali fault earthquake have called upon a variety of mechanisms to explain the deformation. Pollitz (2005) used data from a limited set of sites over the first 16 months after the earthquake and a model that assumed all deformation resulted from viscoelastic of a material obeying a Burger's body transient viscosity. Freed et al. (2006a) showed that no single mechanism could explain the observed displacements, and proposed a model based on afterslip within the lithosphere (approximated as a narrow low viscosity shear zone) and viscoelastic relaxation in the asthenosphere. Freed et al. (2006b) analyzed the time dependence at far-field sites and concluded that a model with a nonlinear (power-law) viscosity in the mantle, consistent with lab measurements of the rheology of olivine, explained these data better than a model with a linear Newtonian viscosity. Johnson et al. (2009) estimated a combined afterslip and viscoelastic model, using an assumed frictional model. However, none of these models have been very successful in predicting displacements into the future, beyond the time span of the data



GPS, Tectonic Geodesy, Figure 4 Postseismic displacements following the November 2002 Denali fault earthquake. Displacements are shown for the time periods 2003.5–2006.5 (*top panel*) and 2006.5–2009.5 (*middle panel*). The pre-earthquake motions have been subtracted from both figures, so the displacements represent the transient component of motion over those time intervals. Pre-earthquake velocities relative to North America were less than 1 cm/year over most of the area shown, and postseismic velocities are several times faster, and diminish in rate over time (*bottom panel*). The time series of eastward motion of the site JANL (*white vector*) relative to North America illustrates the nonlinear character of postseismic deformation. Although the time series appears to be nearly linear several years after the earthquake, there is actually significant curvature of the time series over the entire time period.

used to constrain them (Freymueller et al., 2009). These model shortcomings may result from deficiencies in the estimated coseismic slip model, from a failure to separate the different mechanisms correctly, or from additional processes not considered in the models, possibly including changes in the slip on the subduction thrust in southern Alaska caused by the Denali fault earthquake stress changes (Johnson et al., 2009).

The general pattern of postseismic deformation seen in the 2002 Denali fault earthquake has been observed in many other cases, from moderately large crustal events to great subduction zone earthquakes. However, individual earthquakes have displayed a puzzling variety of postseismic responses. For some large subduction earthquakes, postseismic transients seem to have decayed away after only a few years, while in other cases small transient signals have lingered for decades (Melbourne et al., 2002). After the 1995 M_W 8.1 Antofagasta (Chile) earthquake, there was significant afterslip for a few years but apparently little viscoelastic relaxation of the mantle

because postseismic deformation rates returned to pre-earthquake rates within a few years (Melbourne et al., 2002). The 2003 Hokkaido Tokachi-oki earthquake caused afterslip downdip of the coseismic rupture, which also extended at depth for a significant lateral distance north of the rupture zone (Miyazaki et al., 2004b). In the 2006–2007 Kuril Island doublet, a subduction thrust earthquake followed by a similar-sized outer rise event, afterslip appears to have been limited to the first several months after the thrust earthquake (Steblov et al., 2008; Kogan et al., submitted manuscript). The cause of this wide range of behavior is not understood at this time. For the largest earthquakes, significant postseismic deformation clearly can last for decades (Cohen and Freymueller, 2004; Wang, 2007; Suito and Freymueller, 2009). Postseismic deformation from the great 1960 Chile and 1964 Alaska earthquakes remains very large (rates of 1–2 cm/year), decades after these large events (Wang, 2007; Suito and Freymueller, 2009).

Because of the long duration of postseismic transient deformation and the short length of precise geodetic measurements in most places, it is not clear whether postseismic transients decay away to a relatively steady background deformation rate, or whether deformation rates are never truly steady in time. Answering this question is very important, because the answer will reveal a great deal about the dynamics of earth deformation. Decay to a steady background rate suggests that deformation in the mantle and lower crust associated with fault motion is localized due to lateral variations in properties or nonlinear viscoelasticity. The long-term fault motion rate and background deformation rate would represent a balance between tectonic forces and the effective viscosity of the weak zone beneath the fault. On the other hand, a uniform linear viscoelastic mantle requires that shear in the mantle be distributed broadly rather than localized beneath faults. In this case, deformation at the surface would never be steady in time except when the earthquake recurrence time and mantle relaxation time are roughly equal, and transient deformations would always extend a great distance away from every active fault, even a long time after the last major earthquake (Savage and Prescott, 1978). The apparently linear "interseismic" phase would be essentially an illusion caused by our short measurement history. However, our ability to measure steady rigid plate motions that are very close to long-term geological plate motion estimates argues in favor of some degree of localization of strain in the mantle beneath faults, as does the observation that interseismic motions are localized around faults like the North Anatolian Fault in Turkey regardless of the time since the last earthquake (Hearn et al., 2009). This is also supported by the frequent consistency of geologic estimates of fault slip rates and geodetic estimates based on simple linear models. However, this question is not yet settled and probably will remain a focus of research for some time. Although some progress has been made in the theoretical models, a convincing and complete model for the earthquake cycle that incorporates postseismic and interseismic deformation and agrees with data has not yet been developed.

Transient fault movements and more complex models of the earthquake cycle

Faults also exhibit a range of transient slip behavior, possibly similar to postseismic afterslip, but not necessarily caused by identifiable stress changes such as those caused by large earthquakes. The most notable examples are slow slip events (SSE) on subduction thrusts, also called episodic tremor and slip (ETS) events because the slip is usually accompanied by the emission of seismic tremor (Rogers and Dragert, 2003). There are also several known examples of triggered creep or changes in creep rate, sometimes caused by nearby earthquakes on a different fault. For example, the 1989 Loma Prieta earthquake in California triggered shallow creep on a subparallel thrust fault system (Bürgmann et al., 1997) and caused changes in creep rate on sections of the nearby Hayward and Calaveras faults (Lienkaemper et al., 1997). In the latter case, the earthquake caused a reduction of stress on these nearby creeping faults and some sections responded by ceasing to creep for a period of time, and later restarted, while other sections continued to creep at a reduced rate. These transient fault movements are further evidence that the steady, elastic earthquake cycle model is a significant simplification of reality: even between earthquakes there can be small variations in deformation.

SSE and ETS events were first observed in Japan (Heki et al., 1997) and at the Cascadia subduction zone (Dragert et al., 2001) in North America. A large number of these events have now been identified in Japan, Cascadia, Alaska, Mexico, the Ryukyu arc, and New Zealand, and in most cases, the slip events have been accompanied by emission of seismic tremor (Schwartz and Rokosky, 2007). These events come in a range of sizes, many with slip and area equivalent to magnitude 6–7.5 earthquakes. Small tremor bursts are also observed, as are smaller slip events too small to detect with GPS (but observed on strainmeters or tiltmeters). These mostly aseismic slip events, including small bursts of tremor that do not have resolvable geodetic signals, appear to follow a self-similar (power-law) scaling relation somewhat like regular earthquakes, but with a different power-law exponent (Ide et al., 2007).

The recognition of these transient events, along with the development of models that explained seasonal loading variations (Heki, 2001) has resulted in a transformation of thought about the steadiness in time of site motions. Prior to the recognition of SSEs or ETS events, the typical assumption in tectonic geodesy was that all deviations from a linear trend represented noise in the data, except when there was a known cause of displacement such as an earthquake or postseismic deformation. Today, deviations from a linear trend are likely to be considered signal, although it remains uncertain how to reliably distinguish between transient tectonic signal and

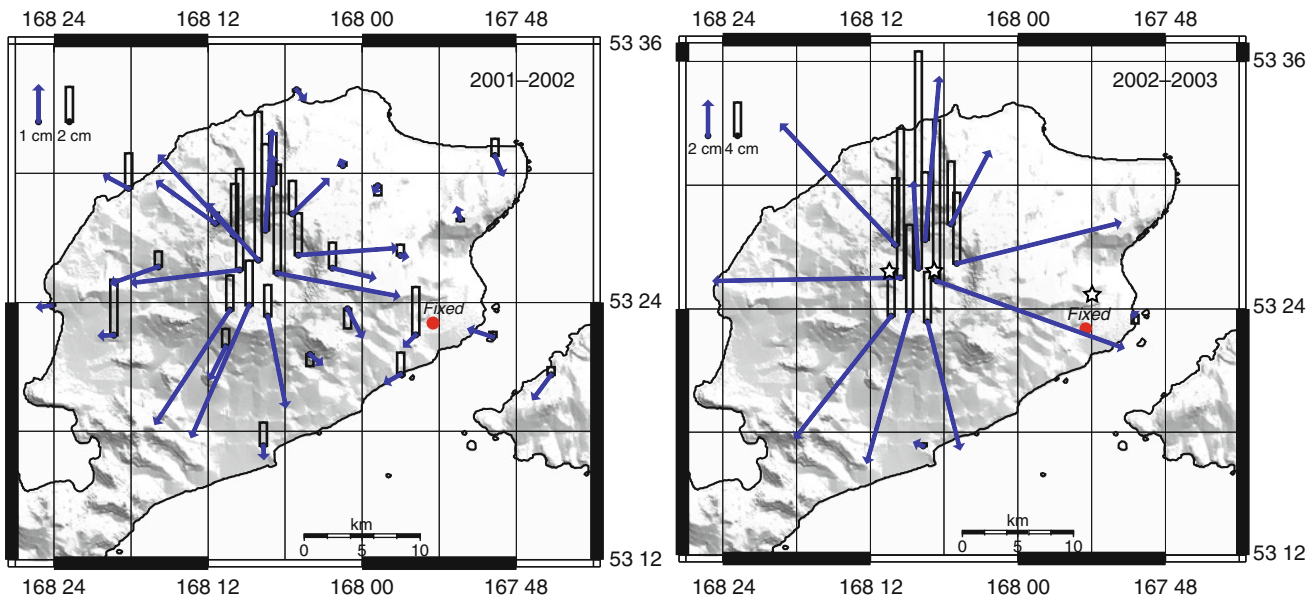
noise. The most successful attempts to do so rely on the spatial coherence of deformation signals, especially when the deformation can be linked to a source model, such as slip on a fault of known geometry. However, noise in geodetic time series can be spatially correlated as well, and the separation of small transient signals from noise remains an area of active research. A particular area of emphasis today is in the automatic detection of transient events from observed time series.

Volcano deformation

Unlike tectonic deformation, which results mainly from slip on faults (shear sources), volcanic deformation results mainly from volumetric or dilatational sources, such as the expansion or contraction of a dike or sill or other magma body. Injection of magma into the subsurface through intrusion or removal of magma from the subsurface as it is erupted cause pressure changes that drive volcanic deformation, and result in deformation at the surface due to the elasticity of the earth. Volcanic deformation commonly results in horizontal displacements that are oriented radially away from or toward the volcano, and can produce significant subsidence or uplift (Figure 5). Some volcanoes have produced very large deformation signals associated with the intrusion of magma before eruption, while others have produced only small deformation signals even as the result of large eruptions. The heterogeneity of behavior may be a result in part of magma properties that vary with magma composition and gas content, or because of variations in eruption style and triggering mechanisms.

The simplest volcanic source model is a spherical point pressure source, usually called the Mogi model after the Japanese scientist who first applied it in the 1950s (Mogi, 1958). This model describes the deformation at the surface caused by a pressure change in a small spherical body in an elastic half-space; the point source approximation actually holds even for relatively large bodies. The Mogi model has provided a surprisingly good fit to observed displacements from volcanic sources. Models for finite spherical or elliptical sources have also been developed. The finite spherical source is rarely used because the size of the source usually cannot be constrained by data, but elliptical sources produce a different pattern of displacements due to the difference from spherical geometry. Dikes and sills, planar bodies of magma that are associated with the opening and filling of planar cracks, can also produce significant deformation. These sources can be modeled using the same dislocation theory that is used for shear faulting, as the most commonly used models include the equations for opening-mode deformation.

Volcanic deformation is inherently time-dependent, and volcanoes can display episodes of both inflation (increasing pressure) and deflation (decreasing pressure). Deflationary episodes probably result from a pressure drop caused by the leaking out of exsolved gases or from the depressurization of a hydrothermal system. During eruption, most volcanoes show deformation associated with decreasing pressure, although in a few cases there have



GPS, Tectonic Geodesy, Figure 5 Displacements from Okmok volcano, eastern Aleutian arc, Alaska, showing significant volcanic deformation. The left panel shows displacements from 2001–2002, and the right panel from 2002–2003. The scale for vertical motion is different from that of the horizontal, and there is a factor of two differences in scale between the two plots, a result of the much larger deformation in 2002–2003. The blue arrows are horizontal displacements, and the white bars show vertical displacements. Data are from Miyagi et al. (2004). The deformation results from the pressurization of a magma body located about 3 km below the surface.

been observations of simultaneous deflation at depth and inflation close to the surface. One example of this is the 2000 eruption of Usu volcano in Japan, for which deformation and gravity change data were fit best by a model with a deflation source at ~4 km depth, connected to the surface by an intruded fissure (Jousset et al., 2003). If the magma is assumed to be incompressible, which is a good assumption for a magma that contains no exsolved gas bubbles, then the volume of magma added or removed to the subsurface is proportional to the pressure change in the reservoir or the opening or closing of a dike or sill, and thus the deformation magnitude is proportional to magma volume. If the magma is compressible, then the deformation magnitude will be a function of the magma volume change, magma compressibility, and the elastic properties of the surrounding rock.

Unlike the tectonic problem, it seems that a simple "eruption cycle" model does not apply to volcanoes. The idea is appealing: magma would accumulate in the subsurface until the pressure reaches some critical level, which causes failure of the overlying rock, opening of a conduit to the surface, and then eruption. However, observations show that the magma supply is not uniform in time (Dvorak and Dzurisin, 1993), while tectonic loading is, and successive eruptions at the same volcano can be quite different in volume and style. Even at volcanoes that erupt frequently, there does not appear to be a clear relationship between the volume of magma that accumulates between eruptions and the volume that erupts. This reflects the fact that the crust beneath active volcanoes may be occupied by a number of bodies of crystal mush or partially solidified magma, and also the importance of gases and volatiles in triggering magma rise and eruption. A small intrusion of fresh, hot magma into a cooler body can trigger exsolution of dissolved volatiles and remobilization of the magma, causing a pressure increase that may be capable of triggering an eruption.

Similarly, although rapid deformation at a volcano is an indication that the volcanic system is active, it is not clear whether episodes of deformation can reliably be treated as short-term eruption precursors. Some large calderas, such as Campi Flegrei in Italy, Yellowstone and Long Valley in the USA, and Rabaul in Papua New Guinea, have experienced episodes of substantial inflation, deflation or both over a period of many years (Dvorak and Mastrolorenzo, 1991; Dvorak and Dzurisin, 1997). Some of this deformation may result from pressure changes in hydrothermal systems associated with the volcano, rather than from changes in the magma reservoirs themselves. Okmok volcano in the eastern Aleutian arc (USA) experienced substantial accumulation of new magma at shallow depth (Figure 5) following its 1997 eruption, causing as much as several decimeters of displacement at the surface (Lu et al., 2005; Fournier et al., 2009), but its 2008 eruption was preceded by a period of ~3 years of relative quiescence. Mt. Etna in Italy is another volcano that has shown significant magma accumulation between eruptions, although not necessarily as a short-term precursor to eruption. Other recent eruptions had only subtle or nonexistent deformation prior to the eruption, including the eruptions of St. Helens in 2004, Augustine in 2006, and Redoubt in 2009 in the USA (Cervelli et al., 2006; Lisowski et al., 2008). However, significant precursory deformation very close to the eruptive vent certainly must happen. A notable example came from a continuous GPS site that was installed on Stromboli volcano (Italy), which showed dramatic displacements in the minutes before it was destroyed by an eruption from a new vent located a very short distance away (Mattia et al., 2004). Such deformation, associated with the final rise of magma to the surface, is very localized.

On the other hand, Kilauea volcano in Hawaii shows distinctive and reliable patterns of deformation prior to almost every significant eruption episode. Most magma erupted from Kilauea in recent decades has been emitted from vents on one of its rift zones, and since 1983 activity has been centered on the flank vent called Pu'u 'O'o. Eruptions of Kilauea are preceded by inflation at the volcano's summit, which then deflates as a pulse of magma that is intruded into the rift zone and proceeds down-rift until it reaches the flank vent (Dvorak and Dzurisin, 1993; Dvorak and Dzurisin, 1997). There is some indication that basaltic volcanoes like Kilauea and Okmok may produce larger and more predictable deformation patterns than more silicic volcanoes like the others mentioned in this section.

Glacial isostatic adjustment and sea level studies

The Earth also deforms in response to changes in surface loads, for example, changes in the mass of glaciers, ice fields, and ice sheets on the surface. The best-known example of this deformation is the dramatic uplift that has occurred in the regions formerly covered by the continental ice sheets in North America and Europe. The ongoing uplift in these regions, due to glacial isostatic adjustment (GIA), is dominated by the viscoelastic response of the mantle to the unloading as the ice sheets collapsed after the last glacial maximum (LGM), about 23,000 years ago. While the ice sheets were growing, the mass of the ice depressed the surface and induced stresses that caused the mantle to flow out of the way. Upon collapse of the ice sheets the process was reversed and mantle is still flowing back at present. In addition to the long-lasting effects of the great ice sheets, deformation due to present-day ice mass changes can be observed as well, and can cause even more rapid deformation even though the ice mass changes are much smaller.

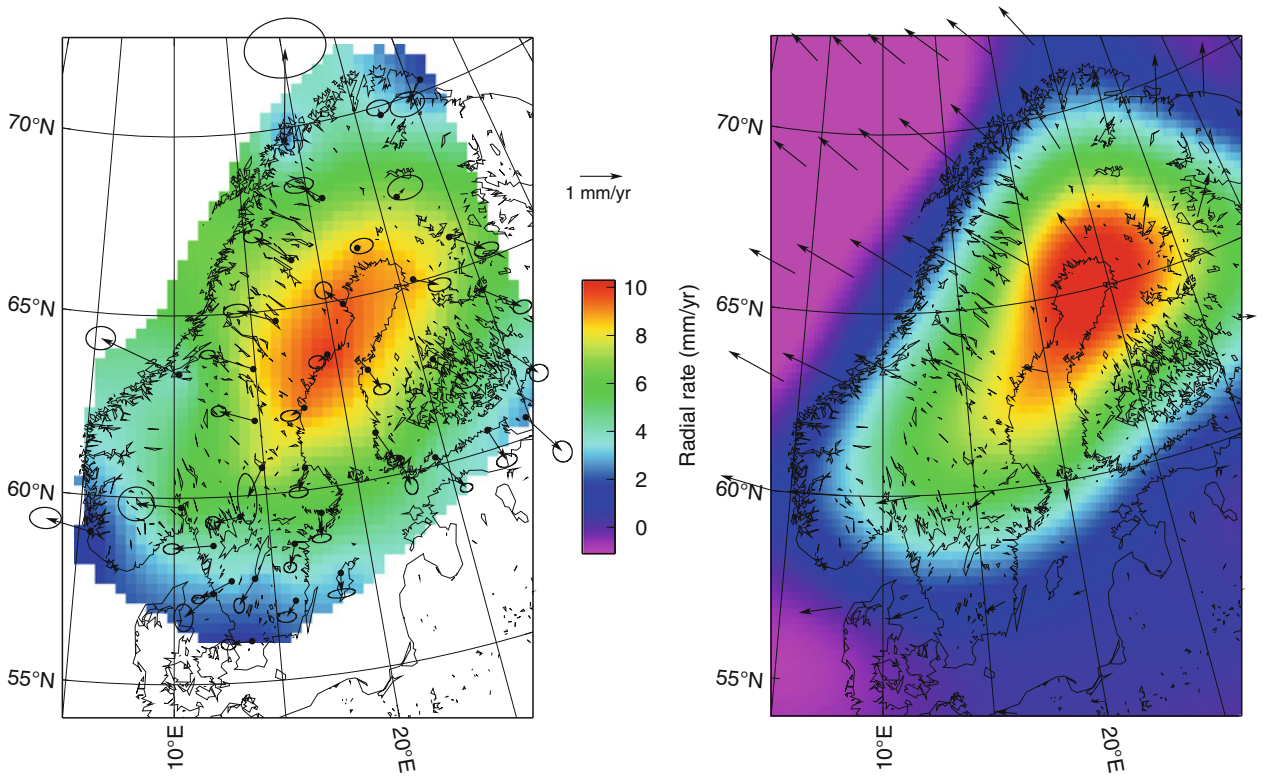
Displacements from load changes are predominantly vertical. Horizontal displacements can be significant relative to geodetic measurement errors, but are usually several times smaller than the vertical displacements. Horizontal displacements are more sensitive than the vertical displacements to assumptions made in the computations (compressibility vs incompressibility, radially symmetric earth structure vs lateral variations, etc.). Thus,

while model predictions for the vertical motions are in general agreement, the best models for the horizontal motions remain a matter of considerable debate.

Conceptually, it is useful to break up the deformation due to load changes into two separate components. The first component is the elastic response, which is instantaneous upon a change in load. After the elastic response at the time of the load change, stresses in the viscoelastic mantle relax with time, causing subsequent displacements until the final relaxed response is reached. The theory for computing the elastic response of the earth dates back to Love in the early twentieth century; Farrell (1972) used this theory to compute the response of a realistic earth model to both point loads and disk loads. Farrell's results are commonly used to compute the elastic response. The viscoelastic problem results in time-dependent deformation, which can be computed in a variety of ways, either in terms of viscoelastic Love numbers or viscoelastic Green's functions for point or finite loads. However it is done, in the viscoelastic problem the time-dependent displacements or displacement rates are computed and include both the elastic and viscous components.

The BIFROST project in Scandinavia was initiated in the early 1990s to study GIA resulting from the post-LGM collapse of the Fennoscandian ice sheet (Johansson et al., 2002; Milne et al., 2004). This project demonstrated the capability of GPS to measure accurate vertical motions. A network of continuous GPS sites was established that encompassed the entire region surrounding the Baltic Sea. The observations revealed the expected pattern of deformation, with the largest uplift rates (12–13 mm/year) located on the northwest margin of the Baltic Sea where the LGM ice sheet had its maximum thickness (Figure 6). Overall, the contours of constant uplift rate are elliptical in shape. Horizontal motions are no larger than 2–3 mm/year and generally are oriented away from the center of the former ice sheet. The GPS observations provided important new constraints on the viscosity structure of the mantle (Milne et al., 2001).

There have been fewer geodetic studies of GIA from the Laurentide ice sheet in North America. The number and spatial density of continuous GPS sites in that part of North America is much smaller than in Scandinavia. However, reliable estimates of the vertical GIA signal have been determined from repeat surveys of sites of the Canadian Base Network and from the available continuous GPS sites (Sella et al., 2007). Peak uplift rates are 10 mm/year near Hudson's Bay and significant uplift is



GPS, Tectonic Geodesy, Figure 6 Observations and model predictions for GIA in the Fennoscandian region, after Milne et al. (2001) using the BIFROST solution of Lidberg et al. (2007) (*left panel*). Horizontal velocities relative to the Eurasian plate (arrows, with 95% confidence ellipses), and vertical velocities (background color) (*right panel*). Model predictions based on ICE-3G with lithosphere thickness 120 km, upper mantle viscosity 5e20 Pa s, and lower mantle 8e21 Pa s. This figure was provided by James L. Davis, Lamont-Doherty Earth Observatory, Columbia University.

observed over most of northern and northeastern North America. The horizontal motions are much smaller, generally at the 1–2 mm/year level, and include motions directed both toward and away from the former ice sheet. The scale of the GIA deformation in North America poses an interesting problem: the estimates of horizontal motion relative to North America depend on the estimated motion of the North American plate in ITRF, but it is difficult to measure the motion of North America without having that estimate biased by horizontal GIA. As a result, independent estimates of the motion of the North American plate tend to differ by more than would be expected from data noise alone.

The most rapid uplift rates from GIA come not from the areas formerly covered by the great ice sheets, but from regional ice masses (glaciers and ice fields) that recently have been losing mass. Ice mass loss in Alaska and surrounding parts of Canada in North America and in Patagonia in South America has been very large since the end of the Little Ice Age (LIA) ~200 years ago, large enough to account for 10–20% of twentieth century global sea level rise (Dyurgerov and Meier, 2005; Larsen et al., 2007; Lemke et al., 2007). In both of these regions, measured uplift rates exceed 30 mm/year at their peak, and significant uplift has been observed in a broad area surrounding the regional ice fields. In Alaska, the observed uplift depends significantly on both the ongoing regional ice mass loss and the nineteenth century deglaciation of Glacier Bay (Larsen et al., 2005). The former source has important elastic and viscoelastic components, while the latter is purely a viscoelastic response. Overall, depending on the place, the contribution to the uplift rate from the present ongoing mass loss ranges from ~1/3 to ~1/2 of the entire signal, and the uplift rate from present mass loss can be as large as ~12 mm/year (Sato et al., in press).

Mass loss in the Greenland and Antarctic ice sheets has begun or accelerated within the last decade and the changes in mass loss rate are reflected in changes in the vertical motions. Southeast Greenland made the transition from no or minimal uplift to significant uplift in the early 2000s, while the onset of uplift in northwest Greenland began a few years later (Khan et al., 2008; Khan et al., 2010). The uplift history measured by GPS is in agreement with the mass loss history estimated by gravity observations of the GRACE satellite mission and is corroborated by direct observation and measurement of glacier mass balance in the area. The prospect of observing changes in Antarctic and Greenland ice sheets has prompted the installation of new networks of continuous GPS sites, which have begun to produce data that will allow researchers to "weigh" the ice sheets as they change over time.

As glaciers, icefields, and ice sheets lose mass, most of the water ends up in the ocean where it raises sea level. Tide gauges measure relative sea level, which is the level of the ocean surface relative to the land surface. Estimates of global sea level rise depend on averaging over a global set of tide gauges where uplift or subsidence of the land is negligible, but more data could be used to analyze sea level variations if land uplift rates at tide gauges were precisely known. Wöppelman et al. (2009) used GPS measurements at a globally distributed set of tide gauges to correct for vertical motions of the land and estimated an average global sea level rise of 1.6 ± 0.2 mm/year, assuming that the vertical motions observed by GPS over the last decade are representative of the last 100 years. This estimate agrees with previous estimates for twentieth century sea level rise.

Sea level does not rise uniformly around the globe when there is a significant redistribution of mass resulting from the melting of ice. Spatial variations in sea level rise result from changes in the geoid caused by the mass redistribution; sea level follows the geoid, so if the geoid height is increasing over a section of ocean, then local sea level would rise in a geocentric reference frame (Mitrovica et al., 2001; Tamisiea et al., 2001). The difference between relative sea level variations measured by tide gauges and vertical motions measured by GPS is a combination of vertical motion of the land, sea level rise due to the addition of water to the oceans, ocean thermal expansion, and the local geoid change. Geoid rate changes at the multiple mm/year level are predicted for areas of significant regional mass loss, such as Alaska and Patagonia, and significant geoid height trends have been measured using GRACE (Tamisiea et al., 2001; Tamisiea et al., 2005). Much larger variations in the geoid would appear in the future if the Greenland and Antarctic ice sheets melt significantly (Mitrovica et al., 2009). Future studies will integrate data and models for all of these effects to provide a complete and self-consistent picture of sea level, gravity change, and height change around the world's coastlines.

Summary

High-precision geodesy is an important tool for the study of active tectonics and other causes of crustal deformation. Motion and deformation of points on the surface of the earth result from a combination of tectonic plate motions, elastic deformation from the slip deficit associated with faults that are locked by friction, and coseismic and postseismic displacements. Deformation caused by pressure changes within volcanic systems is important near volcanoes, and in some areas there is additional deformation caused by past and present surface load changes, most importantly from the melting of ice in glaciers, ice fields, and ice sheets. Deformation due to several or all of these sources may be superposed in some locations, such as southern Alaska and Patagonia. Surface displacements can be related to the underlying sources using elastic or viscoelastic deformation models, the most important of which are based on dislocation theory.

Synonyms

Gravity meters, relative

Definition

An instrument which measures differences in gravity. Units: Practical units are mGal (10^{-6} g) and μGal (10^{-9} g). 1 Gal = 1 cm/s^2.

Introduction

The first relative gravity measurements were made in 1672 by the French astronomer, Richer, who noted a difference in the period of a pendulum when observed in Paris and close to the equator in Cayenne, South America. For the next two centuries, relative gravity measurements, mainly for scientific purposes, were made with pendulums. In 1893, Threlfall and Pollock made the first successful spring-mass gravimeter in Sydney, Australia (Threlfall and Pollock, 1900) using the newly discovered quartz fibers. From the middle of the twentieth century up until the present nearly all relative gravity measurements have been made with instruments based on a mass suspended by a quartz or metal elastic system. Instruments in which the mass is levitated in the field of a superconducting magnet and instruments based on inertial-grade accelerometers are also used in some applications.

Absolute gravity meters, which are sometimes used to make relative gravity measurements (e.g., Brady et al., 2008), obtain a value for gravity through measurement of the quantities distance and time without reference to other gravity values. These instruments are beyond the scope of this article and are described in the "Gravity Measurements, Absolute" entry of this encyclopedia.

Relative gravimeters can be classified into three types according to the mode in which they are operated, with each mode of operation having different performance requirements:

1. Survey: Measurement of relative gravity as a function of position on, or under, the surface of the earth or on the sea floor.
2. Stationary: Continuous measurement of changes in gravity or low-frequency earth motion as a function

of time at a fixed location on, or under, the surface of the earth or on the sea floor.
3. Dynamic: Measurement of relative gravity as a function of position from a moving platform such as an aircraft or a ship.

Performance requirements

Basic performance requirements for relative gravimeters are listed in Table 1. These must be met under a range of environmental conditions, including movement of the sensor between and during readings. Dynamic instruments have to be able to produce data while moving and subject to relatively large accelerations, whereas the defining characteristic of survey instruments is the capability to withstand acceleration and shocks during transport without sustaining changes in the reading value.

Survey instruments can be subdivided into borehole, sea-floor, and land gravimeters all with the same basic performance requirements. However, borehole and sea-floor instruments must have remote reading capabilities and be packaged to withstand high pressure. In addition, borehole instruments have size restrictions and have to operate at higher temperatures. Survey gravimeters have a useable sensitivity of less than 5 μGal (e.g., Zumberge et al., 2008; Merlet et al., 2008). A total range of 7,000 mGal covers the gravity field on the surface of the earth. A minimum continuous operating range of around 50 mGal is needed to provide useful measurement capability.

Stationary gravimeters can be divided into those which require very low noise performance and which are usually located in an observatory and portable instruments. Most applications for observatory instruments (Crossley et al., 1999) are in the frequency range from dc up to approximately 7 mHz which is the maximum frequency at which the seismic normal modes are resolvable (Ingate and Berger, 2004). Minimum earth noise in this band is around $3 \times 10^{-2}\mu\text{Gal}/\sqrt{\text{Hz}}$ (Ingate and Berger, 2004) which represents the minimum useful instrument sensitivity. Superconducting instruments and the metal spring instruments which approach this sensitivity (Banka and Crossley, 1999) have a range of a few mGal or less and are saturated by surface waves of large earthquakes (e.g., Mansinha, 1992; Agnew et al., 1986). Applications for portable instruments require a larger range and less sensitivity and include volcanic monitoring, earth tide, and ocean loading studies, groundwater monitoring, and earthquake monitoring.

Useable sensitivity for airborne gravity meters is limited by GPS precision as described in the *Sensor motion and orientation* section below. With a 100 s low pass filter, this limit is around 0.5 mGal (Argyle et al., 2000).

Technology

Sensor technology

Relative gravimeters are based on one of the four core technologies listed in the top row of Table 2. Technologies have characteristics which better suit them to particular types of gravity meter as discussed below.

Fused quartz

Fused quartz sensors perform well in survey gravimeters because quartz has high strength, remains almost perfectly elastic up to its breaking stress, and can be welded into compact structures which have exceptional mechanical integrity. Sensors are free of tares when transported and do not have to be clamped between readings, making them accurate and quick and easy to operate. The relatively high long-term drift of quartz springs is linear enough to be compensated electronically.

Metal

Metal spring-mass sensors have very low long-term drift and low temperature coefficient, making them well suited to stationary measurements. However, they are more susceptible to tares in response to transportation because the elastic properties of the materials in their elastic suspension are inferior to those of quartz. Also they are assembled from a number of components fixed together, so they do not have the integrity of a welded quartz structure. These inherent disadvantages have been overcome by clamping the mass during transportation and careful handling, but at the expense of added manufacturing complexity, requirement for more skilful operators and lower productivity in the field. Historically, survey gravimeters based on metal spring-mass sensors were used extensively in survey operations because of their low long-term drift and high accuracy, especially for establishing gravity networks and other applications which require measurement of gravity at widely separated points. Absolute gravimeters are now used to make large-scale-network-type

Gravimeters, Table 1 Gravimeter performance requirements

	Performance			
			Range (mGal)	
Type of gravimeter	Signal bandwidth	Sensitivity (μGal)	Total	Continuous (min)
Survey	dc	1–10	7,000	50
Stationary: Observatory	dc − 10 mHz	$3 \times 10^{-2}/\sqrt{\text{Hz}}$	7,000	2
Stationary: Portable	dc − 1 Hz	1	7,000	50
Dynamic	dc − 10 mHz	500	10,000	10,000

Gravimeters, Table 2 Gravity sensor core technology

Technology / Type of gravimeter	Spring/mass		Superconducting	Inertial-grade accelerometer
	Quartz	Metal		
Survey	▨	▨		
Stationary		▨	▨	
Dynamic		▨		▨

measurements and survey instruments with metal spring-mass sensors are being replaced for most other applications by modern quartz instruments which are easier to manufacture and operate, and make extensive use of electronics to obtain similar or better performance.

Metal spring-mass gravimeters were first used for dynamic applications in the late 1950s (Dehlinger, 1978). Since then they have been continually refined and modified for this application and are in widespread use today (e.g., Williams and MacQueen, 2001).

Superconducting

The superconducting gravity sensor is described by one of its inventers (Goodkind, 1999) as "a spring type gravimeter in which the mechanical spring is replaced by a magnetic levitation of a superconducting sphere in the field of superconducting, persistent current coils." Because these currents are very stable, the sensor has extremely low drift which makes it well suited for stationary operation. It is unsuited for survey or dynamic operation as the mass is insufficiently constrained to continue operation in the presence of large accelerations.

Inertial-grade accelerometers

These are devices that have been developed for inertial navigation systems so have excellent dynamic performance on moving platforms and are very compact. They have sufficient sensitivity for dynamic operations, but not for survey or stationary operations. An example of an inertial-grade accelerometer is the Q Flex QA3000 which has a volume of approximately 1 cu. inch and is built around a chemically machined quartz suspension (Foote and Grindeland, 1992). Another example is the Bell Aerospace accelerometer (Torge, 1989) which has similar dimensions.

Design principles

A generalized signal flow diagram for relative gravimeters is shown in Figure 1. The proof mass is suspended so that it moves in a well-defined trajectory in response to a change in the gravitational force on it. The proof mass and suspension are termed the gravity sensor. The gravity reading is derived from the input to the calibrated feedback actuator that returns the output of the displacement sensor to the reference point. Feedback force is applied to the proof mass through an electric field or electromagnetic actuator and/or through a change to the suspension geometry.

Gravity sensor natural period, sensitivity, and seismic noise

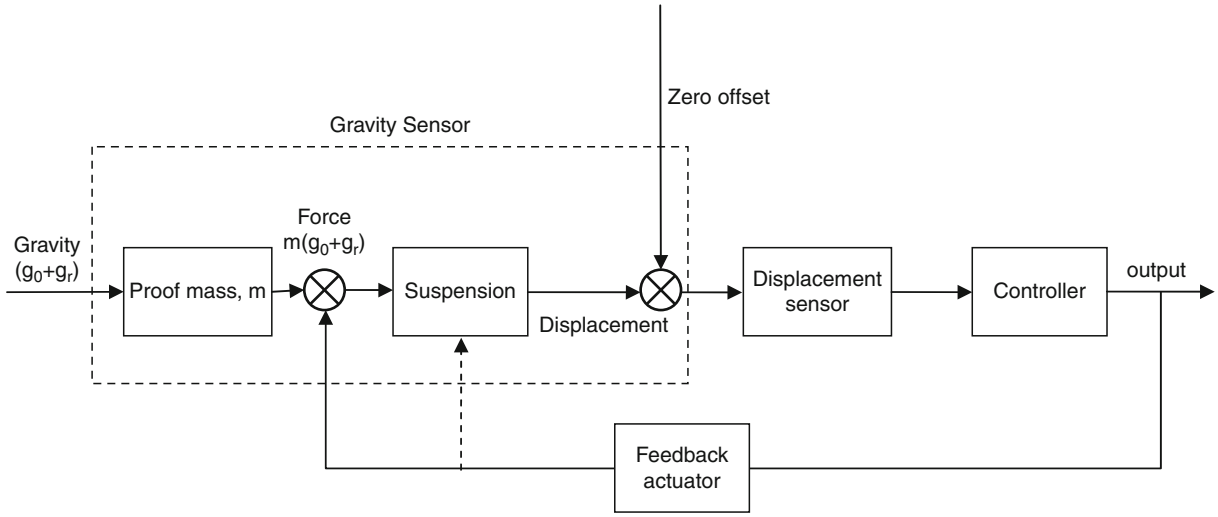
The design principles of the gravity sensor determine important performance characteristics of the gravimeter that are largely independent of the technology used in construction.

The gravitational force on the mass of a spring-mass gravity sensor is balanced by the elastic force generated by the extension of a quartz or metal spring. The extended length of the spring is given by $l = \frac{mg}{k} + l_u$ where k is the spring constant and l_u is the unstressed length of the spring. A change in gravity from a value g_0 to $(g_0 + \Delta g)$ produces a change in spring length from l_0 to $(l_0 + \Delta l)$ where $\Delta l/(l_0 - l_u) = \Delta g/g_0$. As Δl is proportional to $(l_0 - l_u)$ this simple spring-mass system is termed a proportional sensor, or to use the language of seismometry, a short-period sensor.

For a practical sensor with $l_0 - l_u = 2$ cm and a change in gravity of 0.01 mGal (1 Gal = 1 cm/s^2), $\Delta g/g_0 = 10^{-8}$ and the displacement which must be detected is $\Delta l = 2 \times 10^{-10}$ m. This system responds equally to gravity and all acceleration up to its natural frequency $f_n = \frac{1}{2\pi}\sqrt{\frac{k}{m}} = \frac{1}{2\pi}\sqrt{\frac{g_0}{(l_0 - l_u)}} = 3.5\,\text{Hz}$, so unwanted signals, including microseismic and cultural noise, would need to be filtered from the output to recover the gravity signal.

It was not until the 1970s and 1980s that electronics were available to detect sub-nm displacements and effectively filter signals in a portable instrument. The Scintrex CG-3 gravity meter, introduced in 1987, and its successor the CG-5 are based on a proportional spring-mass system and use capacitive displacement sensing and digital filtering to achieve the required level of sensitivity and noise reduction (Hugill, 1990).

Before the advent of modern electronics, many mechanical design concepts were developed (e.g., Hugill, 1984) to increase sensitivity and reduce natural frequency, and thus noise response, of sensors enabling detection of gravity-induced mass displacement by eye, through a microscope. Sensors with increased mechanical sensitivity are termed "astatic" and are analogous to long-period seismometers.



Gravimeters, Figure 1 Relative gravimeter functional diagram.

The most successful of these was the LaCoste suspension based on "zero-length spring" with an unstressed length $l_u = 0$ (LaCoste, 1934). Sensitivity is adjustable and is usually set up with sufficient displacement sensitivity for optical detection by eye with a microscope and a natural frequency low enough for the instrument to be insensitive to seismic noise. Worden-type and LaCoste and Romberg gravimeters, which were introduced in the 1940s and 1950s, are based on the LaCoste suspension.

The sensor in the superconducting gravimeter (Goodkind, 1999) is also astatised with its sensitivity being increased by adjusting the relative current settings in two collinear coils to shape the magnetic field gradient in the vicinity of the levitated proof mass. Superconducting sensors are usually adjusted to operate with a period of 5 s.

Displacement sensing and feedback

Most modern gravimeters use capacitive displacement sensing and either electromagnetic or electrostatic feedback. Electrostatic feedback allows sensor design to be simplified as the same electrodes can be employed for sensing, using high frequency excitation, and feedback at lower frequencies (e.g., Block and Moore, 1966; Hugill, 1984). Examples of instruments using capacitive displacement sensing and electrostatic feedback include the Scintrex CG-3 and CG-5 (Hugill, 1990) and the micro-g LaCoste gPhone (Micro-g LaCoste, 2010).

Electromagnetic feedback has the advantage of inherent linearity and a higher force capability. Instruments with capacitive displacement sensing and electromagnetic feedback include the Bodenseewerke GSS30 (Torge, 1989), the superconducting gravimeter (Goodkind, 1999) and inertial-grade accelerometers. In the latter, feedback supports the full gravitational force on the mass so the spring suspension only provides constraint of the proof mass motion (e.g., Foote and Grindeland, 1992) which is equivalent to having no zero offset in Figure 1.

In most gravimeters with the LaCoste suspension the top of the mainspring is moved to null the mass. This is done in Worden-type meters through a gearbox, screw thread, and auxiliary springs. In the LaCoste and Romberg g meter (LaCoste and Romberg, 1945), the top of the spring is connected to a lever system which is moved by the operator through a calibrated gearbox and screw thread. The required displacement for a change in gravity of 0.01 mGal is 0.25 nm (Torge, 1989). Electrostatic feedback systems are installed in gravimeters with metal LaCoste suspensions as an option for survey instruments to make reading easier and more accurate (e.g., Webring et al., 2004) and to enable high sensitivity automatic reading for stationary instruments (e.g., Block and Moore, 1966).

Error sources

Error sources can be divided into three broad groups: those generated by the gravimeter or intrinsic error sources, those resulting from the response of the instrument to external inputs and those resulting from the effects of transportation.

Intrinsic error sources

Scale factor changes

Changes in the scale factor of gravimeters with quartz sensors can be as high as 10^{-3} in the first year after manufacture; subsequent changes are of the order of 10^{-4} per year (Zumberge et al., 2008; Carbone and Rymer, 1999). Changes in scale factor of around 10^{-3} have also been reported in metal spring sensors (Carbone and Rymer, 1999). In contrast to the smooth drift in the scale factor of quartz sensors, the reported changes in the metal spring

sensor were abrupt and separated by long periods of stability.

As the scale factor, k, relates a reading differences $(R_2 - R_1)$ to the gravity change $(g_2 - g_1)$ through the expression $(g_2 - g_1) = k(R_2 - R_1)$ errors due to changes in scale factor are proportional to gravity difference, so have most effect on measurements made by survey gravimeters. Dynamic instruments are less influenced because the sensitivity requirement is lower. Good field practise, including routine calibration and use of multiple instruments for critical measurements, prevents degradation of survey results.

Instrument noise

Thermal noise determines the detection limit of the sensor and is given by (e.g., Richter et al., 1995)

$$a_t^2 = \frac{25 k_b T}{Q m T_n} \left(\frac{(\mathrm{ms}^{-2})^2}{\mathrm{Hz}} \right)$$

where a_t is the rms noise equivalent acceleration spectral density, k_b is Boltzman's constant, T is absolute temperature, Q is the quality factor, m is the mass of the proof mass and T_n is the natural period. For a metal spring LaCoste and Romberg earth tide gravimeter operating at 323 K with $Q = 1$, $m = 80$ g, and $T_n = 20$ s, the thermal noise is $a_t^2 = 7 \times 10^{-20}$ $\mathrm{m^2 s^{-4}/Hz}$ (Richter et al., 1995) and for a superconducting gravity sensor operating at 4 K with $Q = 0.14$, $m = 4$ g and $T_n = 5$ s, the thermal noise is $a_t^2 = 5 \times 10^{-19}$ $\mathrm{m^2 s^{-4}/Hz}$ and could be a factor of 3 higher, depending on the extent to which the horizontal modes couple into the vertical (Van Camp, 1999).

The thermal noise limit is therefore a significant design parameter for stationary gravimeters measuring in the frequency band dc –7 mHz where earth noise power spectral density can be lower than 10^{-19} $\mathrm{m^2 s^{-4}/Hz}$ (Ingate and Berger, 2004).

Long-term drift

Long-term drift is a characteristic of all relative gravimeters and imposes constraints on the way in which instruments are used. Values range from a few μGal/year for instruments with superconducting sensors (e.g., Crossley et al., 2003) to several hundred μGal/day or more for survey gravimeters with quartz sensors (e.g., Bonvalot et al., 1998; Merlet et al., 2008). Drift is modeled as a function of time and removed from measurements as part of data processing. Model parameters for survey instruments are derived from repeat readings on base stations at different times during a survey. Absolute gravity readings obtained at the same site are used as a reference to model the drift of superconducting gravimeters (e.g., Van Camp and Francis, 2007).

External noise sources

The effect of external inputs on the sensor can be reduced to acceptable levels by a number of approaches which are described below. These include shielding the sensitive elements, compensation, and filtering and reducing the input at its source through setup and choice of location and time.

Sensor motion and orientation

Motion of the gravity sensor can produce a response which is only distinguishable from the gravity signal by its frequency content. If the disturbing motion is outside of the signal bandwidth, then its effects can be removed by filtering, otherwise independent means must be used to determine the sensor motion and compensate for its effects. High frequency motion and vibration can excite higher order sensor modes which can couple into the fundamental mode (e.g., Block and Moore, 1970).

The gravity sensor measures the components of gravity and acceleration that are parallel to its sensitive axis. To accurately measure gravity the sensor is vertically aligned. Vertical misalignment of the sensor results in a component of gravity being measured which varies as the cosine of the angle.

Horizontal acceleration can produce "cross coupling" in sensors that have the proof mass in the form of a horizontal pendulum and feedback control which doesn't keep the mass at the zero position with sufficient accuracy (e.g., Torge, 1989). Horizontal velocity causes centrifugal and Coriolis accelerations which combine to produce the Eötvös-effect (Torge, 1989).

The relative magnitude of each of these error sources depends on the mode in which the instrument is operated:

Airborne gravity precision and spatial resolution are ultimately limited by the recovery of aircraft vertical position with GPS (e.g., Bell et al., 1999). This limit has been estimated to be around 1 mGal rms for an 80 s filter (van Kann, 2004), an estimate which is confirmed by actual measurements of aircraft acceleration with GPS (Wei and Schwarz, 1995). Performance at this level has been reported for at least two airborne gravity systems (Studinger et al., 2008). One of these, the Sander Geophysics system, which is based on inertial-grade accelerometer sensors, is unaffected by turbulence up to 0.6 $\mathrm{m/s^2}$ rms (Argyle et al., 2000).

In marine gravity, the ship moves relatively slowly on an approximately equipotential surface (Torge, 1989) so there is no significant vertical acceleration in the signal bandwidth and the relatively high frequency acceleration caused by wave motion is removed by low pass filtering. Horizontal position and velocity, derived from GPS measurements, are used to compensate Eötvös-effects with sufficient accuracy to enable gravity anomalies of 0.2 mGal to be detected with a 0.5 km spatial resolution (LaFehr et al., 1992).

Survey gravimeters are affected by ground motion in the form of microseismic noise, cultural and wind noise, and earthquakes. Microseismic noise peaks in the range between 3 and 8 s (e.g., Ingate and Berger, 2004) and has amplitudes as high as 1 mGal pp (Laswell et al., 2010). Distant earthquakes produce signals with a peak

amplitude at a period of around 20 s (Ingate and Berger, 2004). Cultural and wind noise is generally above 1 Hz (e.g., Wilson, 1953) and depends on local conditions. The effect of these noise sources can be reduced with low pass filtering. Astatised (long-period) sensors have naturally lower sensitivity to this noise; however, proportional (short-period) sensors with digital filtering can produce readings with an rms noise level of a few μGal in most conditions (Scintrex, 2010).

Stationary gravimeters avoid cultural and wind noise through the choice of a quiet reading site (e.g., Torge, 1989). Earthquakes often generate the signal that is being measured. Filtering is used to suppress signals outside the band of interest (e.g., Agnew et al., 1976).

Temperature, pressure, and magnetic field

Sensitivity of spring-mass sensors to these inputs is largely determined by the material that the gravity sensor is constructed from. For example, the elastic suspension of metal spring instruments is made from a material with an elastic modulus that has low temperature sensitivity, but relatively high magnetic field sensitivity. Fused quartz is not sensitive to changes in magnetic field, but its elastic modulus has high temperature sensitivity.

The amplitudes of temperature, pressure, and magnetic field changes that reach the gravity sensor are reduced by control, sealing, and shielding, respectively. In addition, stationary gravimeters are often placed in environments where the temperature is extremely stable (e.g., Van Camp and Francis, 2007). If residual changes reaching the sensor are significant, they are compensated mechanically or electronically. In the Scintrex CG-3 and CG-5 quartz instruments, the temperature is controlled to the m°C level and further compensated to the μ°C level based on a temperature measurement close to the elastic suspension (Hugill, 1990). In the metal spring LaCoste and Romberg instruments residual pressure changes are mechanically compensated (Ander et al., 1999).

Superconducting penetration depth determines the temperature sensitivity of superconducting gravity sensors (Goodkind, 1999), and the levitation force is directly proportional to magnetic field changes. The amplitude of temperature and magnetic field changes at the sensor are reduced to acceptable levels by controlling temperature to a few μ°C and surrounding the instrument with a double μ metal/Niobium magnetic shield.

Transportation effects

Changes in readings, often called tares, changes in drift rate, and elastic relaxation can all contribute to errors as a result of transportation. However, these errors can generally be avoided through good operating procedures. Careful handling and appropriate protection from shock and vibration (e.g., Hamilton and Brule, 1967) can reduce or eliminate tares. Variable drift can be recovered by frequent base station reoccupation (e.g., Webring et al., 2004) and elastic relaxation is minimized in quartz instruments by maintaining vertical orientation during transport (e.g., Zumberge et al., 2008) and by waiting a fixed time after unclamping in metal instruments (e.g., Torge, 1989).

Gravimeters

Some gravimeters in use today are listed in Table 3.

Summary

Relative gravimeters are based on one of four core technologies: spring-mass systems made from quartz or metal, superconducting sensors, or inertial-grade accelerometers. Performance requirements depend on whether instruments are to be used for surveys or in stationary or dynamic

Gravimeters, Table 3 Some relative gravimeters currently in use

Gravimeter	Type	Sensor technology	Period	Displacement sensor	Feedback actuator	Reference
LaCoste and Romberg g meter	Survey	Metal spring-mass	Long	Optical, capacitive	Mechanical (electrostatic)	Webring et al. (2004)
Scintrex CG-3/5	Survey	Quartz spring-mass	Short	Capacitive	Electrostatic	Hugill (1990), Scintrex (2010)
Bodenseewerke GSS30	Dynamic	Metal spring-mass	Short	Capacitive	Electromagnetic	Torge (1989)
GWR	Stationary	Superconducting	Long	Capacitive	Electromagnetic	Goodkind (1999)
ZLS Burris gravimeter	Survey/ Stationary	Metal spring-mass	Long	Capacitive	Electrostatic (mechanical)	ZLS (2010)
Micro-g LaCoste gPhone	Stationary	Metal spring-mass	Long	Capacitive	Electrostatic	Micro-g LaCoste (2010)
Sander AIRGrav	Dynamic	Inertial-grade accelerometer	Short	Capacitive	Electromagnetic	Argyle et al. (2000)
GT-1A	Dynamic	Inertial-grade accelerometer	Short	Optical	Electromagnetic	Canadian Micro Gravity (2010)
ZLS Dynamic Gravity Meter	Dynamic	Metal spring-mass	Long	Capacitive	Mechanical	ZLS (2010)
Micro-g LaCoste Air-Sea II	Dynamic	Metal spring-mass	Long	Capacitive	Mechanical	Micro-g LaCoste (2010)

modes of operation. Useable sensitivity varies from $3 \times 10^{-2}\mu\text{Gal}/\sqrt{\text{Hz}}$ for stationary instruments operated in observatories to 0.5 mGal for dynamic gravimeters operated in aircraft. The defining characteristic of survey instruments is the capability to withstand acceleration and shocks during transport without sustaining changes in the reading value. Dynamic instruments must be able to produce data while moving and subject to large accelerations.

GRAVITY ANOMALIES, INTERPRETATION

Mikhail K. Kaban

Definition

In geophysics *gravity anomalies* are generally defined as the difference between observed gravity field and the field of a reference model. Depending on the reference gravity model, two different types of anomaly variations are considered: *gravity anomalies* and *gravity disturbances*. The geodetic *gravity anomaly* is defined as the difference between gravity on the geoid and normal gravity on the reference ellipsoid (Heiskanen and Moritz, 1967). On the other hand, the *gravity disturbance* is defined as the difference of the fields at the same point on the reference ellipsoid. It has been demonstrated that the gravity disturbances are more appropriate for geophysical purposes (e.g., Hackney and Featherstone, 2003). In any case, it is necessary to take into account this difference in the interpretation. For more details see *Gravity, Data to Anomalies*. Here we use the general term "anomalies" for both types as traditionally accepted in geophysics.

The observed gravity anomalies reflect the effect of density variations relative to the homogeneous reference model. *Interpretation* of the gravity anomalies implies an estimation of these density heterogeneities. The density model should reproduce the observed gravity field, taking into account that the observations may be affected by measurement errors. A separate type of modeling, which may be also related to the interpretation, is an *enhancement* of the gravity anomalies. The observed field combines effects of various mass anomalies integrated over the whole Earth. Therefore, it is often difficult to select the anomaly, which relates to the object under study. The usual way to cope with the problem is to remove the effects, which mask the anomalies of interest (see also *Gravity Data, Regional – Residual Separation*).

Introduction

Density heterogeneity of the Earth, associated with thermal and compositional variations or with deflected boundaries separating layers of different density, is one of the main factors that control dynamic processes and deformations at both shallow and deep levels. Therefore, interpretation of the gravity anomalies or *gravity modeling* is one of the principal methods, which help to understand nature and origin of the tectonic processes and the Earth's dynamics. On the other hand, gravity field is very sensitive to shallow heterogeneities, in particular related to mineral deposits. For this reason, gravity modeling is an important tool for both fundamental and practical purposes.

Formulation of the problem

The relationship between the density distribution ρ and the gravity field g may be written as an operator equation:

$$A\rho = g, \tag{1}$$

where A is the integral operator. In Cartesian coordinates for a 3D body with density $\rho(x',y',z')$ this equation may be written as (Blakely, 1995):

$$g(x,y,z) = \frac{\partial U}{\partial z} = -\gamma \int_{z'} \int_{y'} \int_{x'} \rho(x',y',z') \frac{(z-z')}{r^3} \mathrm{d}x'\mathrm{d}y'\mathrm{d}z', \tag{2}$$

where (x, y, z) are the observation points, U is the gravitational potential, γ is the gravitational constant, and

$$r = \sqrt{(x-x')^2 + (y-y')^2 + (z-z')^2}.$$

Therefore, the problem of determination of the density distribution ρ may be formulated as finding:

$$\min\{||A\rho - g_{\mathrm{obs}}||^2\}, \tag{3}$$

where g_{obs} is the observed gravity anomaly.

Unfortunately, the problem of gravity data inversion is generally *ill posed*. The operator A has no continuous inverse A^{-1}, thus the solution is neither unique nor stable. To overcome this principal weakness Equation 3 should be modified by adding a so-called regularization term Ω (Tikhonov and Arsenin, 1977):

$$\min\{||A\rho - g_{obs}||^2 + \alpha\Omega(\rho)\}, \quad (4)$$

where α defines strength of regularization. The regularization implies some a priori conditions imposed on the density distribution in order to limit a possible range of the solutions. If these conditions are sufficient, the problem becomes *well posed*.

There are basically two ways to obtain a unique and stable solution with the means of interpretation of the gravity anomalies. The first option implies considering simplified models, the parameters of which should be determined. An inclusion of a certain form in a homogeneous or stratified material, a thin layer with variable density or an interface between two layers with different density contrasts, are methods with which the number of unknowns are reduced and the problem is generalized. These models are adequate for modeling strong density contrasts, like the ocean bottom, the basement, the crust–mantle interface, and are optionally used jointly with the concept of *isostasy*. The methods assuming a spatially restricted source are suited in the exploration of superficial bodies as ore bodies, diamond bearing Kimberlyte cylinders, and salt domes. The methods using a density interface are used to define the ocean bathymetry from the gravity field or to determine the Moho, especially in remote areas where seismic studies are scarce or insufficient (Silva et al., 2006; Smith and Sandwell, 1997; Braitenberg et al., 2002). The other way to cope with the problem implies joint analysis of the gravity anomalies together with supplemental geophysical information, in particularly with seismic data that identify the basic structure of the Earth interiors. Using this method, it is possible to construct advanced models, which describe the structure of the Earth more reliably. Two basic interpretation techniques are used within this approach: forward method and inverse method (Blakely, 1995) (see also *Gravity Method, Principles*).

Gravity anomalies: conditions and enhancement

Spatial *resolution* of the gravity anomalies should be adapted to the scale and purpose of the study; it should be equal or better than the size of the smallest object of interest. *Local studies* range from meters to several tens of kilometers. They are chiefly intended to geophysical prospecting, archaeological and construction purposes. It is also a useful tool to investigate local tectonics, for example, related to volcanic activity. If possible, gravity anomalies defined at the original observation points should be used for these investigations. It is desirable to remove a regional trend from the observed anomalies. It is clear from Equation 2 that the gravity effect of any source rapidly decreases when we move this source to a greater depth. A useful approximation may be obtained from a spectral representation of the gravity field. A gravity effect of density variations at depth Z having the wavelength L is reduced by the factor:

$$\exp(-2\pi Z/L), \quad (5)$$

compared to the effect of near-surface variations.

Regional studies range from tens to first thousands of kilometers. They include various tectonic applications. The required resolution of the gravity anomalies is within approximately 5′–30′. Since the original field contains sharp variation, a special attention should be paid to the data preparation. Normally, the observed values are averaged over the compartments that correspond to the grid used in the study. *Global studies* include the whole Earth and are intended to investigate structure of the planet down to the core–mantle boundary as well as global mantle convection. The required data resolution normally ranges from 1° to 5°.

Enhancement of the gravity anomalies. A straightforward way to reduce the ambiguity of the gravity interpretation is to calculate the gravity effect of those structures, which are known from other geophysical methods, and to remove it from the observed anomalies. Then, the residual will highlight the gravity effect of "unknown" heterogeneities. *Bouguer gravity anomalies* represent the first step of the gravity "*stripping*." However, this procedure may be extended using the data on the crustal structure obtained from seismic studies. Attempts to calculate residual "crust-free" gravity anomalies have been made since the first seismic profiles were measured but a reliable 3D model could be constructed only after sufficient initial data on the crustal structure had been accumulated. One of the first maps of the residual gravity field covering a considerable part of North Eurasia was calculated by Artemjev et al. (1994).

After construction of 3D models of the crust based on seismic data, this method of the gravity interpretation has been extensively used over the last decade (e.g., Yegorova and Starostenko, 2002; Kaban et al., 2003, 2010). Detailed maps of sedimentary basins and their density structure are available from numerous prospecting surveys. A number of seismic data showing crustal structure down to the crust–mantle boundary (Mohorovičić discontinuity) has also significantly increased. Based on these data, a number of 3D crustal models with regional and global coverage have been compiled (e.g., Mooney et al., 1998; Tesauro et al., 2008). Density distribution within the crystalline crust is determined based on the relationships between seismic velocity and density (e.g., Christensen and Mooney, 1995). Then, it is possible to calculate gravity effect of the crustal layers and to remove it from the observed field. The modern calculation methods employ integral equations similar to Equation 2 (also in a spherical case) and can provide any desirable accuracy (e.g., IGMAS, http://www.gravity.uni-kiel.de/igmas/). While doing these calculations, it is important to include the regions surrounding a study area (Kaban et al., 2004). The distance, on which this effect might be important, may be estimated from Equation 5. For the continental regions with deep crust–mantle boundary this distance should be at least 500 km. One of the most recent

global maps of the residual mantle anomalies is shown in Figure 1 (Kaban et al., 2003). This map is extensively used in studies of the mantle structure and dynamics.

Forward method

A gravity model is constructed using an iterative approach. This type of interpretation is used when velocity models obtained from seismic profiles are used to constrain the density model. An initial model is constructed based on a priori data and modeling assumptions. The initial structure is based on seismic boundaries, and seismic velocities are converted to densities. The model's gravity anomaly is calculated and compared with the observed field. Then, the model parameters are adjusted using an iterative process to improve the fit between the modeled and observed anomalies. At the first stage, density of the seismic blocks is modified. If the fit is not sufficient, seismic boundaries might be changed as well. One example of such interpretation along the URSEIS profile crossing the southern Urals is shown in Figure 2 (Kimbell et al., 2002).

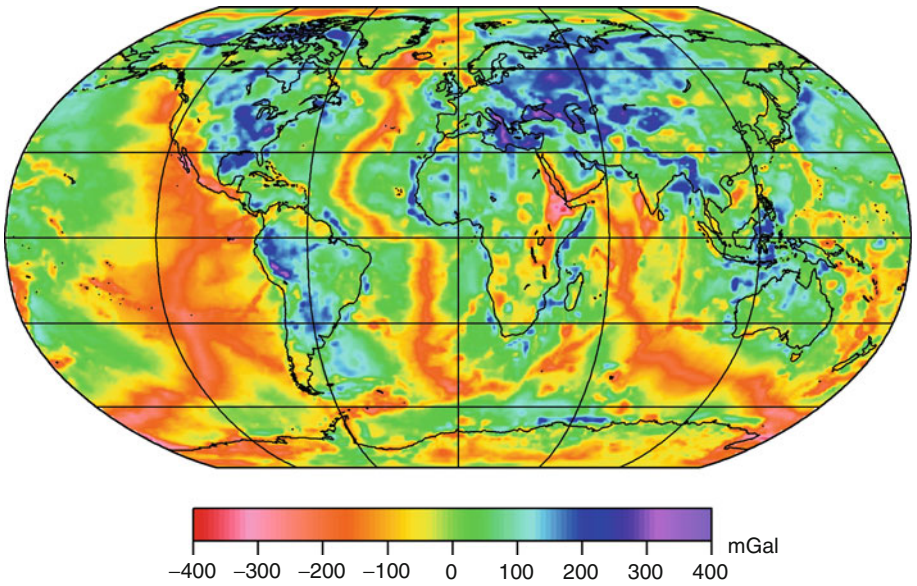
Inverse method

In the inverse method, model parameters are automatically determined by solving Equation 4. This technique is also used for joint interpretation of the gravity and seismic data. For the regional seismic profiles it was developed by Strakhov and Romanyuk (1985), whereas for global studies based on tomography data, by Hager and O'Connel (1981). The idea of the method implies use of seismic velocities to stabilize the solution of Equation 4. Instead of determining density variations in each grid point of the 3D model, a velocity–density relationship for selected blocks and layers should be introduced. This relationship may vary significantly; however, it is rather stable for similar compositions and physical conditions. Therefore, after selecting several blocks and layers, which are supposed to obey the same conditions, it is possible to determine a very limited number of the model parameters (velocity-to-density scaling factors for the specified blocks and layers). This provides the possibility to obtain a unique and stable solution of the inverse problem. A clear advantage of the inverse method with respect to the forward modeling is that it provides a possibility to quantitatively control sensitivity of the gravity anomalies to variations of the model parameters and their uncertainties.

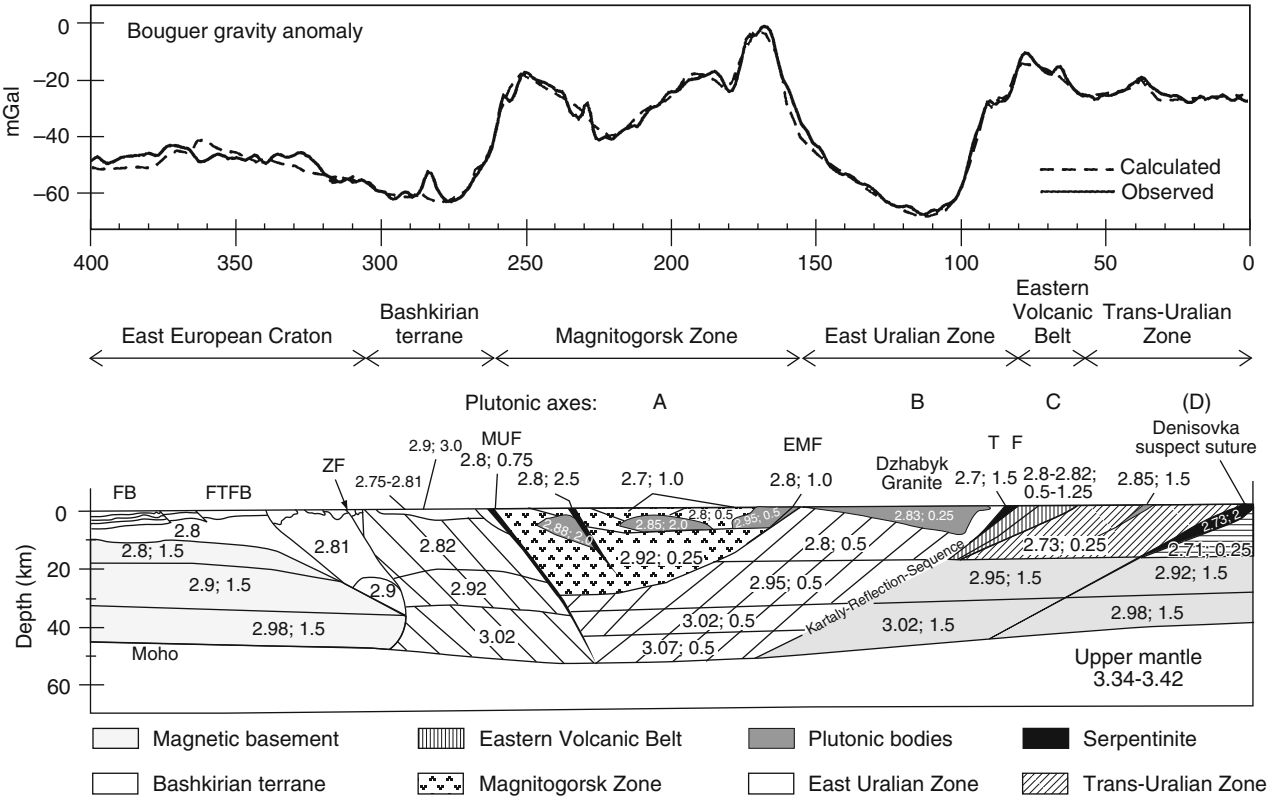
The initial density model is usually produced by a simple linear conversion of the velocity disturbances into density variations. The initial scaling factors (c_j^0) are based on mineral physics and petrological data (j is the number of the selected layer or block). In the inversion they should be rescaled in a least squares adjustment. The inversion can be performed in both space and spectral (or spherical harmonic) domains. The scaling coefficients a_j (to rescale the initially adopted values) are estimated by minimizing the function (Kaban and Schwintzer, 2001):

$$\chi^2 = \sum_i \cos\phi^i \left(\mathrm{dg}^i_{\mathrm{obs}} - \sum_j \hat{a}_j \mathrm{dg}^i_j \right)^2 + \sum_j \alpha_j (\hat{a}_j - 1)^2, \tag{6}$$

where dg^i_j is the initial gravity effect of layer or block j at the surface grid point i characterized by the gravity



Gravity Anomalies, Interpretation, Figure 1 Residual "mantle" anomalies obtained after removing the gravity effect of the crust (relative to a horizontally homogeneous reference model) from the observed field (Kaban et al., 2003).



Gravity Anomalies, Interpretation, Figure 2 2D gravity model for the URSEIS profile (Kimbell et al., 2002). The first number indicates density (Mg/m^3).

anomaly dg^i_{obs}. $\cos\varphi^i$ is a formal weight factor to account for the convergence of the meridians in the equal-angular grid. It is not required in case of the equal-space grid or spherical harmonic inversion. The last term is used to stabilize the solution. In this case it requires that the estimated scaling factors should not be significantly different from the initial ones. α controls strength of regularization. In favorable cases it could be even reduced to zero. Equation 6 leads to the normal equation system with a dimension equal to the number of the unknown scaling factors

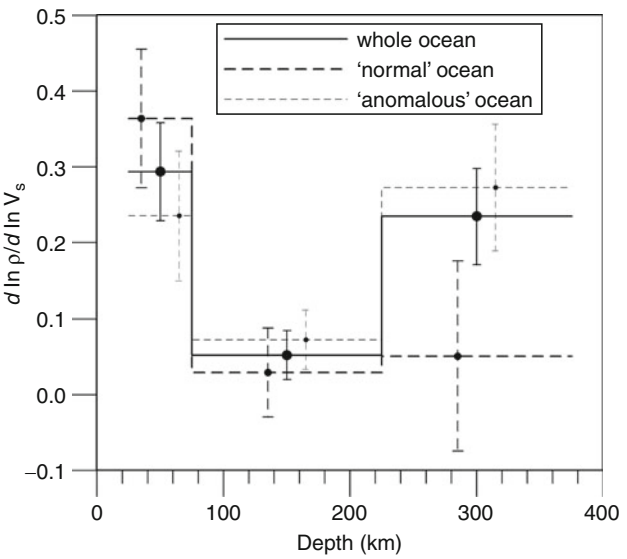
$$\mathrm{B}\hat{\mathbf{a}} = c \tag{7}$$

System (7) is solved for the vector $\hat{\mathbf{a}}$ by inversion of the normal matrix B. The solved-for parameters $\hat{a}_j$ are used to rescale the initial values. The coefficients' standard deviations $s_{\hat{c}_j}$ resulting from the fit in the least squares adjustment then are

$$s_{\hat{c}_j} = c_j^0 s_{\hat{a}_j}, \quad s_{\hat{a}_j} = \sqrt{\frac{1}{f}\chi^2 q_{jj}}\ , \tag{8}$$

where q_{jj} is the diagonal element of B^{-1}, f is the degree of freedom (Kaban and Schwintzer, 2001).

In global studies this technique is used for interpretation of both geoid and gravity anomalies. Geoid is more sensitive to the effect of deep interiors, whereas a use of



Gravity Anomalies, Interpretation, Figure 3 The velocity-to-density scaling coefficients adjusted for "normal" and "anomalous" oceanic areas, respectively, compared with the result for the whole oceanic area. Only the scaling coefficients and standard deviations for the upper mantle are shown, but the inversion was performed for the whole mantle (Kaban and Schwintzer, 2001).

the gravity anomalies provides better resolution, especially for the upper mantle (e.g., Simmons et al., 2009). An example of such study is shown in Figure 3. The velocity-to-density scaling factor is determined for the oceanic upper mantle in the joint inversion of the residual mantle gravity anomalies and seismic tomography (Kaban and Schwintzer, 2001). The obtained density–velocity ratios for the subcrustal layer (down to 75 km) and for the deep part of the oceanic upper mantle (below 225 km) are very close to the ones predicted from the mineral physics analysis. However, for the oceanic layer involving the depths 75–225 km a significantly lower density–velocity ratio is obtained. This may be explained by a compositional layering: dry, partially depleted peridotite residuum underlain by "damp" fertile peridotite and separated by the G discontinuity at a depth of about 70 km. This result is important for geodynamic modeling. It evidences that the base of an oceanic lithosphere plate is defined by a compositional rather than thermal boundary layer or, at least, the base is strongly influenced by a compositional boundary.

Summary

Due to new interpretation techniques and increased computer power, most of the computational problems related to the forward and inverse gravity modeling, which caused big problems even recently, are solved. For example, the direct computations using Equation 2 may be performed for on large grids taking into account 3D density variations. Also a principal difference from the early-stage period is that the interpretation of the gravity anomalies is performed now in combination with other methods. The most profitable results are obtained from the integrative interpretation of the gravity and seismic data. Further combination with geothermal data provides the possibility to separate the effects of temperature and composition variations within the Earth. The obtained density models are used in various applications. This information is essential for a geodynamic modeling that results in determination of the mantle flows, tectonic forces moving the lithosphere blocks, and stress distribution in the crust and mantle at both regional and global levels. Interpretation of the gravity anomalies is also widely used in geophysical prospecting. In some situations the seismic investigations fail to give results, for example, when a high velocity layer masks the underlying low-velocity layers. Here the gravity and magnetic investigations are the principal means to obtain information on the underlying structure.

Two principal problems should be a key issue for the gravity modeling in future. As it was shown, reliability of the gravity modeling depends on additional data used in the interpretation. Therefore, it is necessary to bring together data from various disciplines, which might be used in construction of integrative interpretation models. Geophysicists just started approaching this ultimate goal. The second principal issue is improvement of the technique for integrative interpretation. In particularly, special attention should be paid to solution of nonlinear inverse problems and to ultrahigh dimension problems.

Gravity: spectral methods; Potential field transforms

Definition

Spectral analysis. Estimation and analysis of global frequency content of a signal, assumed stationary, most often using the Fast Fourier Transform (FFT).
Potential field transformations. Process of converting gravity (or magnetic) survey data into a new and physically meaningful form to facilitate its geological interpretation.
Euler and Werner deconvolution. Methods for automatically estimating depths to sources from gravity (or magnetic) survey data.
Wavelet analysis. Estimation and analysis of local frequency content of a non-stationary signal, using a wavelet transform (WT).

Introduction

The use of spectral analysis to interpret gravity anomalies goes back to the 1930s, but the modern approach in terms of the Fourier transform (FT) was developed in the 1960s and 1970s. Most of the methods are equally applicable to magnetic data, which is their more common area of use because of the huge volume of aeromagnetic data now available. Here we will not generally distinguish between the two, though the magnetics case is complicated by the fact that the field and magnetization directions are not in general the same or vertical. Blakely (1995) provides an excellent introduction to the subject, which he divides into two basic aspects: *spectral modeling* and *potential field transformations.*

In spectral modeling, the major advantage of working in the wave-number ($k = 2\pi/\lambda$) domain, after Fourier transforming the data, is that it offers simplifications and insights into the relation between anomalies and their sources. For example, the FT of the gravity anomaly over a thin horizontal layer of variable surface density $\sigma(x,y)$, at depth d, is simply the product of the FT of σ with a constant times $e^{-|k|d}$. Other models similarly separate into products of factors.

Potential field transformations can be carried out in the space domain by either numerical integration or convolution, but in the wave-number domain, the simple forms of the transformations offer considerable insight. They include upward and downward continuation, and vertical and horizontal derivatives, all of which have their uses in enhancing resolution and separating anomalies.

Both aspects were made practical by the development of the FFT, though it should be noted that there are important differences between the theoretical (continuous, infinite) FT and the (discrete, finite) FFT – see below.

The FT assumes that the statistical properties of the data do not vary spatially (i.e., the data are *stationary*), which may not be the case with real data. The wavelet transform allows spectral analysis without this assumption and therefore promises improvements over the FT.

Spectral modeling

Many applications of spectral modeling have been devised: for example, Blakely (1995) gives expressions for the FT of the anomalies for a number of simple models. Here just two of the more commonly used methods will be described.

Parker (1972) extended the simple horizontal layer model (mentioned above) to the case of a layer bounded by irregular top and bottom surfaces. This allows the very rapid calculation (via the FFT) of the gravity anomaly over a square grid for such common cases as sedimentary basins, marine Bouguer corrections from bathymetry, and Airy isostatic corrections from topography.

The method of *statistical models* was pioneered by Spector and Grant (1970) for interpreting magnetic data. In the gravity case, the method assumes that the anomalous field results from an *ensemble* of dense vertical prisms where each of the model parameters is randomly distributed with uniform probability about a mean value. As mentioned above, the FT of the anomaly of each prism is the product of several factors, notably a depth factor ($e^{-|k|d}$), a depth extent (t) factor ($1 - e^{-|k|t}$), and a size factor (a function of the width and breadth of the prism). The method employs the radial *power spectrum* of the observed anomaly, i.e., averaged over concentric annular rings in the (k_x, k_y) plane, implying that isotropy is assumed. The theoretical power spectrum for the ensemble of prisms is the product of the *ensemble averages* of the square of each of the above factors. If the ranges of the parameters are not too large, the ensemble averages will approximate the factors for their mean values. At wavelengths much larger than the body dimensions, the size factor tends to a constant. This is equivalent to assuming a dipole, rather than prism, model. Then the mean depth and depth extents can be estimated by plotting the

logarithm of the power spectrum. The depth factor gives a straight line of slope $-2d$ at medium to large k, and the depth extent factor causes this slope to decrease as k decreases, giving rise to a maximum. Thus in principle the mean values of both d and t can be estimated. The basic problem with the method lies in knowing to what extent the assumptions are justified. If the body dimensions are not small compared to the wavelengths, then it may be possible to estimate their average values, calculate a size factor, and hence correct the power spectrum. But if parameter values are not completely random and uncorrelated, but are self-similar or fractal (for which there is some evidence) then the power spectrum will be proportional to a power of k, invalidating depth estimates. See Blakely (1995) for references.

Potential field transformations

Transformations of gravity and magnetic data have a long history in applied geophysics (e.g., Grant and West, 1965), since their utility was realized long before they could be easily and accurately applied. Three examples of transformations that are commonly used in gravity interpretation are listed below with their uses.

(a) Vertical derivative: largely eliminates the regional and improves resolution.
(b) Upward continuation: very efficiently attenuates near-surface effects; used as a standard "separation filter" (Jacobsen, 1987).
(c) Downward continuation: enhances resolution, i.e., it allows the separation of closely spaced or overlapping anomalies; approximate inversion for a uniform density layer.

These operations depend on a theorem from potential theory stating that the gravity potential caused by any 3D density distribution is identical to that of a thin layer of mass spread over one of its equipotential surfaces. This is *Green's equivalent layer* (Blakely, 1995). For example in the case of upward continuation of gravity data measured on a level surface at height z_0 to a second level surface Δz above it, the equivalent layer is taken to lie in the measurement plane. The theoretical formula for the upward continued field at a point $P(x, y, z_0 + \Delta z)$ is an integral over the complete (and infinite) plane measurement surface since each point in that plane acts as an element of mass. This integral can then be written as a convolution of the data with $\Delta z/r^3$, where r is the distance from point Q in the z_0 plane to point P. Fourier transforming this expression reveals that the FT of the upward continued data is the product of the FT of the measured data and $e^{-|k|\Delta z}$, where $k = \sqrt{(k_x^2 + k_y^2)} = 2\pi/\lambda$ (radians/m). This simple view of upward continuation as a filter with wave-number response $e^{-|k|\Delta z}$ offers physical insight that explains immediately why the operation is effective at attenuating (exponentially) near-surface density anomalies.

The responses of some other common transforms are: downward continuation through height Δz, $e^{|k|\Delta z}$; vertical derivative, $|k|$; vertical integral (potential), $1/|k|$; x-derivative, ik_x. One transform that is particularly useful in mapping is the horizontal gradient amplitude (HGA): $\sqrt{[(\partial g/\partial x)^2 + (\partial g/\partial y)^2]}$ whose maxima occur vertical contacts. Another is the analytic signal amplitude (ASA): $\sqrt{[(\partial g/\partial x)^2 + (\partial g/\partial y)^2 + (\partial g/\partial z)^2]}$.

Using the FFT is much faster than either numerical integration or convolution, except for very small arrays of filter coefficients such as the centered difference approximation generally used for horizontal derivatives. It also implies certain requirements of the data (usually met by *preprocessing*) because the FFT differs from the continuous FT in important ways (e.g., Blakely, 1995). First, it is discrete, with (1D) data spacing Δx, which means that the FFT is periodic, repeating itself every $k = 2\pi/\Delta x$. This leads to aliasing of wave numbers outside the band defined by the *Nyquist* wave number $k = \pm \pi/\Delta x$ into the FFT at smaller wave numbers, unless the data are band limited. The preprocessing can include an antialias filter to ensure this. Second, the FFT is a finite summation over a data length $N\Delta x$, rather than the infinite integral of the FT, and hence implicitly assumes that the data set is periodic, infinitely repeating itself or, equivalently, circular with the last point next to the first. To avoid first order discontinuities at the data edges (which would lead to the Gibbs effect), the preprocessing then includes extending the data in such a way as to produce a smooth transition between neighboring repetitions. With these precautions, the FFT method is capable of accurate results for most transformations, unless they require amplification of wave numbers that are not present in the data, due to it's being either too short (and therefore lacking low wave numbers – below $1/N\Delta x$) or digitized with too large an interval Δx, or otherwise inaccurate.

A modern example of an application that uses a transformation via the FFT occurs in processing data from the Falcon™ airborne gravity gradiometer system, whose sensor measures the horizontal curvature components (Dransfield and Lee, 2004; Nettleton, 1976). The easiest way to convert these components to the more familiar vertical gradient is to grid them and then apply a complex transformation via the FFT.

Euler and Werner deconvolution

These are approximate inversion methods for automatically locating the depths to the tops of multiple sources. The principles of both methods are dealt with by Blakely (1995). The name is by analogy with seismic deconvolution where seismic reflection arrivals are converted into impulses representing reflectors. The methods are similar in many ways, but Werner's method in its original form is only applicable to aeromagnetic profile data, whereas the Euler method can be applied to profiles or grids of magnetic or gravity data. However, generalizations of the methods to different types of gradient data have been made and it has been shown that Werner's method using the analytic signal is in fact

a special case of Euler deconvolution (Nabighian and Hansen, 2001). Werner's method will not be described in detail, but his idea was to linearise the magnetic anomaly on a profile perpendicular to a thin dipping dyke, which contains four unknowns; hence any four measurements along the profile will give four simultaneous equations which can be solved for the position and depth of the top of the dyke.

Euler deconvolution

Euler deconvolution (Thompson, 1982; Reid et al., 1990) is very similar but uses a more general equation than that of a dyke, namely Euler's equation, which can approximately model the behavior of many different simple sources. Euler's equation is satisfied by any homogeneous function $f(x, y, z)$ of degree n (one that is invariant under scaling) and can be written:

$$x\frac{\partial f}{\partial x} + y\frac{\partial f}{\partial y} + z\frac{\partial f}{\partial z} = -nf$$

For example, $f = 1/r$ satisfies this equation with $n = 1$, implying that so does the potential of a point mass. The degree n is called the *structural index*, and defines the attenuation rate of the field f due to the particular source. Examples for gravity field anomalies are (Fitzgerald et al., 2004): point mass, 2; line mass, 1; finite step, 0; contact, −1. Reid et al. (1990) showed that certain extended bodies like thin dipping sheets (e.g., irregular dykes and sills) can also satisfy Euler's equation, but this is not generally true.

In practice, the gradients are generally calculated from a grid of gravity anomaly data as described above. In order to locate the center of a body (x_0, y_0, z_0) from survey data, it is necessary to replace (x, y, z) in Euler's equation by $(x\text{-}x_0, y\text{-}y_0, z\text{-}z_0)$. Implementation of a grid Euler method follows that of a least squares version of Werner's method, where simultaneous equations are formed from a square array (or window) of grid points of between 3 × 3 and 10 × 10 equations and a LS solution found for x_0, y_0, z_0 and a background field B (i.e., f is replace by $f\text{-}B$ on the RHS of the equation). In this case, n cannot be solved for, but must be assumed and the normal procedure is to try several values and select the one giving the most consistent results. The procedure is repeated for all points of the grid, and may generate large numbers of solutions, many of them unrealistic because the assumption of a simple source with constant n for each window is invalid. In practice, most of these solutions can be easily eliminated by selecting only those that (a) have standard deviations for x_0, y_0, z_0 (obtained from the LS solution) of <5–10% of the depth and (b) fall within the window. Another useful way to restrict the number of solutions is to apply the method only close to localized anomalies as defined, for example, by areas of positive curvature of the horizontal gradient (HGA).

Extended Euler deconvolution

For the 2D case, Mushayandebvu et al. (2001) discovered a second equation, similar to Euler's, for homogeneous functions that are also invariant under rotation. They rewrote the two equations for the particular cases of a magnetic contact and a thin dyke so that their right hand sides include terms involving the susceptibility and dip. Their *extended Euler* method finds solutions satisfying both equations that yield susceptibility and dip estimates as well as x_0, y_0, and z_0. Nabighian and Hansen (2001) then showed that the additional equation could be written in terms of the *Hilbert transform* of f (e.g., Li, 2006) which shows that it is just Euler's equation applied to the Hilbert transform. They further extended the new equation to 3D, in terms of generalized x- and y- Hilbert transforms (which can be represented and calculated as potential field transformations with wave-number domain responses $H_x = -ik_x/|k|$ and $H_y = -ik_y/|k|$, as shown by Nabighian, 1984). It has been found that, assuming a value for the structural index and using all three equations for the anomaly data and their x- and y- Hilbert transforms gives better-constrained solutions than using just one equation for the anomaly data. Moreover, the new equations allow a number of other possibilities, including solving for the structural index (Fitzgerald et al., 2004).

Tensor deconvolution

Although gradiometer data can be used with advantage in Euler deconvolution, Mikhailov et al. (2007) show that with full tensor ("FTG") data it is possible to devise a method that dispenses with data windows and locates a source beneath each measurement point based on invariants calculated from the five independent tensor components. They suggest that since this method appears to locate the centers of bodies, whereas Euler deconvolution locates their edges, the methods should complement each other.

Wavelet analysis, with advantages and limitations

Introduction

The wavelet transform (WT) was developed in the early 1980s, in an attempt to better understand the frequency content of seismic signals (e.g., Grossman and Morlet, 1984). Whereas the Fourier transform (FT) provides the amplitudes and phases of all harmonics present in the entire signal (a *global spectrum*), the WT yields these quantities at each time (or space) location of the signal (*local spectra*). For instance, the WT of Beethoven's Ninth Symphony tells one when to play C major, or when to play D minor chords. The FT, however, merely tells the musician that C major and D minor chords occur somewhere in the symphony (e.g., Antoine et al., 2004).

For this reason, the WT is superior in analyzing the harmonic constituents of *non-stationary* signals, that is, signals whose harmonics vary throughout the signal. The application to the Earth's potential fields is evident. The depth, spatial extent, and density/magnetization contrast

of sources vary widely over a given region, leading to anomaly maps with clear differences in spectral characteristics from place to place. The wavelet power spectrum, or "*scalogram*," of such a map thus quantifies the relative power of each harmonic at each spatial location; in contrast, the Fourier power spectrum shows only the total harmonic composition of the map.

The WT has two distinct forms, termed "continuous" and "discrete." Unfortunately, there is no analogy between this use of the terms and their use with the FT: as mentioned, the continuous Fourier transform (CFT) is an integral equation applied to continuous analytic formulae; the discrete Fourier transform (DFT) is its specialization to discretely-sampled signals. Both CFT and DFT, however, use the same *basis functions*, the complex exponentials (sines and cosines). However, with the discrete and continuous wavelet transforms (DWT and CWT, respectively), the names "discrete" and "continuous" apply not to the signal, but to the basis functions (the wavelets). So both CWT and DWT can be applied to discretely sampled signals, and the difference between them lies (mainly) in the wavelets.

Wavelets, whether discrete or continuous, differ from the basis functions of the FT (infinitely or quasi-infinitely extending sinusoids and cosinusoids) in that they are *localized* in space (or time). That is, while they are oscillating functions (with zero mean value), their amplitude decays rapidly with distance (or time) from their center. It is this feature which localizes the wavelet spectra to a region surrounding the point of interest. Contrast this with the DFT, where the complex exponentials maintain their amplitude over the whole study area, rendering localization impossible (though see below). However, a high degree of localization in the space (or time) domain results in a poorer degree of localization in the wave-number (or frequency) domain. This property is referred to as the *uncertainty relation* of spectral analysis, by analogy with Heisenberg's uncertainty principle of quantum mechanics. In the spectral case, the more localized the position (small Δx), the higher the uncertainty in the wave-number content of the signal at that location (large Δk); and vice versa, according to:

$$\Delta x \, \Delta k \geq 2\pi$$

For the DFT, since the Fourier transform of a sine wave is a delta-function (i.e., a spike in the frequency domain), Δk is very (infinitesimally) small and precise, whereas Δx is very (infinitely) imprecise. For the WT, there exists a trade-off between Δx and Δk according to the *scaling* of the wavelet.

It is this scaling that allows harmonic analysis. First, the WT of a given signal is a space (or time) domain convolution of the signal with scaled versions of a mother wavelet, giving *wavelet coefficients* at that scale. When the *wavelet scale* is large, the wavelets are stretched (in space or time), and the convolution yields the low-wave-number (or frequency) components of the signal; when the scale is small the wavelets are squeezed, and the convolution returns the high-wave-number (or frequency) components. However, the uncertainty relation means that large-scale wavelet coefficients tend to be spatially (or temporally) imprecise but spectrally precise, while small-scale coefficients will have the opposite properties.

The difference between the CWT and DWT lies in the choice of scales. In the DWT, the scales are chosen so that the wavelets are orthogonal. This naturally limits the range of scales to the minimum possible without loss of information; a property which is obviously preferable for image compression (e.g., Antoine et al., 2004), and means that the signal can be reconstructed very rapidly from the wavelet coefficients. The scales in the CWT, on the other hand, are not constrained, and the wavelets are hence non-orthogonal. This, though, offers redundancy in the wavelet coefficients which can be put to good use in analysis and interpretation, though reconstruction of the signal is slower.

The CWT and windowed Fourier transform

There are many kinds of discrete and continuous wavelet, each having certain properties that prove useful in a variety of applications. For instance, Morlet wavelets yield global spectra that best approximate those from the Fourier transform (Kirby, 2005), while Poisson wavelets have a close relationship with the Laplacian operator, lending themselves to potential field applications (e.g., Hornby et al., 1999). Furthermore, wavelets may be defined in N dimensions for analysis of N-dimensional signals; in geophysics, the most commonly used are 1D and 2D wavelets. Wavelets may also be complex or real-valued: 2D complex wavelets such as the Morlet wavelet are anisotropic, while 2D real wavelets, such as the Derivative of Gaussian wavelets, are isotropic. Torrence and Compo (1998) provide a description of several 1D continuous wavelets, while Kirby (2005) discusses various 2D continuous wavelets.

The windowed Fourier transform (WFT) is also often used to recover local spectra from a signal. In this, the basis functions are windowed complex exponentials; e.g., the Gabor transform uses a Gaussian window which slides over the signal. In the WFT, while the frequency of the complex exponential can increase or decrease, the window width (Δx) is fixed, meaning a fixed uncertainty in frequency, by the uncertainty relation. With the CWT, however, the window width (and hence frequency uncertainty) is variable (and directly related to wavelet scale). Hence, while the WFT has its uses, it is in general inferior to the CWT for several reasons, two of which are: (1) the WFT is not as good at analyzing signals with a large bandwidth (Foufoula-Georgiou and Kumar, 1994); and, (2) it is not as good as resolving closely spaced spikes or discontinuities (Addison, 2002).

Applications

The advantage of being able to estimate local, as opposed to global, power or phase spectra has seen the WT applied

to many disciplines, not just the Earth sciences. Indeed, a 10-s Scopus search yields over 58,000 articles with "wavelet" in the abstract, with over 4,000 published in 2009 alone. Foufoula-Georgiou and Kumar (1994), Kumar and Foufoula-Georgiou (1997), Addison (2002), and Antoine et al. (2004) discuss many. For example, Moreau et al. (1997) and Hornby et al. (1999) show the usefulness of the CWT for location and edge-detection of sources within potential field data, and subsequent inversion of the wavelet coefficients, by considering the vertical variation of the field and its horizontal derivatives. Ridsdill-Smith and Dentith (1999) also tackle derivatives, but they use the DWT which enables localized frequency-filtering. In another application of the CWT, Panet et al. (2006) reveal density anomalies below Pacific island volcanoes from the new satellite gravity data. And Kirby and Swain (2009) use the CWT to estimate spatial variations in lithospheric elastic thickness via a coherency analysis in the wavelet domain. Finally, there are several types of spherical, rather than planar, wavelet transform, which lend themselves to studies in geodesy (e.g., Klees and Haagmans, 2000; Keller, 2004; Chambodut et al., 2005).

Summary

This contribution outlines the theory and practice of a number of methods for rapidly processing gravity data that are in the form of a grid. The term "processing" here includes transformations, spectral estimation and modeling, and "deconvolution" to produce depth estimates. These are all widely used methods that are equally applicable to grids of aeromagnetic data. We also introduce the continuous wavelet transform which has many potential applications in gravity processing, few of which appear to have been widely used as yet.

A more extensive review of the gravity method, with comprehensive reference list, can be found in Nabighian et al. (2005).

Synonyms

Gravity effect of shallower and deeper bodies; Isostatic anomaly

Definition

Free-air correction. Accounts for the effect of elevation between the observation point and the datum.
Bouguer correction. Accounts for the effect of material between the observation point and the datum.
Observed Bouguer gravity anomaly. Gravity field after corrections for instrumental drift, free-air, Bouguer, terrain, and latitude.
Regional Bouguer gravity anomaly. Gravity anomaly due to deeper and broader structures.
Residual Bouguer gravity anomaly. Bouguer gravity anomaly due to shallower bodies.
Isostatic anomaly. Bouguer gravity anomaly corrected for isostatic crustal root.
Interpolating or shape function. The weighting functions (coefficients) used to compute the regional Bouguer gravity anomaly.

Introduction

The observed Bouguer gravity anomaly field (g_{obs}) consists of two components – a regional (g_{reg}) and a residual (g_{res}) that can be expressed by a simple relation:

$$g_{obs} = g_{reg} + g_{res}$$

Commonly, the regional Bouguer gravity anomaly is the longer wavelength field due to deep sources, whereas the residual Bouguer gravity anomaly corresponds to short wavelength fields of shallower bodies. The short wavelength fields die off with depth.

However, in practice, the terminology of a regional gravity anomaly varies according to the target of the investigation, and therefore does not necessarily refer to the fields generated at crustal or lower crustal depths. If the target is a mineral deposit located at the depths of 100–200 m, the basement rocks will form the regional structure. In case of hydrocarbon accumulation, the target sources are a few kilometers deep, and the regional field is generated by the rocks at the base of the sedimentary columns. In the studies involving large-scale structures like subduction zones, large sedimentary basins, regions of meteorite impact, etc., the regional fields originate at lower crustal depths or still greater depths at Moho.

The regional and residual, therefore, are relative terms. These vary from problem to problem, and from place to place. The early workers like Griffin (1949), Elkins (1951), Nettleton (1954), Roy (1961), Steenland (1962), and Skeels (1967) considered regional and residual from mineral and hydrocarbon exploration viewpoint. For a regional gravity survey on a continental scale, the concept of isostasy is evoked (Jachens and Griscom, 1985; Blakely, 1995; Chapin, 1996) to compute regional and isostatic anomalies.

In problems where the target bodies occur at shallower depths, the deeper regional field masks the response of the shallower targets and effectively acts as a noise. On the other hand, when the target body lies at greater depths, the response of shallower bodies becomes noise.

The above discussion points to the fact that it is important to separate regional and residual gravity anomalies. In effect, regional and residual gravity separation is a filtering process, and it enhances the signal-to-noise ratio. This step is essential for a precise quantitative interpretation.

It may be noted that the gravity method was first used in geodesy. The geodesists assumed the earth to be an ellipsoid for the processing of the gravity observations. Later on, the geophysicists used geoid as the reference surface for processing of gravity data. Therefore, gravity anomaly and the Bouguer field used by geophysicists is different from that used by geodesists. The former uses geoid whereas the latter the ellipsoid as the reference surface. Of late, there is an attempt to define gravity anomaly that can be used by both the groups (Hackney and Featherstone, 2003; Hinze et al., 2005). The processing techniques are valid for both the datums. Here, the Bouguer gravity anomaly is considered from the viewpoint of the geophysicists.

Regional–residual separation

The regional–residual separation is essentially a filtering process and is carried out broadly by two techniques: graphical and analytical. The graphical method is not used these days anymore but it has historical importance. A variety of techniques are used in the analytical method.

Analytical methods

The analytical techniques are developed both in space and frequency domains. Starting from simple four-point and nine-point averaging, Griffin's center-point-and-one-ring (1949), Agocs' least-squares (1951), Grant's statistical (1954) to polynomial fitting (Coons et al., 1967; Rao et al., 1975; El-Batroukh and Zentani, 1980; Belthrao

et al., 1991; Agarwal and Shivaji, 1992; Leao et al., 1996) and second-derivative techniques are in space domain. Mickus et al. (1991) have developed an algorithm using the minimum curvature technique to separate the regional and residual components.

Another approach is to build a density model of the deep-seated structures with parameters constrained by independent methods like seismics, aeromagnetics, fractals, spectrals, etc., and to compute their gravity effects. The fields generated by the deeper sources are subtracted from the observed Bouguer gravity field to arrive at the residual gravity anomalies. This approach developed at USGS employs the theory of isostasy, and is frequently used to compute isostatic residual anomalies (Jachens and Griscom, 1985; Blakely, 1995; Lowrie, 1997). A new deterministic method based on Airy-Heiskanen isostatic model had been developed by Chapin (1996). This technique assumes that the topography is fractal. The algorithm used in this technique inverts the present-day elevations to determine the depth to the base of the crust. This depth is then used as input to a three-dimensional gravity model that computes the gravity response (regional) of the crust. The regional is then subtracted from the Bouguer gravity to yield the final isostatic residual.

In the frequency domain, the high-pass, low-pass, and band-pass filtering techniques (Naidu, 1968; Ulrich, 1968; Cordell, 1985; Pawlowski, 1994) and upward and downward continuations (Roy, 1966) have been developed for regional and residual separation. Green's concept of an equivalent-source layer is invoked by Pawlowski (1994) to construct a data-adaptive, zero phase, Wiener band-pass filter for regional–residual separation (Pawlowski, 1994). The observed gravity field's Fourier power spectrum is modeled with two Green's equivalent source layers, one equivalent layer for the shallower (residual field) geological sources and another for the deeper (regional field) geological features.

Possible drawbacks in regional computation

In all the above-mentioned analytical techniques, the Bouguer gravity values of the target source enter into the computations. Many investigators (Skeels, 1967; Zurfluch, 1967; Ulrich, 1968; Leao et al., 1996; Ojo and Kangkolo, 1997) have discovered that these techniques are not free from inaccuracies. In Griffin's (1949) center-point-and-one-ring method, the center point of the computation moves over the entire map space, including the anomalous target zone. When the gravity values are picked up from one such anomalous target zone for averaging, a small residual still remains mixed with the regional. Besides this, the optimum choice of radius is crucial to arrive at proper residual. Leao et al. (1996) pointed out that "any attempt to model a complex regional by a higher-order polynomial will force the polynomial to represent part of the residual field: thereby distorting the estimated regional." In case of two most used techniques, both least-squares (Agocs, 1951; Coons et al., 1967; El-Batroukh and Zentani, 1980; Leao et al., 1996) and spectral methods (Naidu, 1968; Ulrich, 1968; Cordell, 1985; Klasner et al., 1985; Pawlowski, 1994), the residual is assumed to be zero-mean. Ulrich (1968) and Leao et al. (1996) observed that a departure from this assumption may contaminate the residual by pseudo anomalies.

New approach based on finite element analysis (FEA)

In order to overcome the inaccuracies mentioned above, a new space-domain operator, based on finite element concept, has recently been developed by Mallick and Sharma (1997, 1999) and applied to a variety of research problems (Sharma et al., 1999; Mallick et al., 1999; Mallick and Vasanthi, 2001; Vasanthi and Mallick, 2001; Kannan and Mallick, 2003; Vasanthi and Mallick, 2005; Vasanthi et al., 2006). The method is altogether different from all the existing techniques in the sense that the observed gravity values over the target zones in the map space do not enter into the regional computations. This technique is robust, well performing, and not site specific and overcomes most of the drawbacks encountered in the existing analytical methods.

Figure 1a shows an eight-node element in Cartesian coordinates. The center is located at x_c, y_c with sides 2a and 2b parallel to x- and y- axes, respectively. The nodes 1 through 8 are shown by filled circles. When a gravity survey is superimposed by one such element (or interconnected elements), the regional anomaly can conveniently be approximated at any point (x, y) inside the element by

$$g_d(x,\ y) = \sum_{i=1}^{8} N_i(x,\ y) g_i \tag{1}$$

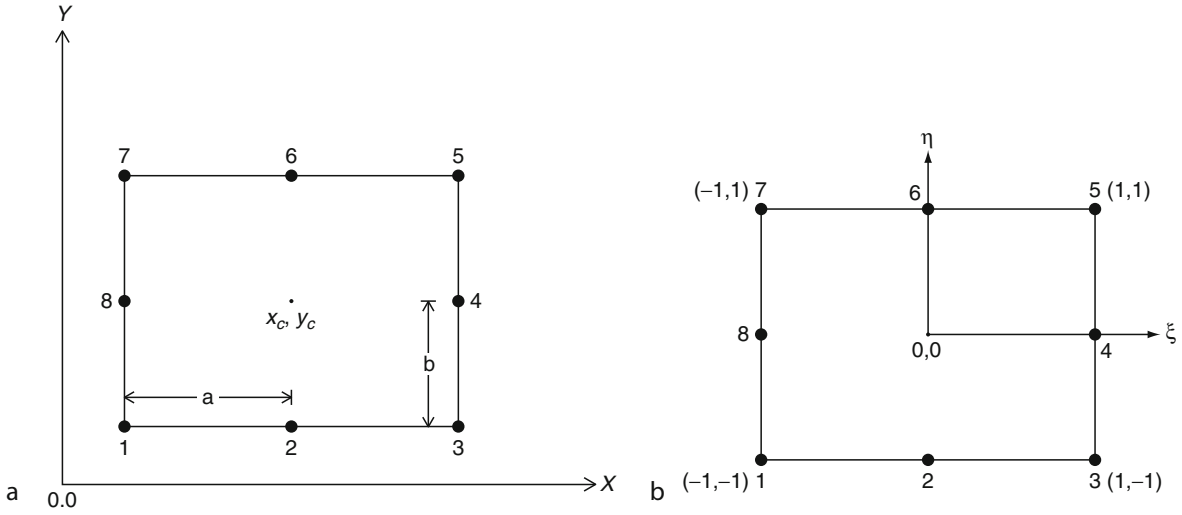
where d stands for the deeper structures, N_i (x, y) are the weights or the shape functions (Cheng and Yeo, 1979) of the element, and g_i represent the nodal gravity values. Although here an eight-node quadratic element is described, a linear element with four nodes or a cubic element with 12 nodes may also be considered. Instead of working in x–y Cartesian coordinate system, it is simpler to carry out the computations in a reference element defined by a nondimensional ξ–η space. This is achieved by the following simple substitution,

$$\xi = \frac{(x - x_c)}{a},\ \eta = \frac{(y - y_c)}{b} \tag{2}$$

These nondimensional coordinates ξ and η vary between -1 and 1. Figure 1b shows the reference element with eight nodes. The regional at any point (ξ, η) inside and on the sides of the reference element is rewritten as

$$g_d(\xi, \eta) = \sum_{i=1}^{8} N_i(\xi, \eta) g_i \tag{3}$$

The nodal gravity values g_i in Figure 1a are reassigned to the corresponding nodes in the reference element. The



Gravity Data, Regional – Residual Separation, Figure 1 (**a**) Eight-node element in *x-y* real space. The center is located at x_c, y_c with sides 2a and 2b parallel to *x*- and *y*- axes, respectively, (**b**) Eight-node element in ξ–η reference space.

8 nodal values in the periphery of the gravity survey represent the regional field.

Equation 3 is an important step in the development of the computational scheme for the following reasons. First, since ξ and η are nondimensional, the reference element can represent an observed gravity map of any size and any orientation. Second, only the nodal gravity values, g_i are used to compute the regional. No other gravity values from the map space enter into the computation, thereby overcoming the effects of the target zones. It may be noted here that all other techniques, both in space and frequency domains, developed so far over the past six decades for the regional computation do use gravity values lying inside the survey space. Some of these internal gravity values are, in fact, due to the target bodies. Therefore, there is a possibility of the regional anomaly getting contaminated by a portion of residual anomaly. Third, the weighting functions N_i (ξ, η) are defined without ambiguity. The strength of this approach lies in its simplicity.

Application to gravity surveys

The efficacy of the new technique was put to test in processing two potential fields – the gravity map of proven oil field structures in western Texas (Coffin, 1950) chosen from the distant past and the other from the large-scale structure covering parts of Klamath Mountains and Cascade Range in north-central California (Blakely, 1995).

Hydrocarbon prospect in western Texas

Figure 2a shows a gravity survey in western Texas (Coffin, 1950). By direct drilling the regions marked A and B have been proved to be oil-bearing. However, over both A and B, there are no strong anomalies. The deflections in gravity contours over regions A and B give slight indications of the presence of the structures. It is evident that a strong NW–SE regional field masked the gravity effects of the shallower structures.

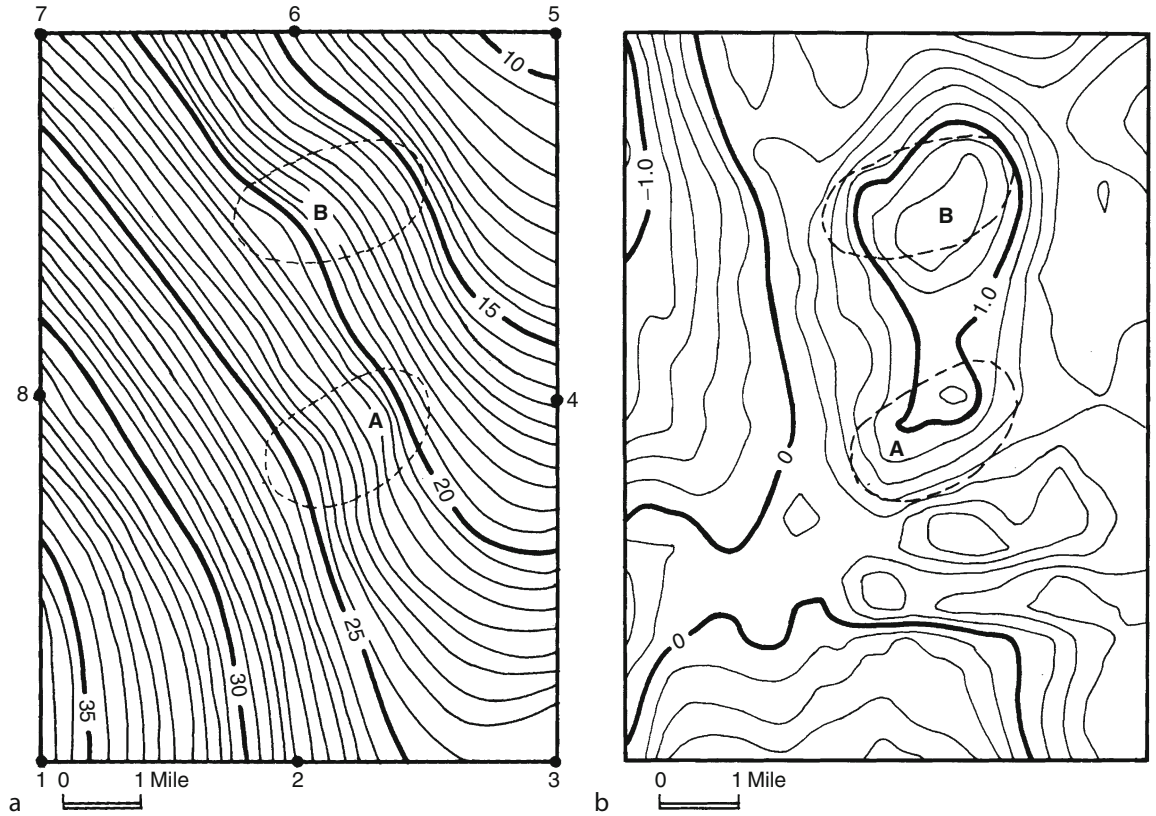
In the next step, the regional trend has been removed from the observed Bouguer gravity field by the present procedure to arrive at a residual gravity field in Figure 2b. In order to achieve this, the observed gravity values at nodes 1, 2, 3, . . ., 8 were used to compute the regional field and then the residual gravity anomalies. The residual map clearly brings out two contour closures over the target responses at A and B. This example makes it clear that the regional trend does mask the target response. The contours at B are more spread out since the target here lies deeper than that at region A.

Klamath mountains and cascade range (model-based space domain)

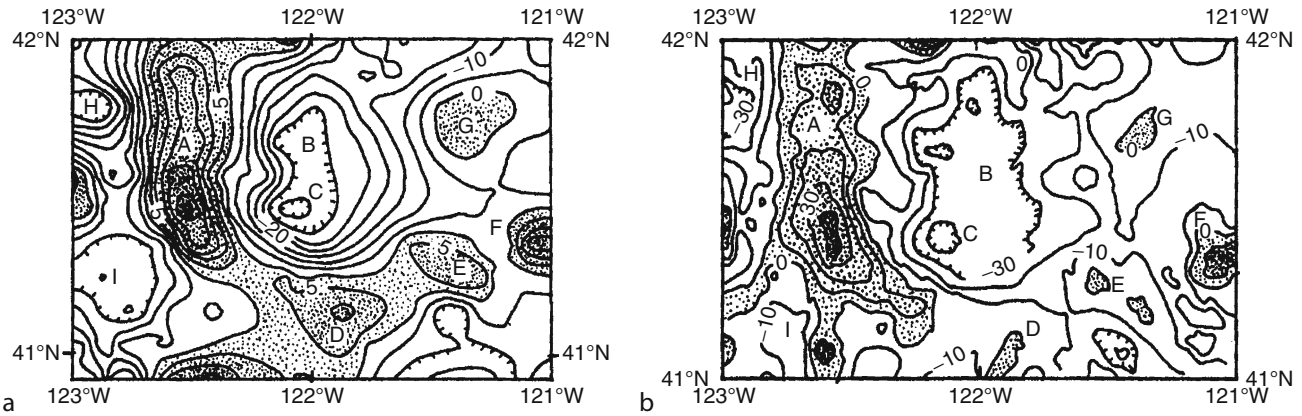
A large-scale gravity survey covering parts of Klamath Mountains and Cascade Range in north-central California lying between lat. 40° 52′ 30″ and 42°N, and long. 121° and 123°W has been taken up.

In order to compute the isostatic residual anomaly, Jachens and Griscom (1985) had adopted Airy-Heiskanen isostatic model and made the following assumptions: (1) A three-layer crust with uniform densities, (2) The density of the top layer, $\rho = 2{,}670$ kg/m^3, (3) Sea-level crustal thickness, $T = 25$ km, obtained by seismic refraction surveys, (4) The crust–mantle density contrast, $\rho = 400$ kg/m^3, close to the density contrast, $\rho = 385$ kg/m^3 (Woollard, 1966) obtained by extensive seismic studies, and more than 15,000 density measurements.

In order to cross-check their results, Jachens and Griscom (1985) had also examined the regional for this region based on Pratt-Hayford model response with a depth of compensation of 113.7 km. This regional did



Gravity Data, Regional – Residual Separation, Figure 2 (**a**) Bouguer gravity map of western Texas (After Coffin, 1950). A and B, shown by *broken line*, are two oil fields proved by direct drilling. Contour interval: 1 mGal. (**b**) Finite element residual gravity map of western Texas.



Gravity Data, Regional – Residual Separation, Figure 3 (**a**) Finite element residual gravity map of the Klamath Mountains and Cascade Range lying between lat. 40°52′30″ and 42°N, and long. 121° and 123°W. Contour interval: 5 mGal. (**b**) Isostatic residual map of the Klamath Mountains and Cascade Range lying between lat. 41° and 42° N, and long. 121° and 123° W (After Blakely, 1995). Contour interval: 10 mGal.

not differ appreciably from that obtained by Airy-Heiskanan isostatic model.

Over the same region, the finite element scheme was employed to compute the regional and the residual gravity anomalies. In the present computational scheme, there were no such constraints with regard to density and crustal thickness. This makes the new technique unique.

Figure 3a shows the finite element residual anomalies. The Klamath Mountains, Cascade Range, and all other important geological features are evident in this figure. For a comparison, the model-based isostatic residual map (Blakely, 1995, Figure 7.21f) is shown in Figure 3b. The FEA residual anomalies in Figure 3a, A through I appear to be better than or comparable to the corresponding model-based anomalies in Figure 3b.

Summary

The separation of regional and residual components from the observed Bouguer gravity (and magnetic) anomaly has remained a subject of debate over the past six to seven decades. Starting from simple graphical to model-based estimation of regional, both in space and frequency domain, the expected uniqueness has not been achieved. This is due to human judgment and mathematical as well as geological assumptions. With this backdrop, a new concept based on finite element theory is described that performs as good as or often better than the existing techniques both in frequency and space domains. This has been demonstrated with two examples. FEA technique is not site specific and can be universally used.

Magnetic Anomalies, Interpretation

GRAVITY FIELD OF THE EARTH

Christopher Jekeli
Division of Geodetic Science, School of Earth Sciences, Ohio State University, Columbus, OH, USA

Definition and scope

The gravitational field of the Earth is generally understood as the field generated by the masses of the terrestrial body. However, actual measurements made on the surface include tidal components due to the sun and moon (and theoretically other planets) and the atmosphere, as well as the centrifugal acceleration due to Earth's rotation. Therefore, geodesists distinguish between terrestrial gravitation (mass attraction of the Earth) and gravity (gravitation plus centrifugal acceleration), where tidal and atmospheric effects are treated as corrections. This chapter develops the basic physical concepts of terrestrial gravitation assumed to be generated solely by the subsurface mass density distribution. After an introduction to the Newtonian gravitational potential and its properties, the subsequent sections of the chapter discuss the spatial variation of the field on and above the Earth's surface, the geophysical interpretation of the low-degree harmonics of the field, and briefly the variation of the field inside to the Earth.

Introduction

Historical notes

A study of Earth's gravitational field is a study of Earth's mass structure, its dynamical influence on satellites, and lately its mass redistribution and transport in time. It is also fundamentally and historically a geodetic study of Earth's shape, described largely (70%) by the surface of the oceans (and their conceptual continuation under the continents). Gravitation is a physical phenomenon so pervasive and incidental that humankind generally has taken it for granted with scarcely a second thought. The Greek philosopher Aristotle (384–322 BC) allowed no more than to assert that gravitation is a natural property of material things that causes them to fall (or rise, in the case of some gases), and the more material the greater the tendency to do so. It was enough of a self-evident explanation that it was not yet to receive the scrutiny of the scientific method. Almost 2,000 years later Galileo Galilei (1564–1642) finally took up the challenge to understand gravitation through observation and scientific investigation. His experimentally derived law of falling bodies corrected the Aristotelian view and divorced the effect of gravitation from the mass of the falling object – all bodies fall with the same acceleration. This truly monumental contribution to physics was, however, only a local explanation of how bodies behaved under gravitational influence. Johannes Kepler's (1571–1630) observations of planetary orbits pointed to other types of laws, principally an inverse-square law according to which bodies are attracted by forces that vary with the inverse square of distance. The genius of Issac Newton (1642–1727) brought it all together in his *Philosophiae Naturalis Principia Mathematica* of 1687 with a single and simple all-embracing law that in one bold stroke explained the dynamics of the entire universe (today there is more to understanding the dynamics of the cosmos, but Newton's law remarkably holds its own). The mass of a body was again an essential aspect, not as a self-attribute as Aristotle had implied, but as the source of attraction for other bodies: each material body attracts every other material body according to a very specific rule (Newton's law of gravitation). Newton regretted that he could not explain exactly why mass has this property (as one still yearns to know today within the standard models of particle and quantum theories). Even Albert Einstein (1879–1955) in developing his theory of general relativity (i.e., the theory of gravitation) could only improve on Newton's theory by incorporating and explaining action at a distance (gravitational force acts with the speed of light as a fundamental tenet of the theory). Through the principle of equivalence of inertial and gravitational mass, Einstein explained gravitation as the effect that mass has on the fabric of space-time. But what actually mediates the gravitational effect (or, attraction) still intensely occupies modern physicists and cosmologists.

Gravitation since its early scientific formulation initially belonged to the domain of astronomers, at least as far as the observable universe was concerned. Theory successfully predicted the observed perturbations of planetary orbits and even the location of previously unknown new planets (Neptune's discovery in 1846 based on calculations motivated by observed perturbations in Uranus's orbit was a major triumph for Newton's law). However, it was also discovered that gravitational acceleration varies on Earth's surface, with respect to altitude and latitude. Newton's law of gravitation again provided the backdrop for the variations observed with pendulums.

An early achievement for his theory came when he successfully predicted the polar flattening in Earth's shape on the basis of hydrostatic equilibrium, which was confirmed finally (after some controversy) with geodetic measurements of long triangulated arcs in 1736–1737 by Pierre de Maupertuis and Alexis Clairaut. Gravitation thus also played a dominant role in geodesy, the science of determining the size and shape of the Earth, promulgated in large part by the father of modern geodesy, Friedrich R. Helmert (1843–1917) (Helmert, 1884).

Knowledge of terrestrial gravitation through the twentieth century was crucial for geodetic determination of a well-defined reference surface (a level surface) for heights and to correct astronomic observations of latitude and longitude for the irregular direction of gravitation (Heiskanen and Veing Meinesz, 1958; Molodensky et al., 1962; Heiskanen and Moritz, 1967; Torge, 1989; Sansò and Rummel, 1997). Also, geophysicists realized the potential of using gravity measurements to infer subsurface structures that could trap oil and gas deposits (e.g., Heiland, 1940; Nettleton, 1976; Telford et al., 1990). The Earth sciences increasingly rely on accurate gravimetry and gravitational models to aid in the interpretation of other sensor data. For example, oceanographers need an accurate level surface to infer surface currents from sea surface heights measured by satellite altimetry. Geophysicists analyzing crust deformation from GPS measurements of surface point coordinates must know whether the uplift or subsidence is accompanied by a change in subsurface mass – is it an elastic or a viscoelastic response? Ice sheet mapping (e.g., in Antarctica) using airborne laser altimetry must be accompanied with other sensors, such as gravity meters, that can infer the ice-bedrock interface. Hydrologists and glaciologists can now monitor the regional seasonal and secular changes in water/ice mass as seen by gravitation-mapping satellites as they continually orbit the Earth. In general, planetary probes glean significant geophysical information about their target from the gravitational effect on their orbits as tracked from Earth.

Other perhaps more utilitarian applications also rely on gravitational information. For example, longer-term precision navigation and guidance in the absence of external references, such as GPS, rely on inertial instruments. These autonomous navigation systems sense only inertial acceleration and require gravitational compensation, since a vehicle follows a path governed by both inertial and gravitational acceleration (Einstein's equivalence principle) (Jekeli, 2000).

Although not as prominent nor as prestigious in modern scientific endeavors, gravimetry at all scales, from point measurements to global surveys, continues to hold a critical, at least desirable place in the quest to answer a plethora of macroscopic inquiries into Earth's systems. For a modern view of the role that knowledge of the Earth's gravity field plays in the Earth sciences see Plag and Pearlman (2009) and references therein.

Newton's law of gravitation

In its original form Newton's law of gravitation applies only to idealized point masses. It describes the force of attraction, $\boldsymbol{F}$, experienced by two such solitary masses as being proportional to the product of the masses, m_1 and m_2; inversely proportional to the square of the distance, ℓ, between them; and directed along the line joining them, as expressed by the unit vector, $\boldsymbol{n}$:

$$\boldsymbol{F} = G\frac{m_1 m_2}{\ell^2}\boldsymbol{n}. \tag{1}$$

G is Newton's gravitational constant that takes care of the units between the left- and right-hand sides of the equation; it can be determined by experiment and the current accepted value is (Mohr et al., 2008):

$$G = (6.67428 \pm 0.00067) \times 10^{-11}\mathrm{m}^3/\left(\mathrm{kgs}^2\right). \tag{2}$$

The unit vector in Equation 1 is directed from either point mass to the other, and thus the gravitational force is attractive and applies equally to one mass as the other. Newton's law of gravitation is universal as far as we know, requiring reformulation only in Einstein's more comprehensive theory of general relativity, which describes gravitation as a characteristic curvature of the space-time continuum (Newton's formulation assumes instantaneous action and differs significantly from the general relativistic concept only when very large velocities or masses are involved, or, conversely, in applications of extremely high precision).

We can ascribe a gravitational acceleration to the gravitational force, which represents the acceleration that one mass undergoes due to the gravitational attraction of the other. Specifically, from the law of gravitation, we have (for point masses) the gravitational acceleration of m_1 due to the gravitational attraction of m_2:

$$\boldsymbol{g} = G\frac{m_2}{\ell^2}\boldsymbol{n}. \tag{3}$$

The vector $\boldsymbol{g}$ is independent of the mass, m_1, of the body being accelerated (which Galileo found by experiment).

By the law of superposition, the gravitational force, or the gravitational acceleration, due to many point masses is the vector sum of the forces or accelerations generated by the individual point masses. Manipulating vectors in this way is certainly feasible, but fortunately a more appropriate concept of gravitation as a scalar field simplifies the treatment of arbitrary mass distributions.

This more modern view of gravitation (adopted by eighteenth- and nineteenth-century mathematicians, such as Lagrange (1736–1813), Gauss (1777–1855), and Green (1793–1841)) holds that it is a *field* having a gravitational potential, V, defined in terms of the gravitational acceleration, $\boldsymbol{g}$, that a test particle would undergo in the field according to the equation

$$\nabla V = g, \tag{4}$$

where ∇ is the gradient operator (a vector). We use here the convention that the potential is always positive. Further elucidation of gravitation as a field grew from Einstein's attempt to incorporate gravitation into his theory of special relativity where no reference frame has particular significance above all others. It was necessary to consider that gravitational force is not a real force (i.e., it is not an applied force, like friction or propulsion) – rather it is known as a kinematic force, that is, one whose action is proportional to the mass on which it acts (like the centrifugal force); see Martin (1988). Under this precept, the geometry of space is defined intrinsically by the gravitational fields contained therein. We continue with the classical Newtonian potential, but interpret gravitation as an acceleration different from the acceleration induced by real, applied forces. This becomes especially important when considering the measurement of gravitation (Jekeli, 2007).

The gravitational potential, V, is a *scalar* function, and it is derived directly on the basis of Newton's law of gravitation. To make it completely consistent with this law and thus declare it a Newtonian potential, we must impose the following conditions of regularity at infinity:

$$\lim_{\ell\to\infty} \ell V = Gm \quad \text{and} \quad \lim_{\ell\to\infty} V = 0, \tag{5}$$

where m is the attracting mass. It easily follows from Equations 3–5 that the gravitational potential at any point in space due to a point mass is

$$V(\boldsymbol{x}) = \frac{Gm(\boldsymbol{x}')}{|\boldsymbol{x}-\boldsymbol{x}'|}, \tag{6}$$

where $\ell = |\boldsymbol{x}-\boldsymbol{x}'|$ is the distance from the mass point, $\boldsymbol{x}'$, to the evaluation point, $\boldsymbol{x}$, of the potential. Note that the field of a point mass has a singularity at $\boldsymbol{x} = \boldsymbol{x}'$.

Applying the law of superposition, the gravitational potential of many point masses is the sum of the potentials of the individual points. And, for infinitely many points in a closed, bounded region with infinitesimally small masses, dm, the summation changes to an integration:

$$V(\boldsymbol{x}) = G \int_{\text{mass}} \frac{dm(\boldsymbol{x}')}{|\boldsymbol{x}-\boldsymbol{x}'|}. \tag{7}$$

Changing variables, $dm(\boldsymbol{x}') = \rho(\boldsymbol{x}')dv$, where ρ represents density (mass per volume) and dv is a volume element, we have:

$$V(\boldsymbol{x}) = G \iiint_v \frac{\rho(\boldsymbol{x}')}{|\boldsymbol{x}-\boldsymbol{x}'|} dv. \tag{8}$$

In spherical polar coordinates the evaluation and integration points are (θ, λ, r) and (θ', λ', r'), respectively. The volume element in this case is given by $dv = r'^2 \sin\theta'\, d\lambda'\, d\theta'\, dr'$. It is readily shown that if the coordinate origin is placed at $\boldsymbol{x}$, then $dv = |\boldsymbol{x}'|^2 \sin\theta'\, d\lambda'\, d\theta'\, dr'$, and the apparent singularity disappears – the integral is said to be weakly singular. Indeed, the potential of a volume of mass density is continuous and differentiable everywhere.

Suppose the density distribution over the volume depends only on radial distance (from the center of mass, assumed to be at the origin): $\rho = \rho(r')$, and that the evaluation is at an exterior point. The surface bounding the masses necessarily is a sphere (say, of radius R) and with an appropriate choice of coordinates, one easily shows (e.g., Jekeli, 2007) that the integral (Equation 8) becomes:

$$V(\theta, \lambda, r) = \frac{GM}{r}, \quad r \geq R, \tag{9}$$

where M is the total mass bounded by the sphere. To a reasonably good approximation the Earth's density structure is spherically symmetric (see Chap. 4), and the external gravitational potential is that of a point mass (the approximation is valid to one part in two thousand).

Besides volumetric mass (density) distributions, it is of interest to consider surface distributions. Imagine an infinitesimally thin layer of mass on a surface, s, where the units of density in this case are those of mass per area. Then, analogous to Equation 8, the potential is:

$$V(\boldsymbol{x}) = G \iint_s \frac{\kappa(\boldsymbol{x}')}{|\boldsymbol{x}-\boldsymbol{x}'|} ds, \tag{10}$$

where κ is the surface mass density. In this case, V is a continuous function everywhere, but its first derivatives are discontinuous at the surface.

Now, imagine two infinitesimally close density layers (double layer, or layer of mass dipoles), where the units of density are those of mass per area times length. The potential in this case is given by Heiskanen and Moritz (1967, p. 8):

$$V(\boldsymbol{x}) = G \iint_s \kappa(\boldsymbol{x}') \frac{\partial}{\partial n}\left(\frac{1}{|\boldsymbol{x}-\boldsymbol{x}'|}\right) ds, \tag{11}$$

where $\partial/\partial n$ is the directional derivative along the perpendicular to the surface. Now, V itself is discontinuous at the surface, as are all its derivatives. In all cases, V is a Newtonian potential, having been derived from the basic formula (Equation 6) for a point mass that follows from Newton's law of gravitation, Equation 1.

The following properties of the gravitational potential are useful and foundational for many applications. First, consider Stokes's theorem for a vector function, $\boldsymbol{f}$, defined on a surface, s:

$$\iint_s (\nabla \times \boldsymbol{f}) \cdot \boldsymbol{n}\, ds = \oint_p \boldsymbol{f} \cdot d\boldsymbol{r}, \tag{12}$$

where p is any closed path in the surface, $\boldsymbol{n}$ is the unit vector perpendicular to the surface, and $d\boldsymbol{r}$ is a differential displacement along the path. From Equation 4, we find

$$\nabla \times \boldsymbol{g} = \boldsymbol{0}, \tag{13}$$

since $\nabla \times \nabla = \boldsymbol{0}$; and hence, applying Stokes's theorem, we find with $f = m\boldsymbol{g}$ that

$$w = \oint_p m\boldsymbol{g} \cdot d\boldsymbol{r} = 0. \tag{14}$$

That is, the gravitational field is conservative: the work, w, expended in moving a mass around a closed path in this field vanishes. In contrast, dissipating forces (real forces!), like friction, expend work or energy, which shows again the special nature of the gravitational force.

It can be shown (Kellogg, 1953, p. 156) that the second partial derivatives of a Newtonian potential, V, satisfy the following differential equation, known as Poisson's equation:

$$\nabla^2 V = -4\pi G\rho, \tag{15}$$

where $\nabla^2 = \nabla \cdot \nabla$ formally is the scalar product of two gradient operators and is called the Laplacian operator. In Cartesian coordinates, it is given by:

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}. \tag{16}$$

Equation 15 is a local characterization of the potential field, as opposed to the global characterization given by Equation 8. Poisson's equation holds wherever the mass density, ρ, satisfies certain conditions similar to continuity (Hölder conditions, see Kellogg, 1953, pp. 152–3). A special case of Equation 15 applies for those points where the density vanishes (i.e., in free space); then Poisson's equation turns into Laplace's equation:

$$\nabla^2 V = 0. \tag{17}$$

It is easily verified that the point mass potential satisfies Equation 17; that is,

$$\nabla^2 \left(\frac{1}{|\boldsymbol{x} - \boldsymbol{x}'|} \right) = 0, \quad \boldsymbol{x} \neq \boldsymbol{x}'. \tag{18}$$

The solutions to Laplace's Equation 17 are known as harmonic functions (here, we also impose the conditions (Equation 5) on the solution, if it is a Newtonian potential and if the mass-free region includes infinity). Hence, every Newtonian potential is a harmonic function in free space. The converse is also true: every harmonic function can be represented as a Newtonian potential of a mass distribution.

Several structures of the Earth's crust may be approximated by forms characterized essentially by a two-dimensional cross section, such as sheets, slabs, dikes, and faults that extend indefinitely in one dimension. The gravitational potential associated with such density contrasts is known as a logarithmic potential, since the potential (up to an arbitrary constant) of an infinite, straight line (that is, a differential element of the cross section) is given by (Telford et al., 1990; Kellogg, 1953)

$$\delta V(\boldsymbol{x}) = 2G\mu \ln \frac{1}{r}, \tag{19}$$

where r is the distance of the evaluation point, $\boldsymbol{x}$, from the line and μ is the constant linear mass density of the line. If the line is indefinitely extended in the y-direction, then the potential of any form with cross A in the x-z plane is

$$V(\boldsymbol{x}) = 2G\mu \iint_A \ln \frac{1}{\sqrt{(x - x')^2 + (z - z')^2}} dx' dz'. \tag{20}$$

Strictly speaking, the logarithmic potential is not a Newtonian potential since it does not vanish when $r \to \infty$ (on account of the arbitrary constant); however, it is a useful approximation in many geophysical applications.

Spatial and temporal variation above the surface

This section develops two types of solutions to standard boundary-value problems when the boundary is a sphere: the spherical harmonic series and an integral with a Green's function. Attention is given to the Dirichlet boundary-value problem for the exterior region (that includes infinity). That is, the gravitational potential, V, satisfies Laplace's Equation 17 everywhere outside the sphere, and the solution to this partial differential equation is sought based on values of V given on the sphere. Other types of boundary-value problems presume given linear combinations of zero- and first-order derivatives of the potential on the boundary. Also, other boundaries that better approximate the Earth yield more difficult solutions – the ellipsoid is relatively easy (Hotine, 1969; Jekeli, 1988); whereas, the Earth's surface is challenging (Molodensky et al., 1962; Moritz, 1980). With the spherical boundary, one obtains a particularly straightforward spectral representation that allows analysis of the spatial variation of the field at different wavelengths.

Spherical harmonics

For simple boundaries, Laplace's Equation 17 is relatively easy to solve provided there is an appropriate coordinate system. For the Earth, the solutions commonly rely on approximating the boundary by a sphere of radius, R. In spherical polar coordinates, (θ, λ, r), the Laplacian operator is given by

$$\nabla^2 = \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 \frac{\partial}{\partial r}\right) + \frac{1}{r^2}\frac{1}{\sin\theta}\frac{\partial}{\partial \theta}\left(\sin\theta \frac{\partial}{\partial \theta}\right) + \frac{1}{r^2 \sin^2\theta}\frac{\partial^2}{\partial \lambda^2}, \tag{21}$$

and solutions to $\nabla^2 V = 0$ in the space outside a sphere of radius R, with the center at the coordinate origin, are as

follows (Kellogg, 1953, p. 143; Morse and Feshbach, 1953, p. 1264; Hobson, 1965, p. 10):

$$V(\theta,\lambda,r) = P_{nm}(\cos\theta)\sin m\lambda\frac{1}{r^{n+1}} \text{ or}$$
$$V(\theta,\lambda,r) = P_{nm}(\cos\theta)\cos m\lambda\frac{1}{r^{n+1}}, \tag{22}$$

where $P_{nm}(t)$ is the associated Legendre function of the first kind and n, m are integers such that $0 \le m \le n$, $n \ge 0$. Other solutions exist, but only Equation 22 is consistent with the problem of finding a real-valued Newtonian potential for the exterior space of the Earth (regular at infinity and 2π-periodic in longitude).

The general solution is a linear combination of solutions (Equation 22) for all possible integers, n and m,

$$V(\theta,\lambda,r) = \sum_{n=0}^{\infty}\sum_{m=-n}^{n}\left(\frac{R}{r}\right)^{n+1} v_{nm}\bar{Y}_{nm}(\theta,\lambda), \tag{23}$$

where $\bar{Y}_{nm}$ are surface spherical harmonic functions defined as

$$\bar{Y}_{nm}(\theta,\lambda) = \bar{P}_{n|m|}(\cos\theta)\begin{cases}\cos m\lambda, & m \ge 0\\ \sin|m|\lambda, & m < 0\end{cases} \tag{24}$$

and $\bar{P}_{nm}$ is a normalization of P_{nm} so that the orthogonality of the spherical harmonics is

$$\frac{1}{4\pi}\iint_{\sigma}\bar{Y}_{nm}(\theta,\lambda)\bar{Y}_{n'm'}(\theta,\lambda)d\sigma = \begin{cases}1, & n = n' \text{ and } m = m'\\ 0, & n \ne n' \text{ or } m \ne m'\end{cases} \tag{25}$$

and where $\sigma = \{(\theta,\lambda)|0 \le \theta \le \pi, 0 \le \lambda \le 2\pi\}$ represents the unit sphere, with $d\sigma = \sin\theta d\theta d\lambda$. For a complete mathematical treatment of spherical harmonics, see Müller (1966). The functions $\bar{Y}_{nm}(\theta,\lambda)/r^{n+1}$, are also known as solid spherical harmonics.

The constant coefficients, v_{nm}, known as Stokes's constants, have identical units of measure. Applying the orthogonality relation, Equation 25, to the general solution (Equation 23), these coefficients can be determined if the function, V, is known on the bounding sphere (Dirichlet boundary condition):

$$v_{nm} = \frac{1}{4\pi}\iint_{\sigma}V(\theta,\lambda,R)\bar{Y}_{nm}(\theta,\lambda)d\sigma. \tag{26}$$

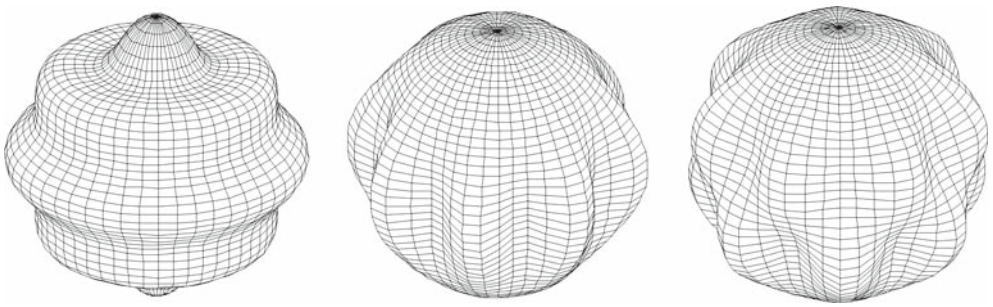
The spherical harmonic expansion of V, Equation 23, with Equation 26 for the coefficients is a solution to the Dirichlet boundary-value problem if the boundary is a sphere. The solution thus exists and is unique in the sense that these boundary values generate no other potential.

In a more formal mathematical setting, the solution (Equation 23) is an infinite linear combination of orthogonal basis functions (eigenfunctions) and the coefficients, v_{nm}, are the corresponding eigenvalues. One may also interpret the set of coefficients as the spectrum (Legendre spectrum) of the potential on the sphere of radius, R (analogous to the Fourier spectrum of a function on the plane or line). The integers, n, m, correspond to wave numbers, and are called degree (n) and order (m), respectively.

The spherical harmonics are further classified as zonal ($m = 0$), meaning that the zeros of $\bar{Y}_{n0}$ divide the sphere into latitudinal zones; sectorial ($m = n$), where the zeros of $\bar{Y}_{nn}$ divide the sphere into longitudinal sectors; and tesseral, where the zeros of $\bar{Y}_{nm}$ tessellate the sphere (Figure 1).

Recent global mappings of the Earth's gravitational field using satellite observations, specifically the GRACE mission (Gravity Recovery and Climate Experiment, Tapley et al., 2004) have emphasized the temporal dependence of the potential due to mass transport on and within the Earth (hydrologic flux, glacial isostatic adjustment, ice mass loss). In terms of the global spherical harmonic expansion this implies a temporal dependence in the Stokes's coefficients:

$$V(\theta,\lambda,r;t) = \sum_{n=0}^{\infty}\sum_{m=-n}^{n}\left(\frac{R}{r}\right)^{n+1} v_{nm}(t)\bar{Y}_{nm}(\theta,\lambda). \tag{27}$$



Gravity Field of the Earth, Figure 1 Spherical harmonics of the types, zonal (*left*), sectorial (*middle*), and tesseral (*right*).

While the spherical harmonic series has its advantages in global representations and spectral interpretations of the field, the support region for each of its basis functions is global, which can be inefficient from the standpoint of data analysis. As more data are incorporated, or improved, each coefficient, v_{nm}, must be reestimated. Representations using local-support basis functions have recently been developed (e.g., Freeden et al., 1998) and are topics of current research. Such constructions also permit multi-resolution decompositions analogous to wavelet analysis.

Green's functions

The Green's function representation of the field also offers a more regional characterization of the field. Although the Green's function strictly has global support, it attenuates rapidly from the evaluation point of the potential and reflects that a remote change in boundary value generally does not appreciably affect the local determination of the field.

When the boundary is a sphere, the solution to the boundary-value problem using a Green's function is easily derived for the potential from its spherical harmonic series representation. Additional integral relationships (with appropriate Green's functions) among all the derivatives of the potential can be derived similarly (Jekeli, 2007). Using the decomposition formula for the nth-degree Legendre polynomial,

$$P_n(\cos\psi) = \frac{1}{2n+1}\sum_{m=-n}^{n}\bar{Y}_{nm}(\theta,\lambda)\bar{Y}_{nm}(\theta',\lambda'), \tag{28}$$

where

$$\cos\psi = \cos\theta\cos\theta' + \sin\theta\sin\theta'\cos(\lambda-\lambda'), \tag{29}$$

and, substituting the harmonic coefficients, Equation 26, into the series, Equation 23, we find

$$V(\theta,\lambda,r) = \frac{1}{4\pi}\iint_{\sigma} V(\theta',\lambda',R)U(\psi,r)d\sigma, \tag{30}$$

where with $\ell = \sqrt{r^2+R^2-2rR\cos\psi}$

$$\begin{aligned} U(\psi,r) &= \sum_{n=0}^{\infty}(2n+1)\left(\frac{R}{r}\right)^{n+1}P_n(\cos\psi) \\ &= \frac{R(r^2-R^2)}{\ell^3}. \end{aligned} \tag{31}$$

The closed formula (right side of Equation 31) comes from an appropriate manipulation of the Coulomb expansion (Cushing, 1975, p. 155) for the reciprocal distance,

$$\frac{1}{\ell} = \frac{1}{R}\sum_{n=0}^{\infty}\left(\frac{R}{r}\right)^{n+1}P_n(\cos\psi). \tag{32}$$

Solutions (Equations 23 and 30) to the Dirichlet boundary-value problem for a spherical boundary are identical. The integral (Equation 30) is known as the Poisson integral and the function U is also known as Poisson's kernel.

The disturbing potential

For convenience, one separates Earth's gravitational potential into a reference potential ("Normal Reference Field") and the disturbing potential, T. The disturbing potential is harmonic in free space, satisfies Poisson's integral if the boundary is a sphere, and is expandable in a series of solid spherical harmonics:

$$T(\theta,\lambda,r) = \frac{GM}{R}\sum_{n=0}^{\infty}\sum_{m=-n}^{n}\left(\frac{R}{r}\right)^{n+1}\delta C_{nm}\bar{Y}_{nm}(\theta,\lambda) \tag{33}$$

where M is the total mass (including the atmosphere) of the Earth and δC_{nm} are unitless harmonic coefficients, being also the difference between coefficients for the total and reference gravitational potentials. The coefficient, δC_{00}, is zero under the assumption that the reference field accounts completely for the central part of the total field. Note that these coefficients also specifically refer to the sphere of radius, R.

The gravity anomaly (in spherical approximation) is defined by

$$\Delta g(\theta,\lambda,r) = \left(-\frac{\partial}{\partial r}-\frac{2}{r}\right)T(\theta,\lambda,r), \tag{34}$$

or, using Equation 33,

$$\Delta g(\theta,\lambda,r) = \frac{GM}{R^2}\sum_{n=0}^{\infty}\sum_{m=-n}^{n}\left(\frac{R}{r}\right)^{n+2}(n-1)\delta C_{nm}\bar{Y}_{nm}(\theta,\lambda). \tag{35}$$

The spectral relationship between gravity anomalies and the disturbing potential, obtained by comparing Equations 33 and 35, leads to a corresponding Green's function that transforms one to the other. This function in geodesy is called more commonly the Stokes function:

$$\begin{aligned} S(\psi,r) &= \sum_{n=2}^{\infty}\frac{2n+1}{n-1}\left(\frac{R}{r}\right)^{n+1}P_n(\cos\psi) \\ &= 2\frac{R}{\ell}+\frac{R}{r}-3\frac{R\ell}{r^2}-5\frac{R^2}{r^2}\cos\psi \\ &\quad -3\frac{R^2}{r^2}\cos\psi\ln\frac{\ell+r-R\cos\psi}{2r} \end{aligned} \tag{36}$$

and thus (Hofmann-Wellenhof and Moritz, 2005; Jekeli, 2007)

$$T(\theta,\lambda,r) = \frac{R}{4\pi}\iint_{\sigma}\Delta g(\theta',\lambda',R)S(\psi,r)d\sigma, \tag{37}$$

which is known as Stokes's integral. This famous equation in geodesy solves the Robin boundary-value problem for the sphere: the potential and its normal derivative are given on the boundary; see Equation 34.

The solution is not unique since, as Equation 35 shows, the gravity anomaly has no first-degree harmonics, which, therefore, cannot be determined from the boundary values. Conventionally, as shown in Equation 36, the Stokes kernel also excludes the zero-degree harmonic and thus the complete solution for the disturbing potential is given by

$$T(\theta,\lambda,r) = \frac{GM}{r}\delta C_{00} + \frac{GM}{R}\sum_{m=-1}^{1}\left(\frac{R}{r}\right)^2 \delta C_{1m}\bar{Y}_{1m}(\theta,\lambda) + \frac{R}{4\pi}\iint_{\sigma} \Delta g(\theta',\lambda',R)S(\psi,r)d\sigma. \quad (38)$$

The central term, δC_{00}, is proportional to the difference in GM of the Earth and reference ellipsoid and is zero to high accuracy. The first-degree harmonic coefficients, δC_{1m}, are proportional to the center-of-mass coordinates and can also be set to zero with appropriate definition of the coordinate system (see Low-Degree Harmonics as Density Moments). Thus, the Stokes integral (Equation 37) is the more common expression for the disturbing potential, but it embodies hidden constraints.

Spectral contributions

The correlation function of the disturbing potential on a sphere is defined as (Moritz, 1980; Jekeli, 2010)

$$\phi_T(\psi) = \frac{1}{8\pi^2}\int_0^{2\pi}\iint_{\sigma} T(\theta,\lambda,R)T(\theta',\lambda',R)\sin\theta d\theta d\lambda d\alpha, \quad (39)$$

where the points (θ,λ,R) and (θ',λ',R) are connected by Equation 29 and their relative azimuth, α,

$$\tan\alpha = \frac{-\sin\theta'\sin(\lambda-\lambda')}{\sin\theta\cos\theta' - \cos\theta\sin\theta'\cos(\lambda-\lambda')}, \quad (40)$$

and where the integration is performed over all possible pairs of these points, with fixed spherical distance, ψ, $0 \le \psi \le \pi$.

Because of its sole dependence on ψ, ϕ_T can be expressed as an infinite series of Legendre polynomials:

$$\phi_T(\psi) = \sum_{n=0}^{\infty}(2n+1)(\Phi_T)_n P_n(\cos\psi) \quad (41)$$

where the coefficients, $(\Phi_T)_n$ constitute the Legendre transform of ϕ_T:

$$(\Phi_T)_n = \frac{1}{2}\int_0^{\pi}\phi_T(\psi)P_n(\cos\psi)\sin\psi d\psi. \quad (42)$$

Substituting Equations 28 and 39 into Equation 42, then simplifying using the orthogonality of spherical harmonics, (Equation 25), and the definition of the Legendre spectrum, Equation 26, we find:

$$(\Phi_T)_n = \frac{1}{2n+1}\sum_{m=-n}^{n} v_{nm}^2. \quad (43)$$

The quantities, $(\Phi_T)_n$, constitute the power spectral density (psd) of T; and,

$$(c_T)_n = (2n+1)(\Phi_T)_n \quad (44)$$

is known as the degree variance or variance per degree, since the total variance, from Equation 41, is

$$\phi_T(0) = \sum_{n=0}^{\infty}(c_T)_n. \quad (45)$$

For the first and second radial derivatives of the disturbing potential, called the gravity disturbance ($\delta g = -\partial T/\partial r$) and disturbing vertical-vertical gradient ($\delta\Gamma = \partial^2 T/\partial r^2$), one has analogous psd's that are related to the psd of T as follows:

$$(\Phi_{\delta\Gamma})_n = \left(\frac{n+2}{R}\right)^2(\Phi_{\delta g})_n = \left(\frac{n+2}{R}\right)^2\left(\frac{n+1}{R}\right)^2(\Phi_T)_n. \quad (46)$$

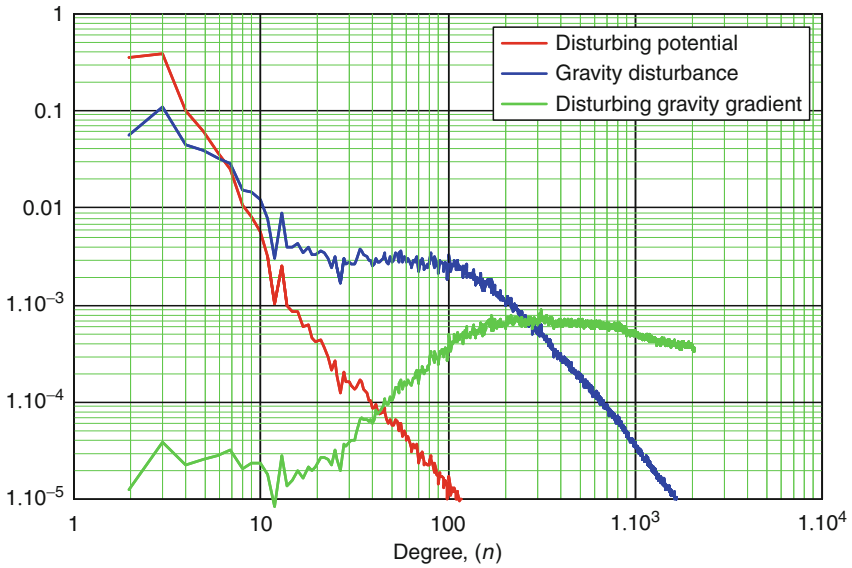
Using the most recent high-degree Earth Gravitational Model, EGM08 (Pavlis et al., 2008), Figure 2 illustrates the relative spectral content of the derivatives of the (disturbing) gravitational potential. Clearly, the higher derivatives emphasize the shorter wavelengths (or higher degrees, higher frequencies). The EGM08 model has maximum degree 2,160, corresponding to about 9.3 km resolution on the Earth's surface ($180^\circ/2{,}160 = 5$ arcmin).

Low-degree harmonics

The low-degree spherical harmonics of the Earth's gravitational potential lend themselves to interpretation with respect to the most elemental distribution of the Earth's mass density, which also leads to fundamental geometric characterizations, particularly for the second-degree harmonics. Let

$$C_{nm}^{(a)} = \frac{a}{GM}\left(\frac{R}{a}\right)^{n+1} v_{nm} \quad (47)$$

be unitless coefficients that refer to a sphere of radius, a, which is the equatorial radius of the Earth ellipsoid. (Recall that coefficients, v_{nm}, Equation 50, refer to a sphere



Gravity Field of the Earth, Figure 2 Degree variances of radial derivatives of the Earth's disturbing potential. All values are normalized by the respective total variance.

of radius, R.) Relative to the central harmonic coefficient, $C_{00}^{(a)} = 1$, the next significant harmonic, $C_{20}^{(a)}$, is more than three orders of magnitude smaller; and, the remaining harmonic coefficients are at least two to three orders of magnitude smaller than that. The attenuation of the coefficients after degree two is much more gradual (Table 1), indicating that the bulk of the potential can be described by an ellipsoidal field. The normal gravitational field is such a field, but it also adheres to a geodetic definition that requires the underlying ellipsoid to be an equipotential surface in the corresponding normal gravity field. The following sections examine the low-degree harmonics from the two perspectives of interpretation and reference.

Low-degree harmonics as density moments

Returning to the general expression for the gravitational potential in terms of the Newtonian density integral (Equation 8), and substituting the spherical harmonic series for the reciprocal distance (Equation 32 with 29):

$$V(\theta,\lambda,r) = \sum_{n=0}^{\infty}\sum_{m=-n}^{n}\left(\frac{R}{r}\right)^{n+1}\left(\frac{G}{R^{n+1}(2n+1)}\iiint_{\text{volume}}(r')^n \bar{Y}_{nm}(\theta',\lambda')\rho(\theta',\lambda',r')dv\right)\bar{Y}_{nm}(\theta,\lambda) \tag{48}$$

yields a multipole expansion (so-called from electrostatics) of the potential. The spherical harmonic (Stokes) coefficients are multipoles of the density distribution:

$$v_{nm} = \frac{G}{R^{n+1}(2n+1)}\iiint_{v}(r')^n \bar{Y}_{nm}(\theta',\lambda')\rho(\theta',\lambda',r')dv. \tag{49}$$

One may also consider the nth-order moments of the mass density (from the statistics of distributions) defined by

$$\mu_{\alpha\beta\gamma}^{(n)} = \iiint_{v}(x')^{\alpha}(y')^{\beta}(z')^{\gamma}\rho dv, \qquad n = \alpha+\beta+\gamma. \tag{50}$$

The multipoles of degree n and the moments of order n are related, though not all $(n+1)(n+2)/2$ moments of order n can be determined from the $2n+1$ multipoles of degree n, when $n \geq 2$ (clearly risking confusion, we defer to the common nomenclature of "order" for moments and "degree" for spherical harmonics). This indeterminacy is directly connected to the inability to determine the density distribution uniquely from external measurements of the potential (Chao, 2005), which is the classic geophysical inverse problem.

The zero-degree Stokes coefficient is coordinate invariant and is proportional to the total mass of the Earth:

$$v_{00} = \frac{G}{R}\iiint_{v}\rho dv = \frac{GM}{R}. \tag{51}$$

It also represents a mass monopole, and it is proportional to the zeroth moment of the density.

[a]GRACE model GGM02S (Tapley et al., 2005)

The first-degree harmonic coefficients (representing dipoles) are proportional to the coordinates of the center of mass, (x_{cm}, y_{cm}, z_{cm}), which are proportional to the first-order moments of the density, as verified by recalling the definition of the first-degree spherical harmonics:

$$v_{1m} = \frac{G}{\sqrt{3}R^2} \iiint_v \rho \begin{Bmatrix} r' \sin\theta' \sin\lambda', & m=-1 \\ r' \cos\theta', & m=0 \\ r' \sin\theta' \cos\lambda', & m=1 \end{Bmatrix} dv \tag{52}$$
$$= \frac{GM}{\sqrt{3}R^2} \begin{Bmatrix} y_{cm}, & m=-1 \\ z_{cm}, & m=0 \\ x_m, & m=1 \end{Bmatrix}$$

Nowadays, by tracking satellites, we have access to the center of mass of the Earth (including its atmosphere) since it defines the center of their orbits. Ignoring the small motion of the center of mass (annual amplitude of several mm) due to the temporal variations in the mass distribution, we may choose the coordinate origin for the gravitational potential to coincide with the center of mass, thus annihilating the first-degree coefficients.

The second-order density moments likewise are related to the second-degree harmonic coefficients (quadrupoles). They also define the inertia tensor of the body. The inertia tensor is the proportionality factor in the equation that relates the angular momentum vector, $\boldsymbol{H}$, and the angular velocity, $\boldsymbol{\omega}$, of a body, like the Earth:

$$\boldsymbol{H} = I\boldsymbol{\omega}, \tag{53}$$

and is given by

$$I = \begin{pmatrix} I_{xx} & I_{xy} & I_{xz} \\ I_{yx} & I_{yy} & I_{yz} \\ I_{zx} & I_{zy} & I_{zz} \end{pmatrix}. \tag{54}$$

It comprises the moments of inertia on the diagonal

$$I_{xx} = \iiint_{\text{volume}} \left(y'^2 + z'^2\right)\rho dv,$$
$$I_{yy} = \iiint_{\text{volume}} \left(z'^2 + x'^2\right)\rho dv, \tag{55}$$
$$I_{zz} = \iiint_{\text{volume}} \left(x'^2 + y'^2\right)\rho dv,$$

and the products of inertia off the diagonal

$$I_{xy} = I_{yx} = -\iiint_{\text{volume}} x'y'\rho dv,$$
$$I_{xz} = I_{zx} = -\iiint_{\text{volume}} x'z'\rho dv, \tag{56}$$
$$I_{yz} = I_{zy} = -\iiint_{\text{volume}} y'z'\rho dv.$$

Note that

$$I_{xx} = \mu_{020}^{(2)} + \mu_{002}^{(2)}, \quad I_{xy} = -\mu_{110}^{(2)}, \quad I_{xz} = -\mu_{101}^{(2)}$$
$$I_{yy} = \mu_{002}^{(2)} + \mu_{200}^{(2)}, \quad I_{yz} = -\mu_{011}^{(2)} \tag{57}$$
$$I_{zz} = \mu_{200}^{(2)} + \mu_{020}^{(2)}$$

and there as many (six) independent tensor components as second-order density moments. Using the explicit expressions for the second-degree spherical harmonics, we have from Equation 49 with $n = 2$:

$$v_{2,-2} = -\frac{\sqrt{15}\,G}{5R^3} I_{xy}, \quad v_{2,-1} = -\frac{\sqrt{15}\,G}{5R^3} I_{yz},$$
$$v_{2,1} = -\frac{\sqrt{15}\,G}{5R^3} I_{xz}, \quad v_{2,0} = \frac{\sqrt{5}\,G}{10R^3}\left(I_{xx} + I_{yy} - 2I_{zz}\right), \tag{58}$$
$$v_{2,2} = \frac{\sqrt{15}\,G}{10R^3}\left(I_{yy} - I_{xx}\right).$$

These are also known as MacCullagh's formulas. Not all density moments (or, moments of inertia) can be determined from the Stokes coefficients.

If the coordinate axes are chosen so as to diagonalize the inertia tensor (products of inertia are equal to zero), then they are known as principal axes of inertia, or also "figure" axes. For the Earth the z-figure axis is very close to the spin axis (within several meters at the pole); both axes move with respect to each other and with respect to the Earth's crust, with combinations of various periods (daily, monthly, annual, etc.) as well as secularly in a wandering fashion. Because of these polar motions the figure axis is not a useful coordinate axis that defines a frame fixed to the (surface of the) Earth. However,

because of the proximity of the figure axis to the defined reference z-axis, the second-degree, first-order harmonic coefficients of the geopotential, and hence the products of inertia, I_{xz} and I_{yz}, are relatively small (Table 1).

The arbitrary choice of the x-axis of our Earth-fixed reference coordinate system certainly did not attempt to eliminate the product of inertia, I_{xy} (the x-axis is defined by the intersection of the Greenwich meridian with the equator; and the y-axis completes a right-handed mutually orthogonal triad). However, it is possible to determine where the x-figure axis is located by combining values of the second-degree, second-order harmonic coefficients. Let u, v, and w be the axes that define a coordinate system in which the inertia tensor is diagonal; and, assume that the approximation, $I_{ww} = I_{zz}$, holds. A rotation by the angle, $-\lambda_0$, about the w- (also z-) figure axis brings this ideal coordinate system back to the conventional one in which we calculate the harmonic coefficients. Tensors transform under rotation, defined by matrix, $\mathcal{R}$, according to

$$I_{xyz} = \mathcal{R} I_{uvw} \mathcal{R}^{\mathrm{T}}. \tag{59}$$

With the rotation about the w-axis given by the matrix:

$$\mathcal{R} = \begin{pmatrix} \cos\lambda_0 & -\sin\lambda_0 & 0 \\ \sin\lambda_0 & \cos\lambda_0 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \tag{60}$$

and with Equation 16 it is straightforward to show that

$$\begin{aligned} v_{2,-2} &= -\frac{\sqrt{15}G}{10R^3}(I_{uu} - I_{vv})\sin 2\lambda_0 \\ v_{2,2} &= -\frac{\sqrt{15}G}{10R^3}(I_{uu} - I_{vv})\cos 2\lambda_0 \end{aligned} \tag{61}$$

Hence, we have

$$\lambda_0 = \frac{1}{2}\tan^{-1}\frac{v_{2,-2}}{v_{2,2}}, \tag{62}$$

where the quadrant is determined by the signs of the harmonic coefficients. From Table 1 and Equation 47, we find that $\lambda_0 = -14.929°$; that is, the u-figure axis is in the mid-Atlantic between South America and Africa.

The second-degree, second-order harmonic coefficient, $v_{2,2}$, indicates the asymmetry of the Earth's mass distribution with respect to the equator. Since $v_{2,2} > 0$ (for the Earth), Equation 61 shows that $I_{vv} > I_{uu}$ and thus the equator "bulges" more in the direction of the u-figure axis; conversely, the equator is flattened in the direction of the v-figure axis. This flattening is relatively small:$1.1 \cdot 10^{-5}$.

Finally, consider the most important second-degree harmonic coefficient, the second zonal harmonic, $v_{2,0}$. Irrespective of the x-axis definition, it is proportional to the difference between the moment of inertia, I_{zz}, and the average of the equatorial moments, $(I_{xx} + I_{yy})/2$. Again, since $v_{2,0} < 0$, the Earth bulges more around the equator and is flattened at the poles. The second zonal harmonic coefficient is roughly 1,000 times larger than the other second-degree coefficients and thus indicates a substantial polar flattening (owing to the Earth's early more fluid state). This flattening is approximately 0.003.

Normal reference field

A model for the Earth's gravitational field that is mathematically simple and yet accurate to better than one part in sixty-three thousand (for the potential) is based on an ellipsoid of revolution rather than the sphere. The precise geodetic definition of the normal (reference) gravitational potential is that it is generated by an ellipsoidal mass that rotates with the Earth such that the gravitational potential plus the potential due to the centrifugal acceleration (as related according to Equation 4) is a constant, U_0, on the ellipsoid. This definition sets up a Dirichlet boundary-value problem, whose solution is an analytic expression in ellipsoidal coordinates (Hofmann-Wellenhof and Moritz, 2005). The boundary is defined by two parameters, the semi-major axis, a, and polar flattening, f, of the (rotationally symmetric) normal ellipsoid; and the boundary values of the potential are defined by the given constant, U_0, and the rotation rate of the Earth, ω_e (which specifies the centrifugal potential at any particular latitude). The normal ellipsoid, by definition, is centered at Earth's center of mass.

The solution for the normal potential is thus based on four fundamental constants, Earth's rotation rate, the size and shape parameters of the ellipsoid, and a gravitational scale parameter. The constant, U_0, is related to several other gravitational quantities, such as the value of normal gravity (mass attraction plus the centrifugal acceleration) at the equator, or the total mass of the ellipsoid, or it could simply be taken as the potential value of the geoid. It can be shown (Hofmann-Wellenhof and Moritz, 2005) that

$$U_0 = \frac{GM}{E}\tan^{-1}\frac{E}{b} + \frac{1}{3}\omega_e^2 a^2, \tag{63}$$

where $b = a(1-f)$ is the semi-minor axis, $E = \sqrt{a^2 - b^2}$ is the linear eccentricity of the ellipsoid, and M is its total mass. The mass density is not constant within the normal ellipsoid and its variation does not approximate Earth's internal structure. Rather the normal gravity potential (the sum of gravitational potential due to mass attraction and the centrifugal potential) is designed to emulate the actual external field, being constant on the ellipsoid, as the actual gravity potential is constant on the geoid.

The normal field is always defined by adopting values of the four parameters that approximately match the corresponding actual parameters for the Earth. Before artificial Earth-orbiting satellites, the gravitational scale could best be accessed by measuring gravity (e.g., a nominal value at the equator served as the physical scale parameter). By tracking satellites, the value of GM for the Earth (total mass including the atmosphere) can be estimated to high accuracy, and is still used today to define the physical scale of the normal potential. The ellipsoid parameters

were traditionally determined from (partially) global geometric surveying networks projected onto a best-fitting ellipsoid. Today, the semi-major axis is well determined from a best fit of an ellipsoid to a global set of ocean heights derived from satellite altimeter data. The polar flattening, according to "Low-Degree Harmonics as Density Moments," is related to the second zonal harmonic of Earth's gravitational potential, which likewise can be estimated very accurately from satellite tracking data. The second zonal harmonic coefficient, the *dynamical form factor*, thus serves as the shape parameter for the normal ellipsoid. Table 2 lists internationally adopted normal ellipsoids over the past 100 years.

The exact analytical expression for the normal gravity potential then yields exact expressions for the normal gravity (and gravitation) and all its gradients. Nevertheless, approximate series expressions are sometimes preferred, especially to conform to a particular coordinate system. For example, the normal gravitational potential (due only to mass attraction) in spherical polar coordinates is given by

$$V(\theta,\lambda,r) = \frac{GM}{r}\left(1 - \sum_{n=2}^{\infty} J_{2n}\left(\frac{a}{r}\right)^{2n} P_{2n}(\cos\theta)\right), \tag{64}$$

where with $e = E/a$ (the first eccentricity),

$$J_{2n} = (-1)^{n+1}\frac{3e^{2n}}{(2n+1)(2n+3)}\left(1 - n + 5n\frac{J_2}{e^2}\right), \tag{65}$$

and where

$$J_2 = \frac{1}{Ma^2}(I_{zz} - I_{xx}) = -\frac{\sqrt{5}R^3}{GMa^2}v_{2,0} = -\sqrt{5}C_{2,0}^{(a)}, \tag{66}$$

making use of Equations 58 and 47. From Equation 65 it is clear that only the first few coefficients (say, up to $n = 4$) are significant for all applications, since $e^2 \approx 0.0066$ (Table 3). Also, the normal potential, comprising only even zonal harmonics, is independent of longitude and symmetric with respect to the equator.

Normal gravity (including the centrifugal acceleration) on the ellipsoid as function of *geodetic* latitude, ϕ (angle of the perpendicular to the ellipsoid with respect to the equator), is given by the Somigliana formula (Moritz, 1980):

$$\gamma(\phi) = \frac{a\gamma_a\cos^2\phi + b\gamma_b\sin^2\phi}{\sqrt{a^2\cos^2\phi + b^2\sin^2\phi}}, \tag{67}$$

where normal gravity on the equator and at the poles is

$$\gamma_a = \frac{GM}{ab}\left(1 - m - \frac{m}{6}\frac{e'q'_0}{q_0}\right), \tag{68}$$

$$\gamma_b = \frac{GM}{a^2}\left(1 + \frac{m}{3}\frac{e'q'_0}{q_0}\right), \tag{69}$$

with $m = \omega_e^2 a^2 b/GM$, $e' = E/b$ (the second eccentricity), and

$$q_0 = \frac{1}{2}\left(1 + \frac{3}{e'^2}\right)\tan^{-1}e' - \frac{3}{2e'^2},$$
$$q'_0 = 3\left(1 + \frac{1}{e'^2}\right)\left(1 - \frac{1}{e'^2}\tan^{-1}e'\right) - 1. \tag{70}$$

At points along the perpendicular to the ellipsoid, the following approximate formula for normal gravity is often used:

$$\gamma(\phi,h) = \gamma(\phi)\left(1 - \frac{2}{a}(1 + f + m - 2f\sin^2\phi)h + \frac{3}{a^2}h^2\right), \tag{71}$$

which is accurate to 1.4×10^{-6} m/s^2, or better, up to altitude, $h = 20{,}000$ m, above the ellipsoid.

Earth's internal gravitational field

While Earth's external gravitational field may be determined entirely from measurements and potential theory,

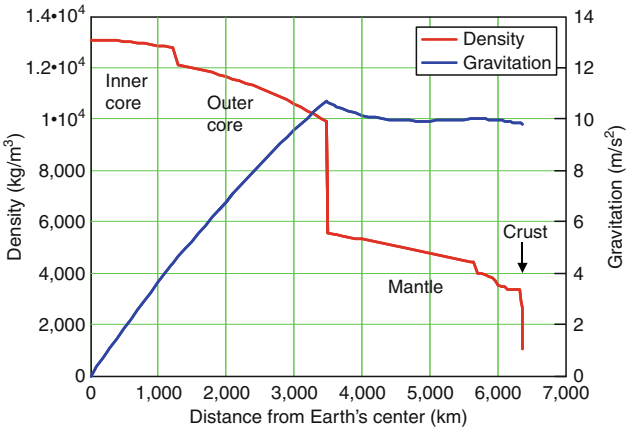
the internal field is much less accessible for measurement and depends on models of the subsurface structure that can only be inferred from surface measurements and constraints provided by various other geophysical observations. Some have likened the study of the Earth's interior to the study of the cosmos – the investigator is incapable of performing in situ measurements and is left to use various (and sometimes ingenious) proxies to infer the Earth's interior makeup. Of course, there are borehole measurements and these are probing ever deeper into the Earth's crust, but they are isolated and expensive. A complete reconstruction of the Earth's (deeper) interior comes at present primarily from seismological data by analyzing the travel times of hundreds of thousands to millions of compressional (P) and shear (S) waves as they pass through the Earth's body. Near surface reconstruction also relies on seismic sounding (seismograms from intentional explosions) as well gravimetry, magnetometry, and other geophysical sensors, including ground penetrating radar, electromagnetic induction, and electric resistivity methods.

We may argue that knowledge of the interior gravity field is of secondary importance to an understanding of Earth's internal structure inasmuch as this knowledge is derived from an Earth model that is already determined from other data. Only when gravity can be measured within the Earth (e.g., in boreholes) does the interior gravitational field offer a contributory importance to our modeling of the Earth's interior. At present the deepest borehole in the world, at just over 12,260 m, is located in Russia on the Kola Peninsula on the Barents Sea northeast of Finland. Most holes are drilled for geological exploration and reach depths of several hundred meters.

Nevertheless it is of interest to compute gravitational attraction along a radius of the Earth, as modeled by a radially layered composite of mass density. From Equation 8 it is easily shown that the gravitational potential inside a radially symmetric body (having radius, R) has the form

$$V(r) = \frac{4\pi G}{r}\int_0^r \rho(r')r'^2 dr' + 4\pi G\int_r^R \rho(r')r'dr', \quad 0 \le r \le R. \tag{72}$$



Gravity Field of the Earth, Figure 3 Gravitation and mass density inside the Earth according to the radially symmetric PREM.

Thus, the gravitational acceleration is given by

$$g(r) = -\frac{d}{dr}V(r) = \frac{4\pi G}{r^2}\int_0^r \rho(r')r'^2 dr'. \tag{73}$$

For the Preliminary Reference Earth Model (PREM) of 1981 (Dziewonski and Anderson, 1981; Dziewonski, 1989), which consists of approximately 80 layers, the radial variation of gravitation is shown in Figure 3 together with the change in density.

On a more local scale, we may use the attraction of an infinite horizontal plate of constant density, ρ_0, as a model to approximate the value of gravity in the crust (or ocean) near the Earth's surface. The attraction of such a plate of thickness, d, anywhere above or below the plate is

$$B = 2\pi G\rho_0 d, \tag{74}$$

which is also known as the Bouguer plate effect. Suppose that g_P is the value of gravity at a surface point, P, on the Earth. Assuming that the topography is relatively flat in its vicinity, remove a plate of material with density, ρ_0, and thickness, d, and the gravity value at P will diminish by B. Now bring the gravity value to the level d through free space using a normal gradient approximation, which changes its value by $F \approx -(\partial\gamma/\partial h)d$ (also known as the free-air reduction). Finally restore the material plate, which again decreases the value of gravity, now at depth, d, by B.

The resulting gravity as a function of depth thus becomes

$$g(d) \approx g_p - \left(\frac{\partial\gamma}{\partial h} + 4\pi G\rho_0\right)d. \tag{75}$$

Using nominal values for the normal gradient, $\partial\gamma/\partial h \approx -0.3086$ mGal/m (where 1 mGal $= 10^{-5}$ m/s^2), and

the ocean water or crust density, $\rho_w = 1{,}027\ \mathrm{kg/m^3}$ or $\rho_0 = 2{,}670\ \mathrm{kg/m^3}$, respectively, this becomes

$$g(d) \approx g_p + 0.2225\ d\ [\mathrm{mGal}], \quad d \text{ in units of meter below sea surface;} \tag{76}$$

$$g(d) \approx g_p + 0.0848\ d\ [\mathrm{mGal}], \quad d \text{ in units of meter below land surface.} \tag{77}$$

This is also known as the Poincaré–Prey reduction and may be used to model gravity in boreholes and in the oceans, given gravity at the surface. The model of gravity within the Earth's upper crust (or ocean) can be improved with more careful modeling of the effects of variable topography and variable density (especially in the oceans).

Summary

The Earth's gravitational field, defined as the field generated by the subsurface mass density, embodies a wealth of geophysical information at global and local scales. The global field is often described in terms of a spherical harmonic expansion, where the low-degree harmonics have a definite (though incomplete) interpretation with respect to the moments of the density distribution. The attenuation of the potential in the spherical harmonic (spatial frequency) domain is sufficiently gradual that first- and second-order radial derivatives readily characterize the local, near surface structure of the Earth. Whereas the external gravitational field of the Earth can be modeled in detail on the basis of surface measurements and potential theory, the deeper internal gravitational field model is derived secondarily from density distribution models obtained from other sources, such as seismological data.

Definition and introduction

Observing the Earth from space over the past 50 years has resulted in spectacular advances in various areas of the geosciences. This is the case, in particular, for measuring the precise shape of the Earth and its broad scale internal structure from detailed measurements of the planet's gravity field. Since the early 1970s, tracking the orbits of tens of satellites at different altitudes and orbit inclinations has gradually improved knowledge of Earth's average (static) gravity field (see section on *Gravity Method, Satellite*). Besides the precise description of the static component, attempts have been made to detect temporal variations of the gravity field. For example, a secular decrease of Earth's flattening (the degree 2, order 0 term) was discovered by precise analysis of the Lageos laser satellites (Yoder et al., 1983; Cox and Chao, 2002), and attributed to postglacial rebound (PGR) (the viscoelastic response of the crust and mantle to melting of the large ice sheets that covered part of the northern hemisphere during the last ice age). Seasonal variations of the low degree terms of the Earth's gravity field expansion (up to $\sim$ degree 6) have been detected from analysis of satellite orbital perturbations (Cheng and Tapley, 2004; Chen et al., 1999). These variations were attributed to seasonal transfer of air mass inside the atmosphere as well as to annual fluctuations of snow and land water storage (e.g., Chen et al., 1999; Cazenave et al., 1999). However until recently, temporal changes of only the longest-wavelength (lowest degree) harmonic coefficients had been monitored from orbital perturbations. This limited effective spatial resolution to several thousand kilometers, because large uncertainty in higher degree coefficients prevented detection of any time-varying signal.

In 2002, the US–German GRACE (Gravity Recovery and Climate Experiment) mission has been providing a precise survey of Earth's time-variable gravity field, with unprecedented temporal and spatial sampling (Tapley et al., 2004; Wahr et al., 2004). GRACE time-variable gravity fields provide a means of measuring temporal and spatial variations of mass redistribution within the Earth system on time scales varying from season to multiyears. The GRACE mission has launched a new era in studying a series of geophysical problems ranging from deep Earth structure to tracking mass redistribution on and near the surface of the Earth. GRACE has greatly improved understanding of mass redistribution in various compartments of the climate system (atmosphere, oceans, terrestrial water, stores and cryosphere). GRACE has fundamentally enriched a number of fields, including (but not limited to) the global water cycle and land hydrology, mass balance of polar ice sheets and mountain glaciers, ocean mass and global sea-level change, and solid Earth geophysics.

The GRACE mission

Launched in March 2002, GRACE utilizes a state-of-the-art technique to observe variation of Earth's gravity by tracking the inter-satellite range and the range rate between two coplanar, low altitude satellites via a K-band ranging system. In addition, each satellite is equipped with a SuperSTAR Accelerometer, GPS receiver/antenna, Star Cameras, and Laser Retro Reflector to complement the science instruments. The GRACE Science Data System uses the range and range rate data, along with ancillary data, to estimate a new gravity field every month, in the form of corrections to a well-defined background gravity model used in the data processing procedure (Bettadpur, 2007). The monthly sampling rate has been selected in order to accumulate sufficient observations to ensure spatial resolution of about 400 km. Generally there is a trade-off in selecting the temporal sampling interval. Accumulating data over longer time intervals increases spatial resolution, but decreases temporal resolution and vice versa.

Modeling temporal geoid variations

The static component of the gravity field G_0 corresponds to nearly 99% of the total field, mainly due to solid Earth contributions. This term can be easily evaluated and removed by computing the temporal mean of a long enough series of GRACE monthly geoids, or alternatively

considering a single geoid computed with a long period of time of satellite observations. In this study, the monthly time-variable geoid $\delta G(t)$ is merely computed as the difference between the monthly geoid $G(t)$ measured by GRACE at time t, and the static mean field component:

$$\delta G(t) = G(t) - G_0. \tag{1}$$

Thus, the corresponding geoid differences (also called monthly GRACE geoids in the following) only reflect short-term geoid change associated with mass redistributions inside the Earth system.

Let $\delta C_{nm}(t)$ and $\delta S_{nm}(t)$ be the time-variable "normalized" Stokes coefficients of the spherical harmonic expansion of geoid height, where n and m are the degree and order, respectively. Thus, the time-variable geoid is classically expressed as (Heiskanen and Moritz, 1967):

$$\delta G(t) = \sum_{n=1}^{N}\sum_{m=0}^{n} (\delta C_{nm}(t)\cos(m\lambda) + \delta S_{nm}(t)\sin(m\lambda))P_{nm}(\cos\theta), \tag{2}$$

where N is the maximum degree of the harmonic decomposition, θ is the colatitude, λ is the longitude, and P_{nm} is the associated Legendre polynomial that is dimensionless.

GRACE geoids are generally further expressed in surface mass change (usually in equivalent water height) assuming that mass redistribution occurs in thin surface layers compared to the Earth's dimension (Swenson and Wahr, 2002), so that:

$$\begin{pmatrix}\delta C_{nm}(t)\\ \delta S_{nm}(t)\end{pmatrix} = \frac{(1+z_n)\mathrm{Re}^2}{(2n+1)M} \int\int_S \delta q(\theta,\lambda,t)\begin{pmatrix}\cos\\ \sin\end{pmatrix}(m\lambda)P_{nm}(\cos\theta)\delta S, \tag{3}$$

where $\delta q(\theta, \lambda, t)$ is a surface density of water/ice/air mass, expressed in terms of equivalent water thickness at time t, whose harmonic coefficients, $\delta A_{nm}(t)$ and $\delta B_{nm}(t)$, can be evaluated from the corresponding geoid anomaly coefficients through the linear filtering:

$$\begin{pmatrix}\delta C_{nm}(t)\\ \delta S_{nm}(t)\end{pmatrix} = W_n\begin{pmatrix}\delta A_{nm}(t)\\ \delta B_{nm}(t)\end{pmatrix}. \tag{4}$$

W_n is an isotropic spatial filter that weights the surface density coefficients, and whose analytical expression is (Swenson and Wahr, 2002; Ramillien et al., 2005):

$$W_n = \frac{2\pi G\mathrm{Re}\rho_W}{(2n+1)\gamma(\theta)}(1+z_n). \tag{5}$$

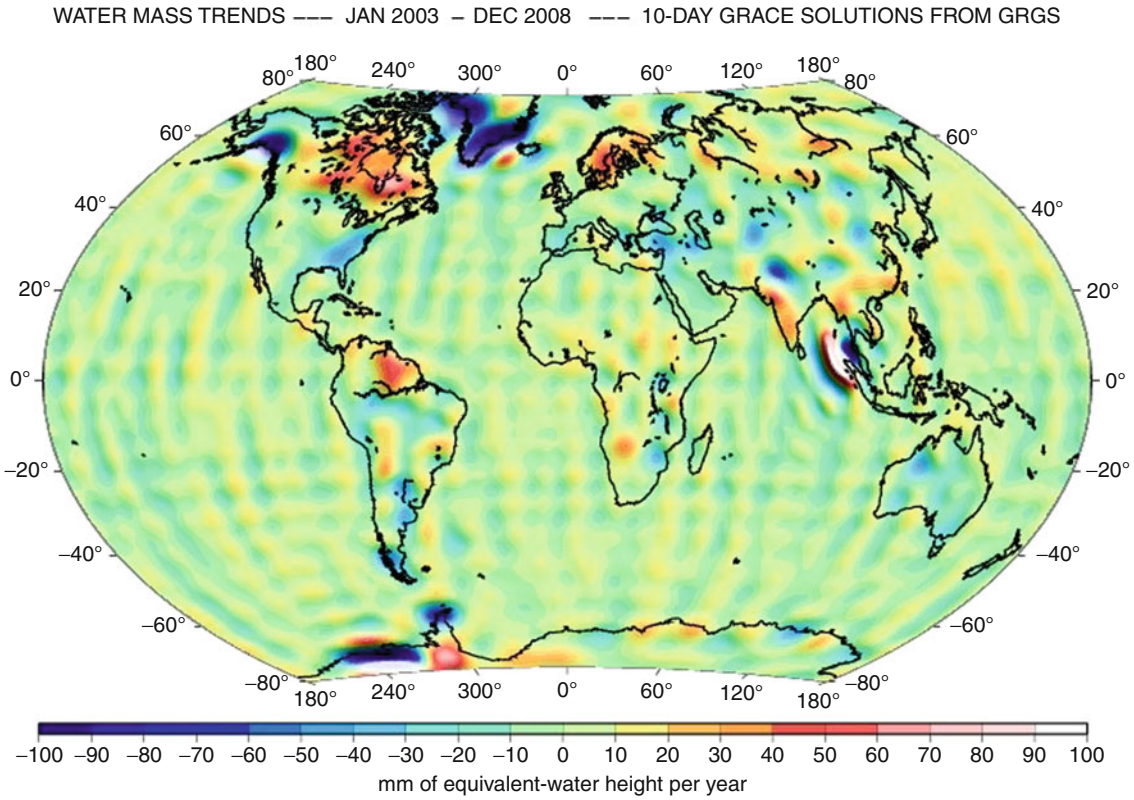
In Equations 3 and 5 above, z_n represents the Love numbers that takes into account instantaneous elastic compensation of the Earth' surface to the load; $\gamma(\theta)$ is the normal gravity on the reference ellipsoid at the colatitude θ. G ($\sim$6,67.10^{-11} $m^3kg^{-1}s^{-2}$) is the gravitational constant, M is the total mass of the Earth ($\sim$5,97602.10^{24} kg), and Re ($\sim$6,378 km) is mean Earth's radius. ρ_W ($\sim$1,000 kgm^{-3}) is the water density.

Equations 4 and 5 are used to compute surface density variations $\delta q(\theta, \lambda, t)$ (or mass redistribution due to air, water, and ice mass change in surface fluid envelopes) from the monthly geoid harmonic coefficients.

GRACE data errors

Assessing the errors of GRACE monthly solutions is a major challenge. Two categories of errors are recognized: (1) errors introduced by data processing (errors of GRACE measurements and models used to remove other geophysical signals) and (2) post-processing errors (e.g., spatial smoothing of the GRACE solutions to remove high-frequency noise and leakage errors due to signal contamination from regions outside the studied area). Among errors in category (1) correlated errors due to un-modeled effects and contamination of other geophysical signals during data processing are highly problematic. Because of the limited spatiotemporal sampling provided by the GRACE satellites, these errors are aliased into the estimated spherical harmonic coefficients, giving rise to north–south stripes evident in GRACE geoid maps. To reduce this organized spatial noise, different smoothing methods have been proposed (category 2 errors), which significantly affects GRACE estimates of surface mass change by reducing signal amplitude at the higher degrees and orders suppressed by these filters. Another post-processing error arises from the waveband-limited spherical harmonics considered in the solution (typically 50 or 60, corresponding to spatial resolution of 350–400 km). The result is contamination from surrounding regions ("leakage"). The GRACE orbital configuration (altitude and inter-satellite distance) and the need for spatial filtering are the main limitations to spatial resolution, estimated to be on the order of 400 km. Current accuracy of monthly GRACE solutions is estimated to $\sim$2 cm equivalent water layer over areas exceeding 1 million km^2 (e.g., Wahr et al., 2006).

Figure 1 shows a map of global mass trends from GRACE, over a full 6-year time span (January 2003 through December 2008), computed from best-fit linear trends to time series at every location (based on GRACE solutions computed by GRGS, Biancale et al., 2006). Units are in equivalent water height per year. On land, this map shows predominantly water mass gain or loss in major river basins and ice mass loss over ice-covered regions (e.g., the Greenland and west Antarctica ice sheets, Alaska glaciers, etc.). The large positive mass trends over Northern Canada and Fennoscandia are due to postglacial rebound (the solid Earth response to last deglaciation). The signature of the 2004 Sumatra-Andaman Earthquake is also well visible.



Gravity Field, Temporal Variations from Space Techniques, Figure 1 Map of surface mass trends (expressed in millimeters of equivalent water height) estimated from GRACE data between January 2003 and December 2008. Blue color corresponds to negative mass trend (mass loss) while red color represents mass increase (Data updated from Biancale et al., 2006).

Applications of GRACE

In this section are presented a few examples of present-day mass variations detected by GRACE over continental river basins, Greenland and Antarctica ice sheets, and the oceans. The capability of GRACE in measuring solid Earth mass changes (e.g., postglacial rebound and co/post-seismic deformations due to large earthquakes) is also briefly discussed.

Hydrology

The global water cycle that exchanges water among oceans, atmosphere, and land plays a key role in the physical and chemical processes that influence Earth's climate and its change over time. On land, terrestrial water storage (TWS) change, as a major component of the global water cycle, reflects changes in water stored in soil, snow over land, and ground-water reservoirs, and is closely connected to accumulated precipitation (P), evapotranspiration (ET), and surface and subsurface runoff (R) within a given area or basin, through the water balance equation relating a change in TWS in unit time Δt:

$$\frac{\Delta(TWS)}{\Delta t} = P - ET - R. \quad (6)$$

For many areas (not covered by snow), TWS is virtually a measure of total water content in surface stores, soil layers, and ground-water reservoirs, and is also a good indicator of abnormal climate conditions, such as droughts and floods. Accurately quantified TWS change provides a key measure of the continental water cycle and available water resources in a given region or river basin. However, estimating TWS change is difficult because limited ground water and soil moisture observations are available, and often are simply nonexistent (e.g., Rodell and Famiglietti, 1999) at basin or smaller scales.

In recent years, GRACE data have been successfully applied to the study of global and basin scale TWS changes (e.g., Ramillien et al., 2008a). Early studies focused on the seasonal cycle and showed good agreement with global hydrological models. Now exceeding 7 years in length, the GRACE time series provides some measure of interannual variability in TWS. For example, several studies have detected drought events in different regions of the world (e.g., Amazonia in 2005, Chen et al., 2009a; East Africa in 2005, Swenson and Wahr, 2009; Australia in 2006, Leblanc et al., 2009). Anthropogenic effects on the terrestrial water cycle, such as ground-water pumping, are also detectable by GRACE (e.g., Rodell et al., 2009;

Tiwari et al., 2009). Other studies have used GRACE TWS in combination with additional information to estimate changes in vertical or horizontal fluxes, for example, P-ET, ET, or R, of the right-hand side of the water balance equation (Equation 6).

Ice sheets mass change

The mass balance of ice sheets is of considerable interest in the context of global warming and present-day sea-level rise. GRACE satellite gravity measurements offer the opportunity to study the mass balance of polar ice sheets from a new perspective, using GRACE gravity change to directly measure mass variation or redistribution. A series of recent studies has created a clear picture of present-day ice loss from the two largest ice sheets on Earth and demonstrated the unique potential of satellite gravimetry for monitoring large-scale ice mass change. Using extended GRACE time series (6–7 years), studies indicate a clear acceleration of ice loss from both ice sheets since about 2006. For example, estimates by Velicogna (2009) over Greenland indicate an ice loss rate of 267–286 Gt/yr during 2006–2009, compared with a loss rate of 137–159 Gt/yr during the period 2002–2005. Over Antarctica, Chen et al. (2009b) find a mass loss of 220–246 Gt/yr during the period 2006–2009, an alarming acceleration of the already large loss rates of 104–144 Gt/yr estimated for 2002–2005. On average over 2002–2009, ice mass loss reported by GRACE over the two ice sheets corresponds to ~1 mm/yr sea-level rise, that is, about 1/3 the observed rate of rise (Cazenave and Llovel, 2010, Cazenave and Chen, 2010).

Ocean mass change

Net water flux into and out of the ocean causes its mass to change. Such changes cause gravitational variations detectable by GRACE (e.g., Chambers et al., 2004). This has allowed, for the first time, direct estimates of the global ocean mass contribution to sea-level change. However, GRACE is also sensing postglacial rebound. On average over the oceanic domain, this effect is large, and of the same order of magnitude as the ocean mass change due to current land ice melt itself. As postglacial rebound models vary significantly from each other with respect to this effect (e.g., Paulson et al., 2007; Peltier, 2009), GRACE ocean mass rates combined with land ice melt rates can place an independent constraint on the postglacial rebound correction.

Satellite altimetry allows precise measurement of present-day global mean sea-level change (e.g., Cazenave and Llovel, 2010). When combined with the GRACE-based ocean mass change contribution, the steric component (i.e., effects of vertically integrated sea-water temperature and salinity changes) to sea level can be deduced (e.g., Chambers, 2006; Lombard et al., 2007). The results appear to be comparable to estimates based on in situ hydrographic (temperature and salinity) data.

Postglacial rebound

Large-scale readjustment of Earth's crust and mantle (postglacial rebound) follows melting of ice loads. Postglacial rebound induces secular changes in the gravity field observable by GRACE. The large positive mass trend centered over the Hudson Bay (Canada) in Figure 1 is one of the most prominent signatures of this process. Comparison between GRACE and other measures of postglacial rebound (e.g., surface gravity change, vertical crustal motions, model estimates of ice-load extent, and melting history) has confirmed that GRACE is detecting Earth's recovery following melting of the Laurentide ice sheet at the end of the last ice age (e.g., Peltier, 2009; Wu et al., 2010).

Co-seismic and post-seismic deformations due to large earthquakes

Besides postglacial rebound (Peltier, 2009) and the refinement of Earth's static gravity field (Pavlis et al., 2008), GRACE has contributed to the understanding of other solid Earth processes. In particular, GRACE appears able to detect the sea-floor deformation, afterslip, and viscoelastic relaxation associated with large earthquakes. This is the case with the Sumatra-Andaman earthquake (magnitude of 9.3) of December 26, 2004, the largest recorded seismic event in about 40 years. GRACE successfully detected the gravity change associated with the corresponding co-seismic subduction and uplift, in agreement with model predictions (e.g., Han et al., 2006; Panet et al., 2007).

Summary

Since 2002, the US–German GRACE (Gravity Recovery and Climate Experiment) mission has been providing a precise survey of Earth's time-variable gravity field, with unprecedented temporal and spatial sampling. GRACE time-variable gravity fields provide a means of measuring temporal and spatial variations of mass redistribution within the Earth system. The GRACE mission has launched a new era in studying a series of geophysical problems ranging from deep Earth structure to tracking mass redistribution on and near the surface of the Earth. GRACE has greatly improved understanding of mass redistribution in various compartments of the climate system (atmosphere, oceans, terrestrial water, and cryosphere) (Ramillien et al., 2008b; Cazenave and Chen, 2010). GRACE has fundamentally enriched a number of fields, including (but not limited to) the global water cycle and land hydrology, mass balance of polar ice sheets and mountain glaciers, ocean mass and global sea-level change, and solid Earth geophysics. While such novel data offer new possibilities for studying regional to global scale mass redistributions occurring inside and at the surface of the Earth, they complement measurements performed by in situ gravity meters (absolute and relative, including super conducting gravity meters) for detecting a variety of local phenomena such as volcano deformations,

seismic activity, land subsidence, water table movement and water storage change, etc. (see examples in Budetta and Carbone, 1998; Mrlina et al., 2003; Zerbini et al., 2007; Richter et al., 2004; Anderson et al., 2005).

Synonyms

Earth's dynamic gravity field; Temporal variations of the Earth's gravity

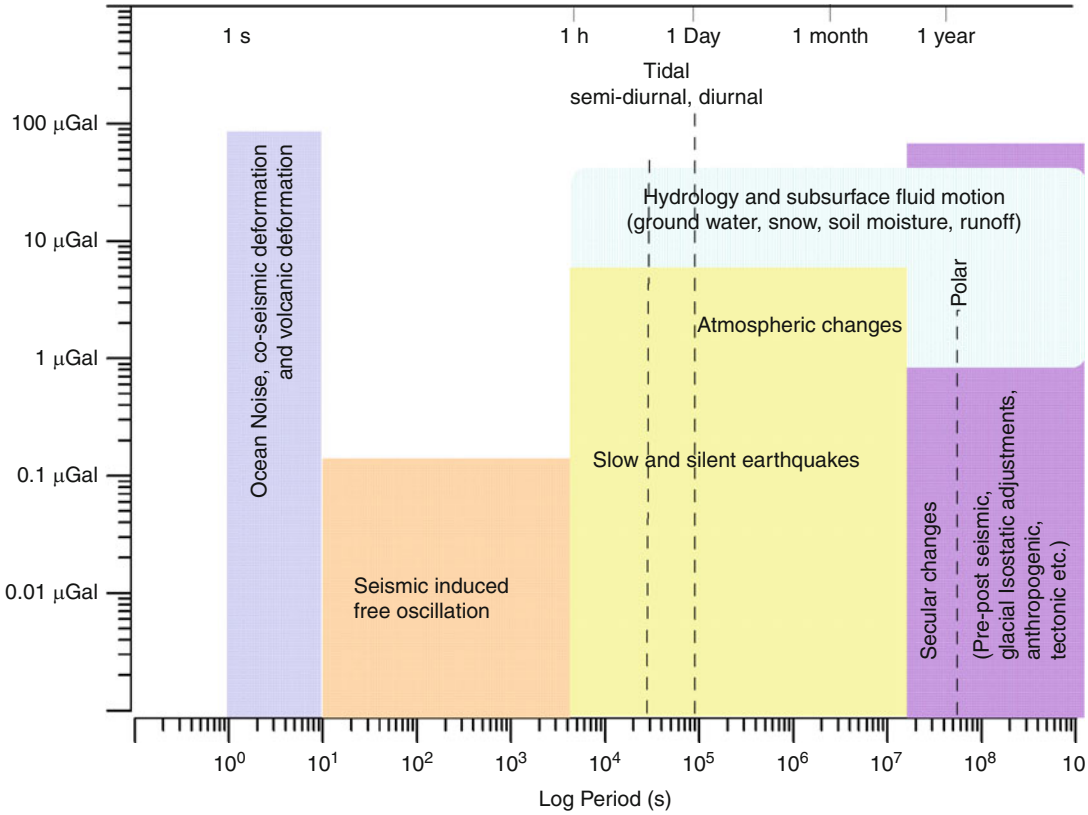
Definition

Temporal gravity changes. Variation of Earth's gravity field with time due to various tidal, oceanic, atmospheric, hydrological, glaciological, and tectonic processes.
Tidal gravity changes. The periodic variation of gravity field due to the attraction of Sun and Moon.
Non-tidal gravity changes. Gravity changes unrelated to the attraction of Sun and Moon.

Introduction

The gravity field of the Earth is an attraction force exerted by the Earth on any unit mass normal to the equipotential surface. It is a function of mass distribution and its spatial location, inside, on, and above the Earth's surface, following the Newton's law of gravitation. Continuous changes in the Earth system and its fluid envelops related to the solid and ocean tides, oceanic circulation, atmospheric changes, hydrological changes, Earth's polar motion, Earth's inner and fluid core motions, redistribute the mass and produce variations in the Earth's gravitational field on a large range of spatial and temporal scales (Figure 1). The variation in the gravity field on timescales of thousands to millions of years caused by redistribution of mass due to the processes that shape the Earth's surface is termed "static gravity field" as this change does not occur over human timescale.

Temporal variation of Earth's gravity field is determined by measurements of the gravitational field at the same location with time. Surface measurements of time-varying gravity field started in the nineteenth century using spring type relative gravity meters and were mainly employed to study tidal related gravity changes. Gravity changes can now be precisely recorded by terrestrial measurements using absolute gravity meters (AG), superconducting gravity meter (SG), relative gravity meter, or a combination of them. AG is the most precise instrument available that can measure the absolute gravity field with an accuracy of 1–3 μGal (1 μGal = 10^{-8} m s^{-2} = 10 nm s^{-2}; Niebauer et al., 1995). SG can measure changes in the Earth's gravity field with 0.1 μGal accuracy (Hinderer et al., 2007). A strong effort to monitor the time-varying gravity field globally has been made recently with the launch of the CHAMP and GRACE satellites (Wahr, 2007). Precise measurements of the changes in the Earth's gravity field either by satellite (NRC, 1997; Wahr, 2007) or from surface measurements (Hinderer and Crossley, 2000) thus offer the possibilities to constrain the underlying causes of dynamic changes of mass distribution in the Earth system processes. Both measuring methods have some advantages and drawbacks. For example, localized gravity changes (i.e., effect due to injection of water in oil field) cannot be detected in satellite measurements and similarly gravity changes occurring over a large region, particularly over remote areas cannot be mapped using surface measurements. An attempt is made to intercompare the satellite-derived gravity fields with surface gravity measurements observed with superconducting gravimeters (SG) in the Global Geodynamics Project (GGP; http://www.eas.slu.edu/GGP/ggphome.html) despite the fact that the ground and space gravity measurements are not sensitive to the same effects. Radial displacement is important for ground observations but has no effect on satellites and ground gravity measurement is a point measurement while satellite measurements are integrated response over a large region (typically a few hundreds of km; Wahr, 2007). Nevertheless, first results of intercomparison of gravity changes observed by the European SG network and GRACE satellite data reported a fair agreement in the time-varying gravity field originated due to hydrological changes (Crossley and Hinderer, 2005; Hinderer et al., 2006).



Gravity Field, Time Variations from Surface Measurements, Figure 1 Schematic diagram showing temporal gravity changes that can be studied from the surface gravity measurements (1 μGal = 10^{-8} m s^{-2} = 10 nm s^{-2}).

Concepts and applications

Primarily there are two categories of time-varying gravity signals; one that varies periodically and another one that is non-periodic. Periodic gravity changes such as tides can be separated from the observations based on their periodicity but non-periodic changes that arise from combinations of different contributing sources are difficult to recognize. However, they are identified using other complementary information. There are about 30 SGs in the world, which are continuously measuring gravity changes and form an international network called GGP (GGP Project; Crossley et al., 1999). GGP stations are sparsely distributed worldwide with a very few stations in the southern hemisphere. These data are shared within network for various applications and are also used for comparison with satellite-derived gravity changes that allows upscaling of terrestrial data and downscaling of satellite data (Hinderer et al., 2007) for broader understanding of causes of gravity changes. AG measurements are also made at these locations for calibrations of SGs and for cross validation of secular changes. Both instruments (AG and SG) are essentially laboratory instruments; however, AG can be transported but SG is unsuitable for relocation. A combination of different surface gravity measurements is used to estimate spatiotemporal changes in Earth's gravity field. Details of surface gravity measurements, their accuracy, and potential application, as suggested by Crossley and Hinderer (2005) with minor modifications, is summarized and presented in Table 1.

The following sections present a brief description of the main sources of gravity changes that are recorded by surface gravity measurements and used to study the sources responsible for these changes. An example of different contributions (solid tides, polar motion and length of the day, atmospheric loading, tidal and non-tidal ocean loading, soil moisture and snow loading) to the time-varying gravity in Strasbourg is presented in Figure 2. The amplitude of the solid tides and the ocean tidal loading would be ten times larger compared to plotted amplitudes in the Figure 2, where only long-period tides are considered.

Tides

Tidal gravity changes are caused by the attraction of other planetary bodies like the Sun and Moon. The attraction of these planetary bodies deforms the Earth's solid and fluid surface and produces changes in the gravity field. These changes are periodic, mainly semi-diurnal and diurnal, but also with long-period components (fortnightly, monthly, half-yearly, and yearly as shown in Figure 2). The semi-diurnal and diurnal tides can be very large

Gravity Field, Time Variations from Surface Measurements, Table 1 Types of surface gravity measurements and their potential applications in studying time variable gravity field

	Absolute gravity meter (AG: FG 5)	Superconducting gravity meter (SG: GWR type)	Relative gravity meters (CG: Scintrex, CG3M, CG5M)
Precision	$\leq$1 μGal	0.001 μGal	1 μGal
Accuracy	1–3 μGal	0.1 μGal	10 μGal
Drift	0	0.01–0.05 μGal/day (variable)	3–10 μGal/day (variable)
Setup time and Operation	AG is a transportable instrument that operates in a controlled temperature environment. It can be set up in 1–3 h. 1–3 days measurements are desirable to get best results	Setup of SG requires a few days and some weeks to stabilize. It is housed at one place and needs calibration and drift monitoring by AG for better accuracy	CG is a field instrument that can be set up in a few minutes. A network of stations is used for measurement loops. Requires repeated measurements at a reference station every few hours
Dominant noise	Microseismic and man-made noise	Environmental effects	Environmental effects, microseismic noise, vehicle shaking, drift
Possible applications	Tidal, hydrological changes, pre-co-post seismic changes, glacial isostatic adjustment, tectonics, oil, gas, and geothermal reservoir monitoring, volcanic mass changes	Tidal, polar motion, hydrological changes, atmospheric and ocean loading's core processes, pre-co-post seismic changes, free oscillation of the glacial isostatic adjustments, volcanic mass changes	Tidal, hydrological changes, co-seismic changes for large quakes, volcanic mass changes

(with peak to peak value of $\sim \pm$ 150 μGal) according to the station location and usually are the largest contribution in any surface gravity measurements. They can be computed accurately and therefore can be removed from observed gravity changes to study non-tidal gravity changes (Wenzel, 1996). The precise tidal gravity changes are measured with SGs, AGs, and other surface gravimeters (Hinderer et al., 2007) on land and are recorded in satellite altimetry data over the oceanic region (Wahr, 2007). Tidal gravity changes are the elastic response of the Earth to the tidal forces and hence, modelling of tidal gravity changes provide information on the internal structure and properties of the Earth as its elastic transfer function varies according to the internal distribution of density, compressibility, and rigidity parameters. Tidal observations also provide independent evidence of general relativity theory of planetary movements (Warburton and Goodkind, 1977).

Sea level variation

Non-steric redistribution of ocean mass causes non-negligible changes in the Earth's gravity field. These are commonly recorded in satellite altimetry data. Movement of ocean waters also affects gravity changes inland; this may be quantified using results from satellite altimetry data (Fukuda and Sato, 1997). It is reported that gravity changes caused by sea level change deducted from satellite altimetry data are of the order of few μGal near coastal regions that can be observed in SG data.

Atmospheric pressure

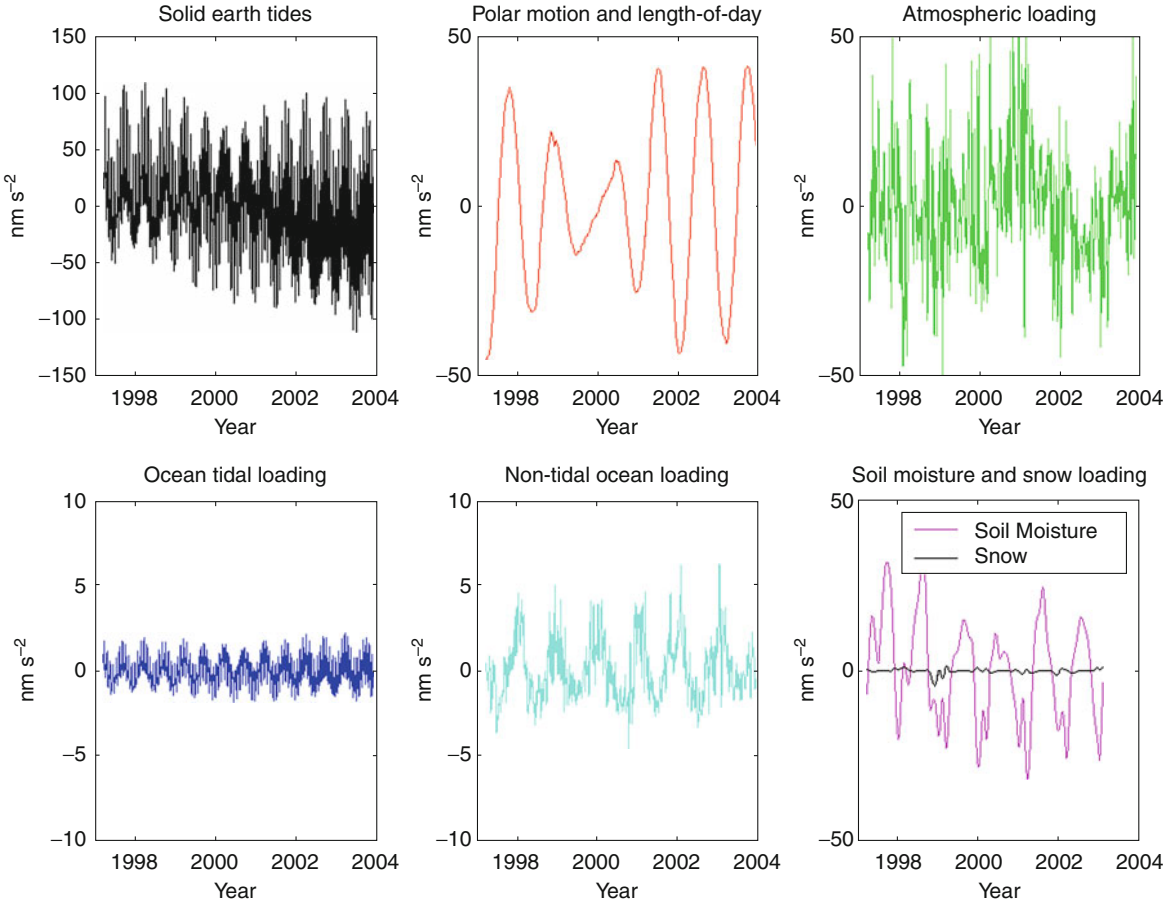
Atmospheric pressure changes alter surface gravity values because of the redistribution of mass in the atmosphere (attraction force) and the surface loading (elastic deformation) due to the change in the surface mass (Kroner and Jentzsch, 1999; Boy et al., 2002). The induced gravity changes are in the order of $\pm$ 5 μGal (Figure 2) and can reach up to 10–15 μGal for large pressure fronts (30–50 hPa). They are often estimated using a simple atmospheric admittance function between gravity and atmospheric pressure – that is 0.3 μGal/hPa (Crossley et al., 1995). These effects are generally considered as noise in gravity data and corrected using local barometric pressure data.

Polar motion

The direction of the Earth's axis of rotation is not steady in space but rather varies with time with two dominant periods (1 year and 435 days); this motion is generally known as polar motion or oscillation of the rotation pole. The 435-day component is referred to as Chandler wobble by astronomers. This signal can be detected by various techniques (spectral analysis, least squares adjustment) in surface gravity using continuous and stable SG observations (Hinderer et al., 2007). The related signals are of several μGal and change according to the station coordinates (Figure 2).

Free oscillation of the Earth

Large quakes are known to excite the free oscillations of the Earth (Hinderer et al., 2007; Arora et al., 2008), which lead to surface gravity changes in the seismic frequency



Gravity Field, Time Variations from Surface Measurements, Figure 2 Various contributions to time-varying gravity in Strasbourg, France (Courtesy J.-P. Boy; (1 μGal = 10 nm s^{-2}). The amplitude of the solid tides and the ocean tidal loading would be ten times larger than plotted amplitudes, which are only long-period tides.

band. These changes accompanying the eigenmodes occur at periods between a few hundreds of seconds and 54 min, which is the period of the free elastic oscillation of the Earth, and can be well investigated using SG records (Rosat et al., 2004). Besides, free oscillations unrelated to quakes but rather due to atmosphere–ocean–solid Earth interactions (termed "hum") were first reported from the SG measurements at Syowa, Antarctica (Nawa et al., 1998).

Glacial isostatic adjustment

On long timescales the Earth behaves like a viscoelastic material and deforms when submitted to a load. Major changes in climatic conditions of the Earth, from its birth to the present, caused large scale changes in strengthening and weakening of the ice sheets of the cold regions of the Earth's surface. The response of the Earth to the glaciations and deglaciations is known as Glacial Isostatic Adjustment (GIA). Land based gravity measurements have provided useful constraints to GIA, for instance, in the North American region (Lambert et al., 2001), Greenland (van Dam et al., 2000), or in Svalbard (Sato et al., 2006). One of the important properties of deep Earth that GIA can provide is information about the viscosity of the Earth materials.

Volcanic mass changes

The growth of the volcanic dome and fluxes of volcanic masses cause local gravity changes. Volcanic mass redistributions produce gravity change in the order of tens to hundreds of μGal and can be observed using any kind of surface measurements. Surface gravity measurements along with other geodetic measurements like GPS are prospective tools for the estimate of mass changes during the volcanic processes (Jousset et al., 2000).

Crustal deformation associated with quakes

Sudden displacements of faults during a quake cause redistribution of mass as well as change in the elevation, both leading to local gravity changes. An example of gravity changes before and after Haicheng quake, 1975, and the Tangshan

quake, 1976 is reported by Chen et al. (1979). Later on there have been several studies that document co-seismic gravity changes in surface measurements with SGs (Imanishi et al., 2004) and also in GRACE satellite observations (Han et al., 2006; Tiwari et al., 2008). Gravity records of silent and slow quakes, for example, from Cascadian subduction zone showing the concordance of gravity changes of about 10 μGal with episodic slip and seismic tremor activity (several times a year) is one of the interesting observations in temporal gravity changes (Hinderer et al., 2007).

Hydrology

Variations in land water storage (surface water, ground water, soil moisture, and snow) induce variations in the gravity field recorded on the surface (Crossley and Hinderer, 2005). The contributions of soil moisture and snow at Strasbourg, France are plotted in Figure 2. The amplitude of gravity changes associated with seasonal hydrological changes are larger than secular changes (Tiwari et al., 2006, Hinderer et al., 2007) and sometimes spread over a large area that can be mapped through satellite measurements (Tiwari et al., 2009) because large scale variations are difficult to be evaluated using ground-based observations due to the difficulty of adequate sampling. Hydrological fluxes at different time and spatial scales can now be mapped by monitoring temporal gravity changes, which holds promise to provide closing water cycle on local and regional scale (Cazenave et al., 2011, this book). Recent studies using the European regional network of SGs demonstrated that surface measurements of the seasonal component of continental hydrology can help in validating the satellite missions (Hinderer et al., 2007) and also suggest the complementary nature of satellite and ground-based observations.

Oil and gas reservoir monitoring

Time lapse gravity measurements are regularly used for monitoring subsurface density changes due to the fluid motions of the injected water and gas in the reservoir for enhancing recovery as well as for sequestration of CO_2 gases (Hare et al., 1999; Alnes et al., 2008). The amplitude of gravity changes is quite appreciable in the region where injections are large and reservoir depth is small. Such changes in gravity field occur over injection time period and are generally in the order of few tens of μGal to hundreds of μGal depending on the volume of injection and depth of injection. An estimate of other sources of the gravity changes (e.g., water table, atmospheric changes) in the area of measurements is required to model injected mass precisely.

Summary

Measurements and modelling of time-varying gravity changes allow understanding of various phenomena, as discussed in the earlier sections. Isolating the individual contributions from the aggregate effect in the temporal series of gravity changes has been a major challenge over a long time. Nevertheless, as number of observations and complementary information of temporal gravity changes are increasing, different components of time series of gravity changes can be better separated. Above mentioned examples and discussion suggest that repeat or continuous surface gravity measurements can be utilized for a wide variety of geophysical processes that deform the Earth's surface and move mass inside, on and above the Earth's surface causing the gravity field to vary with time. Surface measurements are also vital as they could provide a test, or validation, for satellite-derived temporal gravity changes (Crossley and Hinderer, 2005).

Synonyms

Absolute acceleration due to gravity; Absolute *g*

Definition

Gravity. The mutually attractive force between any two masses.
Acceleration due to gravity, g. The value of the acceleration of a mass due to the force of gravity observed in a reference frame rotating with Earth.
Absolute. Measured with calibrated instruments traceable to metrologic standards. For the case of gravity, this requires length and time standards.
Absolute gravity meter or *absolute gravimeter.* An instrument used to measure gravity absolutely, traceable to time and length standards.

Introduction

The value of the acceleration due to gravity on Earth's surface, *g*, depends on position and time. A worldwide variability of roughly 0.5% from 9.8 m/s^2 is caused by Earth's rotation, variations in density, and variations in geometry caused both by tidal fluctuations and tectonic deformation. Studying how *g* varies can reveal important facts about Earth as a whole and about a long list of local phenomena ranging from volcanic activity to evolution of oil and gas reservoirs.

Often scientists are interested only in changes in gravity with either position (gravity maps) or with time (time-lapse gravity). Many of these studies can be completed with simple, relative gravity meters, which commonly consist of an electromechanical spring-mass sensor (Torge, 1990). Relative gravity measurements (i.e., the difference in *g* between two sites) are more common because the interesting variations in *g* are small and its absolute value is not important for most geophysical applications. Almost all relative gravity meters undergo drift, however, making it difficult to separate real temporal gravity changes from drift in the sensor. Drift can be calculated and accounted for in cases where it is feasible to make redundant observations at multiple sites and assume that gravity values at reference sites are constant. In a number of important cases, however, such drift compensating efforts are inadequate and absolute measurements are needed – they are inherently free from drift because of their reliance on length and time standards.

A note on units: Practitioners in the field of gravity measurement use the unit *Gal* (after Galileo), which is defined as 1 cm/s^2. The nominal value of *g* is around 980 Gal. More common usage is the mGal (= 10^{-3} Gal)

and the μGal (= 10^{-6} Gal or about $10^{-9}g$). A precision of a few μGal is available from the best relative gravity meters (following a significant drift compensation effort within the measurement process) and 1 or 2 μGal with the best absolute gravity meters. Absolute determinations are characterized by both precision (the smallest observable signal or change) and accuracy (level of uncertainty or the discrepancy between the measured value and the unknown true value).

History

Late in the seventeenth century, it was discovered that a pendulum would swing with a slightly different period if it were moved to a different latitude. This effect, caused by gravity's dependence on latitude (primarily because of Earth rotation), was used to make some of the earliest estimates of the deviation of Earth's figure from a sphere (Lenzen and Multhauf, 1965). Two kinds of pendulum gravity meters, the reversible pendulum and the invariable pendulum, provide a good example of the difference between absolute and relative sensors. A reversible pendulum, used extensively by Henry Kater in the nineteenth century, exploits the curious fact that two pivot points on an asymmetric pendulum, which are found to yield equal oscillation periods are separated by the length of a simple pendulum (a point mass suspended from a massless rod) having that same period. This allows an absolute calculation of gravity based on the measurement of the period and the distance between the two oscillation points, which have a common period, and is therefore an absolute measurement. Invariable pendulums, on the other hand, were simply swung around a single point and changes in gravity were observed as changes in the period. Pendulum measurements were made extensively by geodesists to refine the figure of the Earth and for mineral exploration up until the early twentieth century when electronic methods became adequately advanced to measure accurately the time needed for a mass in a vacuum chamber to fall a known distance. Cook (1965) and Faller (1963) pioneered some of the early free-fall measurement techniques. Toward the end of the twentieth century, the advent of the laser allowed for great improvements in absolute gravity measurement (Hammond and Faller, 1967; Alasia et al., 1983; Zumberge et al., 1982; and Niebauer et al., 1995). Now, in the beginning of the twenty-first century, atomic methods are becoming viable. The most commonly used method today is to determine the acceleration of a mass freely falling in a vacuum by means of laser interferometry.

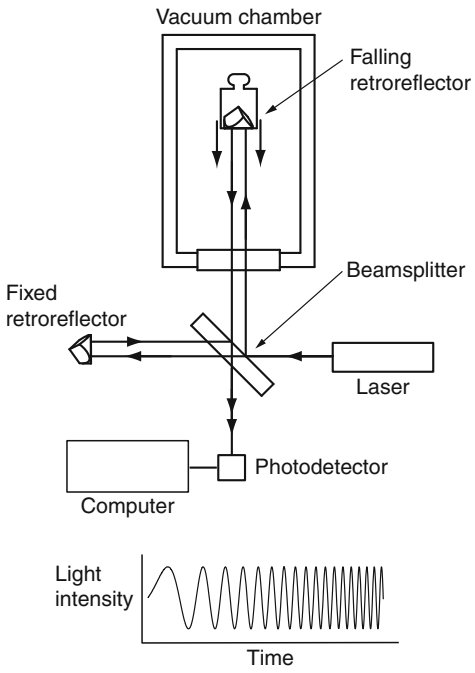
Principles of modern measurements

Macroscopic falling test mass

Figure 1 is a schematic diagram of the mainstay of modern absolute gravity measurements. A mechanical system inside a high vacuum chamber effects the release of a test mass. A retro-reflecting prism mounted to the test mass returns laser light entering and exiting the chamber through a window in the bottom. A beam splitter (or half-silvered mirror) combines this reflected light with that similarly reflected from a fixed retro-reflector. The two reflected beams interfere with one another, evermore rapidly producing successive light and dark fringes as the falling mass accelerates. Two cycles of light-to-dark interference fringes are completed for each advance in the fall of a distance equaling the laser's wavelength. A photodetector senses the passage of interference fringes and generates an electrical signal from which the local value of gravity (the rate at which the falling mass accelerates) can be calculated through appropriate timing analysis performed by a computer. Typically, the mass falls a distance of 10–20 cm and a thousand or more drops over a period of a day provide a statistical uncertainty of a few μGal. Because the measurement is based on calibrated length and time standards – the wavelength of the laser light and the frequency of the timing oscillator – the measurement is absolute.

Microscopic falling test masses

A new and promising method for the absolute determination of gravity makes use of cold atom interferometry (Kasevich, 2002). Toward the end of the twentieth century, physicists learned to use lasers to trap and manipulate clouds of atoms. Atoms can now be confined in an evacuated magneto-optical trap, cooled to very low



Gravity Measurements, Absolute, Figure 1 A schematic diagram of a free-fall absolute gravity meter. A mechanical system (not shown) inside the vacuum chamber releases and catches the falling object. An interferometer determines the position of the test mass as it falls; the interference fringe signal is an increasing frequency sine wave.

temperatures with laser cooling, and then launched vertically (again, with lasers) to create an "atomic fountain." Exploiting the fact that all matter can be described as waves, atomic physicists have learned to interfere atomic wave functions with one another and, in so doing, perform a number of highly precise measurements using them. In particular, because the phase of an atom's wave function depends on gravity, interfering atoms that have traversed separate paths through a gravitational field can yield an absolute measure of gravity. The first experiments performed by Kasevitch and Chu (1992) and followed by others (Peters et al., 2001; Lamporesi et al., 2008) required a laboratory full of complex optical, vacuum, and electronic equipment. Recently, however, the technology has advanced to a state where portability may become feasible (Merlet et al., 2010). Commercial versions of cold atom interferometric absolute gravity meters are currently under development (e.g., AOSense, Sunnyvale, California, USA).

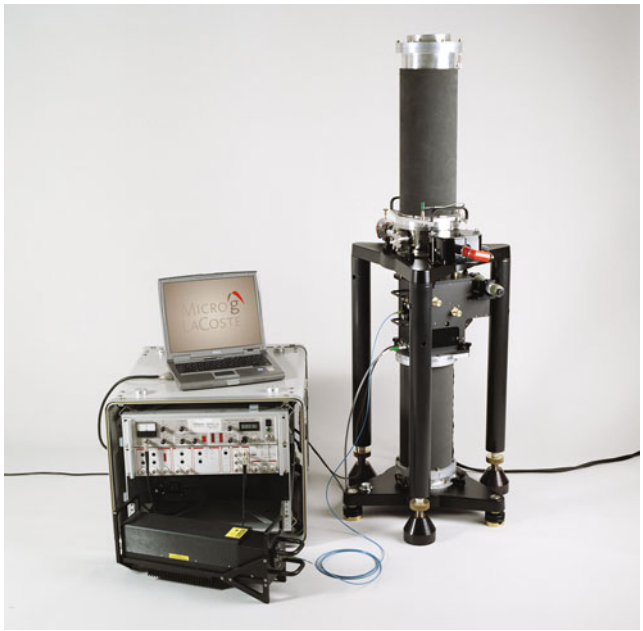
Instrumentation

The mechanical details of conventional free-fall apparatuses vary. In some, the test mass's fall is initiated by a small elevator inside the vacuum chamber, which also surrounds the mass as it falls and acts as a shield against minute non-gravitational forces. In others, the mechanical system resides at the bottom of the vacuum chamber and launches the test mass upward, providing a mass in free flight, the acceleration of which can be measured during both its rise and fall. Another important variation is the use of a spring suspension system to isolate the reference reflector from vibrations.

Currently, the most widely used absolute gravity meter is the model FG5, manufactured by Micro-g LaCoste (Lafayette, Colorado, USA) and shown in Figure 2. With laser interferometry, it tracks the descent of a 300 g mass during a 15-cm drop. The portable system weighs 320 kg, can be assembled in an hour or so, requires 500 watts of electrical power, and can produce an absolute gravity value accurate to 2 μGal after an hour of data collection. Significant care has been taken by its developers to ensure that systematic errors – those whose signs do not vary and cannot be reduced by averaging – are less than the quoted accuracy. Such errors include forces on the falling mass other than gravity (e.g., residual air-drag and magnetic or electrostatic forces) and imperfections in the optical and timing systems. Periodically, many absolute gravity meters make measurements simultaneously in one of the world's standards lab for an intercomparison to test the assessments of the instruments' accuracies (Sasagawa et al., 1995).

Applications to geophysics

Near Earth's surface, the rate of change of gravity with altitude is about 3 μGal per cm. Therefore, a detection of a gravity change of a few μGal yields information on cm-level height changes. Observing gravity changes



Gravity Measurements, Absolute, Figure 2 The micro-g LaCoste FG5 is a commonly used portable absolute gravity meter.

together with height information obtained by other means can provide important information for modeling the causes of surface deformation. An increase in density of 0.1 g/cm^3 occurring throughout a 25-cm thick layer below the observer (such as might be caused by water saturation) increases gravity by 1 μGal. These changes can occur very slowly, which makes it desirable to use absolute measurements to detect such changes. Examples of long time series of absolute gravity used to study geophysical phenomena include observations of post-glacial rebound (Lambert et al., 2001), water flooding in a natural gas reservoir (Hare et al., 1999), vertical land movement near tide-gauges (Teferle et al., 2006), and observations of coseismic offsets from an earthquake (Tanaka et al., 2001).

A very important geophysical application of absolute gravity measurement is the establishment of calibration lines for relative gravity meters (Sasagawa et al., 1989). Absolute g measurements are also necessary in certain metrology applications, including piston-cylinder pressure calibrations and in defining the standard kilogram.

Summary

Absolute gravity measurements are much less common than those made with relative gravity meters. However, because of their freedom from drift, made possible through the use of modern atomic length and time standards, absolute g meters are extremely important for monitoring long-term changes associated with crustal deformation and density change and for calibrating

relative meters. New advances in atomic physics may result in an absolute gravity meter, which is similar in size to typical relative gravity meters, advancing the use of absolute gravity measurements in geophysics.

Definition

Airborne. Anything carried by a fixed wing aircraft, a helicopter, an airship, or an unmanned aircraft.
Aero. Anything related to the atmosphere above ground.
Gravity. In this context nonrelativistic mass attraction as defined by Newton.
Gravimetry. In this context the measurement of the gravity field variation by mass attraction.

Introduction

The law of gravity is one the most fundamental in natural sciences. Instruments for gravity measurements have been developed first for use on land surface, later for use on ships. The instruments used for maritime surveying needed a special platform to compensate the movements of the vessel that add additional components to the main value of the measurement: the acceleration of a well-defined mass due the gravity field of the Earth. The same accounts for airborne applications of gravity meters: The aircraft's variations in roll, pitch, and yaw angles and height changes must be either compensated for or measured for later reductions and corrections. Therefore, most instruments used in the early stages of airborne gravity meter development were basically upgraded marine gravity meters (LaCoste, 1967). Due to the problem of the fast aircraft movements and therefore the even larger accelerations implied, only after the practical implementation of a global satellite-based positioning system (as GPS) non-inertial navigation became precise enough to enable satisfactory corrections and reductions (Bruton et al., 1999). At present, three different categories of airborne gravity instruments evolved: scalar gravity meters, vector gravity meters, and gradient or full tensor meters. All instruments are used to measure the regional variation of the Earth's gravity field over often inaccessible areas in a quick fashion.

Principle idea of airborne gravity

In the still most common airborne gravity applications, scalar gravity meters are used. Such meters usually

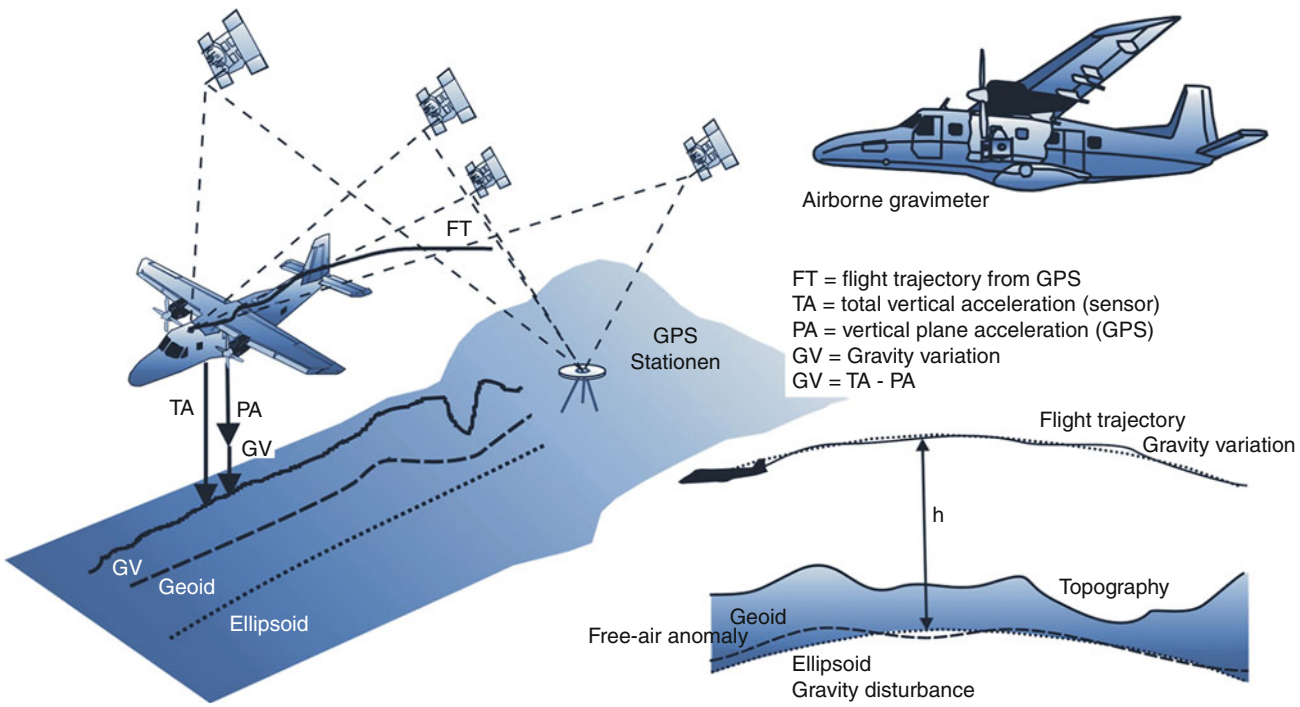
measure only the relative vertical component of the Earth's gravity field using a mass coupled to a spring, a principle that was adopted from gravity land-based surveying (Figure 1). In airborne gravity, much larger accelerations than the desired signal are introduced by attitude and height changes of the aircraft, carrying the gravity meter. Beyond these inertial accelerations, vibrations occur that are usually damped by suitable mechanical or electromechanical means. The residual effect of the vibrations in the aircraft's cabin is usually dealt with as a noise signal. Therefore, we focus on the gravitational and inertial accelerations only. The instrument and the navigation equipment are placed in a rigid aircraft that defines the body frame. Within this body frame, we primarily measure the accelerations in the axes of the aircraft: forward, down, and sideward in a right-hand system. The gravity sensor is fixed on a platform that compensates some of the aircrafts forward and sideward accelerations that are coupled to attitude variations but not the vertical acceleration components. The main aim of the platform is to keep the gravity sensor in horizontal level in order to keep the measurement range and sensitivity of the gravity meter high. Additional navigation equipment as global positioning system antennas and inertial measurement units monitor the movements of the aircraft's body frame in the geodetic frame. Consequently, lever arms between the navigation measurement units and the gravity sensor must be corrected for in the body frame and the resulting accelerations and force must be transferred to the geodetic reference frame for later gravity mapping.

Attitude compensation platforms

Most platforms designed to carry a gravity sensor on a moving vehicle are two axes gimbal constructions to compensate coupled roll, pitch, and yaw variations (LaCoste et al., 1967). The attitude information is commonly acquired by a gyro for short wavelengths and an accelerometer for wavelengths up to some minutes for each directional component. Some platforms compensate heading variations as well. Such platforms are Schuler-tuned. The platforms are designed to compensate attitude changes almost instantaneously in the dynamic range of the gravity sensor. Therefore, special filters are applied that define the platform period, which is usually in the order of some minutes.

Scalar gravity meters

Most meters in use for airborne gravity surveying are based on a test mass coupled to a spring or on torsion balance. Some new developments utilize superconductive gravity sensing systems. Such instruments measure the relative changes of the main vertical component of the Earth's gravity field. Beyond the residual platform errors, an independent non-inertial vertical acceleration determination is needed to reduce for the vertical accelerations of the body frame. This is possible only since global satellite-based positioning system navigation data is available. Scalar systems generally have a very low drift rate and therefore can be used for long wavelength gravity mapping as required for geodesy. The shortest detectable



Gravity Method, Airborne, Figure 1 Principle of airborne gravity.

wavelengths are dependent on flight velocity, the dynamic range of the gravity sensor, and the platform period. Generally, some few mGal (1 mGal = 10^{-5} m/s^2) are achieved in accuracy related to some few kilometers wavelength resolution at an average speed of about 160 km/h above ground.

Vector gravity meters

Vector gravity meters are in most cases adapted inertial measurement units that measure the three vertical components of the Earth's gravity field in the body frame of the aircraft (Jekeli, 2001). Analogue to most attitude-compensating platform designs, the signal is gathered from a combination of directional gyro and accelerometer measurements. In this configuration, global satellite-based positioning system navigation data must be applied for all directional acceleration reductions. The drift rates of such instruments are usually higher than those of scalar meters. At present, only very few systems are available, that are not only able to measure the significant vertical component but also the horizontal components in sufficient accuracy and resolution. Most vector gravity meters are not installed on an attitude-compensating platform but are placed on dampers only. The resolution and accuracy for the vertical component of available vector systems is better than those of scalar spring tension or torsion balance meters.

Gravity gradient meters

In order to enhance the short wavelengths resolution and the measurement accuracy significantly, gravity gradient meters were developed (Heiland, 1940). The main idea is to eliminate the impact of the aircrafts attitudes and accelerations in the measurements by measuring the directional gradients directly. To achieve this, diagonally arranged pairs of highly accurate accelerometers are placed on a slowly rotating disk, one for each direction. Since the two accelerometers measure in opposite directions, the largest effects of the body frame accelerations are ruled out by the acceleration difference between the two accelerometers and mainly the directional gravity gradient remains. Such gradients are not stable enough for large-scale integration and therefore are only suitable for short wavelength detections in local to small-scale regional areas. This sensing system needs an exceptionally accurate attitude compensation platform. If all directional gradient components are measured, this system is called a full tensor gradient gravity meter. Available resolutions are in the order of 0.5–1 Eotvoes (1 Eotvoes (E) = 0.1 mGal/km = 10^{-9} s^{-2}).

Processing, reductions, and corrections

The original data set is the sum of all measured accelerations in one or more components within the body frame of the aircraft. In order to get the gravity variation on flight level, the directional components of the body frame accelerations in a chosen geodetic frame have to be reduced for. As a next step, an Eotvoes correction has to be applied to compensate for the gravitational impact due to varying centrifugal forces (Harlan, 1968). Next, a platform error correction has to be applied, usually a Harrison correction for scalar meters.

The gravity disturbance (gravity variation on ellipsoidal level) is determined by the normal gravity reduction and the free-air gravity reduction between observation level and ellipsoid.

In order to achieve the gravity anomaly, the same is done with reference to the geoid instead of the ellipsoid.

Applications and aircraft

Airborne gravity can either be used to determine the regional geoid more precisely or for geophysical reconnaissance and prospection. For geodetic purposes rather high altitude straight and level fixed wing aircraft flights utilizing scalar gravity meters are most common (Forsberg et al., 1996). In geophysics, two aspects occur: large to mid-scale reconnaissance surveys to get an overview on tectonic or geological settings and small-scale prospection in search for mineral deposits or similar tasks (Veryaskin and McRae, 2008). For reconnaissance, fixed wing aircraft with long-range capabilities are preferred. In prospection, high-resolution vector or gradient gravity meters are used on small fixed wing aircraft, helicopters, or airships. First attempts to use unmanned airborne vehicles (UAV) are under way. New instrumental developments try to utilize modern superconductive meters, absolute gravity meters, or devices based on cold atom interferometry.

Summary

Airborne gravity has become a practical and accurate method to measure the variations of the Earth's gravitational field over regional areas. In geodesy, fixed wing aircraft equipped with scalar gravity meters are preferred. In geophysics, the same configuration is often used for reconnaissance surveys. For aerogeophysical prospection, low- and slow-flying aircraft are favored combined with vector or gradient gravity meters.

Introduction

By gravimetry (Latin "gravis") methods are identified, which can be used to measure the gravity field of the Earth. The determination of this potential field is of greater importance for geodesy, geophysics, and geotechnics, *Gravity Method, Surface*. In particular, in geophysics and geodynamics, gravity is used to investigate the Earth's interior and its dynamic processes. Furthermore, precise balances and other technical equipment need gravity data for their calibration.

The main objective of gravity/gravimetry is the determination of the Earth's gravity field and of other celestial bodies (e.g., the Earth's moon). The gravity field and its gravity gradients are measured as a function of position and time on, below, and above the Earth's surface (e.g., by gravity meters on ships, in boreholes, or on board aircrafts and, nowadays, satellites: CHAMP, GRACE, and GOCE Mission), *Gravity Method, Satellite*.

In the seventeenth and eighteenth centuries, scientific interest and first measurements have been caused by the understanding and development of the physics of deformable and rigid bodies. At that time, determinations of position (distances) and time became accurate enough to enable gravity measurements. Later, after scientists discovered the position dependency of gravity, it has been used to determine the figure of the Earth – then until today. Developments of the gravity method were always correlated with the interaction of technical possibilities and scientific objectives in physics (geophysics) and land surveying (later geodesy) because geodetic surveying and geophysical exploration became a strong influence on growing societies (e.g., Torge, 1989). Today the gravity field and its variations – measured by satellites with very high and unexpected accuracy – are closely related with the distribution and transport of masses in the Earth's system: the ocean circulation, changes of ground water level and solid Earth moisture, melting of continental ice sheets, river run off, changes of sea level, and mass flows in the Earth lithosphere and mantle, all of which cause transport and redistribution of masses. Using innovative and extremely precise gravity sensor systems dedicated to observe the gravity field, the implication of these processes can be established. Even in the investigation of other celestial bodies' gravity gains in importance: e.g., in the 1970s the "Lunar surface gravity meter" was deployed at the Apollo 17 ALSEP site (Talwani, 2003). The state of lunar and planetary gravity field investigations are described and discussed (e.g., by Janle and Meissner, 1986; Konopliv et al., 2001).

In the following chapters, all values of parameters of the Earth's gravity field are related to the World Geodetic System 1984 (WGS 84), Geodesy, Figure of the Earth.

Potential function

It is accepted that the force **F** of a mass point m, which is influenced by a timely constant gravity acceleration **g** can be expressed by

$$\mathbf{F} = m\mathbf{g}$$

To move this mass along a path C with path elements d**r** from a space point P_1 to a second point P_2, an energy U_{12} has to be applied:

$$U_{12} = -\int_{P_1}^{P_2} \mathbf{F} \cdot d\mathbf{r} = -m \int_{P_1}^{P_2} \mathbf{g} \cdot d\mathbf{r} \tag{1}$$

There is no loss of energy and we call U_{12} independent from its path and only dependent from start and end point P_1 respective to P_2. Equation 1 shows that only the difference of potential energy at points P_1 and P_2 can be calculated. The force **F** can be derived from the potential energy as:

$$\mathbf{F} = -\text{grad } U = -\nabla \cdot U \tag{2}$$

F is a potential field. Equation 2 holds even if we add a constant U_0. This constant will be selected in a way that potential energy disappears in the infinite. In this case, U(P) defines the energy in the field of gravity acceleration which has to be applied to m to move it from point P to the infinite:

$$U(P) = -\int_{P}^{\infty} \mathbf{F} \cdot d\mathbf{r}.$$

In geophysics and geodesy, the potential energy U is replaced by the potential (potential function):

$$V = -U/m. \tag{3}$$

This is the negative potential energy per mass unit, and with (Equation 2) one has:

$$\mathbf{g} = \nabla V.$$

Therefore, gravity field can be described in entire space by a single function V. The potential function fulfills the POISSON differential equation:

$$\Delta V = -4\pi f \rho \tag{4}$$

with:

$f = (6.67428 \pm 0.00067) \cdot 10^{-11}\ m^3/kg\ s^2$ (gravitational constant)

ρ = mass density.

The POISSON equation forms the base of potential theory and is an elliptic differential equation. If space is mass free ($\rho = 0$) the LAPLACE equation holds in Cartesian coordinates:

$$\Delta V = \frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} + \frac{\partial^2 V}{\partial z^2} = 0 \tag{5}$$

It became the most universal differential equation in the physical sciences because of the wide range of phenomena that is described by the equation. There exists a multitude of solutions of this differential equation which are not always potential functions. For both differential equations hold the following *definition*:

> A space function and its second derivatives which are continuous and bounded in a region where defined are called harmonic functions if they fulfill the LAPLACE and – in the interior of a mass filled space – the POISSON differential equation.

Newton's law and Newtonian potential

In 1687 Sir Isaac Newton published his famous treatise "Philosophiae Naturalis Principia Mathemetica" which contains the Newton's law of gravitational attraction:

> The magnitude of a gravitational force between two masses is proportional to each mass and inversely proportional to the square of their distance.

In a Cartesian coordinate system, a mass m_0 is centered at point $P_0\,(x', y', z')$ and at point P (x, y, z) a mass m. Then a force, F(P), acts on mass m_0 (Figure 1):

$$\mathbf{F}(P) = -f\frac{mm_0}{R^2}\mathbf{e}_R \tag{6}$$

with

$\mathbf{R} = P_0\,P$ (vector which points from P_0 to P)

$\mathbf{e}_R = \mathbf{R}/R$ (unit vector) of $\mathbf{R}$

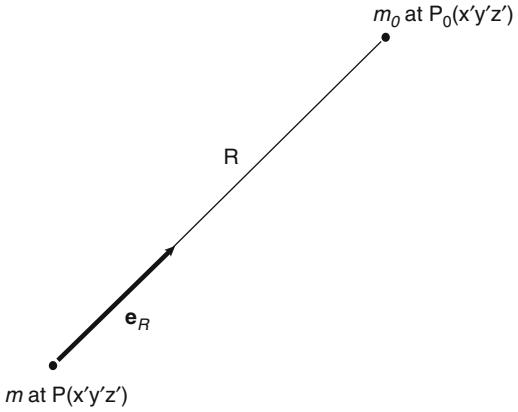
$R = [(x - x')^2 + (y - y')^2 + (z - z')^2\,]$ (norm of vector $\mathbf{R}$)

The gravity acceleration $\mathbf{g}$ which is caused by mass m is:

$$\mathbf{g}(P) = \frac{\mathbf{F}(P)}{m_0} = f\frac{m}{R^2}\mathbf{e}_R \tag{7}$$

and in Cartesian coordinates one can write:

$$\mathbf{g}(P) = fm/R^3[(x - \acute{x})\mathbf{i} + (y - \acute{y})\mathbf{j} + (z - \acute{z})\mathbf{k}] \tag{8}$$



Gravity Method, Principles, Figure 1 Masses m_0 and m experience a gravitational force which follows Newton's law: it is proportional to m_0 and m and $1/r^2$. By convention the unit vector $\mathbf{e}_R$ is directed from the gravitational source point (P) to the "observation" point P_0 which is located at the mass m_0.

$\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$ are the components of unit vector in the coordinate system.

At the Earth's surface, gravity acceleration is approximately $g = 9.81\ m/s^2$. The potential V is a scalar and an additive quantity. Therefore, the gravity potential of n point masses can be written as:

$$V(P) = f\sum_{i=1}^{n}\frac{m_i}{R_i},\ \text{with } R_i \text{ (spaces of the n points P)}$$

At the point masses, V(P) is not defined due to $R_i = 0$. However, except for these singular points the LAPLACE equation holds.

For a mass continuum we obtain from Equation 6 the Earth's gravitation by Newton's law of gravitation:

$$\mathbf{b}(\mathbf{r}) = f\iiint_{\text{Earth}}\frac{\mathbf{r}' - \mathbf{r}}{|\mathbf{r}' - \mathbf{r}|^3}\,dm$$

where r' and $\mathbf{r}'$ are the geocentric position vectors of a mass element dm and the attracted point P (unit mass = 1) and $|\mathbf{r}' - \mathbf{r}| = R$. The mass element dm can be expressed by the volume density $\rho = \rho(\mathbf{r}')$ and the volume element $dm = \rho\,dv$.

$$\mathbf{b} = \text{grad } V$$

For the Earth's gravitational potential with v = volume of the Earth we have:

$$V(\mathbf{r}) = f\iiint_{\text{Earth}}\frac{\rho(\mathbf{r}')}{|\mathbf{r}' - \mathbf{r}|}\,dv \tag{9}$$

Besides the attraction of the Earth at points P generally all cosmologic masses contribute to this attraction.

However, in most cases only the influence of sun and moon is considered. The entire gravity attraction can be obtained by:

$$\nabla \cdot \mathrm{V(P)} = \mathbf{a}_\mathrm{E}(\mathrm{P}) + \mathbf{a}_\mathrm{C}(\mathrm{P}) \tag{10}$$

$\mathbf{a}_\mathrm{E}$ – attraction of Earth
$\mathbf{a}_\mathrm{C}$ – attraction of cosmological masses

$\mathbf{a}_\mathrm{E}$ causes time-dependent deformations of the Earth by tidal effects and each mass point P is dislocated by a very small value $\mathrm{R_D}$. Each mass point is influenced by the rotation of the Earth, and its angular velocity is given by $\omega_E = 7.292115 \cdot 10^{-5}$ rad/s, Gravity field of the Earth.

In an Earth-centered coordinate system, the position vector $\mathbf{R}_\mathrm{P}$, which points to point P is given by (refer also to Figure 2):

$$\mathbf{R}_\mathrm{P} = \mathbf{R}_1 + \mathbf{R}_\mathrm{D}$$

Then, the gravity vector $\mathbf{g}(\mathrm{P})$ can be calculated by: $\mathbf{g}(\mathrm{P}) = \nabla \cdot \mathrm{V(P)} - \ddot{\mathbf{R}}_p$

It holds:

$$\dot{\mathbf{R}}_\mathrm{P} = \dot{\mathbf{R}}_\mathrm{D} + \dot{\mathbf{R}}_1 = \dot{\mathbf{R}}_\mathrm{D} + (\omega_E \times \mathbf{R}_1)$$

$$\ddot{\mathbf{R}}_\mathrm{P} = \ddot{\mathbf{R}}_\mathrm{D} + (\omega_E \times (\omega_E \times \mathbf{R}_1))$$

disregarding the small changes of rotational velocity $\dot{\omega}_E$. The gravity vector can be written as:

$$\mathbf{g}(\mathrm{P}) = \mathbf{a}_\mathrm{E}(\mathrm{P}) + \mathbf{a}_\mathrm{c}(\mathrm{P}) - \ddot{\mathbf{R}}_\mathrm{D} + (\omega_E \times (\omega_E \times \mathbf{R}_1)) \tag{11}$$

The first term represents the attraction of Earth, the latter the centrifugal acceleration which is caused by Earth rotation.

The middle terms $\mathrm{a_c(P)} - \ddot{\mathbf{R}}_\mathrm{D}$ display the time-dependent part of Earth-tides. For precise gravity field determinations it must be observed and eliminated from the observations. The tidal correction which is caused by the sun and the moon never exceeds 3×10^{-5} m/s^2.

For the centrifugal acceleration $\mathbf{a}_z$, we can write:

$$\begin{aligned}\mathbf{a}_z &= (\omega_E \times \mathbf{R}_1) \times \omega_E \\ &= \omega_E{}^2 \mathbf{R}_1 - (\omega_E{}^2 \cdot \mathbf{R}_1)\omega_E = \omega_E{}^2 \cdot \mathbf{R}_\perp\end{aligned} \tag{12}$$

with

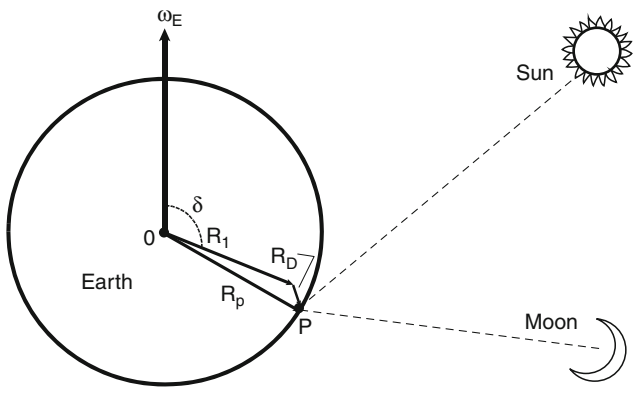
$\mathbf{R}_\perp$ = to the Earth's rotation axis perpendicularly oriented component of $\mathbf{R}_1$.

Because $\mathbf{R}_\perp = 1/2 \ \nabla \ \mathrm{R_\perp}^2$ also $\mathbf{a}_z$ is a gradient field:

$$\mathbf{a}_z = \nabla \cdot \mathrm{Z} \text{ and } \mathrm{Z} = 1/2 \omega_\mathrm{E}{}^2 \mathrm{R_\perp}{}^2$$

Z is called the potential of the centrifugal acceleration and one obtains for the complete potential of the Earth with (Equation 9):

$$\mathrm{W} = \mathrm{V} + \mathrm{Z} \text{ and } \mathrm{g} = \nabla \cdot \mathrm{W}. \tag{13}$$



Gravity Method, Principles, Figure 2 To illustrate the calculation of gravity effects in a point P at the Earth's surface, which depend on the attraction of celestial masses (sun and moon) and the centrifugal acceleration (δ = pol distance, ω_E = angular velocity vector).

Anomalies

From Equation 13 the normal gravity field (γ_0) can be deduced from a "normal Earth body" (among others, e.g., Heiskanen and Moritz, 1967; Torge, 1989; Blakely, 1996). Geodesists and geophysicists agreed that the "normal gravity" is defined at an equipotential surface which is part of a spheroidal surface that bounds a rotating, uniformly dense Earth. Due to the gravity (attraction) and rotation forces, such a spheroid has a very comparable shape to an ellipse of rotation. Consequently, it is called a reference ellipsoid: in the WGS84 geodetic system, the flattening of the ellipsoid is f = 1/298.257223563. Readers wishing additional information are referred to publications by Li and Götze (2001) and Hackney and Featherstone (2003).

Local variations in altitudes and densities of crust and mantle, and geological formations cause variations in the Earth's gravitational field, known as gravitational anomalies (see *Gravity, Data to Anomalies*). Some of these anomalies can be very extensive and cause even bulges in sea level. The study of these anomalies forms the basis of the gravity discipline in geophysics. The anomalies are measured with extremely sensitive gravimeters, and today detected also with gradiometers. The effect of topography and other known factors (see below) are subtracted from the observations. Such techniques are used by geophysics to explore oil and mineral deposits and global structures. Denser rocks (often containing mineral ores) cause higher than normal local gravitational fields on the Earth's surface; less-dense sedimentary rocks cause negative anomalies (see *Gravity Anomalies, Interpretation*). The separation of gravity anomalies which are caused by local density variations of rocks and geological formations implicate corrections of the observed gravity. It was suggested by Blakely (1996) to describe these corrections as contributions to the field which was measured:

Observed gravity	= Attraction of the reference ellipsoid (normal gravity) + Effect of heights above geoid (FREE – AIR correction) + Effect of topographic masses above geoid (BOUGUER and TOPOGRAPHIC correction) + Effect of time-dependent variations (TIDAL correction) + Effect of moving platforms (EÖTVÖS corrections) + Effect of masses that support loads (ISOSTATIC corrections) + Effect of both known and unknown crust/mantle density variations (GEOLOGY)

It is the goal of each interpretation to isolate the effect of geological bodies from all other terms. We have to consider that the magnitude of this effect is relatively small if compared with the value of normal gravity:

Normal gravity approximately is	$9.81\ m/s^2$ and
Gravity effects of "Geology" approximately is	$10^{-5}\ m/s^2 - 10^{-3}\ m/s^2$

This is less than 0.01 % of the observed gravity field magnitude. In geophysics, one distinguishes the standard anomalies: free air, Bouguer, Isostatic, explained in the entry *Gravity, Data to Anomalies* in this encyclopedia.

Ambiguity and principle of equivalence

The interpretation of gravity anomalies is not unique and boundary condition/information is always required, mainly from other geophysical disciplines and/or geology. It can be easily shown by modeling that for a given anomaly and a given density contrast, a wide range of possible interpretations can be made: at various depths, based upon the different geometrical shapes. Nor does the method of interpretation by the gravity field gradients allow us to make a unique interpretation, or to distinguish deep from shallow anomalies as has been claimed: It has been shown that we cannot escape the ambiguity by using second derivative quantities (gradients) or curvature, and that, in fact, gravity and its derivatives are related by a corollary of Green's theorem. This theorem provides an analytical proof of ambiguity not only for the case of gravity data but for magnetic data as well (e.g., Skeels, 1947).

The inversion problem

The ambiguity of the inverse problem of gravimetry originates from potential theory (Stokes). It is related with the computation of density functions from the observed gravity field. Density functions yield information of location, shape, and densities of causing masses. The computation leads to an integral equation, for which no unique solution exists (see *Inverse Theory, Global Optimization*). For a gravity anomaly generated by a particular mass distribution, infinitely many equivalent disturbing masses can be constructed at depths above the maximum depth of a disturbing body (Figure 3). However, the total mass of the disturbing body (surface integral of the gravity anomaly), the lateral position of its mass center, and the corresponding coating on the surface of the Earth (special case of an equivalent disturbing mass) can be determined uniquely. If certain conditions are met, limiting values of maximal depth, density (difference), thickness, and lateral extension of the disturbing body can be found. The necessary additional independent information (constraints) is taken from other geophysical methods and geological and/or petrological investigations.

In practical solutions of inversion problems, the *direct problem* of gravity appears, i.e., the computation of gravitational effects caused by particular mass contributions given in terms of location, shape, and density. In this case, a unique solution is always possible by application of the law of gravitation, Equation 9.

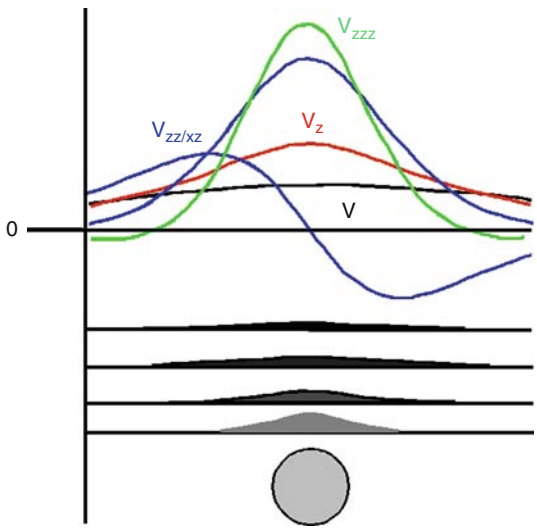
Units and gravitational constant

Gravity is measured in ms^{-2} which is the standard unit in the "système international d`Unités" (SI units are used in physics since 1972). The six independent components of the gravity gradients are measured in s^{-2}. For many applications of gravity field, the following units are useful:

$$1\ nm\ s^{-2} = 10^{-9} ms^{-2} \text{ or}$$

$$1\ \mu m\ s^{-2} = 10^{-6} ms^{-2}.$$

Also the older cgm – units are still used in geophysics and geodesy:



Gravity Method, Principles, Figure 3 Gravitational potential (V), vertical gravity component, and derivatives of gravity over a homogeneous sphere with a depth 5 km, a radius of 1 km, a density contrast of 1 t/m^3, and the equivalent masses between surface and maximum depth (After Torge, 1989).

$1\ \text{Gal} = 1\text{cm s}^{-2}$

$1\ \text{mGal} = 10^{-5}\text{ms}^{-2}$ or

$1\ \mu\text{Gal} = 10^{-8}\text{ms}^{-2}$.

"Gal" was (is) used in honor of the famous Renaissance Physicist Galileo Galilei (1564–1642). Although these older cgm units are no longer admitted, in applied geophysics they are still in use, together with "gravity units" (g.u. = 1 μm^{-2}).

Measurements and refinements of the gravitational constant have progressed since the time of Newton. However, up to now, laboratory experiments and physical research have not rendered a significant or generally accepted proof of $f \neq 0$. Fixler et al. (2003) reported on a new experiment. The Newtonian constant of gravity, f, was measured by using a gravity gradiometer based on atom interferometry. They report a value of $f = 6.693 \times 10^{-11}$ m / kg s^2, with a standard error of the mean of $\pm 0.027 \times 10^{-11}$ and a systematic error of $\pm 0.021 \times 10^{-11}$ m^3 / kg s^2.

Summary

This contribution describes the principles of the gravity method that was developed by Sir Isaac Newton in the seventeenth century and holds until today. The theory bases on the definition of a potential function which replaces potential energy. A space function and its second derivatives which are continuous and bounded in a region where defined are called harmonic functions if they fulfill the LAPLACE and – in the interior of a mass filled space – the POISSON differential equation. A normal gravity field can be deduced from a "normal Earth body" and geodesists and geophysicists agreed that a "normal gravity" is defined at an equipotential surface which is part of a spheroidal surface that bounds a rotating, uniformly dense Earth. Due to the gravity (attraction) and rotation forces such a spheroid has a very comparable shape to an ellipse of rotation. Consequently, it is called a reference ellipsoid. Local variations in altitudes and densities of the Earth's crust and mantle, and geological formations cause variations in the Earth's gravitational field, known as gravitational anomalies. In geophysics elevation is used in all the corrections including the height correction and the complete Bouguer correction. In addition, one should correct observed gravity for the geoid shape. The gravity effects due to the geoid undulations (N) are called the "indirect effects." Any gravity field interpretation effected by the ambiguity of the inverse problem of gravimetry which originates from potential theory; it is related with the computation of density functions from the observed gravity field.

Definition

After recalling the need for measuring the Earth's gravity field at fine spatial scale and high precision with respect to

applications in the geosciences, we broadly review the classical ways of determining global gravity models. We then describe the new satellite gravity missions with their basic principles, and finally give our vision of the future in this domain.

Details in a gravity model recovery (functional representation, dynamical approach, inverse problem of celestial mechanics, disturbing forces, etc.) and in the principles of satellite-to-satellite tracking and satellite gradiometry (and instruments) are to be found in other chapters of this Encyclopedia. Broad concepts only and most important mathematical methods are given here.

Introduction

The knowledge of the gravity field of the Earth and of an associated reference surface of the altitudes (the geoid) is necessary for geodesy, for improving theories of the physics of our planet interior and surface, including various mass transfer mechanisms, and for modeling the ocean circulation in absolute. This knowledge comes from several observing techniques; on the global scale it mostly benefited from the observation of artificial satellite orbits and has been improved over decades. The current approach, based on the accumulation of information from a large number of satellites, one being observed at a time, reached its limits around the year 2000. Dramatic improvements now come from newly implemented space techniques already proposed in the 1970s and rendered possible thanks to technological progress; they are exemplified by the CHAMP, GRACE, and GOCE missions, which are realizations of the satellite-to-satellite (SST) tracking principles (in the high-low and low-low modes), of satellite gradiometry, together with the systematic use of micro-accelerometry to measure the surface forces that are a source of uncertainty in gravity field mapping from satellites.

Geodesy, gravity field, and scientific applications: why?

Geodesy is a science whose major goal is to define and study the shape of the Earth, its deformations (from relative movements of points on its surface), and its gravitational field (or its gravity field if one includes the rotational effects). It is an old discipline that acquired its fame in the eighteenth century when French scientists went measuring arcs of meridians – in Lapland and Peru, in order to determine whether the Earth was flattened at the poles or at the equator. Two hundred years later, the use of artificial satellites yielded a global and continuous view of our planet, and geodesy, too, benefited from this revolution. It became a science at the crossroads of others; for instance it is used daily for navigating satellites with high precision for oceanography, geophysics, and a variety of societal applications. In the mid-1960s first global models of the Earth's gravity field from satellites initiated a revolution in geophysics from space; about 40 years later we are witnessing a new era that sees the deciphering of our planet's gravity with unprecedented resolution and accuracy.

For a better understanding of both surface and deep phenomena that are related to the interior structure of the Earth and its temporal evolution, for studying the dynamics of the oceans and their interaction with meteorological and climate changes, for modeling the ice caps–oceans–continents relationships, and for predicting the long-term evolution of the mean sea level, also for unifying vertical reference systems and for the precise determination of satellite orbits in space, it is mandatory to know our planet gravity field to ever increasing resolution and precision – including its temporal variations induced by the aforementioned phenomena. Details are provided by Jekeli (*this Encyclopedia*); we limit ourselves to qualitative arguments on the dual role of the gravity field in Earth sciences.

On the one hand, by comparing the real field with the field of an idealized body (e.g., an ellipsoid in hydrostatic equilibrium) one defines gravity anomalies that characterize deviations from a state of internal equilibrium (that is non-radial density variations), which constitutes one method of sounding our planet's interior. The magnitude of gravity anomalies is in the range −1,000/+1,000 mgals ($1\ \text{mgal} = 10^{-5}\ \text{ms}^{-2}$). As a matter of fact this is one of four ways of "looking" inside, the other three being seismology, magnetic field studies, and the analysis of the Earth's rotation. However, the gravity analysis approach is unique in providing direct information on the density field (although this is integrated and cannot be univocally inverted). When one strips the Earth from its topographic blocks (with assumed, or known density) one is left with residual gravity anomalies whose magnitude is not much different from the magnitude of the original ones; this exemplifies the phenomenon of isostasy, which is the concept of mechanisms of support of the topographic masses. Therefore the residual field mirrors mass excesses or deficits in depth, which inform us on the lateral structure of the lithosphere and upper mantle. A significant part of this information is today provided by seismology, by tomographic analysis, but still suffers from uncertainties due to hypothesis on which such inversions are based. The combination of both types of data (seismic velocities and gravity anomalies) is a powerful tool to get a better picture of the interior and to make progress in the understanding of several phenomena for instance the accumulation of stresses and triggering of earthquakes.

On the other hand a surface that is intimately related to gravity, the geoid, is used as the reference for defining and measuring the altitudes on the continents but also under the oceans or over the ice caps. The geoid is a particular equipotential surface of the gravity potential (the sum of the gravitational and centrifugal potentials), which may be viewed, in oceanic areas, as the surface of an ocean at rest. The Earth's rotation being sufficiently well known and its effects being smooth at the surface (they essentially decrease with increasing latitudes), the irregularities of the geoid (in the ±100 m range, as measured with respect to an ellipsoid of revolution that approximates the Earth's

shape) characterize the density field variations in a way similar to the gravity anomalies. In addition, on the topographic surface water naturally flows along the geoid (or other equipotential) slope; over the oceans sea water circulates (under the forcings of winds and density-salinity fluctuations) and these movements (different from the vertical displacements of water due to tides) and associated amounts of transported water (and heat, chemicals, nutrients, etc.) can be quantified with respect to the geoid: these are the ocean currents. One distinguishes between the mean and the variable parts of the circulation: the latter can nowadays be monitored by satellite altimetry, whereas the former (which is needed in the modeling of the climate by quantifying the long-term absolute transports of heat – especially in the shallow parts of the oceans) requires the precise knowledge of the difference between the mean sea surface and the geoid (the so-called sea surface topography); the mean sea surface itself can be deduced from long series of altimeter measurements but it is demanded that the geoid be independently determined.

For both solid Earth physics and oceanography, the requirements today are (at least) for a 100-km resolution geoid (and gravity field) with a cumulated error – that is, up to that resolution, of 1 cm (and 1 mgal) or better. Clearly the classical domains of geodesy (unification of vertical reference systems, inertial navigation, accurate satellite orbits for monitoring the Earth's deformations, the sea surface, the Earth's kinematics, etc.) will greatly benefit from such knowledge.

In addition to this, there is a growing interest, in relationship with environmental studies and prediction capabilities, in measuring the time variations of the gravity field (see *Gravity Field, Temporal Variations from Space Techniques*). Some of them (e.g., the oceanic and solid tides) are deduced from the measurements or modeling of phenomena that are responsible for them, with satisfactory precision and resolution – or close to be satisfactory. On the contrary others can only be determined from direct observations, from which the responsible phenomena are then modeled. These are the postglacial rebound of the lithosphere (therefore of the planet surface); the variations of the ice caps, of the sea level, of the large continental aquifers; and the distribution of precipitations (rain, snow), the soil moisture, the evapo-transpiration, that is, the water cycle in general.

Classical ways of measuring the Earth's gravity field

Up to a few years ago three types of information have been used to describe or model, at local, regional, and/or global scales, the Earth's gravitational potential and various functionals:

- Surface measurements of gravity, on land, at sea (with ships and submarines), by plane (more recently). This is the oldest approach, much improved along its history. The measurements are often reduced to gravity anomalies, then gridded and made available at a variable resolution that depends on the area, on the actual density of observations, also on restrictions still exerted by many countries for protecting national economic (sometimes military) interests. The resolution of such grids varies from a few to hundreds of kilometers, and the precision ranges from about 1–10 mgals – the accuracy may be worse due to systematic errors in many data sets (such as the old marine surveys). The data are archived at world level, mainly at the National Geo-Intelligence Agency (NGA) in the USA, and at the Bureau Gravimetrique International (BGI) in France. Airborne measurements are slowly expanding but the precision at ground level (after downward continuation) is still insufficient. More information on gravimetry is provided in cross references.
- The classical analysis of satellite orbit perturbations: since the 1960s a few groups in the world have determined global gravity field models from the inversion (via the law of the dynamics) of satellite orbit perturbations – which reflect the forces acting on a satellite. This has also been the current and very successful way of determining the gravity field of other solar system bodies (Nerem, 1995). Most used Earth's satellites were indeed never designed for such purpose: the space geodesists simply took benefit of the more or less accurate measurements made from ground stations on these satellites for orbit knowledge. Various techniques were exploited, essentially the Doppler effect on the signal transmitted from a stable oscillator on board a spacecraft to ground stations – or the reverse (case of the DORIS system), and roundtrip ground to satellite distances measured by laser systems – and optical determination of the satellite positions on the star background was also used at the beginning. The main limitations of these models come from the altitude of the observed satellites (due to the quasi-exponential decay of the perturbations with altitude), from the observation coverage (limited by the ground station networks and pass duration), and from uncertainties in modeling the surface forces (atmospheric drag, solar radiation pressure, and Earth albedo). If the data coverage has improved for some satellites thanks to the development of denser station networks (e.g., the DORIS system), or by starting to track satellites from "above," that is, by the GPS (Global Positioning System) constellation, the other limitations remain and prevent from making significant progress. Solutions derived from satellite data only up to the year ~2000, covered spatial scales from 500 to 40,000 km, but they were reliable (say at the centimeter level on the geoid knowledge) only down to a resolution of about 1,000–1,500 km. That is why they have been – and are still combined with surface gravimetric measurements and altimetric data (see below), which bring higher resolution if not precision – depending on the area; such combined models globally reach 50 km resolution. The same strategy recently applied with a much better satellite solution based on GRACE mission data yielded the EGM 2008 model,

which has, in principle, a 10 km resolution though it represents the field with such details solely over areas with enough surface data. A detailed account of global gravity modeling history, techniques, and satellites used so far is given by Pavlis (*this Encyclopedia*). In a subsequent section we give an overview of the mathematical methods used to retrieve gravity field information from satellite dynamics.

- Satellite altimetry over the oceans: this is a space technique by which one measures (by radar or laser) the distance between a spacecraft and the sea surface; provided that the spacecraft position is known with sufficient precision it provides the sea surface whose time average is close to the geoid but differs from it (up to about 1 m in areas of strong currents such as the Gulf Stream, the Arctic Circum-polar Current, the Kuro-Shio). For several applications in marine geodesy and geophysics, it is sufficient to correct for the mean circulation with the present (approximate) models, though coastal currents, uncertainties in tidal models, and larger error measurements close to the shore limit the usage of the information to the off-shore and open ocean areas. Such restriction being understood, satellite altimetry data have had an important contribution to global Earth's gravity models in increasing their resolution over the oceans – but without providing the true geoid.

New satellite missions

Basic principles were found years ago; technological advances have allowed for their implementation.

To get rid of the limitations of past systems, any new satellite approach should satisfy as many of the following criteria as possible: quasi-polar orbit (for the coverage), 3-D uninterrupted measurements (for recovering the gravity signals with an isotropic error), mean altitude as low as possible (for higher resolution), counteract the effects of signal attenuation with altitude by a differencing measurement method, isolate the gravitational signals by measuring and/or compensating the surface forces (which involves ultra-sensitive accelerometers). The missions launched during the 2000–2010 decade satisfy more or less these criteria. Working at low altitude is the constraint that has received most attention and all missions fly at or below 450 km (compared to the altitudes of satellites used so far: 800 km or larger). Surface forces are measured by micro-accelerometers (and even compensated in the case of the gradiometric mission). The other criteria have been considered differently according to the type of mission and the used technology.

The first dedicated satellite mission, launched in 2000, was CHAMP (Challenging Mini-Satellite Payload for Geophysical Research and Application) (Reigber, 1996); its two main objectives were the mapping of the magnetic field and of the gravity field of the Earth. It was developed by Germany, with French contributions (magnetometers, and a tri-axial electrostatic micro-accelerometer) and the provision of a GPS receiver by the USA; this is one realization of the SST approach in the high-low mode (with a lower segment altitude of 450 km, decreasing to about 320 km toward the end – probably in 2011), which resulted in the first significant leap in gravity modeling precision.

CHAMP appears as the precursor of the second gravity mission GRACE (Gravity Recovery and Climate Experiment), which is a US mission (JPL, 1998) conducted in cooperation with Germany and launched in 2002. It consists in flying two satellites separated by about 200 km from each other, on the same mean polar orbit; the satellites are each tracked by the GPS (like CHAMP) and besides measure their relative distance and velocity with a micrometric accuracy – this observable (of the low-low SST type) may be viewed as an extremely fine measurement of the gravitational potential difference at the satellites. Each spacecraft is equipped with a micro-accelerometer (of a class superior to the CHAMP one). The mission has exceeded its designed life time (like CHAMP); besides improving our knowledge of the mean gravity field (by more than one order of magnitude), it is bringing a wealth of information on the seasonal and inter-annual time variations of the gravity field, especially those related to the hydrological cycle and ice cap volume changes.

The third mission, which was selected in November 1999 as the first core mission of the Earth Explorer program of ESA (European Space Agency) is GOCE (Gravity field and steady-state Ocean Circulation Explorer) (ESA, 1999) launched in 2009. For the first time, a gradiometer is flown on board a satellite on a very low altitude orbit (around 250 km) of 96.5° inclination, with drag-free control. The gradiometer instrument consists in six ultra-sensitive micro-accelerometers of a new class (capable of measuring accelerations of 5.10^{-13} ms^{-2}) and delivers gravity gradients (second derivatives of the gravitational potential) in spacecraft axes with an accuracy of a few milli-Eötvös (1 E = 10^{-9} s^{-2}) per $Hz^{1/2}$ in the 0.005–0.1 Hz measurement bandwidth. The satellite is also tracked by the GPS (and by ground laser stations, actually like CHAMP and GRACE – for control and safety), and the combination of these trajectory observations and of the gradiometer measurements should yield a global gravity model with a resolution of about 100 km at least with a total uncertainty of ~2 cm on the geoid.

Overview of satellite dynamics methods

In the following we describe the main mathematical concepts and tools that are in common use in satellite geodesy, that is:

1. The representation of the gravitational potential
2. The solution of the dynamical problem, with two subparts:
   - The equations of motion and their solution

- The equations, derived from the preceding ones, necessary for obtaining the trajectory and physical parameters at stake (i.e., for the inverse problem)

3. The setting up of the observation equations and their linearization in the inverse problem
4. The solution of the inverse problem

Some of the described material may be redundant with Pavlis (ibid).

The representation of the gravitational potential

For most global studies the potential of the Earth's attracted masses is usually modeled by a spherical harmonic series, written at each point P as:

$$U = \frac{GM}{r} + \sum_{l>0} \frac{GM}{r}\left(\frac{R}{r}\right)^l \sum_{m=-l}^{+l} K_{lm} P_{lm}(\sin\phi) e^{im\lambda}$$

with G: gravitational constant, M: mass of the Earth, K_{lm}: dimensionless harmonic coefficient of degree l and order m, and r, φ, λ are the spherical coordinates of the point P in a reference system fixed with respect to the Earth; the P_{lm}'s are the Legendre functions of the first kind (polynomials when $m = 0$) and, for computational stability reason, are usually normalized (like the K_{lm}'s) – which we will assume in the following.

Alternatively, the sum of all terms of the same degree l can be written with real (normalized) coefficients and functions, in the form:

$$U_l = \frac{GM}{r}\left(\frac{R}{r}\right)^l \sum_{m=0}^{+l} (C_{lm}\cos m\lambda + s_{lm}\sin m\lambda) P_{lm}(\sin\varphi)$$

The C_{l0} coefficients are called zonals, the C_{lm}, S_{lm} ($m > 0$) are the tesseral harmonics with the sectorials ($l = m$) being a special subclass. They may vary with time.

Practically the potential series is truncated at maximum degree L, that is, $|m| \le l \le L$, and therefore dim $\{K_{lm}\} = (L + 1)^2$. L depends on the type of satellite orbits and data sensitivity.

When the K_{lm} are known, it is straightforward to compute any geodetic functional F, which is linear in these parameters:

$$F(U) = \sum_l f_l U_l$$

For instance:

- For the gravity anomaly field: $F = \Delta g$ and $f_l = (l\text{-}1)/r_E^2$
- For the geoid height: $F = N$ and $f_l = 1/\gamma\ (r_E, \varphi)$

where r_E is the radius vector and $\gamma\ (r_E, \varphi)$ is the normal gravity at the evaluation point on some adopted reference ellipsoid (E) approximating the shape of the geoid.

Variances and covariances can also be propagated to these functions from the covariance matrix (see further down) of the spherical harmonic coefficients (in particular the variances δC^2_{lm} and δS^2_{lm}). Useful indicators of the precision of a model are the mean errors per degree on some given geodetic functional – usually the geoid and/or the gravity anomaly field, computed as:

$$< \delta F >_l = f_l \left[\sum_{m=0}^{l} \left(\delta C_{lm}^2 + \delta S_{lm}^2\right)\right]^{\frac{1}{2}}$$

The solution of the dynamical problem

The equations of motion are most often considered in rectangular coordinates with respect to a given reference system, and written in a specific time scale. Although approximate analytical theories exist for describing the evolution of an orbit subject to disturbing forces (they are still in use for mission analysis and first order scientific investigations), numerical integration is systematically used for higher precision. Forces acting on a satellite are not only of gravitational origin and their complete modeling involves parameters, such as the K_{lm} coefficients, whose determination requires integrating other systems of equations associated with those providing the trajectory.

Reference system and time scale

One makes a choice of a time scale, such as the Geocentric Coordinate Time or the Terrestrial Time, and of reference systems: one related to the Earth's surface (the International Terrestrial Reference Frame, or ITRF), and one fixed in space (the International Celestial Reference Frame, or ICRF) as defined by the International Astronomical Union and the International Association of Geodesy (IERS, 2004). The K_{lm} coefficients are expressed in ITRF, and the equations of motion of a satellite are usually written in a system (EME2000) defined by the Earth mean equator and mean equinox of epoch J2000 (January 1, 2000 at 12 h) and fixed in ICRF. The transformation from ITRF to EME2000 involves all phenomena related to the rotational motion of Earth in space, that is precession, nutation, sidereal time, and polar motion – of which parameters may be part of the unknowns in the inverse problem.

Equations of motion

The spacecraft motion obeys the differential equations, in EME2000:

$$\ddot{\bar{r}} = \bar{\nabla} U + \bar{\nabla} U^* + \bar{\Gamma}_{SP} + \bar{\Gamma}_D + \bar{\Gamma}_{th}$$

with $\bar{r}(t_0) = \bar{r}_0$; $\dot{\bar{r}}(t_0) = \dot{\bar{r}}_0$ (initial conditions at beginning of a piece of trajectory – an arc).

In the above, U is the Earth's gravitational potential, U^* the so-called third body gravitational potential, Γ_{SP} is the acceleration vector due to solar pressures (direct from the Sun, indirect, i.e., reflected by the Earth – known as the albedo effect) and infrared pressure (radiated by the Earth considered as a black body), Γ_D is the acceleration due to drag from the atmosphere, and Γ_{th} designates the residual acceleration due to poorly known effects

(e.g., thrusters accelerations in the case of an orbit controlled spacecraft). U^* includes the Sun, the Moon, and planets.

For computing the surface accelerations Γ_{SP} and Γ_D, a so-called box-and-wing (macro) spacecraft model (with a few planar faces) is used (together with ad hoc physical coefficients), and one has also to use an attitude model. Alternatively, Γ_{SP} and Γ_D may be measured by very sensitive micro-accelerometers such as in the CHAMP, GRACE, and GOCE satellites. The Γ_{th} effects may be modeled via time series or as window (rectangular) functions at some specific epochs (for instance the times of attitude maneuvers).

Integration of the equations of motion

This is the direct dynamical problem. Numerical integration is systematically used. Robust multistep integrators, of the Adams, Adams–Moulton, or Cowell type, in normal form or in summed form (which reduces the accumulation of round-off errors), are preferred. Such integrators have a starting phase, then a running phase with a predictor–corrector iterative scheme. One big advantage of such class of methods is that one can easily speed up the algorithm, by sometimes a dramatic factor in performing a pseudo-correction by which the full force function (right-hand side member of the dynamical equations) is replaced (after the first loop of the corrector part) by an approximation (e.g., the central term of the gravity field plus a few other important terms).

Variational equations and their integration

The inverse dynamical problem consists in determining the physical model parameters (or a subset of them) from the observation of the satellite trajectory – by any mean. It also implies the determination of the equations of motion initial conditions in a first step or simultaneously (usually by iteration).

As it is known, and as we describe it in the next subsection, this requires to obtain at each time t the partial (first) derivatives of the satellite state vector $(\bar{r}, \dot{\bar{r}})$ with respect to the components of the initial conditions vector (which we call $\bar{Z}$) and similarly with respect to the vector of all searched for physical parameters (which we call $\bar{P}$). This is achieved via the variational equations.

We rewrite the equations of motion as follows:

$$\ddot{\bar{r}} = \bar{\gamma}\ (\bar{r}, \dot{\bar{r}}, t, \bar{P})$$
$$\text{with } (\bar{r}, \dot{\bar{r}})_{t0} = \bar{Z}$$

$\bar{r}$ and $\dot{\bar{r}}$ are functions of t, t_0, $\bar{Z}$, and $\bar{P}$. Let w be any Z_j or P_k. Then:

$$\frac{\partial}{\partial w}\ddot{\bar{r}} = \frac{\mathrm{d}^2}{\mathrm{d}t^2}\left(\frac{\partial \bar{r}}{\partial w}\right) = \frac{\partial \bar{\gamma}}{\partial \bar{r}}\left(\frac{\partial \bar{r}}{\partial w}\right) + \frac{\partial \bar{\gamma}}{\partial \dot{\bar{r}}}\left(\frac{\partial \dot{\bar{r}}}{\partial w}\right) + \frac{\partial \bar{\gamma}}{\partial w}$$

We note that $\partial \dot{\bar{r}}/\partial w = d(\partial \bar{r}/\partial w)/\mathrm{d}t$ and that the last term is present only if $w = P_k$.

Therefore any vector $\bar{g} = \partial \bar{r}/\partial w$ is solution of the system of so-called variational equations:

$$\ddot{\bar{g}} = \frac{\partial \bar{\gamma}}{\partial \bar{r}}\,\bar{g} + \frac{\partial \bar{\gamma}}{\partial \dot{\bar{r}}}\,\dot{\bar{g}} + \begin{Bmatrix} 0 \\ \partial \bar{\gamma}/\partial w \end{Bmatrix}_{w=P_k}^{w=Z_j}$$

with

$$g_i(t_0) = \dot{g}_i(t_0) = 0 \quad \forall i \text{ if } w = P_k, = \delta_{ij} \text{ if } w = Z_j,$$

since this is nothing but the Jacobian $\left[\frac{D(r_i, \dot{r}_i)}{D[r_i(t_0), \dot{r}_i(t_0)]}\right]_{t0}$.

We have one such system for each parameter to be estimated, which could be very costly to integrate, but we note that: $\partial \bar{\gamma}/\partial(\bar{r}, \dot{\bar{r}})$ is common to all systems $(\forall w)$ and can be evaluated once (at convergence of the predictor–corrector loop) at each stepsize in the course of the integration of the main system; these variational equations are linear (with coefficients function of time); therefore they can be economically integrated by quadrature or, more efficiently, by using solely the predictor part of the integrator (another approach uses the matrizant of the associated homogeneous system, followed by quadratures).

The observation equations for the inverse problem

The recovery of the gravity field model parameters is an inverse problem that consists, here, in deriving the gravity coefficients (K_{lm}) from a set of observation equations.

General form of the equations

Each measurement q of a functional f of the satellite position (or velocity) is of the type:

$$q = f(\bar{r}, \dot{\bar{r}}, t, \bar{Q})$$

or:

$$q = f(\bar{r}_1, \bar{r}_2, t_1, t_2, \bar{Q})$$

Direct measurements of a gravity field functional (such as gravity gradients along one or several spacecraft axis) are of the form:

$$q = f(\bar{r}, \dot{\bar{r}}, t, \bar{P})$$

In the above, $\bar{r}, \dot{\bar{r}}, \bar{r}_1, \bar{r}_2$ are usually functions of $\bar{Z}$ and $\bar{P}$, respectively, the initial condition (state) vector (often comprising other "fudge" parameters – e.g., empirical multiplying factors for the surface forces) and the dynamical parameter vector (of which the gravity field parameter is a subset). $\bar{Q}$ is a vector of geometric quantities (for instance coordinates of observing stations) and/or other physical parameters (e.g., propagation delays in a medium).

The observation equations are usually nonlinear with respect to the unknown parameters. The classical approach is to linearize them around starting values:

$$\Delta q = q^{\text{obs}} - q^{\text{comp}} = \frac{\partial q^{\text{comp}}}{\partial \bar{Z}} \Delta \bar{Z} + \frac{\partial q^{\text{comp}}}{\partial \bar{P}} \Delta \bar{P} + \frac{\partial q^{\text{comp}}}{\partial \bar{Q}} \Delta \bar{Q}$$

with

$$\Delta \bar{Z} = \bar{Z} - \bar{Z}_0, \quad \Delta \bar{P} = \bar{P} - \bar{P}_0, \quad \Delta \bar{Q} = \bar{Q} - \bar{Q}_0$$

Partial derivatives are computed via the variational equations of the equations of motion of the satellite(s) when q is a distance, velocity between an observing reference point (a tracking station on Earth, another spacecraft – like in the Earth gravity mapping missions CHAMP, GRACE and GOCE), or are directly evaluated if q can be expressed as a simple function of the physical phenomena at stake at the satellite location, such as a gravity gradient in the case of a gradiometer sensing the gravitational potential (case of the GOCE mission).

More precisely, we have

$$\frac{\partial q^{\text{comp}}}{\partial \bar{Q}} = \frac{\partial f}{\partial \bar{Q}}$$

$$\frac{\partial q^{\text{comp}}}{\partial (\bar{Z}, \bar{P})} = \frac{\partial f}{\partial \bar{r}} \frac{\partial \bar{r}}{\partial (\bar{Z}, \bar{P})} + \frac{\partial f}{\partial \dot{\bar{r}}} \frac{\partial \dot{\bar{r}}}{\partial (\bar{Z}, \bar{P})}$$

(or $\partial f / \partial \bar{r}_1$, $\partial f / \partial \bar{r}_2$ if the observable involves two spacecrafts with both orbits being adjusted simultaneously like in GRACE). In current observation systems $\partial f / \partial \dot{\bar{r}}$ is not present: the only case would be a Doppler type measurement, but this is always treated as a difference of ranges (between the beginning and the end of a given count time).

The quantities $\partial f / \partial \bar{Q}$, $\partial f / \partial \bar{r}$ are in principle easy to compute at the observation epoch although in practice one has to take account of the signal propagation duration, of small motions at the observing stations (solid and fluid tides loading effects, tectonic movements), of relativistic clock effects, etc.

Finally $\partial \bar{r} / \partial (\bar{Z}, \bar{P})$ is obtained by integration of the variational equations as described in the previous subsection.

Example: range measurement generic observation equation

All tracking observations of a satellite orbit involve one or several range values. Consequently, it is logical to construct a generic observation equation for a single range measurement between two points S_1, S_2, being understood that the final equation for a real measurement is a combination of generic equations. Besides this allows an easy generalization to the case when the observing station is replaced by another spacecraft (a high altitude navigation satellite – e.g., from the GPS constellation, or a co-orbiting satellite like in the GRACE mission). Therefore let us consider the case where S_2 is the satellite of interest and S_1 can be a station or another spacecraft.

Firstly propagation times must be taken into account by an iterative scheme that allows to refer the quantities to the true epochs (t_1 for S_1 and t_2 for S_2). Various corrections being properly applied the range S_1S_2 then reduces to the geometric quantity:

$$r_{12} = \|\overline{r_2} - \overline{r_1}\|$$

The observation equation is therefore:

$$r_{12}^{\text{obs}} - r_{12}^{\text{comp}} \approx \mathrm{d}r_{12} = \hat{u}_{12.}(\mathrm{d}\overline{r_2} - \mathrm{d}\overline{r_1})$$

with $\hat{u}_{12} = \bar{r}_{12}/r_{12}$ and:

$$\mathrm{d}\bar{r}_{n,i} = \sum\nolimits_j \frac{\partial \bar{r}_{n,i}}{\partial (PInt^j_{n,i})} \Delta (PInt^j_{n,i}) + \sum\nolimits_k \frac{\partial \bar{r}_{n,i}}{\partial (PExt^k)} \Delta (PExt^k)$$

($n = 1, 2$).

The quantities with comp superscript are derived from the numerical integration of the equations of motion of the satellite(s), the Jacobian matrices $\partial\{...\}/\partial\{P...\}$ are obtained from the integration of the variational equations; the i subscript refers to the ith arc in a strategy where the ensemble of the processed data is split into several batches, and we have distinguished between internal (or inner) parameters (proper to the ith arc) and external parameters (common to all arcs). For each batch of data the inner parameters are solely solved for in an iterative process (because of significant non linearities); at the end all parameters are considered and the equations are solved in ensemble. The whole procedure may then be iterated.

The solution of the inverse problem

The observation equations have been linearized, which yield the system:

$$Ax = b$$

where x is the vector of unknowns (of dimension N), A is a M*N matrix (M is the number of observations and usually M> > N), and b the residual vector (of the Δqs). A weight matrix Π (M*M) is associated to the observations; it is very often reduced to its diagonal part for practical reasons.

These equations can be solved by least squares, usually by forming the normal equation system:

$$\left(A^T \prod A\right) x = A^T \prod b$$

from which x is computed; $\boldsymbol{N} = A^T \Pi A$ is a (N*N) matrix.

A regularizing procedure may be used when the observability and/or sufficient decorrelation of all parameters are not guaranteed; in such a case $\boldsymbol{N}$ is replaced by $\boldsymbol{N} + \boldsymbol{R}$, where $\boldsymbol{R}$ is the regularizing matrix. This is usually

necessary for the inner unknowns (initial orbital elements, empirical parameters, etc., which may not be fully determinable). For the physical parameters, $\boldsymbol{R}$ may be as follows:

- Derived from an approximate physical law (e.g., Kaula's law for the gravitational harmonic coefficients – usually applied above a certain degree or for particular classes of coefficients such as the zonals)
- Obtained from a priori physical information

The covariance matrix of x is finally computed as:

$$\mathrm{cov}(x) = \sigma_0^2 (N + R)^{-1}$$

where σ_0 is the variance of unit weight estimated from the system and residual vector.

Other methods (orthogonal decomposition – e.g., using QR factorization) may be used for computational accuracy reasons.

The computational cost of the formation of the normal system and of its solution is as follows:

- Proportional to MN^2 for forming the normal equations, or for an orthogonal decomposition
- Proportional to N^3 for obtaining the solution *and* the covariance matrix

The first step is obviously the most demanding and this aspect has always driven the strategy of research teams working on the determination of global gravity field models.

Progress made: a short summary

Early in the space age several research groups started working on the determination of the gravity field of the Earth. One of the first global models published was the Standard Earth I, by an American team at the Smithsonian Astrophysical Observatory (Lundquist et al., 1966); it was a solution derived solely from analytical theory and satellite tracking (optical) data and complete to degree and order 8 (plus a few so-called resonant harmonics of higher degree and order). It was quickly followed by a combined solution (to degree-order 16), which was based on a little more satellite data and on mean surface gravity values (Gaposchkin and Lambeck, 1969); this model was enriched a few years later (Gaposchkin et al., 1973). Meanwhile similar work (but based on numerical integration approach) had started at the NASA Goddard Space Flight Centre (GSFC), and in Europe where two groups (at CNES, the French Space Centre, and at the Technical University in Munich) joined their efforts. This resulted in two series of models: the GEM models on the American side (Lerch et al., 1972a, b), the GRIM models on the European side (Balmino et al., 1976a, b). For several years these two series of models were improved, the GSFC team joined efforts with a group from the University of Texas at Austin, the German side of the European alliance was transferred at the DGFI (Deutsches Geodatisches ForschungsInstitute) then at the GFZ (GeoForschungsZentrum). All teams involved in this domain produced many global models, each milestone being marked in general by a new satellite solution, followed by a combined model, that is, with the added (higher spatial frequency) contribution of surface gravimetry and ocean altimetry (see Pavlis, ibid.).

At the end of the twentieth century, models were limited (mostly in the precision of knowledge of their long and medium wavelength components) by the weaknesses of the satellite solutions; for instance the cumulated geoid error at degree 50 (400 km resolution) was still over 1 m. The revolution came with the advent of the new dedicated gravity missions: CHAMP quickly provided a gain of a factor 5–10 (depending on the resolution) to the models derived from it (and from other good past satellite data), GRACE yielded models whose quality now reaches a centimeter error at degree 100 (allowing the study of time variations); GOCE looks very promising after 1 year in orbit, with its capability of complementing GRACE mean (static) models in the higher degrees (very likely up to degree 250 or even above). Due to the difficulty and importance of this type of research (whose outputs require extremely thorough validation – by cross-verifications), many more groups have engaged in the processing of the new missions data, such as the Institute of Theoretical Geodesy at the University of Bonn, which recently produced a very good gravity model from GRACE (Mayer-Gürr et al., 2010).

Finally, Table 1 lists some of the main satellite only solutions published since 1966.

Conclusion and vision of the future of gravity mapping from satellite

New progress can only come from a space approach for this only can satisfy the scientific needs (homogeneous data, full coverage, higher resolution and precision) within reasonable time and cost.

From the results already obtained, which demonstrate that the new gravity missions are (close to) meeting the expected outcome, one can say that several of the objectives previously discussed have been reached. However, and like in other domains, new requirements are emerging, encouraged by the findings of these missions: higher resolution and precision models and therefore measurements are needed.

If we restrict ourselves to the approach by satellite-to-satellite tracking or satellite gravity gradiometry, which are used in the new satellite missions of this decade, we may foresee improvements:

– On the precision of deciphering the time variations of the gravity field at shorter spatial scale, by exploiting further the co-orbiting satellites case like in GRACE; this could be done by performing inter-satellite range measurements by laser interferometry, a technique that has been under study and development (at laboratory scale) for several years

– On the resolution of the static field (mapping of finer lateral variations of gravity) by a satellite-borne gradiometer of enhanced sensitivity, such as a cryogenic instrument that had been studied in the USA and in Europe

Future progress may also be possible by revisiting the differential approaches, for instance by differencing (or double differencing) relative velocity measurements, or by flying two or more satellites in specific geometries (gravimetric "wheel," pendulum configuration, etc.).

But there comes a critical aspect: GRACE results have shown the great potential of such a mission for environmental studies and call for the need to continue monitoring the Earth's gravity field variations (much like we continue monitoring the mean sea level by altimetry). Considering that the GRACE mission may soon come to its end, the main issue is – and will be at each time a new gravity satellite system is flown – to decide on the follow-on mission as quickly as possible so as to avoid any discontinuity in the data series.

Definition

Gravity method. Geophysical method based on measuring the variations in the earth's gravity field.
Gravity stations. Locations, where gravity measurements are made.
Base gravity stations. Locations, where absolute value of the earth's gravity field is known.
Primary base. Gravity observation stations, which are made on stable platform and absolute value of the gravity field is known to a greater accuracy.
Secondary bases. Temporary bases established for a particular survey.
Closed loop. Bases that are connected in a loop for base loop correction.
Drift correction. Correction applied for nontidal variation of gravity, which is mainly dependent on the behavior of gravitymeters with time.
EOTVOS correction. Correction applied to marine gravity data for the movement of ship.
mGal; 1 mGal = 10^{-5} m/s^2
μGal; 1 μGal = 10^{-8} m/s^2

Introduction

Gravity method in geophysics is employed to determine subsurface density distribution by measuring the variation of the earth's gravity field. Measurements of gravity field are usually made on the earth or ocean surface. The scale of investigations (accuracy and spatial distance of gravity measurements) depends on the type of geological problems being investigated. These vary from a few μGal to mGal of measurements accuracy, which is a few millionth of average earth's gravity field (9.8 m/s^2) and station intervals of a few meters to a few kilometers. Based on applications, gravity survey can be broadly classified in the following three groups:

1. Regional gravity surveys: Station spacing is a few kilometers and survey accuracy is of about 1 mGal. It is generally used for tectonic and geodynamic studies.

2. Reconnaissance gravity surveys: Station spacing is a kilometer or so and survey accuracy is of 0.1–0.5 mGal. Such surveys are normally planned for delineating promising zones for hydrocarbon and mineral exploration, tectonic and lithological mapping.
3. Detailed gravity surveys: Mainly done to demarcate local geological structures favorable for mineral deposits, engineering applications, and groundwater studies. Survey accuracy is in the order of ~0.01 mGal and station interval is in the order of a few meters.

Measuring equipments

Gravity measurements

There are primarily three methods of measuring earth's gravity field:

(a) A method, in which period of pendulum is used to find absolute value of gravity
(b) Method based on measuring velocity of free-falling body in the vacuum chamber that also provides absolute value of gravity
(c) Sensitive spring balance, in which change in the spring length offers variation in the earth's gravity. They are relative measurements.

The spring balances are relative instruments, however they are main source of gravity data recording. They measure the differences in the gravity field between two or more points. Worden gravity meter is one such gravimeter, which is employed extensively in several countries. Scintrex gravity meters are now only commercially available gravity meters, which have least count of 1 μGal. Similar kind of gravity meters are also used on the ship, however they are specially designed to take care of vertical and horizontal accelerations with gyroscopic adjustments.

Elevation and position measurements

Gravity field of the earth increases as we move toward poles due to flattening and centrifugal force. The factor that affects the earth's gravity field most is the distance from center of the earth (R). Therefore, the elevation of stations and its position should be precisely known for gravity surveys. There are several ways to know the position and elevation but nowadays Global Positioning System (GPS) provides a best method of determining position and elevation by utilizing information from several orbiting satellites. Sometimes, when measurements are made in shadow regions particularly in the forests, the GPS navigations are not very good. In such cases, theodolite, navigation based on maps, and elevation using pressure measurement devices are often used as per the requirements of survey accuracy. GPS measurements are improved by using them in differential GPS mode (DGPS). DGPS navigation systems that provide position, speed, and heading information of ship are common now for shipborne gravity measurements.

Land gravity survey

Gravity survey often refers to the measurement of the earth's gravity field along with the position and elevation of the observation point. Elevation effect is approximately 0.2–0.3 mGal/m implying that an error of 1 m in elevation of the stations will affect the gravity measurement by about 0.2 mGal which is quite significant, especially when the accuracy of gravimeters is 0.01–0.001 mGal. Therefore, ample efforts are made to record elevation of the stations of the desired accuracy for a particular survey. In general, gravity measurements are made over a plain area a few meters away from depression, ponds, mound, etc., which can affect the gravity readings.

Preprocessing of field data

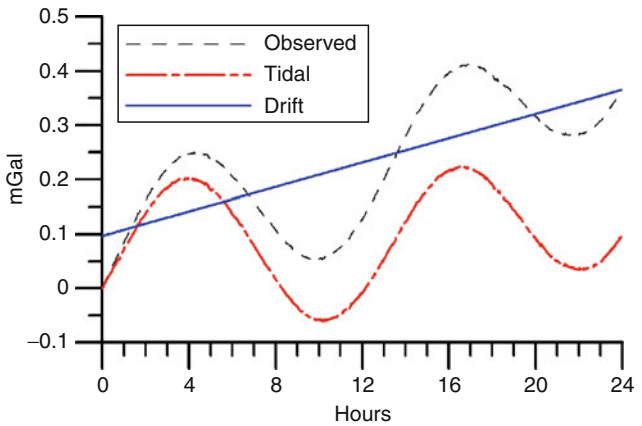
Gravimeters are highly sensitive and they are affected by the changes caused due to the mechanical and environmental changes such as jerks, pressure, and temperature. Gravimeters measure variations in the gravity field, thus the measurements using them are required to tie with the base stations where the absolute values of the gravity field are known. Therefore, measurements need to be corrected for factors influencing measurements to achieve the needed accuracy. There are mainly two corrections, namely, (1) drift correction and (2) base loop correction, which are applied during course of the field work.

Drift correction

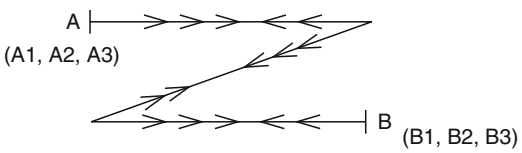
When the repeat observations are made by a gravimeter at the same location, it is found to be varying with time. The variation in the gravity field with time is caused due to several geophysical phenomena (Tiwari and Hinderer, 2011). In a gravity survey, time-varying gravity field is primarily attributed to the tidal effect and nontidal changes, primarily caused due to the mechanical behavior of the gravimeter and contributions from atmospheric or hydrological effects during few hours of repeat observations. The peak to peak tidal effect is about 300 μGal during new moon day and can be precisely calculated for specific locations using standard available softwares. The nontidal variation is referred as drift of the gravimeter (Figure 1). This is normally ~0.0–0.03 mGal/h and is corrected after removing tidal effects computed for that specific location. The drift correction is estimated by making repeat observations at the interval of 1–2 h and the difference in the two nontidal gravity values, known as drift of the instrument, is distributed proportionally to the other observations made during that period. Figure 1 shows the variation of the gravity field with time, tidal effect and drift at Hyderabad. Repeat observations at a fixed location are also important to understand the condition of gravimeters. If drift of the gravimeter is more than a permissible limit of <0.05 mGal/h, the instrument needs to be thoroughly checked for scale adjustments, battery, etc., or survey needs to be redone.

Base loop correction

Gravity base stations are the points where the absolute value of the gravity field is known to an accuracy of 0.01 mGal (10 μGal) and are used to obtain the absolute value of the gravity field at the stations in the field by measuring its variations with respect to base stations. There are primary base stations in the country usually at fixed locations such as railway stations, airports, etc. In any gravity survey, a network of secondary bases is established encompassing survey block, which is connected to any of the known primary base. To achieve the accuracy, a particular procedure of measurements is followed. The bases are connected by looping three times between two bases A and B as A-B-A-B-A-B (A and B being two stations, Figure 2) and occupying them usually within an hour to ensure that the instrument drift is linear and minimum. This measurement procedure is referred to as double tie of bases. This kind of looping provides three observations at every base, which are corrected for the drift of the gravimeter based on consecutive five readings. The consistent value from the three observations or the average of close-by readings if they are not consistent is chosen for every base station. In case of large survey area such as in a regional survey or hydrocarbon exploration, bases are first established in the region that are subsequently used to tie the gravity stations for their absolute values and simultaneously used for drift correction so as to avoid reoccupying same base after 2 h. In these cases, the survey starts from a base station and closed at some other base station after every 1–2 h. The difference in the gravity field is adjusted with respect to their absolute values distributed to the station occupied during that period.



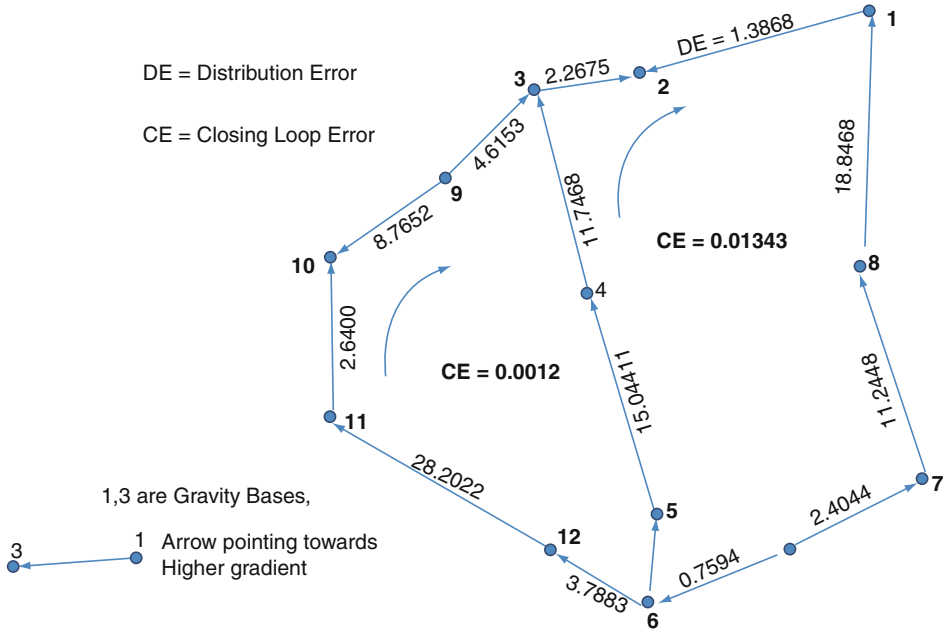
Gravity Method, Surface, Figure 1 Observations of gravity changes at Hyderabad for a day. Tidal and drift of the instrument are plotted separately.



Gravity Method, Surface, Figure 2 A and B are two bases that are occupied five times starting from A to B and going back and forth that provide three diurnal corrected readings at each station which are used to obtain correct reading at base stations.

The bases are established on permanent structures for easy identification during the survey and afterward. Figure 3 shows a typical example of a network of bases, which shows the differences in the gravity values between two bases along the arms with arrows showing toward higher values. These differences along the arms of a network (loop) are added or subtracted as the case may be depending on the direction of the arrows to obtain the difference at closing base of the loop. Ideally, it should be zero but in all practical surveys a difference is found, which is known as closed loop error (CE). This difference is divided by number of arms that gives the distribution error (DE). The arrow inside the loop points in the direction of the positive loop error. In this case, station number 1 is a primary base that is used to establish secondary bases in the survey block for ease of recording the gravity readings in the survey block. Initial checks for loop closure errors are done in the field itself in order to repeat the erroneous bases in case the loop error is found to be more than the permissible error. The permissible error for the closed loop is $0.02\ \sqrt{n}$ mGal, where n is number of arms in a loop. Sazhina and Grushiny (1971) have provided detailed description of these corrections under "Adjustment of Gravity Networks" similar to geodetic networks. Having established the requisite number of base stations in an area, the gravity observations at various stations are tied to these bases within a maximum time limit of 1–2 h for drift correction during that period. In regional surveys where survey is conducted along roads at station spacing of 3–5 km, it may not be possible to make loops. However, as the desired accuracy of the gravity data in this survey is limited to 1 mGal, bases can be tied along the roads at about 20–30 km interval as A-B-A-B which provides two drift corrected readings at every base. The average of the two readings is taken as the base value. In case of mineral exploration, if the area is small and isolated far away from any known base, an arbitrary base is chosen near the camp with any arbitrary value, for example, 0, 100, 1,000, etc., and all the readings are reduced to this arbitrary base value. This provides the gravity anomalies in the survey block with reference to the arbitrary base. In case it is desired, this arbitrary base can be tied to standard bases in the nearby region even after the survey and observed gravity values at stations are updated with reference to the absolute value of the gravity field at the base station accounting for the arbitrary value adopted previously for the survey.

There are several other corrections like latitude, terrain, elevation corrections, etc., that are applied to the observed gravity field at a station to obtain Bouguer anomaly or simply gravity anomaly at a station (Lafehr, 1991; Gotze and Li, 1996). These corrections are dealt under data reduction or preparation of gravity anomaly maps.



Gravity Method, Surface, Figure 3 Closed loops of gravity base stations for loop correction. Station numbers are marked as filled circle with arrows indicating toward the increasing values. The closing loop error (CE) is the departure of vector algebraic sum of the each arm (differences in the observed gravity field at adjoining bases) from zero. Observed gravity difference between two adjoining stations (values of arm) is written on the corresponding arm and CE is also written for each loop. Distribution error (DE) is CE divided by number of arms in the loop, which is added to each loop to arrive final values.

Marine gravity survey

The fundamental difference of marine gravity survey from the land survey is measurements on moving platform, which distorts the measurement accuracy. However, if the speed and accelerations are measured, the corresponding corrections might be applied to the gravity data. Nevertheless, the measurement accuracy on the moving platform like ship will not be as accurate as measurements made on ground. The standard accuracy of marine gravity survey is an order of magnitude less than ground survey. The sea state pose another difficulty in the marine survey, it is apparently calm in the deep water and more predictable than the shallow sea or near the coast. Thus, marine gravity measurements are generally corrected for effects of moving platform, earth's tide, drift, and adjusted for crossover tracks as briefly explained below.

Moving platform correction

The gravity field measurements are distorted due to movement of ship, as well as due to horizontal and vertical accelerations, which can be corrected and eliminated by using supplementary data. They are classified in three categories (Dehlinger, 1978).

EOTVOS corrections: When a ship moves, particularly in the east west direction, it experiences centripetal accelerations about the earth's axis that modifies the acceleration due to gravity. This can be precisely corrected if the speed and heading of ship is known.

Corrections for horizontal and vertical accelerations: These corrections are applied to gravity measurements for any horizontal and vertical motion of the platform. In the modern type of gravimeter, they are adjusted by designing stabilized platform or gimbal-suspended systems. They are also removed using GPS data and then averaging of several gravity values.

Corrections for cross coupling accelerations: This correction is applied to a beam type of gravity measuring instruments when it is rigidly attached to stabilized platform. The error occurs when horizontal and vertical components of ship accelerations have equal periods and have a phase difference.

Earth tide correction

As discussed above, earth and ocean are subject to the gravitational attraction of Sun and Moon. Over the land, major part of tidal effect is perturbation of solid earth; however, over ocean the perturbation of outer water surface also has pronounced effect. Therefore, tidal correction applied to shipborne gravity data should have a model of both solid earth and ocean.

Drift correction

All the marine gravity surveys start with known absolute gravity value at the port of sailing and closed to the known gravity station at the end of survey. Since the time of reoccupation of known gravity bases (reference stations) are generally weeks to month, the drift computed are not

very accurate. Nevertheless, all the spring associated gravity meters also have long time drift that are generally taken into account while closing the marine survey though they are often small.

Network or crossover adjustments

The problem of offset in the marine gravity survey is quite known. It arises due to several reasons (Wessel and Watts, 1988). One of the main reasons of offset is mechanical tare or jar of the spring type of gravity meters. Cross over corrections in the same Leg of the marine survey is similar to close loop correction discussed for land survey. In case of marine survey over a block, a cross cutting profile is recorded that is used for instrumental check, drift, and data accuracy.

Design of survey

Designing of gravity survey is a vital component to optimize the resources according to the geological problems. Following are the details.

Regional surveys for geodynamic studies

As the name indicates these surveys are basically regional in nature and are conducted in large regions for geodynamic studies especially for crustal and upper mantle structures. These surveys are carried out along roads and tracks at a station spacing of 3–5 km, which delineates long wavelength anomalies related to large scale structures and density inhomogeneities. Anomalies recorded in these surveys are of the order of tens of mGal (10–100 mGal) spread over a few hundred km (~100–1,000 km). The accuracy of such surveys is limited to ±1–2 mGal that can be obtained by controlling elevation of stations using Differential Geographic Positioning Systems (differential GPS) with accuracy better than 1 m in elevation.

Hydrocarbon exploration

There are two aspects of gravity surveys for hydrocarbon exploration on land, namely, (a) reconnaissance gravity survey and (b) detailed/integrated gravity surveys (Nettleton, 1976).

Reconnaissance gravity survey

Gravity surveys for exploration of hydrocarbons are basically conducted as reconnaissance surveys to delineate basement structures and structures in sedimentary basins to delimit the areas for seismic surveys. It is generally, carried out in a large area covering a specific basin along roads and tracks at a station spacing of approximately 2.0 km. It is planned in such a way that network of stations at about 2.0 km spacing are available in the entire region. The order of gravity anomalies expected from such structures are of a few mGal in amplitude and therefore, the desired accuracy of such surveys are ±0.1 mGal. Station elevation is therefore obtained by geodetic leveling or Differential GPS providing elevation to an accuracy of a few cm (<10 cm). To check the accuracy of recorded gravity value, 5–10% of gravity stations are repeated on different days and preferably by different observers. In ocean, surveys are conducted along profiles 4–5 km apart over a specific block and bathymetry is recorded with echo sounder.

Detailed/integrated gravity survey

While conducting seismic surveys for exploration of hydrocarbons, it is a general practice to follow the same profiles by gravity surveys at closer stations spacing of 0.5–1 km. These surveys are basically conducted for an integrated approach to supplement the information derived from seismic surveys and delineate structures within the sediment. The desired accuracy of such surveys are ±0.01 mGal (10 μGal) and therefore, station location and their elevation to accuracy of a few centimeter (<5 cm) are usually obtained from geodetic surveys or dual frequency differential GPS. In case of shallow gas occurrences, such surveys can be conducted over a grid with both profile and station spacing of 10–100 m as the case may be. At the places, where reflection seismic data is poor, gravity survey is conducted to supplement the seismic.

Surveys for minerals, groundwater, and engineering sites

The application of gravity survey for mineral and groundwater exploration primarily lies in delineating surface/shallow structures such as faults, fractures, etc., which may be mineralized (Parasnis, 1997). Same is the case with engineering sites where shallow structures such as faults, fractures, etc., are delineated to avoid those sections for large scale constructions such as dams, power plants, etc. The survey procedures for application to these studies are therefore, similar in logistics. They fall under two categories, namely, reconnaissance and detailed/integrated surveys.

Reconnaissance survey

This kind of survey is carried out to limit the area of interest from a larger area. It is conducted along profiles separated by a few hundred meters a part (100–500 m) at stations spacing of a few tens of meters (10–100 m). If the area is large and inaccessible to lay down specific profiles, it is conducted along available roads and motorable tracks at a station spacing of a few tens of meters (10–100 m). Due to desired accuracy of gravity data, elevation of stations in these surveys are obtained by geodetic leveling or differential GPS, providing elevation to an accuracy of a few centimeters (<10 cm). If the area is not large and accessible, a base line is laid out parallel to the general strike of the geological formation in the center of the block and profiles are laid out perpendicular to it at desired intervals. Stations are marked along the profiles at regular intervals by geodetic survey or using differential GPS. Based on these reconnaissance surveys, promising zones and geologically significant structures such as faults are delineated which are followed up by detailed gravity and other geophysical surveys such as electrical, electromagnetic, etc. In case of surveys for

engineering sites, same reconnaissance procedure is followed to delimit the area as described above for mineral exploration.

Detailed/integrated gravity survey
Detailed gravity survey for the mineral exploration is basically limited in areas of a few square meters and are carried out in grids with profiles and station spacing of a few meters (1–10 m) or may be even less depending on the size of the area and the target. A baseline is laid out parallel to the general strike of the geological formations, and profiles are laid perpendicular to it at almost same spacing of 1–10 m as per requirement of particular survey. Stations along the profiles are marked by the geodetic survey at the same interval as profiles forming a grid. In certain cases, the observed gravity anomaly may be less than 0.1 mGal, which require survey accuracy of about 0.01 mGal (10 μGal).

Summary

Gravity method, surface includes both onshore and offshore measurements of the gravity field of the earth for geodynamic studies and resource exploration. Accuracy of the gravity survey required for various purposes and precautions to be observed in this regard are discussed. Geodynamic studies to an accuracy of 1–2 mGal can be carried out using normal gravity survey but resource exploration usually requires high-resolution gravity survey to an accuracy of ~10 μGal using microGal gravimeters. In such cases, base loop correction in ground surveys and correction for crossover points in marine surveys are essential and are emphasized.

GRAVITY MODELING, THEORY AND COMPUTATION

Jean-Pierre Barriot, Lydie Sichoix
Observatoire Géodésique de Tahiti, University of French Polynesia, Faaa-Tahiti, French Polynesia

Definition

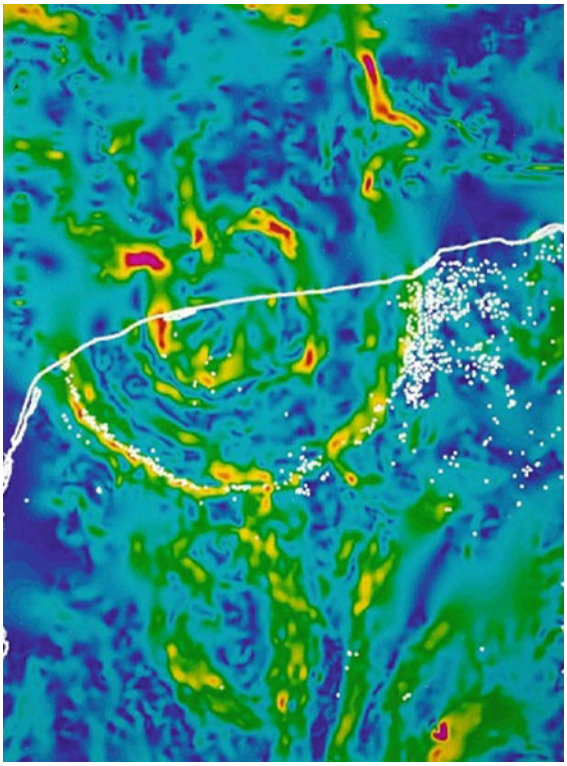
Gravity modeling. Explaining the variations of the external gravity field of a body in terms of its internal density variations. Applications range from oil prospecting to the deep structure of the Earth.
Inverse problem. In Gravity modeling, the forward problem is to compute the external gravity field of a body knowing its internal density distribution. The inverse problem is the opposite, and is much more difficult to solve for.

The gravity modeling from a theoretical point of view

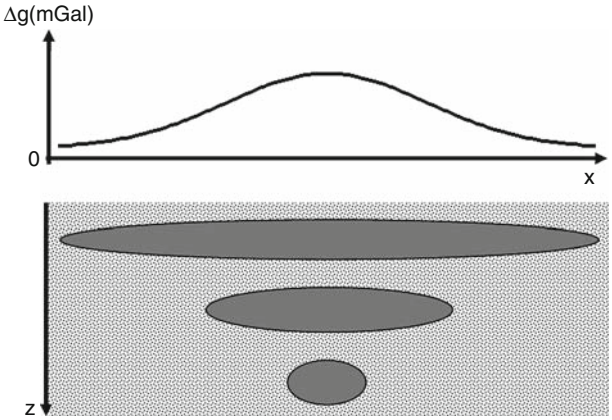
Gravity is an elusive quantity to deal with, but a powerful one. This is mainly because unlike electromagnetic forces, gravity cannot be shielded as there are no negative masses. We refer to LaFehr (1980) and Milsom (1996) for an introduction to the gravimetric techniques (see also *Gravity Method, Principles*), and Zidarov (1990) for the subtleties of gravimetric inversion. Good monographs are available on the theory and computational aspects of gravity modeling. The one from Blakely (1996) is particularly exhaustive (see also *Gravity Anomalies, Interpretation*). Here we give just a short introduction, with emphasis on the modeling directly done on the data, and not on its Fourier transforms.

A landmark success of the application of gravimetric interpretation is the identification of the Chicxulub crater buried underneath the Yucatan Peninsula (Hildebrand et al., 1991, Figure 1, see *Impact Craters on Earth*).

The reasons why gravity is so elusive are profound and lie deep in potential theory. Let us start with a simple example. The radial gravity outside a homogeneous sphere of mass M and radius r is given by GM/R^2, where G is the Newtonian constant and R the distance from the center of the sphere. But r does not intervene in the computation, as long as $R > r$. This means that two homogeneous spheres of radius r and r' have the same external field, as long as they have the same mass. This nonuniqueness has been studied in detail and theory shows that a 3D repartition of density that causes a gravity anomaly can be split in two additive parts: one that is harmonic, that is, that satisfies the Laplace equation, and another that is anharmonic. Only the harmonic part of the anomalous density can be unambiguously



Gravity Modeling, Theory and Computation, Figure 1 The Chicxulub structure (diameter 180 km) is widely believed to be the remnant of the impact that killed the dinosaurs 65 millions of years ago. This structure was identified on a gravity map of the coast, with no other visible evidence. The impacting asteroid that formed the crater was at least 10 km in diameter (Image source: Shuttle radar topography mission, Chicxulub Crater Gravity Map with Cenotes Shown as White Dots with the Yucatan Coastline Being the White Line).



Gravity Modeling, Theory and Computation, Figure 2 Each one of these underground bodies (*gray*) creates the same gravity anomaly. If we suppose that the body is reduced to a point mass, one can infer from this assumption the maximum possible depth for the causative body (Image source: Dubois and Diament, 2005, redrawn).

reconstructed from the anomalous gravity signal (Moritz, 1989; Vanicek and Kleusberg, 1985; Ballani et al., 1993). The anharmonic part of the density belongs to the so-called null-space of the model. In terms of geophysics, a typical example of nonuniqueness is shown in Figure 2.

Far more useful is to note that the ambiguity in gravity modeling can be reduced, or even zeroed if we know the support, in mathematical terms, that is, the spatial extension, of the density anomaly. For example, if we know by other means the radius r of the homogeneous sphere of paragraph one, the density ρ is automatically fixed, with $g = GM/R^2$ by $M = 4/3 \times \pi \times \rho \times r^3$. Chao (2005) has extended this reasoning to the modeling of gravity in terms of spherical harmonics (see *Spherical Harmonic Analysis Applied to Potential Fields*). If we consider a 2D spherical skin covering the Earth, the inverse solution of the surface density distribution is unique. The latter applies quite readily in the inversion of time-variable gravity signals originating from within the crust (such as those observed by the GRACE/GOCE space missions, see *Gravity Method, Satellite*).

Another possibility is to suppose the density known a priori. In that case, the radius of the sphere of paragraph one instantly follows. This seems trivial, but it is not. It has been demonstrated that the gravity field outside a body can be totally explained by a combination of point masses, linear masses, and sheet masses that lie deep inside the body (Zhdanov, 1988). But here also, this result is of little help for the geophysicist. Moreover, the inverse gravity problem is unstable: small variations in the data (errors) can cause unbounded variations in the solution. Technically, the inverse gravity problem is ill-posed in Hadamard's sense (1902, see also Sabatier, 2000 and Menke, 1989, and Inverse Theory, Global Optimization).

The core fact that permits a useful application of gravity anomalies in geophysics is that these anomalies, even contaminated by noise, reflect *real* structures, that is, structures that *we know* have a reasonable density contrast with the surroundings, and/or exhibit a density that varies smoothly inside the expected structure – except at the edges or along faults – and/or are located inside a given volume, for example, we know from borehole measurements that the iron ore is located between two depths: one at −1,000 m and the other one at −2,000 m. To have bounds on the possible densities and/or the locations reduce tremendously the world of possibilities. In short, we are then looking for *plausible* structures.

With such cautions and restrictions, gravity modeling is a powerful tool if correctly used. The best use of gravity measurements is to team them up with other measurements with different null-spaces, like magnetic surveys or even seismic imaging. For example, the velocity of seismic waves increases with density, and the anomalous delays of propagation are linked to the anomalous velocity field (and so to the density through an equation of state) by an averaging integral along the ray known as the Radon

transform (Troyan and Hayakawa, 2002). A joint seismic/gravity inversion is a powerful tool and probably the best way to remove nonuniqueness (Strykowski, 1998, see also *Seismic Tomography*).

But this is hardly done in practice. The driver for field measurements is cost. A gravity survey, even on remote areas, is cheap, and often done as a precursor to more expensive and accurate methods, like seismic tomography. Gravity modeling must thus be able to identify promising structures on its own. The game is tricky, as the observed gravity is of course affected by noise, but also by data reductions (see *Gravity, Data to Anomalies*) that ensure that the gravity data is corrected for drifts, referred to some "constant" reference in altitude (usually the geoid), and is corrected from the gravity signature of the topography (Bouguer correction, see *Gravimeters*). Besides, the gravity signal is by nature nonlocal, and sums up the signature of distant bodies or interfaces, like the discontinuity of the Mohorovic boundary, for example. These distant signatures must be guessed and withdrawn from the gravity signal *before* any local geological interpretation is undertaken (see *Gravity Data, Regional – Residual Separation*).

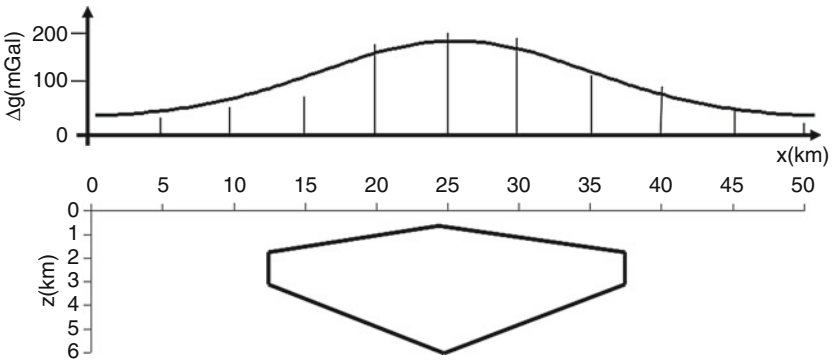
There are two ways to have the job done. One is to use direct modeling with feedback. Technically, an operator draws a 2D *educated* guess of the plausible structure see (Figure 3) on a tablet or other graphic device, and the computer program derives the anomalous gravity model caused by the structure and draws it against the real signal. The operator then modifies slightly the guessed structure in order to obtain a better match with the real signal. For the geophysicist, "anomalous gravity" is synonymous with "Bouguer anomaly," that is to say a measurement of gravity corrected for the variation of altitude and for the topography-induced variations. Other definitions of "anomalous gravity" are possible. For example, it is theoretically possible to work indifferently with geoid undulations or Bouguer anomalies. In practice, the modeling of geoid undulations is reserved for very-large-scale structures in isostatic equilibrium (see *Isostasy*), while Bouguer anomalies are reserved for small- and medium-scale structures (see *Gravity, Data to Anomalies* and *Geoid Undulation, Interpretation*).

This process can be automated with the program adjusting step by step the shape of the structure to exactly match the observed gravity anomaly. With a little bit more complexity in terms of calculus, 3D modeling can be done in almost the same manner, with polyhedra replacing polygons. But there is a huge difference at another level. A human operator has always trouble to visualize and modify 3D solid models, even with the assistance of powerful 3D graphic representations, and such a tedious tool is used with parsimony. Efficient formula that replaces volume integrals by integrals along vertices have been developed, from Talwani et al. (1959), to Tsoulis and Petrovi (2001) to implement polygon/polyhedron calculus.

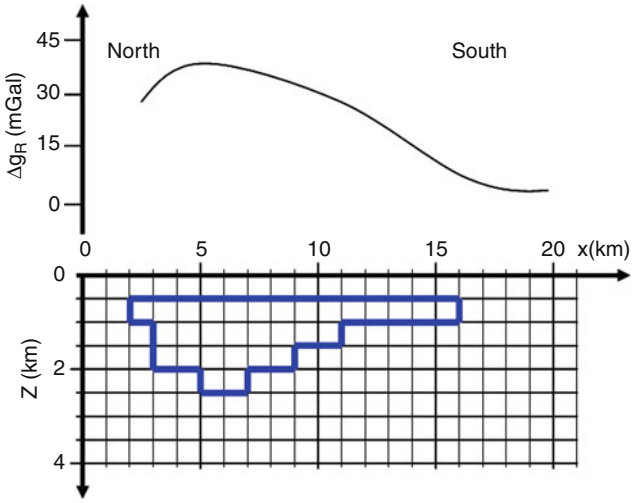
For 3D modeling, a better approach is to discretize the volume where we are seeking for the geological structure in tiny adjacent cells of simple fixed shape (e.g., cubic) but of unknown densities. It is important to note the difference with the previous approach: by looking at the densities, we obtain a mathematically linear problem, in the sense that the effect of each cell sums up additively in the gravity model. To the contrary, altering the skeleton of a polyhedron of constant density (even only a single corner point) has a nonadditive effect on the computed gravity. Technically, we are dealing with a nonlinear model. Nonlinear problems are intrinsically much more difficult to solve for.

The linear inverse gravimetric problem

Let us focus on the linear gravimetric inverse problem, illustrated in Figure 4. We have to define how the discrepancies between measurements and computed gravity from the model are accounted for. The usual way is to measure this discrepancy as a Euclidean distance, by summing up the square of the differences per data point between measurements and computed gravity and then taking the square root of the sum. This is called the



Gravity Modeling, Theory and Computation, Figure 3 The geological body is approximated by a polygonal structure of infinite length perpendicular to the paper sheet and of constant density contrast with the surroundings. The game is to move the summits of the polygon in order to match (*solid curve*) the observed gravity (*needles*).



Gravity Modeling, Theory and Computation, Figure 4 The linear inverse gravimetric problem. The subsurface is divided in small squares (2D) or small cubes (3D), and we are looking for the anomalous densities for each *square* or *cube* (Image source: Blakely, 1996, redrawn).

L2 norm of discrepancies. Another way is to sum up the absolute values of the discrepancies. This is called the L1 norm of discrepancies.

The set of all unknown densities x over the mesh and the set g of the gravity measurements on the ground are linked through the matrix relation $Ax = g$. In the frame of the L2 norm, to solve for the ill-posed inverse linear gravimetric problem can be cast as finding a set u of densities that verifies at the best this relation, and fulfilling at the same time another relation of the form $Bx = k$, where k is another physical or mathematical quantity. For example k can be magnetic measurements and B a design matrix linking densities to magnetic measurements. If we add in such way "sufficient" physical information, the solution of this augmented problem becomes unique. Very often, additional physical information is lacking, and uniqueness is imposed by setting $B = I$ and $k = 0$, where I is the identity matrix. This is equivalent to looking for a set u of densities that realizes a compromise between $Ax = g$ and $x = 0$, that is, an x that explains the gravity signal and is not too large (i.e., in the neighboring of zero). This is known in the literature as a Tikonov–Arsenine (1976) regularized inverse or Marquardt-Levenberg inverse (Levenberg, 1944; Marquardt, 1963). Technically, the solution depends also on the way that the hidden Euclidean spaces used to set up the problem are defined. They are not necessarily orthonormal spaces. The angular separation of their axes and unit lengths can carry additional information about the physical problem (called in the literature as "a priori weights"). Tarantola (2005) gives a complete survey of the probabilistic setting for the Tikonov–Arsenine formula, with the weights seen as the inverses of a priori covariance matrices. The covariance linked to I is especially important as it controls to which extent the density contrasts found are "reasonable." A density contrast of 0.2 is sound; a density contrast of 20 is not, even if the computed gravity matches more closely the observed signal!

The simplest form of the Tikonov–Arsenine inverse formula is of the form:

$$x^*(p) = \text{inv}(\text{trans}(A)A + pI)\text{trans}(A)g$$

where $x^*(p)$ is the solution of the inverse problem (here densities over the mesh), A is the design matrix defined above, p is a scalar parameter, I the identity matrix, and g the set of gravity measurements. In the Tarantola–Valette approach, p is the ratio between the variance of the noise error and the "variance" (the size) of the expected solution wrt zero. The scalar p is the "smoothing" parameter. The geophysicist chooses "by hand" p in order to have both "reasonable" L2 residuals, defined as $\text{trans}(Ax^* - g)(Ax^* - g)$, and a reasonable L2 size (densities) of x, defined as $\text{trans}(x^*)x^*$.

This solution x^* minimizes, with a unique minimum, the following functional (or cost function) $Q(x)$ with respect to x:

$$Q(x) = \text{trans}(Ax - g)(Ax - g) + p\ \text{trans}(x)x$$

Without doubt, the celebrated Tikonov–Arsenine formula is the workhorse of gravity inversion.

Another approach, also very popular, but unimplementable for large problems, is to look at the so-called singular value decomposition of A, a generalization of the eigenvalue decomposition of square matrices (Campbell and Meyer, 1979, see *Inverse Theory, Singular Value Decomposition*).

Looking at a solution of the inverse problem in terms of the L1 norm seems just a little adjustment with respect to the L2 norm. However, it is a totally different approach. Let us imagine that we have a set of n gravity measurements and a mesh of m cells, assuming that n is larger than m. Technically, the problem is overdetermined, with a matrix A with far more lines than columns. To solve for this system in the L1 sense can be casted as solving with respect to x each subset of m lines of A (each subsystem is now square with a trivial inverse), and looking at the solution that gives the best L1 residuals with respect to the complete matrix A. There are $n!/m!/(n-m)!$ subsystems. For 1,000 measurements and 50 cells, a computer crushing numbers from the dawn of the universe will have trouble to handle this inversion. Thankfully, Dantzig and colleagues (see Branham, 1990) found a way to carry out the L1 inversion with on-the-shelf computers, called the simplex algorithm (linear programming, see *Inverse Theory, Linear*). This type of inversion of gravity data has also to be supplemented with a priori (external) constraints to obtain a geologically "sound" solution, for example, by imposing that the inertia moments of the repartition of densities are minima (Cuer and Bayer, 1980), or by looking at extrema solutions, for example,

the "ideal" body of Parker (1975, see also Goodacre, 2006), that is, the set of densities characterizing the geological structure that gives a minimum density contrast with the surroundings.

The nonlinear inverse gravimetric problem

Let us return to the polygon/polyhedron modeling of gravity anomalies, where we assume that the density of the body is uniform.

Mathematically, the problem can be cast as $g = f(x)$, where now x is the set of coordinates of the corner points, and is nonlinear. We want to find a set of coordinates that explain "at the best" the gravity signal, that is, g(observed) $- f(x)$ is kept to a minimum, for example, with respect to the L2 norm.

We then have to minimize a cost function of the form:

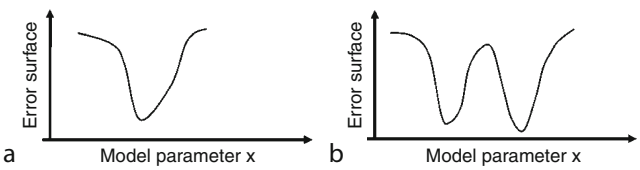
$$Q(x) = \text{trans}(g - f(x))(g - f(x))$$

There is a big difference with the linear case. We can have several well-separated, inherent minima to this functional (Figure 5). There are two ways to solve for this inverse problem. The first one is to linearize the problem, that is, to look at a solution close to a known estimate x_0, that is, by writing that $x = x_0 + dx$, with a dx bounded in some way.

A typical illustration in gravimetry is to look at the shape of an unknown interface between two strata of different and constant densities see (Figure 6). This is an extension of the polygonal model where some points are pushed to infinity and has been discussed by Tarantola and Valette (1982) in their milestone paper as an extension of the pioneering work of Cordell and Henderson (1968). This is often used to refine a model obtained by the modeler from a priori geological evidence, but can be hardly used without any a priori knowledge of the solution. The Backus and Gilbert approach (1968), very popular during the 1970s, can also be seen as a nonlinear problem.

The other approach, more radical, consists in trying to explore the whole set of possible minima of the nonlinear cost-functional. A popular mechanism to do so is to mimic the biological process of evolution. The genetic algorithm of Holland (1975) can be summarized in four basic steps: coding, selection, crossover, and mutation.

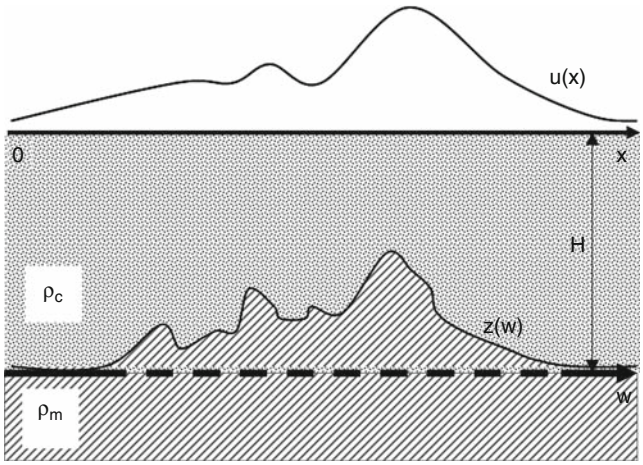
Common to any genetic algorithm is the digitization of an a priori and sufficiently populated list of model parameters using a binary code scheme (for example, we know that the density we are looking for is bounded by 2.5 and 2.8. Assume that the desired resolution (discretization) is 0.01. Then we can make a one-to-one correspondence between a binary word of 5 bits (a "chromosome") and this discretization. A subset of models is then selected from the model population by using some global fitness criterion, for example, the ratio of each model fitness (evaluated in the L2 sense with respect to the observed gravity and using the one-to-one correspondence) to the sum of all fitnesses for all the models. We then take the models the ratio of which is over a given threshold. For example, for a population of L models, we choose a subset of L/2 of "best fit" models. We then mate the L/2 models by pairs, each pair bearing two offsprings by recombination of their chromosomes by processes called crossover and mutation that mimic the meiosis of real chromosomes, giving birth to a complete new generation of L models that replaces the old one. Generally, the average fitness increases between generations, since only the best models from each generation are selected for breeding. Other algorithms exist to locate the "best" minimum, like the tunneling algorithm (Levy and Montalvo, 1985) or the particle swarm optimization (Monteiro Santos, 2010). See also in this Encyclopedia *Inverse Theory, Artificial Neural Networks* and *Inverse Theory, Monte Carlo Method*.



Gravity Modeling, Theory and Computation, Figure 5 (**a**) The cost function of the linear inverse problem presents only one minimum. (**b**) The cost function of the nonlinear inverse problem may present several minima, indicating a nonunique solution (Image source: Dimri, 1992, redrawn).

Spectral approaches

Spectral approaches rely on the expression of the gravity along a basis of given functions: very often a Fourier decomposition in the planar case or spherical harmonics on a global basis. New basis are gaining a wide acceptance, like wavelets, that are like "sine" or "cosine" waves but with a limited spatial support (Chui, 1992). Large



Gravity Modeling, Theory and Computation, Figure 6 Modeling an interface between two homogeneous separate strata. The problem is a special case of the polygon/polyhedron inverse problem (Image source: Tarantola and Valette, 1982, redrawn).

classes of inverse gravimetric problems can then be recast as deconvolution problems (Dimri, 1992), with all the artillery available from Fourier analysis (Dean, 1958; Blakely, 1996). Nevertheless, this approach suffers from all the drawbacks of the Fourier analysis, especially the need to smooth the discontinuities of the gravity signal at the edges of the zone of interest (this is of course not the case for spherical harmonics). Such approaches have been used in planetary geophysics to estimate the global and local average depth of the Moho interface on Mars (Zuber et al., 2000) from models of the gravity field and of the topography of the planets in spherical harmonics, without any other surface or subsurface information.

Summary

Gravity modeling is a cheap tool in geophysical prospecting. It can also be a very potent tool if used with some precautions. This always implies the introduction, both in forward and inverse modeling, of some a priori knowledge of the shape of structures that are guessed, or some bounds about their dimensions or about acceptable density contrasts.

Definition

Gravity anomaly. The difference between gravity measured at a point and a model value at that point that is based on the normal gravity of a reference ellipsoid, corrected for the gravity effects of elevation above the reference ellipsoid and the mass of rock between the point and the reference ellipsoid.

Introduction

The study of anomalous gravity has its roots in geodesy where it is used to determine the shape of the Earth (see *Geodesy, Physical* and *Geodesy, Figure of the Earth*). Gravity anomalies have also proved extremely useful in the interpretation of subsurface geological structure at various scales. Like many geophysical techniques, resource exploration has been the greatest driver of the use of gravity data (e.g., Nabighian et al., 2005). Gravity anomalies are often useful in the early stages of an exploration program as they provide insight into the form of low-density sediment accumulations (basins) or the location of high-density ore deposits. At larger scales, gravity anomalies provide insight into crustal structure and, most recently, time variations in the long-wavelength gravity field measured using satellites (see *Gravity Method, Satellite*) provide insight into changes in polar ice mass and groundwater fluctuations.

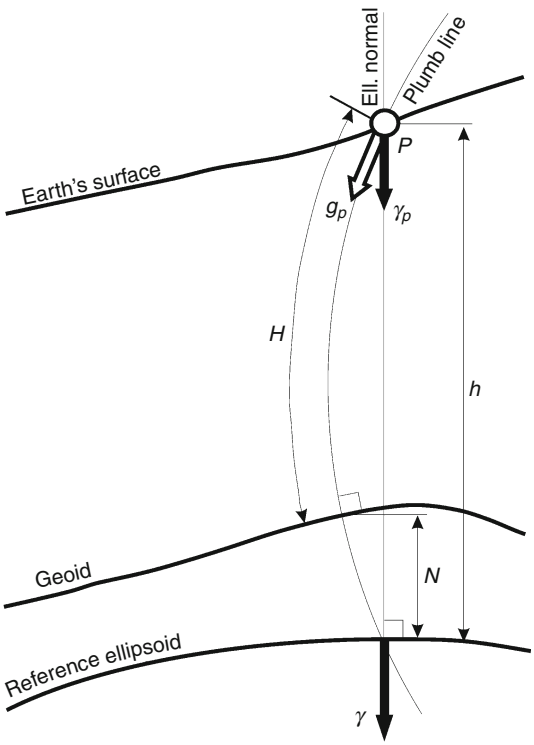
Before gravity data are useful in resource exploration or crustal studies, non-geological contributions to the gravity field that obscure the anomalies of interest need to be accounted for and effectively removed. This chapter explains the process of converting gravity measurements to gravity anomalies for geophysical applications. It is important to stress the geophysical context as there are often subtle differences in the way geodesists and geophysicists think of and use the various gravity-related quantities (cf. Li and Götze, 2001; Hackney and Featherstone, 2003; Hofmann-Wellenhof and Moritz, 2006).

Key parameters

Figure 1 shows the key parameters required for computing anomalous gravity. The relevant gravity quantities for geophysical applications are:

- Gravity measured at the point P, g_P
- Normal gravity on the surface of the reference ellipsoid, γ
- A model or predicted gravity value at the measurement point P, γ_P, derived from γ

The elevation of the point P is also required to account for the decrease in gravity with increasing elevation and the gravity effect of the mass of rock between the measurement point and the reference ellipsoid. Two height quantities need to be considered (Figure 1). The height of the point P above the geoid, H, is measured along a plumb line, a curved line that is perpendicular to equipotential surfaces (the geoid is the equipotential surface that most closely approximates mean sea level – see *Geoid Determination, Theory and Principles*). The ellipsoidal height, h,



Gravity, Data to Anomalies, Figure 1 Diagram illustrating the key parameters required for computing geophysical gravity anomalies.

is measured along an ellipsoidal normal, the line through P that is perpendicular to the surface of the reference ellipsoid. When computed algebraically (i.e., disregarding the vector nature of gravity), the difference between h and H gives the geoid–ellipsoid separation, N, where

$$N = h - H. \quad (1)$$

Observed gravity

The measured value of gravity at a point P is the value typically determined from relative gravity measurements that are converted to an observed value by tying to an international network of reference gravity stations, currently the International Gravity Standardization Network of 1971 (IGSN71: Morelli et al., 1974). Country-specific datums may also be used (e.g., Tracey et al., 2007), but these are also generally tied to IGSN71. The relative measurements may be made on land or at sea (see *Gravity Method, Surface*) or even in the air (see *Gravity Method, Airborne*). The relative measurements will have been corrected for instrument drift and Earth tide variations (see *Gravity Method, Surface*).

Anomalous gravity in geophysics

An anomaly is the difference between something that we measure at a particular place and what we expect from a reference model at that place. In seismology, measured travel times are compared to those expected from simplified models of the whole Earth (see *Seismic Tomography*). The resulting travel-time anomalies tell us about regions through which seismic waves travel faster or slower than through the simplified representation of reality. This in turn tells us something about the temperature or composition of the Earth's interior. In geophysical applications, gravity anomalies are best thought of in a similar way: Measurements of the gravity field at the Earth's surface are compared to the gravity expected from a reference model of the Earth. The differences in gravity between our measurements and the reference model tell us something about lateral mass-density variations within the Earth.

In this context, a geophysicist generally seeks to remove large-scale, non-geological gravity effects that mask the gravity anomalies that can be related to subsurface density variations (e.g., related to ore deposits, sedimentary basins, or crustal structure). The large-scale effects include Earth mass and rotation and, depending on the application, maybe some or all of the crust and mantle. Most of the large-scale effect is accounted for by normal gravity, the acceleration due to gravity on the surface of a reference ellipsoid, an ellipsoid of rotation that best fits the shape of the Earth (represented by the geoid – see *Geodesy, Figure of the Earth*).

If a model value is required at a point that does not lie on the surface of the reference ellipsoid, adjustments must be made to normal gravity to account for gravity effects related to (a) the difference in height between the measurement point and the surface of the reference ellipsoid (because gravity decreases with distance from the Earth proportionally to $1/r^2$) and (b) the body of rock (or water) lying between the measurement point and the reference ellipsoid. Other regional-scale gravity effects that arise from crustal structure might also be removed by a process of regional–residual field separation (see *Gravity Data, Regional – Residual Separation*) or filtering (see *Gravity Data, Advanced Processing*).

In the geophysical context, anomalous gravity is calculated by subtracting a predicted or model gravity value for a point P from the measured (observed) gravity at that point. This anomalous gravity quantity is technically referred to as a gravity disturbance (cf. Hackney and Featherstone, 2003), but the use of gravity "anomaly" is and will likely remain entrenched in the geophysical vernacular. In a geophysical sense, a gravity anomaly can be expressed as

$$\textit{Gravity anomaly} = (\textit{Measured value}) - (\textit{Model value}),$$

or mathematically as:

$$\Delta g_P = g_P - \gamma_P \quad (2)$$

where

- Δg_P is the anomalous gravity
- g_P is measured gravity at the point P
- γ_P is a predicted or model value of gravity *at the measurement point P* (our best estimate of the Earth's gravity field at P that considers Earth's mass and rotation and the elevation, h, of the point P with respect to the reference ellipsoid)

As illustrated in Figure 2, the predicted gravity value, γ_P, is computed by applying corrections to normal gravity that account for the height of the measurement point above the reference ellipsoid (free-air correction) and the mass of rock that lies between the measurement point and the reference ellipsoid (Bouguer and terrain corrections). Mathematically, the computation of γ_P can be expressed as:

$$\gamma_P = \gamma - \delta g_F + \delta g_B - \delta g_T \quad (3)$$

where

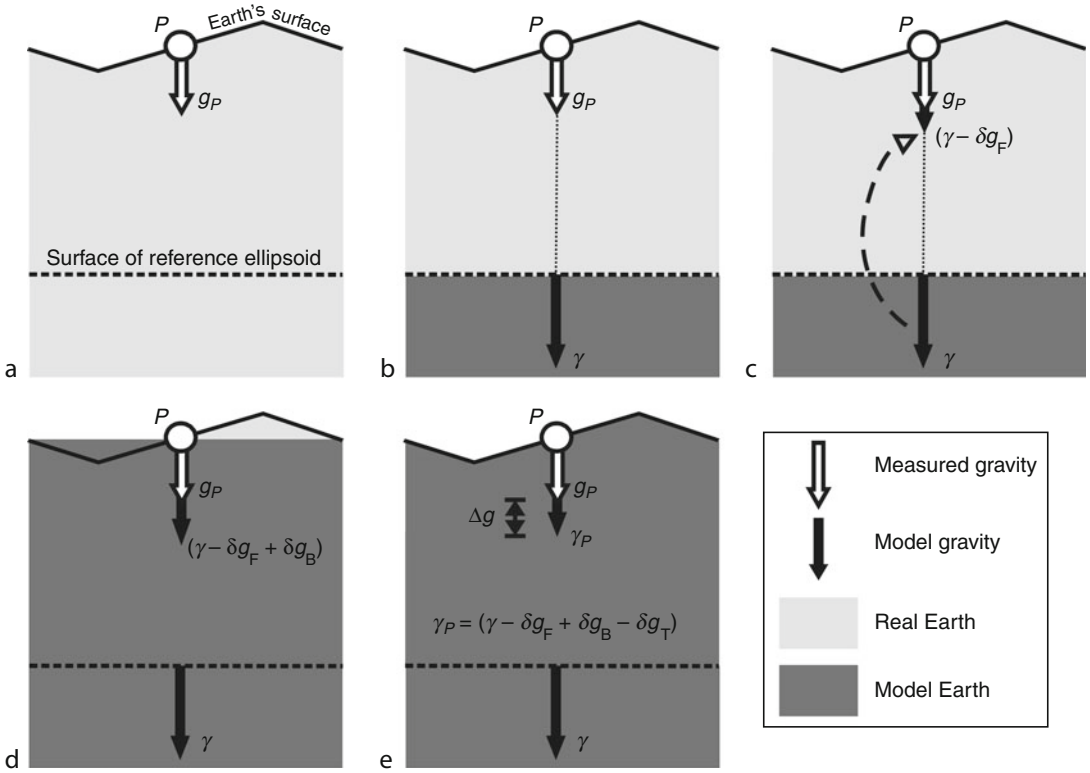
- γ is normal gravity on the reference ellipsoid
- δg_{F} is the free-air correction
- δg_{B} the Bouguer correction
- δg_{T} the terrain correction

The application of these corrections is described in the following section.

Computing model gravity at the measurement point

A note on units

The standard SI unit of acceleration due to gravity is $\mathrm{m{\cdot}s^{-2}}$. However, because gravity anomalies are generally about 3–7 orders of magnitude smaller than total gravity acceleration, the use of derivative units is more practical.



Gravity, Data to Anomalies, Figure 2 Illustration of the process of computing anomalous gravity in geophysics. (**a**) Observed gravity g_P reflects mass below the Earth's surface (*light gray shading*). (**b**) Normal gravity, γ, considers only mass below the reference ellipsoid (*dark gray shading*). (**c**) The free-air correction, δg_F, accounts for the elevation difference between the point *P* and the surface of the reference ellipsoid, but not the rock mass in that space. (**d**) The Bouguer correction, δg_B, adds the gravity effect of rock mass between *P* and the surface of the reference ellipsoid, but assumes that rock mass has a smooth upper surface. (**e**) The terrain correction, δg_T, corrects for the smooth-topped Bouguer plate or cap.

Historically, the mGal was the standard derivative unit (1 mGal = 10^{-5} m·s^{-2}). The mGal is still in common use, but gravity anomalies and related quantities are often also given in μm·s^{-2} (10^{-6} m·s^{-2}). In this description of the anomaly computation procedure, physical constants are given in standard SI units. This means that unless otherwise stated, the equations presented give quantities in m·s^{-2}.

Normal gravity (Figure 2b)

Normal gravity, γ, represents the gravity effect of a reference ellipsoid whose geometry is defined to best represent the shape of the Earth. Because an ellipsoid is a mathematically defined body, computing its gravity effect is straightforward. A closed-form expression for computing normal gravity on the surface of a *geocentric* reference ellipsoid is given by the Somigliana–Pizetti formula (e.g., Hofmann-Wellenhof and Moritz, 2006; see also *International Gravity Formula*):

$$\gamma = \gamma_a \frac{1 + k\sin^2\phi}{\sqrt{1 - e^2\sin^2\phi}}, \tag{4}$$

where γ_a is normal gravity at the equator of the reference ellipsoid, ϕ is the *geocentric* latitude of the measurement point, and k and e^2 are quantities derived from the parameters describing the form of the reference ellipsoid (Table 1).

Equation 4 is exact and has now been adopted in many countries as a standard when computing gravity anomalies for geophysical applications (e.g., Hinze et al., 2005; Tracey et al., 2007). In the past, simpler expressions were used for computing normal gravity (cf. Li and Götze, 2001). These approximate formulae were used largely for computational convenience, but given the measurement accuracy achievable today, their continued use is difficult to justify.

Free-air correction (Figure 2c)

Equation 4 gives normal gravity on the surface of the reference ellipsoid. However, the measurement point *P* is almost never located exactly on the surface of the reference ellipsoid. This means that the model value at a measurement point above the reference ellipsoid will be less than γ. The decrease in gravity above the reference ellipsoid is accounted for by the free-air correction. This

Gravity, Data to Anomalies, Table 1 Parameters defining the GRS80 geocentric reference ellipsoid (Moritz, 2000), the reference ellipsoid currently recommended by the International Union of Geodesy and Geophysics as representing the size, shape, and gravity field of the Earth with an accuracy sufficient for most geodetic, geophysical, astronomical, and hydrographic applications. Note that the parameters a, GM, J_2, and ω are exact defining parameters – the other parameters are derived geometric and physical constants

Parameter	Name	Equation	GRS80 value
a	Semi-major axis (equatorial radius)		6,378,137 m
GM	Geocentric gravitational constant		$3{,}986{,}005 \times 10^8$ m^3·s^{-2}
J_2	Dynamic form factor		$108{,}263 \times 10^{-8}$
ω	Angular velocity		$7{,}292{,}115 \times 10^{-11}$ rad·s^{-1}
b	Semi-minor axis (polar radius)		6,356,752.3141 m
γ_a	Equatorial normal gravity		9.780 326 7715 m·s^{-2}
γ_b	Polar normal gravity		9.832 186 3685 m·s^{-2}
k	Normal gravity constant	$(b\gamma_b/a\gamma_a) - 1$	0.001 931 851 353
e^2	First numerical eccentricity	$(a^2 - b^2)/a^2$	0.006 694 380 022 90
f	Ellipsoidal flattening	$(a - b)/a$	0.003 352 810 681 18
m	Geodetic parameter	$\omega^2 a^2 b/GM$	0.003 449 786 003 08
R_E	Arithmetic mean Earth radius	$(2a + b)/3$	6,371,008.7714 m

correction essentially uses the rate of change in gravity above the surface of the Earth to correct for the decrease in gravity with elevation.

Historically, the value of the free-air correction was approximated as 0.3086×10^{-5} m·s^{-2}/m (i.e., 0.3086 mGal/m), the gravity gradient above a spherical Earth. A more rigorous expression for the free-air correction, δg_F, can be derived from the gradient of normal gravity above the surface of the reference ellipsoid. Normal gravity at a height h above the ellipsoid can be computed directly from (Hofmann-Wellenhof and Moritz, 2006):

$$\gamma_h = \gamma\left[1 - \frac{2}{a}\left(1 + f + m - 2f\sin^2\phi\right)h + \frac{3}{a^2}h^2\right], \quad (5)$$

or the magnitude of the free-air correction, δg_F, to be subtracted from γ can be computed using

$$\delta g_F = \frac{2\gamma_a}{a}\left(1 + f + m + \left(-3f + \frac{5}{2}m\right)\sin^2\phi\right)h - \frac{3\gamma_a}{a^2}h^2. \quad (6)$$

The parameters f (ellipsoidal flattening) and m (geodetic parameter) are defined in Table 1.

Bouguer correction (Figure 2d)

Once normal gravity is corrected for the vertical separation between the reference ellipsoid and the measurement point, a further adjustment needs to be made for the body of rock between that point and the reference ellipsoid. The gravity effect of this rock is not represented in normal gravity and is not accounted for by the free-air correction. This correction, the Bouguer correction, δg_B, was historically computed by representing the body of rock between the measurement point and surface of the reference ellipsoid as a horizontal slab extending to infinity. The infinite-slab Bouguer correction is given by:

$$\delta g_B = 2\pi G\rho t \quad (7)$$

where ρ is the assumed density of the slab, t is the thickness of the slab, and G is the universal gravitational constant (6.67428×10^{-11} m^3·kg^{-1}·s^{-2}, the 2006 value recommended by the Committee on Data for Science and Technology, International Council of Science). In most cases, the slab thickness is equivalent to the height of the measurement point above the reference ellipsoid, h. The density of the slab generally takes on a standardized value of 2,670 kg·m^{-3}, a value that closely represents the average density of crustal rocks (Hinze, 2003). In some cases, a density that is more representative of local geology may be used to minimize the correlation between the Bouguer anomaly and topography. However, using standardized values facilitates the comparison of different datasets and avoids incorporating geological interpretation into the anomaly computation procedure (LaFehr, 1991a).

More sophisticated representations of the rock mass below the measurement point take into account the curvature of the Earth's surface. A commonly used representation is the spherical cap, the gravity effect of which is given by (LaFehr, 1991b):

$$\delta g_B^{cap} = 2\pi G\rho[\mu t - \lambda(R_E + t)] \quad (8)$$

where R_E is the mean radius of the reference ellipsoid (Table 1), t the thickness of the cap (generally equivalent to the height of the measurement point above the reference ellipsoid, h), and μ and λ are dimensionless coefficients related to R_E and the angle subtended by the spherical cap at the center of the Earth. The spherical cap is generally taken to extend to a distance of 166.735 km from the measurement point, the distance originally selected by Bullard (1936) to minimize the difference between the gravity effect of the spherical cap and the infinite slab

for a range of elevations (cf. LaFehr, 1991b). Equation 8 is valid for surveys made on land, but Argast et al. (2009) present an extended form of the equation that is valid for gravity measurements made in the air and at sea.

Terrain correction (Figure 2e)

Regardless of whether the Bouguer correction is computed from an infinite slab or from a spherical cap, it is computed for a body with a flat or curved top that does not match topography. Topographic variations can have a significant influence on measured gravity, particularly in areas of high relief (e.g., mountain ranges or near the continental slope). For this reason, it is often beneficial to compute a terrain correction that effectively imparts an irregular surface onto the top of the Bouguer plate or cap.

Various methods exist for computing the terrain correction (cf. Nowell, 1999; Hackney and Featherstone, 2003), but the methods generally involve dividing the region around the measurement point into a series of rectangular prisms or concentric ring segments. A digital elevation model is then used to determine the average elevation for each prism relative to the height of the measurement point. Accuracy can be improved by using prisms with sloping tops. The size of the prisms is generally increased away from the measurement point as the influence of distant prisms is less than for nearer prisms. To further simplify computations, some methods approximate the more distant prisms as a line mass and fast-Fourier transform techniques have also been developed.

Often the different methods for computing terrain corrections are combined. For example, Hinze et al. (2005) describe the procedure adopted for the North American gravity database that uses segmented rings and estimated topography within 100 m of the measurements point, segmented rings and high-resolution digital elevation data from 100 to 895 m, and vertical prisms and digital elevation data from 895 m to 166.7 km (including corrections for Earth curvature beyond 14 km).

Historically, the most commonly used terrain correction procedure was based on computing the gravity effect of a number of concentric rings divided into individual segments (Hammer, 1939). The gravity effect of each prism can be computed from:

$$\delta g_{\text{prism}} = 2\pi G\frac{\rho}{n}\left(r_2 - r_1 + \sqrt{r_1^2+z^2} - \sqrt{r_2^2+z^2}\right) \quad (9)$$

where n is the number of prism segments in each concentric ring (zone), r_2 is the outer radius of the concentric ring, r_1 the inner radius, and z is the elevation difference between the measurement point and the mean elevation of the ring segment. The other parameters are the same as in Equations 6 and 7. The density, ρ, used in Equation 9 should be the same as that used for the Bouguer correction.

The Hammer (1939) formulation includes concentric rings out to a distance of 22 km, but ideally terrain corrections should be computed out to 166.735 km (~1.5°), the full radius of the standard spherical cap. When terrain corrections are computed to this distance, Earth curvature must also be considered. However, the influence of terrain corrections beyond about 10–20 km from the station is often insignificant and sometimes ignored.

Anomaly computation

Once the free-air, Bouguer, and terrain corrections are applied to normal gravity, the gravity anomaly at the point P can be computed from Equations 2 and 3, i.e.,

$$\begin{aligned}\Delta g &= g_P - \gamma_P \\ &= g_P - (\gamma - \delta g_{\text{F}} + \delta g_{\text{B}} - \delta g_{\text{T}}) \\ &= g_P - (\gamma_h + \delta g_{\text{B}} - \delta g_{\text{T}})\end{aligned} \quad (10)$$

In Equation 10, the term in brackets represents the predicted or model value of gravity at the measurement point. The free-air correction is subtracted because normal gravity is reduced above the surface of the ellipsoid (Figure 2c), while the Bouguer correction is added because the extra gravity effect related to the body of rock between P and the reference ellipsoid is not included in γ (Figure 2d). The terrain correction must be subtracted from γ (Figure 2e) to remove the effect of the non-existent slab/cap mass assumed to fill valleys and to reduce the model valley of gravity for topography higher than the measurement point (mass above the measurement point reduces gravity).

Once the model value of gravity is subtracted from the measured value of gravity at P, the remaining quantity is the anomalous component of the gravity field that cannot be explained by large-scale gravity effects related to the Earth's shape and rotation, changes in gravity with elevation, and the bulk influence of rock below the measurement point. The resulting anomalous gravity reflects subsurface density variations and can be interpreted geologically (see *Gravity Anomalies, Interpretation*; *Gravity Modeling, Theory and Computation*).

Other factors

Atmospheric correction

The parameters that define the GRS80 reference ellipsoid (Table 1) rely on satellite-based measurements, meaning that normal gravity includes the mass of the atmosphere. The application of a correction to normal gravity for the atmospheric mass is usually insignificant in comparison to errors associated with terrain corrections, meaning that its application is not essential for many geophysical applications (e.g., Featherstone and Dentith, 1997). Nevertheless, the application of an atmospheric correction is included in new standards for gravity anomaly computation (e.g., Hinze et al., 2005; Tracey et al., 2007). If it is to be applied, the value to be subtracted from normal gravity can be computed using (Wenzel, 1985)

$$\delta g_{\text{A}} = 0.874 - 9.9\times10^{-5}h + 3.56\times10^{-9}h^2. \quad (11)$$

This equation has an accuracy of about 0.01×10^{-5} $m \cdot s^{-2}$ to 10 km elevation.

Further isolating anomalies of interest

The Bouguer anomaly computed using Equation 10 is dominated by the gravity effect of crustal-thickness variations that more-or-less isostatically compensate for topography (thick crust under mountains, thin crust under ocean basins – see *Isostasy*). While the Bouguer anomaly is useful for constraining crustal-scale studies, the gravity effect of smaller-scale density variations within the upper crust (e.g., ore deposits or sedimentary basins) is often obscured by the long-wavelength gravity signature related to crustal-thickness variations.

The long-wavelength component of the Bouguer anomaly can be removed using regional–residual field separation techniques (see *Gravity Data, Regional – Residual Separation*). Alternatively, some form of isostatic compensation can be assumed (see *Isostasy*) and the gravity effect of the Moho that compensates for topography can be computed and subsequently subtracted.

Distant relief

Computation of the Bouguer correction and associated terrain corrections are generally made out to a standard distance of 166.735 km. In certain circumstances, the gravity effect of topography beyond this distance can be significant (e.g., surveys in areas of high topography and continental- and global-scale studies: LaFehr, 1991a; Mikuška et al., 2006). Users of gravity data should be aware of these distant relief effects and consider them if necessary.

Efforts to include the effects of whole-Earth topography are emerging. For example, Kuhn et al. (2009) present a grid of terrain corrections for the Australian continent that considers topography globally and Tenzer et al. (2009) computed gravity anomalies for the entire Earth that incorporate corrections for global topography.

The geophysical "indirect effect"

The formulation for anomalous gravity described here (Equation 2) is the most logical way in which to think of gravity anomalies for geophysical applications. However, the process of anomaly computation is often described as a reduction of g_P to the sea level datum. While this process is useful in geodesy, it is not strictly correct in geophysical applications (Hackney and Featherstone, 2003).

The misconception that gravity anomaly computation for geophysical purposes involves reducing gravity measurements to the geoid (or sea level) is partly related to the measurement of elevation. Before the advent of GPS (see *GPS, Data Acquisition and Analysis*), elevations were normally determined by leveling over long traverses from reference tide gauges at the coastline (see *Geodesy, Ground Positioning and Leveling*). Leveling thus provided heights relative to sea level, or the geoid. However, normal gravity is derived from a mathematically defined body, the reference ellipsoid, which does not coincide exactly with the geoid.

The reference ellipsoid is generally chosen to best fit the geoid either regionally or globally, but the ellipsoid never perfectly matches the geoid. This means that if heights relative to sea level are used to compute anomalous gravity, then the corrections applied will either be an under- or over-correction, depending on whether the ellipsoid is above or below the geoid (Figure 3). The magnitude of this under- or overcorrection is referred to as the *geophysical indirect effect* (e.g., Hackney and Featherstone, 2003). Globally, the geoid–ellipsoid separation is about ± 100 m at most, meaning that the geophysical indirect effect varies by about $\pm 30 \times 10^{-5}$ $m \cdot s^{-2}$. This variation can induce long-wavelength errors in gravity data, especially in areas of high geoid gradient. For more regional surveys, the effect is generally minor and, in many cases, essentially constant. For regional surveys, the geophysical indirect effect is a bias that will often be accounted for during regional–residual field separation.

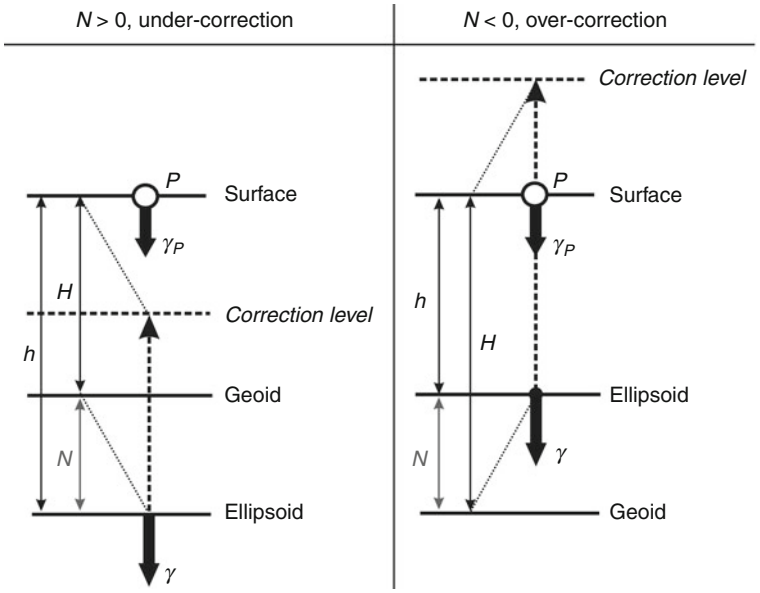
With the advent of GPS, elevations tied directly to the WGS84 ellipsoid became readily available. Because the differences in the dimensions of the WGS84 and GRS80 ellipsoids are minor, anomalous gravity can be computed directly from the heights measured by GPS. However, care is required in order to ensure that consistent heights are used for both older and newer datasets. Updated procedures adopted in some countries recognize the need to use heights tied to the reference ellipsoid (e.g., Hinze et al., 2005; Tracey et al., 2007).

Gravity anomalies for geodetic purposes

This entry focuses on the geophysical approach to computation of gravity anomalies, but it is worth outlining the ways in which gravity anomalies are computed for geodetic purposes. In geodesy (see *Geodesy, Physical* and *Geoid, Computational Method*), gravity anomalies are used to determine the shape of the Earth using either a "classical" or "modern" approach (e.g., Hofmann-Wellenhof and Moritz, 2006). In the classical approach, the geoid is determined using gravity anomalies computed from the difference between surface gravity measurements reduced (downward) to the geoid and normal gravity on the reference ellipsoid. The modern approach leads to the computation of a surface referred to as the telluroid and requires gravity anomalies computed from the difference between surface gravity and normal gravity corrected (upward) to the telluroid. The separation between the telluroid and the surface (the "height anomaly") can then be used to determine a geoid-proxy referred to as the quasigeoid.

Computation example: the Central Andes

The Central Andes in South America are an ideal region to illustrate the process of computing anomalous gravity for geophysical purposes. This is because the high topography and associated thick crust lead to large corrections



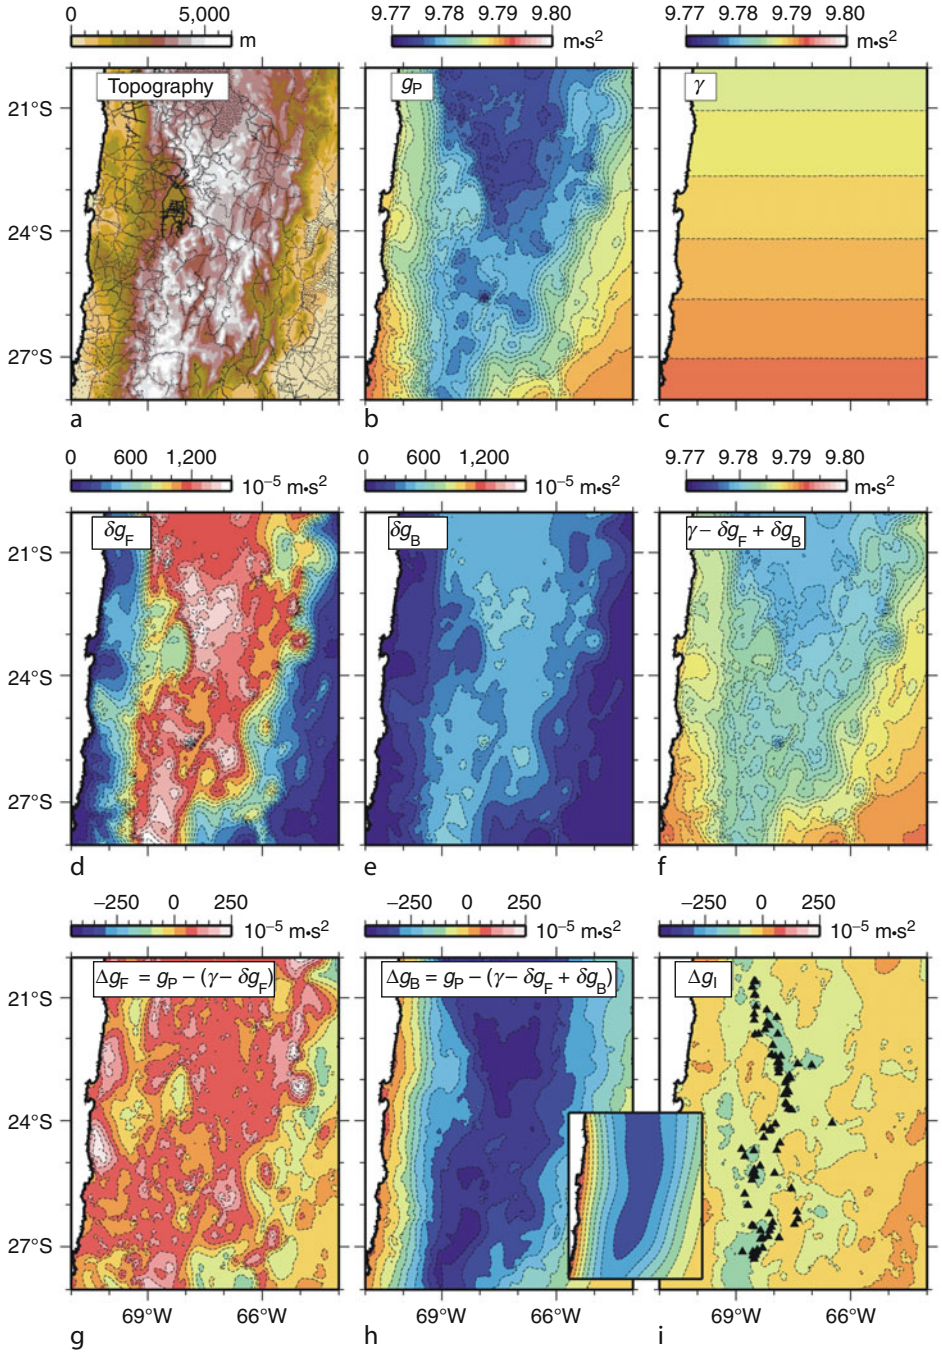
Gravity, Data to Anomalies, Figure 3 Illustration of the under- or over-correction of model predicted gravity that results when the free-air and Bouguer corrections are computed using heights relative to mean sea level (geoid) rather than relative to the reference ellipsoid. *N* is defined by Equation 1.

and high-amplitude gravity anomalies. Observed gravity and the different types of corrections, model values, and anomalies for the Central Andes are illustrated in Figure 4. The gridded data shown in Figure 4 are based on a dataset that contains more than 4,000 surface gravity measurements (Schmidt and Götze, 2006) (Figure 4a). Figure 4b shows the observed (measured) values of gravity, g_P, that are tied to reference stations linked to the IGSN71 gravity datum. Observed gravity values are large (9.773–9.796 $m{\cdot}s^{-2}$) and the highest parts of the Central Andes are associated with the lowest measured gravity. This is due mostly to the pronounced decrease in gravity with elevation, but the mass deficit associated with the thick, low density crust (with respect to the underlying mantle) also contributes to the decreased gravity in the mountainous areas.

Normal gravity on the GRS80 reference ellipsoid (Equation 4 and Figure 4c) shows a north-to-south increasing trend that reflects the pole-ward increase in gravity related to the shape and rotation of the reference ellipsoid. To derive a model value directly at each of the data points shown in Figure 4a, free-air (Equation 6) and Bouguer (Equation 7 or 8) corrections are applied to normal gravity. The magnitude of the free-air correction, δg_F, is shown in Figure 4d – the correction is largest where topography is highest. The free-air correction is subtracted from normal gravity to account for the decrease in normal gravity with elevation above the reference ellipsoid. The free-air anomaly results when the height-corrected normal gravity is subtracted from observed gravity (Figure 4g). Compared to observed gravity, the amplitude range of the free-air anomaly is significantly reduced ($\pm 300 \times 10^{-5}$ $m{\cdot}s^{-2}$).

A map of free-air anomalies (Figure 4g) is difficult to interpret geologically because it retains a strong correlation with topography. This correlation is modified when the gravity effect of the rock between the surface and the reference ellipsoid is accounted for using the Bouguer correction (Figure 4e). The Bouguer correction is added to normal gravity (because normal gravity does not include the gravity effect of the rocks) and, together with the addition of the free-air correction, results in a model value, γ_P, that resembles the observed gravity (Figure 4f). When this model value is subtracted from the observed gravity, the Bouguer anomaly results (Figure 4h). The Bouguer anomaly of the Central Andes is large and negative (minimum values reach about -450×10^{-5} $m{\cdot}s^{-2}$), which reflects the thick crustal root beneath the Central Andes.

An isostatic residual gravity map is shown for the Central Andes in Figure 4i. The regional field (inset between Figure 4h, i) is computed by assuming regional isostatic compensation of topography using an effective elastic thickness of 20 km (see *Isostasy*). Crustal thickness is computed for this model and then the gravity effect of the isostatic Moho is estimated and subtracted from the Bouguer anomaly. The Central Andean isostatic residual field has a vastly reduced amplitude (-150 to $+ 60 \times 10^{-5}$ $m{\cdot}s^{-2}$) and bears a closer resemblance to surface geology, particularly the location of active volcanoes. The coincidence between active volcanoes and negative isostatic residual anomalies suggests the presence of low-density material within the crust or that the assumption of regional isostatic compensation is not applicable to the volcanic chain.



Gravity, Data to Anomalies, Figure 4 Illustration of the various components of anomalous gravity for the Central Andes in South America. (**a**) Topography from the GTOPO30 global digital elevation model – points show the location of gravity measurements (Schmidt and Götze, 2006) where the various corrections are computed and gridded using a cell size of one arc minute; (**b**) observed gravity; (**c**) normal gravity on the surface of the GRS80 reference ellipsoid computed using Equation 4 – note the latitudinal variation; (**d**) the magnitude of the free-air correction that is subtracted from normal gravity to account for the reduction in normal gravity above the reference ellipsoid; (**e**) the Bouguer correction that represents the gravity effect of the mass of rock between the surface and the reference ellipsoid; (**f**) model value for gravity at the surface that is subtracted from the observed gravity shown in b to produce the Bouguer anomaly; (**g**) the free-air anomaly; (**h**) the Bouguer anomaly (map in **b** minus map in **f**); (**i**) isostatic residual anomaly, δg_I, computed by subtracting from the Bouguer anomaly an isostatic regional field (inset between **h** and **i**) computed by assuming regional isostatic compensation of Andean topography with an elastic thickness of 20 km. The triangles in (**i**) show active volcanoes (Trumbull et al., 2006). Note that the Bouguer anomaly in (**h**) does not incorporate a terrain correction, but when plotted at this scale, the effect of the terrain correction is not evident.

Summary

From a geophysical perspective, a gravity anomaly is best thought of as the difference between measured gravity and a model value, at the same point, that accounts for large-scale, non-geological effects that mask anomalies related to subsurface geology. The model gravity value is derived by correcting normal gravity for the effects of height above the reference ellipsoid (free-air correction) and the mass of rock between the reference ellipsoid and the measurement point (Bouguer correction). Additional corrections (terrain and atmospheric corrections, indirect effect) improve on the relatively straightforward free-air and Bouguer corrections. Since the earliest use of gravity data, our ability to compute the corrections to normal gravity has improved to the point where simplistic application of the corrections is giving way to procedures that consider global influences.

Depending on the application, long-wavelength field components remaining in the Bouguer anomaly may also be removed (isostatic correction or regional–residual field separation). Gravity anomalies can then be used to constrain geological interpretations of relatively shallow crustal features (e.g., basins, ore bodies, or even archeological sites), or be used to examine crustal structure and isostatic state.

Definition

A *Global Gravitational Model* (GGM) is a mathematical approximation to the external gravitational potential of an attracting body.
Gravitation is the term used to describe the potential generated by the masses of an attracting body like the Earth.
Gravity is the term used for the potential of gravitation plus the centrifugal potential due to the rotation of the attracting body.

Global gravitational models

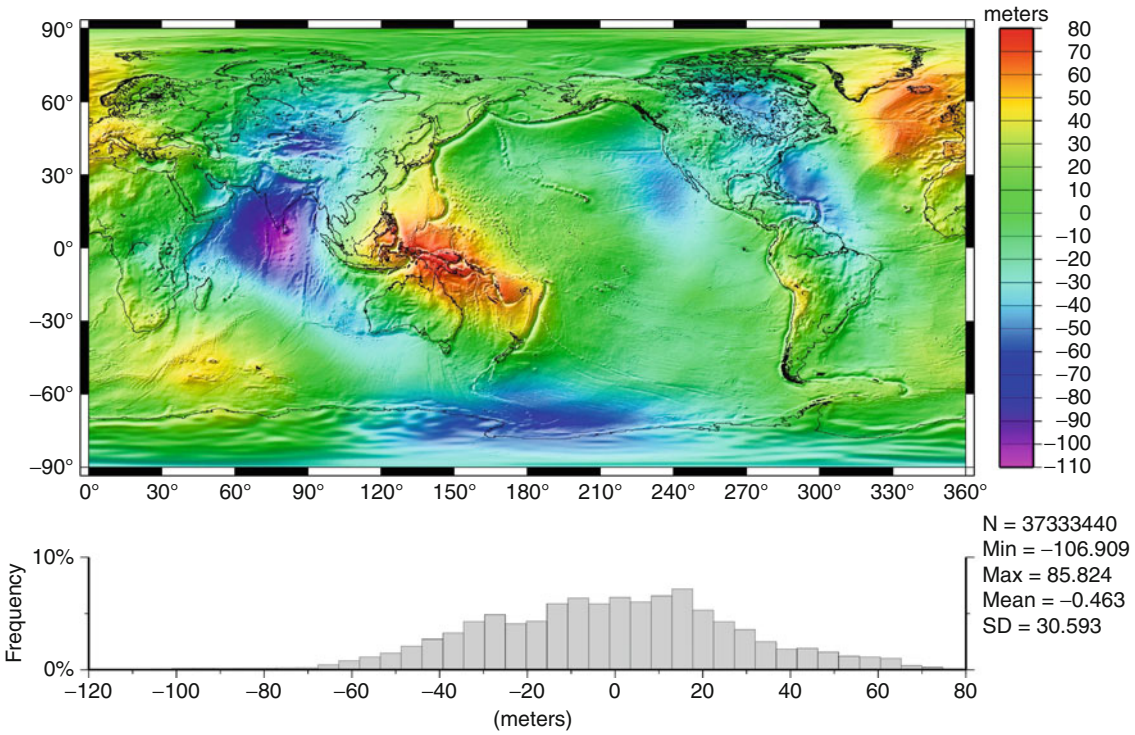
Introduction

A GGM is a mathematical approximation to the external gravitational potential of an attracting body. We will focus here on the case where the attracting body is the Earth, although many of the concepts that we discuss apply equally well to other planets and celestial bodies. In its most complete and general form, a GGM consists of a set of numerical values for certain parameters, the statistics of the errors associated with these values (as described, e.g., by their error variance-covariance matrix), and a collection of mathematical expressions and algorithms that allow a user to perform:

1. *Synthesis*, that is, computation of the numerical values of quantities related to the gravitational potential (*functionals* of the gravitational field), given the position of the evaluation point.
2. *Error Propagation*, that is, computation of the expected errors of the computed functionals, as implied by the propagation of the errors of the parameters defining the GGM.

A GGM must be able to support such computations at arbitrary points, located on or above the Earth's surface, in a fashion that is both rigorous and efficient. In addition, a GGM should fulfill certain conditions stemming from the underlying physics. Namely, it should represent a scalar function of position that is harmonic outside the attracting masses and vanishes at infinity as the reciprocal of the distance between attracted point and attracting mass element. Moreover, the GGM should permit the computation of any functional of the field in a way that guarantees *self-consistency*. This means that the model should preserve the relationships (differential or integral) between the various functionals. A GGM has numerous uses, both operational and scientific (see also [Tscherning, 1983]), including:

1. Orbit determination applications necessary for space surveillance (the detection, tracking, and orbit prediction of Earth-orbiting objects).
2. Inertial navigation applications for trajectory determination of airplanes and missiles.
3. *Geoid* determination. The geoid is one of the infinitely many *level* (or *equipotential*) surfaces of the gravity field of the Earth, that is, the gravity potential is constant at every point on the geoid. The geoid is the specific equipotential surface that would coincide exactly with the mean ocean surface of the Earth, if the oceans were in equilibrium, at rest, and extended through the continents (such as with very narrow canals). Figure 1 shows the geoid surface that is implied by the EGM2008 GGM (Pavlis et al., 2008). Geoid determination allows one to transform a *geometric* (ellipsoidal) height to an *orthometric* one, that is, to an elevation referenced to an equipotential surface, as those elevations that appear on topographic maps. This application has attracted great interest in recent years, because GPS positioning and geoid determination offer the possibility of determining orthometric heights and height differences without the need for the expensive and laborious spirit leveling (Schwarz et al., 1987).
4. Oceanographic applications that require the estimation of the Dynamic Ocean Topography (DOT), an estimate of which is shown in Figure 2, and of its slopes. These quantities are directly related to ocean circulation. This application puts very stringent accuracy and resolution requirements on GGMs (Ganachaud et al., 1997).
5. An accurate and high-resolution GGM may be used to provide a reference surface – a global, high-resolution geoid surface – suitable for the realization of a global vertical datum (Rapp and Balasubramania, 1992).
6. Geophysical prospecting applications where, in combination with other information (e.g., seismic data), a GGM may provide important constraints that aid the determination of the subsurface density distribution.
7. Comparisons of the decay of the spectrum of the gravitational potential to the decay of the spectrum of the Earth's topography (Rapp, 1989).



Gravity, Global Models, Figure 1 Geoid undulations (in meters), implied by the EGM2008 Global Gravitational Model, to degree 2,160, with respect to the WGS 84 reference ellipsoid.

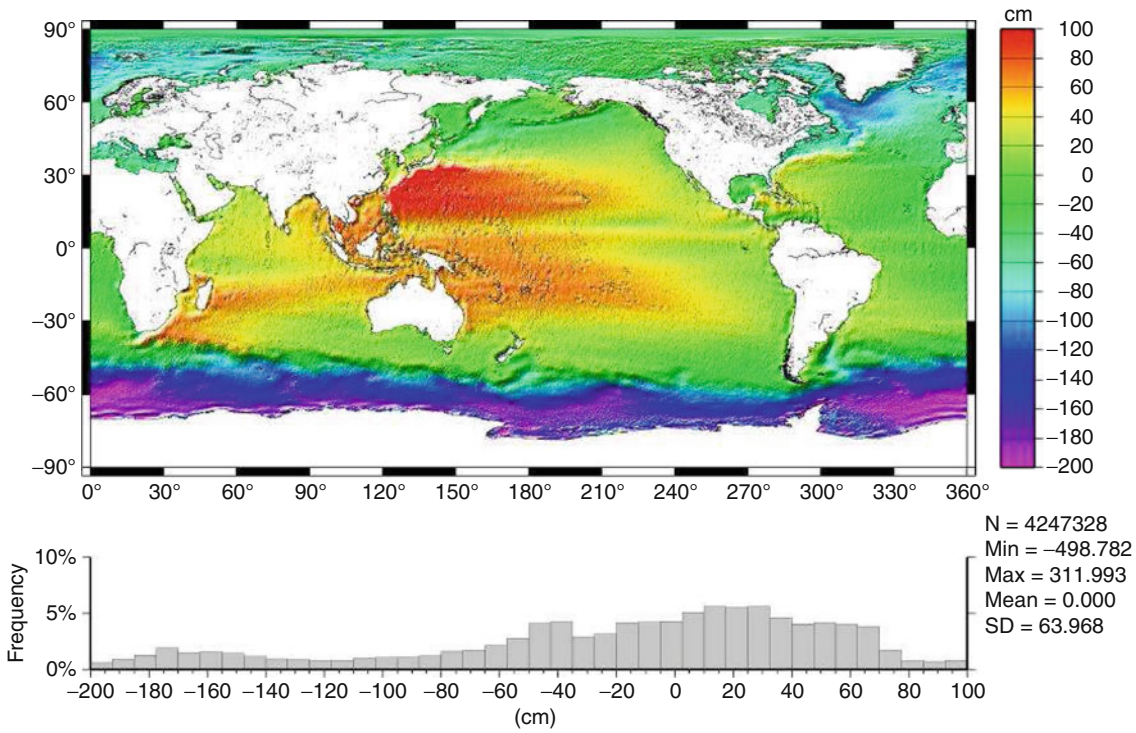
These and other applications represent integral parts of various civilian and military activities. Each of these applications has (in general) different accuracy and resolution requirements, as far as the supporting GGM is concerned. For example, due to the attenuation of the gravitational field with increasing altitude, a relatively low-resolution GGM (e.g., a *Spherical Harmonic Analysis Applied to Potential Fields* to maximum degree and order 70 or 90) is currently adequate for the precise orbit determination of most Earth-orbiting satellites. In contrast, accurate determination of the slopes of the equipotential surface (deflections of the vertical) demands a GGM of much higher resolution.

Geodesists have at various times developed "special purpose" GGMs that optimize performance for a particular application (e.g., orbit determination of a particular satellite, or geoid undulation computation over a specific geographic region). Although such "tailored" models have found some uses in the past, the ultimate goal has always been the development of a *single,* general purpose, GGM that addresses the different and diverse applications in an optimal manner, without over-performing in one application at the expense of its performance in others.

The development of a high-resolution GGM is a task that involves the optimal combination of a variety of data (satellite, land, marine, airborne). This is because a single data type with both global coverage and with uniformly high accuracy and high *spectral* sensitivity does not (yet) exist. The aforementioned data are of complementary character (in terms of spectral sensitivity and/or of geographic coverage), so that their optimal combination enables a GGM to satisfy the variety of applications described before. Comprehensive GGM solutions that combine different types of data may involve the simultaneous estimation of the parameters that describe the gravitational potential, along with parameters that describe the dynamic ocean topography, solid Earth and ocean tides, Earth orientation and tracking station position parameters, as well as a plethora of "nuisance" parameters necessary to model completely the content of certain data types (e.g., biases and delays associated with certain satellite tracking data). The result of a successful GGM development effort is a model that can be used as a *standard* for numerous applications, over a substantial period of time.

Local and regional gravimetric models

The accuracy and the resolving power of the data that were used in its development dictate the accuracy and resolution of a GGM. Geopolitical and/or proprietary data issues many times prevent the individual or the team developing a GGM from having access to *all* the existing data.



Gravity, Global Models, Figure 2 Dynamic Ocean Topography (DOT) (in centimeters), obtained by subtracting the EGM2008 geoid undulations from a Mean Sea Surface grid computed at the Danish National Space Center (DNSC). Notice the low associated with the Antarctic Circumpolar Current (ACC) and the highs associated with the Pacific Ocean gyres.

However, over some regions, data of higher accuracy and/or resolving power (e.g., geographically dense sets of gravity and elevation data) may be available to some individual(s) or may become available *after* a GGM has been developed. These data may be used in combination with the existing GGM to improve the accuracy and/or resolution of the determination of *one or more specific functionals of the field*, over the region where the detailed data became available. This local or regional "densification" can produce a specific local or regional gravimetric product or model.

Such densification has been among the favorite geodetic activities over many decades now, and represents the geodesist's way of creating a *multi-resolution* gravitational model resembling a "quilt." In effect, patches of fine detail (the *Local Gravimetric Models* – LGMs) are sewn on top of a more or less homogeneous piece of fabric (the reference GGM). The GGM is the foundation upon which any regional or local gravimetric approximation study and application is built. Geodesists do not necessarily have to reevaluate the reference GGM every time a new set of data becomes available locally. Such reevaluation is mostly warranted if new and improved satellite data become available, spanning a sufficiently long time period, and/or if new terrestrial data (of higher accuracy and/or resolution) become available over areas with substantial geographic extent.

Signal representation and data characteristics

Although geodesists have variously considered and studied the representation of the gravitational potential using *point masses* (Sünkel, 1981, 1983), *finite element* methods (Meissl, 1981; Baker, 1988), and *splines* (Sünkel, 1984; Jekeli, 2005), these approaches have seen only limited application in the representation of (especially) the "static" (i.e., the time-averaged) gravitational field of the Earth. *Spherical harmonic functions* have prevailed as the standard form used for the representation of the gravitational potential globally, from the very early days of global determinations to the present. Indeed, the set of coefficients of a *Spherical Harmonic Analysis Applied to Potential Fields* of the gravitational potential has become pretty much synonymous with a GGM.

Nerem, Jekeli, and Kaula (1995) provide a review of the gravity field determination process, including a review of global-scale modeling. Bouman (1997) provides a comprehensive "survey" of global gravity field models starting from the 1970s. Rapp (1998) provides a review of the geopotential modeling developments of

the twentieth century, which includes an extensive list of references.

The Earth's external gravitational potential, V, at a point P defined by its geocentric distance (r_P), geocentric colatitude (θ_P) (defined as 90° minus the geocentric latitude), and longitude (λ_P), can be expressed as:

$$V(r_P, \theta_P, \lambda_P) = \frac{GM}{r_P}\left[1 + \sum_{n=2}^{\infty}\left(\frac{a}{r_P}\right)^n \sum_{m=-n}^{n} C_{nm} Y_{nm}(\theta_P, \lambda_P)\right]. \quad (1)$$

GM is the geocentric gravitational constant (the product of the universal gravitational constant, G, times the mass of the Earth including its atmosphere, M) and a is a scaling factor associated with the fully normalized, unitless, spherical harmonic coefficients C_{nm} (a is usually numerically equal to the equatorial radius of an adopted mean-Earth ellipsoid). The absence of first-degree terms in Equation 1 is a consequence of placing the origin of the coordinate system at the Earth's center of mass. The *Spherical Harmonic Analysis Applied to Potential Fields* are defined as (Heiskanen and Moritz, 1967, Sect. 1–14):

$$Y_{nm}(\theta_P, \lambda_P) = \overline{P}_{n|m|}(\cos\theta_P) \cdot \begin{Bmatrix} \cos m\lambda_P \\ \sin|m|\lambda_P \end{Bmatrix} \begin{matrix} \text{if } m \geq 0 \cdot \\ \text{if } m < 0 \end{matrix} \quad (2)$$

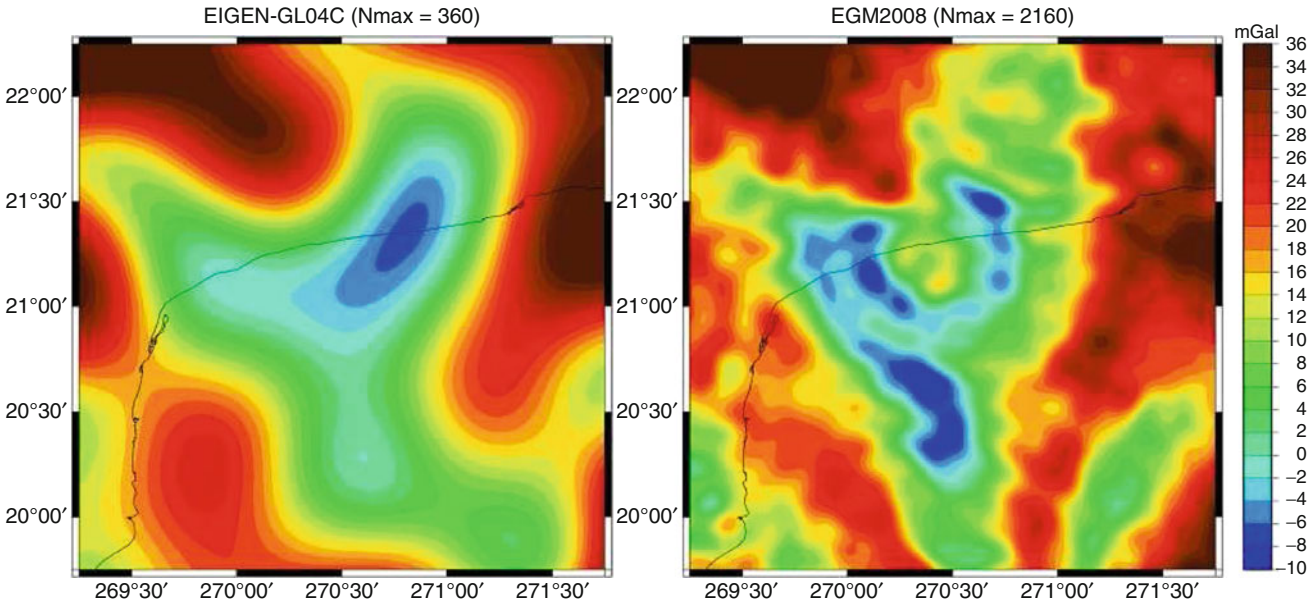
$\overline{P}_{n|m|}(\cos\theta_P)$ is the fully-normalized associated legendre function of the first kind, of degree n and order $|m|$. The normalization of the surface spherical harmonic functions Y_{nm} is such that:

$$\frac{1}{4\pi}\iint_{\sigma} Y_{nm}^2 \, d\sigma = 1, \quad (3)$$

where the integral is taken over the unit sphere σ, whose area element is $d\sigma$. In practice, the degree summation in Equation 1 is truncated to some finite degree N, which defines (approximately) the resolution of the GGM. A useful rule of thumb is that the half-wavelength linear resolution ($\lambda/2$), on the Equator, expressed in kilometers, is related to N by:

$$\lambda/2 = \frac{180^\circ}{N} \cdot 111 \quad (km). \quad (4)$$

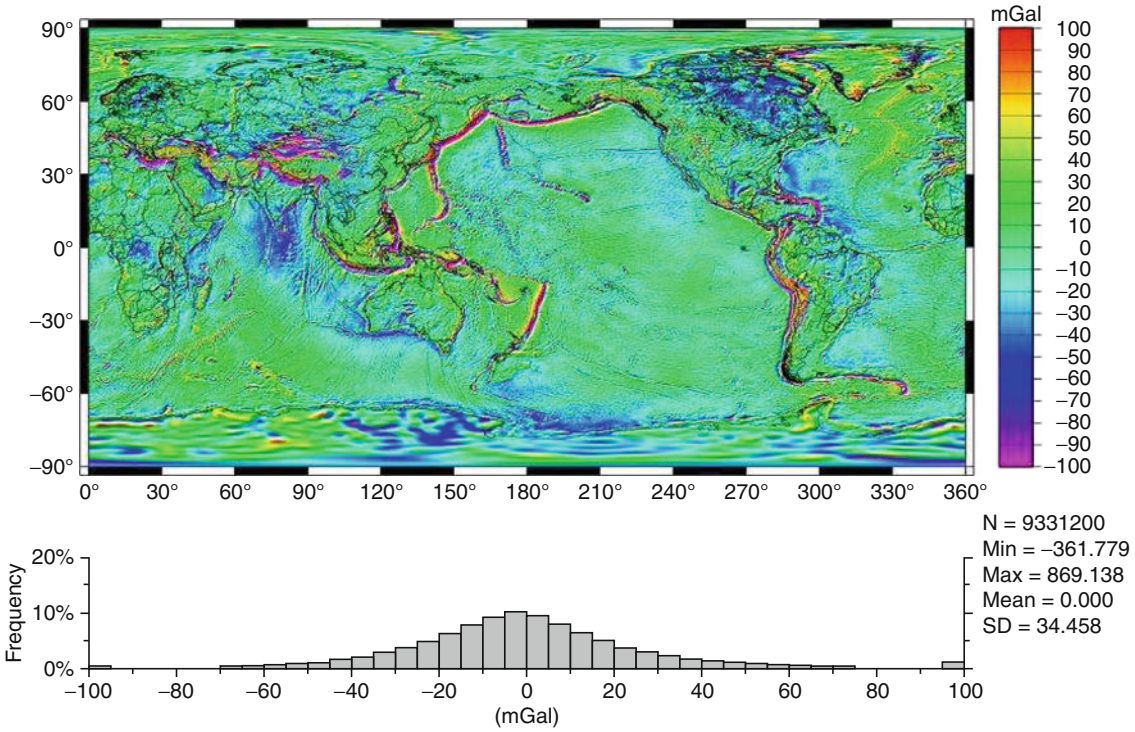
Figure 3 shows a representative example of the fine detail (high resolution) that can be captured with an expansion to degree 2,160, compared to the lower-resolution information that is retrievable using an expansion to degree 360. A spherical harmonic expansion complete to degree and order N involves $(N + 1)^2$ spherical harmonic coefficients, a number that grows rapidly as the maximum degree, and therefore the resolution of the model, increases. For example, an expansion to degree 360, as the EGM96 model involves $O(130\,\text{k})$ coefficients, while EGM2008, which extends to degree 2,160, involves



Gravity, Global Models, Figure 3 Free-air gravity anomalies (in mGal, where 1 mGal = 10^{-5} m/s^2) implied by two GGMs of different maximum degrees (different resolving powers), over the Yucatán Peninsula. EIGEN-GL04C extends to degree 360, while EGM2008 extends to degree 2,160. The Chicxulub impact crater "ring" is clearly visible in the EGM2008 gravity anomalies, but cannot be discerned in the EIGEN-GL04C gravity anomalies due to the lower resolution of this model.

approximately 4.7 million coefficients. The availability of efficient numerical algorithms for the estimation and for the subsequent use of these spherical harmonic expansions is obviously of critical importance. The goal of global high-resolution gravitational modeling is to estimate, as accurately as possible, the coefficients C_{nm}, to as high degree as possible, through the optimal combination of gravitational information from a variety of data sources. Of equal importance is the estimation of reliable error estimates for the C_{nm} values. The estimated C_{nm} values can then be used to compute functionals of the field (e.g., Geoid *undulations*, *gravity anomalies,* deflections of the vertical) while their associated errors (and error correlation when available) can be propagated to yield the errors of the derived functional(s). *Before* the dawn of the new millennium and the availability of data from the satellite missions CHAMP, GRACE, and GOCE, four kinds of gravitational information were commonly available for the development of high-degree combination gravitational models like EGM96 (Lemoine et al., 1998):

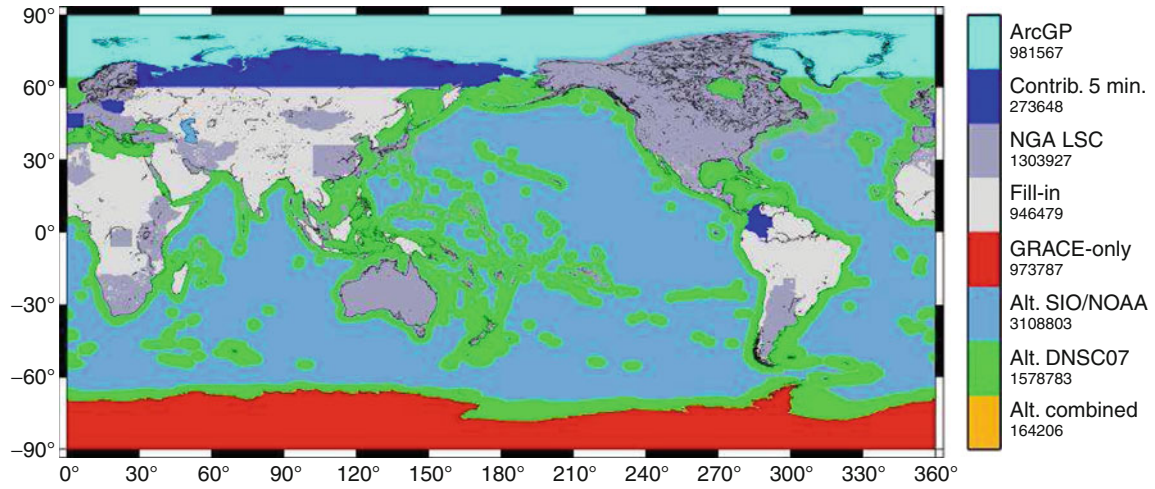
1. Gravitational information obtained from the analysis of satellite orbit perturbations that are deduced from tracking data. This is of critical importance for the accurate determination of the low degree part of the model. *Satellite-only* models have progressed from solutions to degree 4 in the early 1960s, to models complete to degree 70 or 90 available by the end of the twentieth century. These advances were made through the availability of ever more accurate tracking data acquired over a continuously expanding constellation of Earth orbiters. Tracking data from approximately 40 satellites have been used in the development of the satellite-only solution supporting EGM96 (denoted EGM96S) (Lemoine et al., 1998). These data include optical, radio Doppler and radio interferometric observations, Satellite Laser Ranging (SLR), Doppler Orbit determination and Radiopositioning Integrated on Satellite (DORIS), and Satellite-to-Satellite Tracking (SST) data from the Global Positioning System (GPS) and Tracking and Data Relay Satellite System (TDRSS) constellations to lower Earth orbiters. Despite these advances, these tracking data types are incapable of resolving the fine structure of the field due to the attenuation of the gravitational signal with altitude. Moreover, the available satellites do not sample uniformly the range of orbital inclinations and altitudes, which is a necessary condition for the de-correlation of the harmonic coefficients estimated from satellite tracking data only. This causes strong correlation especially among coefficients of higher degrees within satellite-only solutions, and necessitates the use of a priori constraints in the development of satellite-only models (Lerch et al., 1979).
2. Surface (land, marine, and airborne) gravimetric data, which are (essentially) measurements of the magnitude of the acceleration of gravity. These data are in principle capable of resolving both long and short wavelength features of the gravity field. This, however, requires uniform global coverage with dense gravity data of uniformly high accuracy. The best available data sets ca. 1996 (Kenyon and Pavlis, 1996) represent information derived from over 4,000 sources of detailed gravity data collected over several decades. The accuracy and density of point data vary substantially with geographic region, with extended regions (e.g., Antarctica) being practically void of gravity measurements. *Gravity Anomalies, Interpretation* values are the remainders after subtraction from the gravity measurements of the gravity acceleration implied by an ellipsoidal reference (normal) field (see also Figure 4). These gravity anomalies are susceptible to various systematic errors (Heck, 1990). These errors, in conjunction with the nonuniformity of coverage, degrade the long wavelength integrity of the gravitational information that can be extracted from surface gravimetry. Nevertheless, surface and airborne gravimetry presently provide the only data that can resolve short wavelength gravity features, especially over land areas. In addition, shipborne gravity measurements may aid the separation of the geoid from the DOT signal when used in combination with satellite altimetry. The processing of surface gravity data also requires accurate and high-resolution information of the Earth's topography. This information is necessary both for the preprocessing of the gravity data and for the computation of correction terms that are necessary in order to determine the geoid surface over the continents, from the estimated GGM coefficients (Rapp, 1997). It may also be used to supplement low-resolution gravitational information that may be available over certain geographic regions, with high-resolution information implied by the gravitational effects of the Earth's topography. This approach was used effectively for the development of EGM2008, as it is discussed by Pavlis et al. (2007).
3. Satellite altimeter data have enabled an unsurpassed mapping of the field over the oceans, in terms of both accuracy and resolution. TOPEX/Poseidon (T/P) (Fu et al., 1994) was the first satellite altimetry mission that routinely provided measurements of the Sea Surface Height (SSH), which were not significantly contaminated by radial orbit error (RMS radial orbit error at the ± 2 cm level). However, altimetric measurements are confined over the ocean areas bounded by the satellite's inclination, and furthermore provide a mapping of the sum of the geoid undulation (the height of the geoid surface with respect to the surface of an ellipsoid of revolution) plus the DOT. These aspects weaken somewhat the contribution of altimeter data in the determination of the long wavelength gravitational field and necessitate the appropriate modeling and estimation of the DOT when altimeter SSH data are used in combination solutions. There is, however, another way of incorporating altimeter data into a high-degree GGM, which is discussed next.



Gravity, Global Models, Figure 4 Free-air gravity anomalies (in mGal) implied by EGM2008 to degree 2,160, averaged over 5′ × 5′ cells on the surface of the Earth. These values reveal numerous geophysical features, such as oceanic trenches, ridges, subduction and fracture zones, and seamount chains. The lack of detailed data over Antarctica is also clearly evident from the smoothness of the values over this region (for the development of EGM2008, only GRACE satellite information was available over Antarctica).

4. The combination of altimeter data from multiple missions (spanning several years), some of which have produced very closely spaced ground tracks, has provided a dense sampling of most of the ocean's surface. These data, in the form of SSH and/or SSH slopes, can be used to estimate ocean-wide sets of gravity anomalies, at very fine resolution (e.g., 2′ × 2′ and even 1′ × 1′). Spatial averages of these values can be "merged" with corresponding land and airborne gravity data and gravity information obtained from models of the potential generated by the topography and its *isostatic* compensation (Pavlis and Rapp, 1990) to produce a complete global equiangular grid of gravity anomaly values. Figure 5 shows the identification of the data sources, which were used to compile the "merged" 5′ × 5′ free-air gravity anomaly data file that supported the development of EGM2008. The geometry of such a grid, in conjunction with the symmetry properties of the Legendre and the trigonometric functions, allows the applicability of very efficient harmonic analysis and *synthesis* methods (Rizos, 1979; Colombo, 1981a). These methods have revolutionized the development and use of very high-degree spherical harmonic expansions. These approaches also allow efficient combination with *satellite-only* information, as was done, for example, by Rapp and Pavlis (1990). However, incorporation of altimeter data into a GGM in this fashion requires some a priori knowledge of the DOT, so that the altimetry-derived gravity anomaly values are estimated from appropriately corrected SSH.

Satellite tracking, altimetric, and surface gravimetric data are of complimentary character both in a spectral as well as in a geographic sense. Their combination enables the determination of the gravitational field, over a wider band of its spectrum, with improved accuracy, than can be obtained by using any of the three data types alone. The particular means of combining these data, in order to develop a high-degree GGM, constitutes a solution strategy. A critical consideration in the design of a solution strategy is the treatment of altimeter data (Rapp, 1993), that is, if these data will be incorporated as in (3) or as in (4) above. OSU91A (Rapp, Wang and Pavlis, 1991) and EGM96 (Lemoine et al., 1998) represent the result of implementing a particular solution strategy, whereby altimeter data were used as in (3) for the determination of the low degree part of these models (maximum degree 50 and 70, respectively), and as in (4) for the higher degree part. The OSU89A/B models (Rapp and Pavlis, 1990) and the EGM2008 model (Pavlis et al., 2008) incorporated satellite altimeter data as in (4) above. Certain characteristics of the above data types that are particularly important for their effective combination are discussed next.



Gravity, Global Models, Figure 5 The major sources of free-air gravity anomaly data used to compile the "merged" file that supported the development of EGM2008. ArcGP stands for "Arctic Gravity Project," SIO/NOAA for "Scripps Institute of Oceanography/National Oceanic and Atmospheric Administration," which provided the major portion of the altimetry-derived gravity anomalies. Fill-in values were computed by augmenting low-resolution gravitational information, by the high-resolution gravitational information implied by the topography.

- *Information Content.* The observables within the above four categories contain information not only about the gravitational field, but also about numerous other effects. Some of these effects are of interest in their own right (e.g., the DOT information contained within altimetric SSH), while others represent, at least as far as gravitational modeling is concerned, systematic noise (e.g., the nonconservative forces acting on a satellite). In either case, effective incorporation of a particular data type into the combination solution requires precise modeling and optimal estimation of all the effects and signals contained within the observable. Otherwise, the estimated gravitational model can be severely corrupted by the mis-modeled (or unmodeled) systematic effects.
- *Spectral Sensitivity Overlap.* The development of a GGM through a *least squares adjustment* procedure combining different data types is meaningful, provided that the data used in the adjustment share some common degree of sensitivity to the gravitational signal over a certain portion of its spectrum (a range of harmonic degrees). Otherwise, there is little "adjustment" being performed to data representing disjoint spectral bands. For example, pre-GRACE satellite-only models have a narrow spectral sensitivity overlap with models recovered from surface gravity data alone. This complicated considerably the problem of optimal combination of these two data types. On the other hand, this also means that setting up and inverting extremely large linear systems corresponding to very high degree models may not be necessary, if a single data type (e.g., a complete global equiangular grid of gravity anomalies) uniquely determines the higher-degree portion of such a GGM.
- *Relative Weighting.* The optimal estimation of a GGM depends critically on the optimality of the relative weights assigned to the different data types. Considering the numerous sources of data that may be involved, this may require the solution to a very large *component of variance* estimation problem, complicated further by the fact that the extraction of gravitational information from satellite orbit observations is a strongly nonlinear problem. Although approximate solutions to this relative weight estimation problem have been used with considerable success (Lerch, 1991), many times the experience and intuition of the model developer(s) guide the selection of appropriate data weights more than anything else.

The recent gravity-mapping satellite missions

The satellite data used for the development of all GGMs published by the end of the twentieth century represent tracking of "targets of opportunity," that is, of spacecraft designed and equipped with instrumentation for applications other than the mapping of the gravitational field from space. As a result of three satellite missions, this situation has changed dramatically during the last decade. These three missions are CHAMP (Reigber et al., 1996), GRACE (GRACE, 1998), and GOCE (ESA, 1999). Table 1 summarizes the main characteristics of these missions.

A comprehensive discussion regarding the concepts involved in these three mission scenarios can be found in (ESA, 1999, Sect. 2.3). Mapping of the gravitational field from space requires missions that adhere as much as possible to the following fundamental design constraints:

Gravity, Global Models, Table 1 Main characteristics of three gravity-mapping satellite missions

Mission	Status	Orbit	Mission objective	Instrumentation, tracking, and comments
CHAMP	Launched on 7/15/2000 active	Alt. = 450 km e ≈ 0.004 i = 87°	Gravity and magnetic fields Atmospheric limb Sounding Ionosphere sounding	3-axis STAR accelerometer GPS and SLR altitude will decay from 450 km (BOL) to 300 km (EOL)
GRACE	Launched on 3/17/2002 active	Alt. = 485 km e ≈ 0.001 i = 89°	Gravity field and its temporal variation	3-axis accelerometers (1 per s/c) GPS and SLR K-band inter-satellite ranging between the 2 s/c
GOCE	Launched on 3/17/2009 active	Alt. ≈ 250 km i = 96.7° Sun-synchronous	Gravity field (Especially static)	Six 3-axis accelerometers forming the gradiometer GPS/GLONASS and SLR

- Uninterrupted tracking in three spatial dimensions.
- Measurement or compensation of the effects of nongravitational forces.
- Orbital altitude as low as possible, to enhance sensitivity to the gravitational signal, and inclination as high as possible, to permit (near) global coverage.
- Counteraction of the field's attenuation at altitude through the measurement of derivatives of the potential.

All three missions have in common the high–low Satellite-to-Satellite Tracking component (SST-*hl*) from the GPS (and GLONASS in the case of GOCE) constellation, and the measurement of nongravitational forces by the onboard accelerometers. These data permit highly accurate orbit determination for all three missions, and in addition may enhance the gravitational field determination at very long wavelengths (very low degrees). In addition to that, GRACE involves the continuous measurement of the range between two identical satellites that "chase each other," which constitutes a low-low SST formation (SST-*ll*). GOCE's accelerometer array on the other hand provides the measurements necessary to determine the gravitational *tensor* (i.e., the 3 × 3 matrix of second-order spatial derivatives of the gravitational potential) at altitude. GOCE is unique in the sense that it will provide boundary data at altitude covering the entire Earth, *except* for two polar cap areas of ∼6.7° radius (due to the satellite's inclination). The data acquired by each of these three missions result in different sensitivities to the gravitational spectrum. Simulation studies examining the geopotential recovery attainable from these (and other) mission scenarios have been reported, for example, by Sneeuw and Ilk (1997). When considering the data from these satellite missions two main questions arise:

1. What is the optimal way of analyzing their data?
2. What is the optimal way of combining their data with existing data, for example, from surface gravimetry and from satellite altimetry, in order to develop high-degree combination gravitational models?
    1. *Data Analysis.* In the case of CHAMP, the gravitational information is extracted from the analysis of the perturbations of a low Earth orbiter, in a fashion similar to other preexisting satellite missions. However, CHAMP's low orbit, in conjunction with the accelerometer data and with the availability of nearly global tracking data coverage, enabled *for the first time* the determination of an accurate long wavelength global gravitational model from a *single* satellite's data. Indicative of this "new state of affairs" was the fact that a very preliminary solution (complete to degree and order 91) was already developed based on a *single* month's worth of CHAMP data *only* and was presented during the 2001 meeting of the International Association of Geodesy (IAG) by Reigber et al. (2001). Although significantly better models that include GRACE data have by now surpassed considerably this preliminary solution, it served as a good example of the improvements that were to follow.
    Compared to CHAMP, GRACE added the SST-*ll* component, which permitted higher-resolution gravitational information to be extracted from the analysis of the orbital perturbation *differences* along the line of sight of the two low orbiting satellites. One can use traditional orbit perturbation analysis methods to process the GRACE data and derive a GGM, for example, in spherical harmonics. GGM01S (Tapley et al., 2004) and GGM02S (Tapley et al., 2005) were estimated following such a procedure. This analysis scenario, albeit costly, is within current computational capabilities for models extending to degree and order 180 or so. Geodesists have also considered alternative analysis methods for GRACE-type missions (e.g., Wolff, 1969; Colombo, 1981b; Jekeli, 1999a; Rowlands et al., 2002). Such methods provide higher computational efficiency at the cost of introducing certain approximations. Setting aside for a moment the details of optimal GRACE data processing, it is important to recognize here the quantum leap that has been accomplished with the GRACE mission. Approximately 14 months of GRACE data *alone* have been used to develop GGM02S, whose cumulative global Root Mean Square (RMS) geoid undulation error to degree 70 is less than ±1 cm (Tapley et al., 2005, Figure 2). By comparison, the cumulative geoid undulation global RMS error to degree 70 for EGM96, which required the combination of data from tens of satellites, along with surface gravity

and satellite altimetry, was ±19 cm (Lemoine et al., 1998, Table 10.3.2-1).
As far as GOCE is concerned, numerous investigations of the various aspects of its data analysis and of the development of a GGM from them can be found in (ESA, 2000). One particular issue that receives increased attention relates to the polar gaps and their impact on analysis schemes that exploit regularity and completeness in the data coverage.

2. *Data Combination.* While the existing satellite gravity-mapping missions (CHAMP and especially GRACE) have already delivered (or promise to deliver as in the case of GOCE) quantum leaps in the accuracy and resolution of the *satellite-only* gravitational models, there is still a need to combine that information with terrestrial gravity and satellite altimetry data in an optimal fashion. This is required so that a "seamless" extension of the gravitational spectrum can be achieved, taking advantage of the rich high frequency content of the surface and altimetric data. The higher resolution of GRACE-based and GOCE-based *satellite-only* models will significantly increase the spectral overlap with surface gravity and altimetry. This will enable for the first time the estimation of high-resolution models of the DOT as well as the significant reduction of systematic errors present in surface gravity data (see also [Pavlis, 2000]).

Beyond the sensitivity of satellite data

Due to the attenuation of the gravitational signal with increasing altitude, there is obviously a limit to the gravitational information that can be extracted from spaceborne sensors. This implies a limit to the resolution (maximum degree) of satellite-only models. Spectral estimation indicates that for GRACE, the signal-to-noise ratio becomes one around degree 170, while for GOCE the corresponding degree is not expected to exceed 300. Observations made on the Earth's surface (or on airplanes flying at low altitudes) can extend the resolution of gravitational models considerably. Surface and airborne data like *gravity anomalies*, *gravity disturbances*, etc. are therefore capable of supporting the development of much higher resolution gravitational models than those developed based on satellite data only. One way of developing such high-degree models involves first the formation of a regular grid of spatially averaged values of some functional of the field that completely covers the globe. These values represent data derived on the basis of other primary observables, using techniques like *Least Squares Collocation* (LSC) (Moritz, 1980). Surface gravity anomalies are a suitable choice for such a functional, both from a spectral sensitivity and from an availability viewpoint. Very high-degree and order spherical harmonic models are then developed from the analysis of such global anomaly grids, using efficient harmonic analysis techniques like those put forward by Colombo (1981a). Wenzel (1998, 1999) reported such expansions complete to degree and order 1800. Pavlis et al. (2005) reported the development and evaluation of the PGM2004A preliminary gravitational model, which combined GRACE information with a global set of $5' \times 5'$ gravity anomalies, and extended to maximum degree and order 2,160. The final product of that modeling effort was EGM2008 which also extends to degree 2,160 (Pavlis et al., 2008). EGM2008 was completed and released to the public in April 2008.

State-of-the-art global gravitational modeling

We briefly outline the main aspects of the development of two global gravitational models, representative of the state-of-the-art, given the data that were available, at the time of each model's development: EGM96 (Lemoine et al., 1998), which represents the state-of-the-art before the availability of data from the CHAMP and GRACE missions, and EGM2008 (Pavlis et al., 2008), which represents currently (March 2010) the model with the highest resolution and accuracy, prior to the anticipated availability of data from GOCE. A comparison of the approaches that were followed for the development of these two models reveals the critical changes in model development, which were brought about by the availability of GRACE data on one hand, and of high quality $5' \times 5'$ area-mean gravity anomalies (from the combination of terrestrial and altimetry-derived data sources) on the other.

In theory, the estimation of a GGM complete to some (arbitrary) high degree and order, from the combination of various (heterogeneous) data, could be carried out as follows:

(a) Form separate normal equations from each individual data type, to a maximum degree and order that corresponds to the resolution of the available data and their sensitivity to the gravitational signal.
(b) Treat satellite altimeter data as "direct tracking" observations, that is, ranges from the spacecraft to the ocean surface whose upper endpoint senses (through the orbit dynamics) attenuated gravitational signals (static and time varying), while their lower end point senses the combined effects of geoid undulation, DOT as well as tides and other time varying effects, without any attenuation. In this manner, altimeter data contribute to the estimation of the satellite's orbit, as well as the estimation of the DOT and of the potential coefficients.
(c) Combine the various normal equations (with appropriate relative weights) and invert the resulting system, to estimate the combination solution to its high degree, along with its *full* error covariance matrix.

Such an "ideal" approach would permit the most rigorous modeling of the observables and would allow the greatest flexibility in terms of data weighting. A combination solution to degree 360, if performed as outlined above, would require the formation of full (symmetric) normal equation matrices (from satellite altimetry and surface gravimetry) for approximately 130,000

parameters (considering *only* the gravitational potential coefficients). For maximum degree 2,160, there would be approximately 4.7 million such parameters involved. Such computational tasks are beyond our present computational capabilities. Therefore, at present, one may choose between, or combine, two main solution strategies to attack the problem:

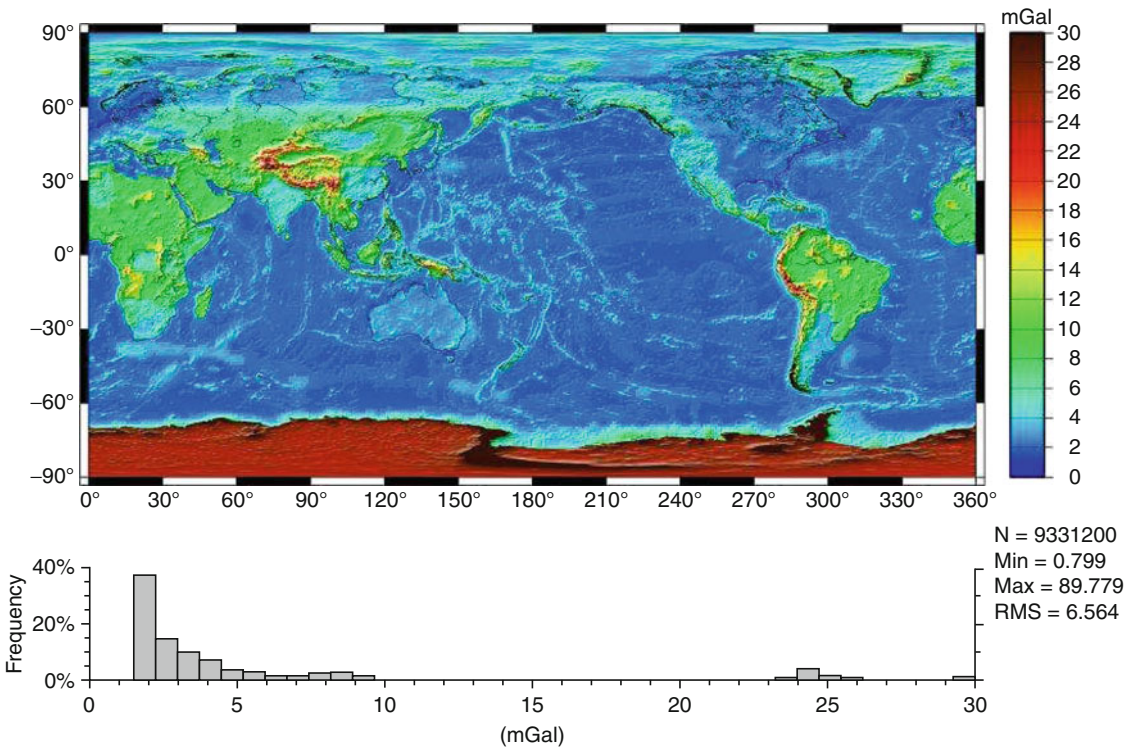
- *Solution Strategy (A)* Apply the "ideal" estimation strategy outlined above, to obtain a combination solution for the lower degree part of the field, up to a maximum degree that is computationally manageable. Apart from reasons of computational feasibility, this maximum degree should enable the appropriate modeling of the gravitational signal contained in the currently available satellite tracking data. Furthermore, since the DOT signal is of long wavelength nature, the benefits of "direct" altimetry are almost entirely retained here. To avoid aliasing effects however, the contribution to the altimetry and surface gravity data from the coefficients beyond the solved-for degree has to be filtered out of the data prior to the normal equation formation. This may be done using a preexisting high-degree solution (Pavlis, 1988; Denker and Rapp, 1990). Herein, we will refer to this type of solution as the *comprehensive* low-degree combination model. The obvious shortcomings of this approach are the relatively low maximum attainable degree (approximately 250 at present) and its computational demands. Some models developed using this approach (or similar ones) include JGM-1 and JGM-2 (Nerem et al., 1994) and JGM-3 (Tapley et al., 1996), the part of EGM96 up to degree and order 70 (see Lemoine et al., 1998, Chapt. 7), and EIGEN-GL04C (Förste et al., 2008).
- *Solution Strategy (B)* Consider that one is willing to make the following two approximations:
  1. The orbits of the altimeter satellites, whose data are included in the combination solution, are perfectly known (at least radially). This approximation is justifiable if one is working with altimeter satellites supported by T/P-class precise orbit determination. Moreover, after the availability of GRACE-based gravitational models for precise orbit determination of altimeter satellites, errors arising from gravitational model inaccuracies do not dominate the orbit error budget of these satellites. Errors due to, for example, mis-modeling of nonconservative forces acting on the spacecraft are likely to be more significant at present. In this regard, to allow the orbits of altimeter satellites to contribute (through their dynamics) to the determination of gravitational parameters within a combination solution may not be a desirable approach presently, because the effects of orbit errors of nongravitational origin could corrupt the solved-for gravitational parameters.
  2. The DOT is known a priori, for example, from an Ocean Circulation Model (OCM) or from a previous low-degree comprehensive combination solution.

The implication of (1) is that satellite altimetry does not have to be treated as "direct" tracking anymore, which simplifies the problem considerably, since now orbit dynamics are not involved in the altimeter data processing. One is left with a "surface" problem, where the geoid (N) and the DOT (ζ) signals have to be separated, given the "observed" SSH (h), which is their sum. If in addition, the approximation (2) is introduced, then altimetry contributes to the combination solution "observed" geoid heights (N) over (parts of) the ocean.

In addition to the above two approximations, a key issue here is that altimetric information may also be provided in a *gridded* form. This is possible through the use of a Mean Sea Surface (MSS), obtained from multiple altimetric missions. The success of T/P has significantly improved the accuracy of MSS data sets (especially at long wavelengths). This is accomplished by adjusting the SSH data from other altimetric missions (e.g., ERS-1, ERS-2, GEOSAT, GEOSAT-Follow-On), to the surface defined by T/P, using crossover minimization techniques. Such MSS data sets have been developed by, for example, Yi (1995); Kim et al. (1995); Anzenhofer et al. (1996); Wang (2001), and more recently by Andersen and Knudsen (2009). One may also have available in *gridded* form, altimetry-derived gravity anomaly values. Such values have been estimated using various techniques, on an ocean-wide basis by, for example, Rapp and Basic (1992); Andersen and Knudsen (1998), Andersen, Knudsen and Berry (2010), Trimmer and Manning (1996) and Sandwell and Smith (1997, 2009) among others.

The two simplifying approximations discussed above and particularly the availability of altimetric information in gridded form (especially in the form of gravity anomalies) make applicable an alternative class of high-degree combination solution techniques. These techniques combine the satellite-only information, with potential coefficient information obtained from the analysis of *complete*, regular grids of functional(s) of the disturbing potential (e.g., N, Δg), and are based on the highly efficient harmonic analysis algorithms originally studied and put forward by Colombo (1981a). These algorithms exploit the regularity of the data grids and the symmetry properties of Legendre and trigonometric (sine/cosine) functions. Inherent in these algorithms is the use of Fast Fourier Transform (FFT) techniques to process data arrays residing over latitude bands that are symmetric with respect to the equator, in a highly efficient manner. Estimators of this type are the (simple) Numerical Quadrature (NQ), the Block-Diagonal (BD) least-squares adjustment, and the Optimal Estimation (OE) technique. Models developed using the NQ approach include OSU86E/F (Rapp and Cruz, 1986a) and OSU89A/B (Rapp and Pavlis, 1990). BD techniques of varying sophistication have been used to develop GPM2 (Wenzel, 1985), DGFI92A (Gruber and Bosch, 1992), GFZ95A (Gruber et al., 1996), and EGM2008 (Pavlis et al., 2008). OE was used to develop the OSU86C/D models (Rapp and Cruz, 1986b).

The two solution strategies (A) and (B) discussed above have their respective advantages and disadvantages. Due to computational limitations, the development of a GGM to spherical harmonic degree 360 or higher, currently requires the implementation of either a combination of the two strategies (as it was done for EGM96 and EIGEN-GL04C), or the implementation of strategy (B), as it was done for OSU89A/B and EGM2008. EGM96 (Lemoine et al., 1998) employed a comprehensive solution to degree 70, augmented by a BD solution from degree $n = 71$ to degree $n = 359$, while the $n = 360$ coefficients (which cannot be estimated using the BD technique) were obtained from an NQ model. The main reason for the choice of this solution strategy was the fact that the satellite-only component of EGM96 (denoted EGM96S), was accompanied by a variance-covariance matrix that was fully occupied. This was due to the fact that the heterogeneous tracking data from the (approximately) 40 satellites that were used to derive EGM96S to degree and order 70, were incapable of de-correlating adequately the spherical harmonic coefficients up to this degree and order. Therefore, in order to preserve the integrity of the least-squares adjustment used to combine EGM96S with the surface gravity and altimetry data, one had to consider the satellite-only normal equations in their complete (fully occupied) form. Any block-diagonal approximation of these normal equations would result in estimation errors that could not be tolerated. This situation changed dramatically with GRACE, where the corresponding normal equation matrix, due to the global coverage and uniform GRACE data accuracy could be safely approximated by a block-diagonal matrix, without significant loss of accuracy. In addition, after the availability of satellite-only models from GRACE, there is really no need to incorporate altimeter data into the combination solution in the form of "direct" tracking. Instead, a preliminary model from GRACE and an MSS can be used to estimate a preliminary model of the DOT. This could then be used to correct the SSH of the MSS and estimate an ocean-wide set of altimetry-derived gravity anomalies. These can be "merged" with terrestrial and airborne data to form a complete global grid (see also Figure 5). The gravitational information implied by these gridded data could then be combined (in a least-squares adjustment) with the satellite-only model from GRACE, to derive the combination solution, up to the high degree (2,160), in a single step. The entire process may be iterated, using the high-degree combination solution to derive the next estimate of the DOT, and so on. This is essentially the approach that was used to develop EGM2008 (Pavlis et al., 2008). Two iterations of the estimation of the altimetry-derived gravity anomalies were performed, which was sufficient for the process to converge. Despite its iterative nature, this approach permits the development of very high-degree combination solutions in an efficient manner, and moreover



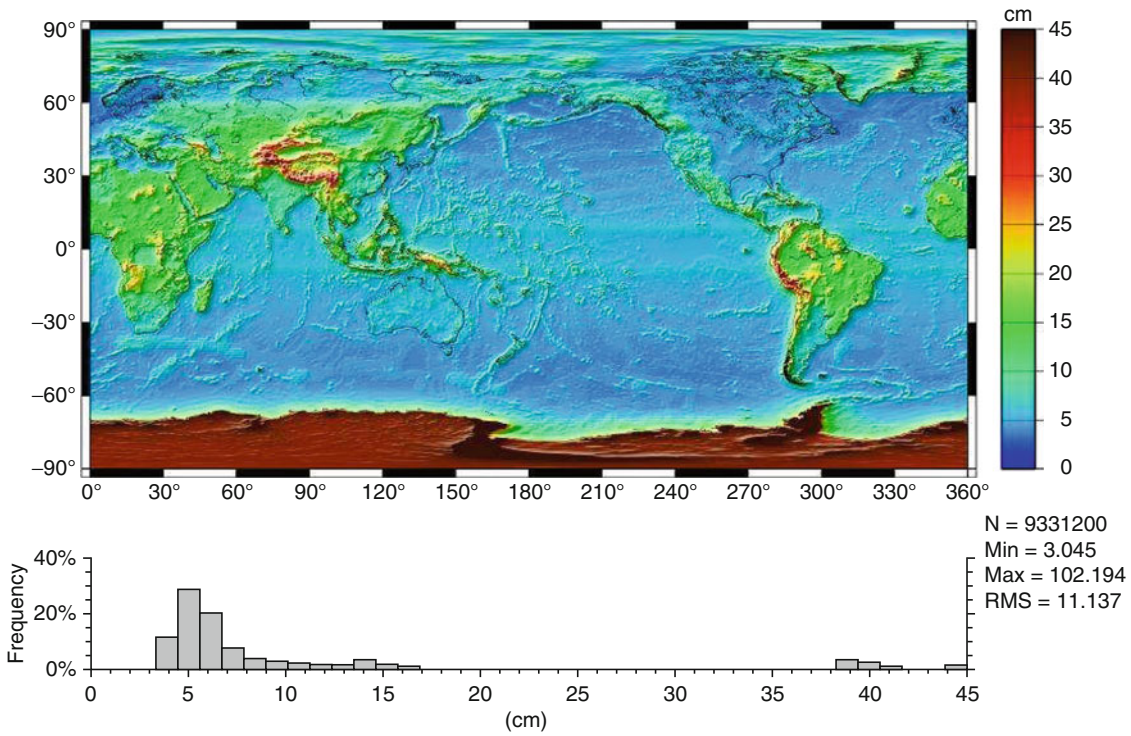
Gravity, Global Models, Figure 6 Propagated error estimates (in mGal) of the free-air gravity anomalies computed using the EGM2008 model. Notice the large error estimates over Antarctica and over mountainous areas (Himalaya, Andes), due to the lack of accurate and detailed data.

in a single adjustment step, thereby avoiding the "piecewise" nature of models like EGM96.

Model evaluation and accuracy assessment

Of central importance to the development of a GGM are the evaluation of its performance, and the estimation of reliable error measures to quantify its accuracy. The former requires the comparison of model-derived quantities to corresponding values obtained *independently*. Several different data types, withheld from a model's development, are used for this purpose. These independent data have different spectral sensitivities and/or occupy different geographic regions. Tests that are usually employed here include satellite orbit determination and comparisons with tracking data, comparisons with geoid undulations obtained from GPS and leveling data, comparisons with deflections of the vertical obtained from astrogeodetic techniques (Jekeli, 1999b), comparisons employing altimetry and general ocean circulation models, etc. A useful practice, introduced during the development of EGM96, and used also during the development of EGM2008, is to invite a voluntary evaluation working group, independent of a model's developers, that evaluates and provides feedback to the model's developers regarding candidate preliminary solutions, as well as the final outcome from a modeling effort, in a manner as objective as possible. These groups work under the auspices of the International Association of Geodesy (IAG) and upon completion of a certain evaluation effort they report their findings in IAG-sponsored publications, which can be accessed freely by the public. In the case of EGM2008, the results from such an evaluation by 25 different international investigating teams are reported in *Newton's Bulletin No. 4*, which is jointly published by the Bureau Gravimétrique International (BGI) and the International Geoid Service (IGeS).

The estimation of reliable errors that should accompany a model's derived quantities is also very important. These errors are geographically dependent, reflecting the different quality of the data used to develop the model, as a function of geographic area. For models like EGM2008, which involve a very large number of parameters (approximately 4.7 million), one cannot perform such error propagation using variance-covariance matrices and linear algebra methods, due to the excessively large sizes of the matrices involved. Instead, Pavlis and Saleh (2005) introduced and implemented an alternative approach that employs global convolutions with band-limited kernels. This technique is capable of providing very reliable error estimates, with geographic specificity, in a very efficient manner. Figures 6 and 7 illustrate



Gravity, Global Models, Figure 7 Propagated error estimates (in centimeters) of the geoid undulations computed using the EGM2008 model. The larger values around the equator are due to the lower density of GRACE data at low latitudes.

geographically the propagated errors in free-air gravity anomalies and in geoid undulations, implied by EGM2008 to degree 2,160.

Summary

Accurate knowledge of the gravitational potential of the Earth, on a global scale and at high resolution, is a fundamental prerequisite for various geodetic, geophysical, and oceanographic investigations and applications. Over the last 50 years, continuing improvements and refinements to the basic theory have been paralleled by the availability of more accurate and complete data and by dramatic improvements in the computational resources available for numerical modeling studies. These advances have brought the state-of-the-art from the early spherical harmonic models of degree 8 (Zhongolovich, 1952) to solutions like EGM2008 that extends to degree 2,160. The availability of satellite missions like CHAMP, GRACE, and GOCE, dedicated to the mapping of the gravitational field from space, is enabling the determination of the long wavelength features of the field with unprecedented accuracy. Nevertheless, the determination of the fine details of the field still relies on the availability of terrestrial and airborne data, of high accuracy and sufficient geographic coverage and density. In this regard, several areas of the Earth, most notably Antarctica, await more comprehensive gravimetric surveying.

Introduction

Gravity gradiometry is over 110 years old and it offers a rich perspective of the Earth's external gravitational field as generated by its internal mass density structure. Like the measurement of gravity, gradiometry is used to make both qualitative and quantitative interpretations of the Earth's near subsurface interior. The spatial gradients of the Earth's gravity acceleration vector form a tensor of nine elements, three components for each of the three vector components. They emphasize the fine structure and the short-wavelength characteristics of the field. They are largest over sharp subsurface geologic contrasts, such as faults, the edges of salt domes and igneous intrusions, and the flanks of synclines and anticlines. As the second derivatives of the gravity potential, the gravity gradients describe the curvature of the potential, and values of the differential curvature help to indicate directions of principal axes of source bodies. Gravity gradiometry also plays a significant role in understanding the fundamental nature of gravitation from a cosmological viewpoint.

While popular in the early part of the twentieth century to aid in the exploration for oil and gas, static gravity gradiometry has largely been replaced by scalar gravimetry (measurements of the magnitude of the gravity vector), both in the static mode and on airborne platforms, due to its greater efficiency and yet equal accuracy. Gradiometry has resurfaced recently because for moving-base systems (e.g., aircraft and satellites), it is arguably the preferred system of measurement since it does not require an independent system that determines kinematic accelerations of the vehicle with equal precision, as does the gravimeter due to the principle of equivalence between inertial and gravitational masses.

The static or moving-base measurement of gradients requires exquisitely sensitive instrumentation, which over the last 100 years has improved less in accuracy than in resolution (integration time) for the surface and airborne systems. Typical airborne systems today advertise the same precision that the static instruments had at the beginning of the twentieth century. However, they have a much higher temporal resolution (of the order of a few seconds) compared to the many hours required for the early static instruments. On the other hand, the recent launch of a satellite-borne gradiometer represents a major advance in global gradiometry with an anticipated accuracy improvement of several orders of magnitude, but at the expense of the relatively far removed (from the sources), but dynamically quiet environment of space. Because of

the relatively great expense of current gradiometer technology, to date only a few terrestrial (airborne and shipborne) systems are in operation.

The following sections cover the basic theory of gravitational gradients, the history of the sensor technology from the first torsion balance to modern-day gradiometers, the forward modeling of gravitational gradients, and applications in geodesy, geophysics, and physics.

Mathematical foundations

Gravitational gradients

Newtonian gravitational field theory adequately serves both to develop the necessary field equations, their solutions, and the derivation and use of gravitational gradients. No attempt is made or needed for present purposes to discuss the gradients in terms of Einstein's theory of general relativity. We start with Newton's law of gravitation that posits the force between two point masses as proportional to each of the masses, inversely proportional to the square of the distance between them, and directed along the connecting line. An equivalent concept is the Newtonian gravitational field potential that quantifies the work (energy) needed to bring a unit test mass from a position, $\boldsymbol{x}$, to infinity for a given attracting point mass, m, located at $\boldsymbol{x}'$:

$$V(\boldsymbol{x}) = \frac{Gm}{|\boldsymbol{x} - \boldsymbol{x}'|}, \tag{1}$$

where G is Newton's gravitational constant. We use the geophysical convention of positive potential. By the law of superposition, the potential may be generalized by summation to a discrete set of mass points; and, ultimately, using the concept of mass density, ρ, to continuous distributions of mass:

$$V(\boldsymbol{x}) = G \int_v \frac{\rho(\boldsymbol{x}')}{|\boldsymbol{x} - \boldsymbol{x}'|} \mathrm{d}v, \tag{2}$$

where v is the region in space occupied by the mass density. The potential is a continuous function for all points inside and outside v and on its boundary.

The spatial gradient of the gravitational potential is the gravitational acceleration (gravitation) experienced by the test mass at $\boldsymbol{x}$:

$$\mathbf{g}(\boldsymbol{x}) = \nabla V(\boldsymbol{x}). \tag{3}$$

The spatial gradient of the components of the gravitation vector constitutes the elements of the gravitational gradient tensor:

$$\Gamma(\boldsymbol{x}) = \nabla\nabla^{\mathrm{T}} V(\boldsymbol{x}) = \nabla \boldsymbol{g}^{\mathrm{T}}(\boldsymbol{x}), \tag{4}$$

where "T" denotes the transpose of a vector (or matrix). The gradient tensor is a continuous function where the density is continuous.

In Cartesian coordinates, $\boldsymbol{x} = (x_1, x_2, x_3)^{\mathrm{T}}$, the gravitational gradient tensor is given by

$$\Gamma = \begin{pmatrix} \frac{\partial^2 V}{\partial x_1^2} & \frac{\partial^2 V}{\partial x_1 \partial x_2} & \frac{\partial^2 V}{\partial x_1 \partial x_3} \\ \frac{\partial^2 V}{\partial x_2 \partial x_1} & \frac{\partial^2 V}{\partial x_2^2} & \frac{\partial^2 V}{\partial x_2 \partial x_3} \\ \frac{\partial^2 V}{\partial x_3 \partial x_1} & \frac{\partial^2 V}{\partial x_3 \partial x_2} & \frac{\partial^2 V}{\partial x_3^2} \end{pmatrix} = \begin{pmatrix} \frac{\partial g_1}{\partial x_1} & \frac{\partial g_2}{\partial x_1} & \frac{\partial g_3}{\partial x_1} \\ \frac{\partial g_1}{\partial x_2} & \frac{\partial g_2}{\partial x_2} & \frac{\partial g_3}{\partial x_2} \\ \frac{\partial g_1}{\partial x_3} & \frac{\partial g_2}{\partial x_3} & \frac{\partial g_3}{\partial x_3} \end{pmatrix} = \begin{pmatrix} \Gamma_{11} & \Gamma_{12} & \Gamma_{13} \\ \Gamma_{21} & \Gamma_{22} & \Gamma_{23} \\ \Gamma_{31} & \Gamma_{23} & \Gamma_{33} \end{pmatrix}. \tag{5}$$

The tensor is symmetric by the continuity of the derivatives of the potential. Poisson's field equation characterizes a Newtonian gravitational field through its second-order gradients, or the trace of the gravitational gradient tensor:

$$\nabla \bullet \nabla V(\boldsymbol{x}) = \nabla^2 V(\boldsymbol{x}) = -4\pi G \rho(\boldsymbol{x}), \tag{6}$$

where the Laplacian operator in Cartesian coordinates is

$$\nabla^2 = \frac{\partial^2}{\partial x_1^2} + \frac{\partial^2}{\partial x_2^2} + \frac{\partial^2}{\partial x_3^2}. \tag{7}$$

Therefore, the gravitational gradient tensor has only five independent elements for points where the mass density distribution is known. For later reference, the potential in free space satisfies Laplace's equation:

$$\nabla^2 V(\boldsymbol{x}) = 0. \tag{8}$$

If the local coordinate system has its third axis aligned with the vertical, positive downward, and the first axis points northward, then the horizontal rate of change of the vertical component of gravitation, g_3, is called the horizontal gradient, with magnitude and direction of greatest variation (from north) given by

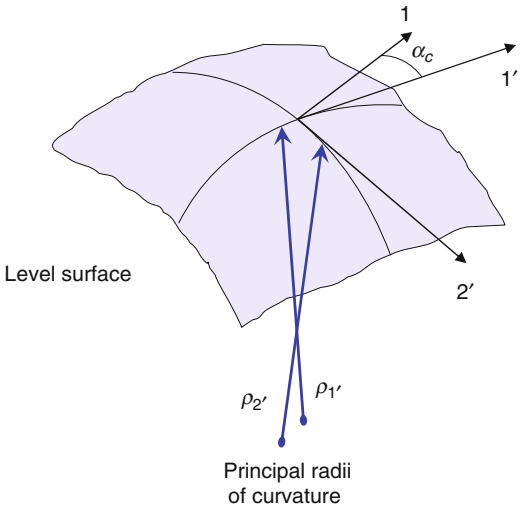
$$\Gamma_H = \sqrt{\Gamma_{13}^2 + \Gamma_{23}^2}, \quad \alpha_H = \tan^{-1} \frac{\Gamma_{23}}{\Gamma_{13}}. \tag{9}$$

Gravitational gradients also describe the curvature of a surface of constant gravitational potential (a level surface) (Figure 1). Let $\rho_{1'}$ and $\rho_{2'}$ be the two principal radii of curvature at a point on the surface, representing the minimum and maximum curvatures along corresponding (orthogonal) axes, $x_{1'}$ and $x_{2'}$. It can be shown (Heiland, 1940; Nettleton, 1976) that the differential curvature, $\Delta\kappa = g_3(1/\rho_{2'} - 1/\rho_{1'})$, is given by

$$\Delta\kappa = \sqrt{(2\Gamma_{12})^2 + (\Gamma_{22} - \Gamma_{11})^2}. \tag{10}$$

The direction of minimum curvature is

$$\alpha_c = \frac{1}{2} \tan^{-1} \frac{-2\Gamma_{12}}{\Gamma_{22} - \Gamma_{11}}. \tag{11}$$



Gravity, Gradiometry, Figure 1 Principal radii of curvature at a point on an equipotential surface.

If $a_c = 0$, then the coordinate axes, x_1 and x_2, coincide with the directions of minimum and maximum curvatures; and $\Gamma_{12} = 0$. In general, we also have

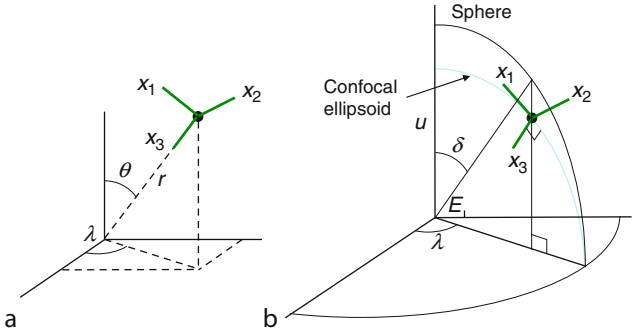
$$\Gamma_{22} - \Gamma_{11} = g_3 \left(\frac{1}{\rho_{2'}} - \frac{1}{\rho_{1'}} \right) \cos 2\alpha_c,$$
$$\Gamma_{12} = -\frac{1}{2} g_3 \left(\frac{1}{\rho_{2'}} - \frac{1}{\rho_{1'}} \right) \sin 2\alpha_c. \tag{12}$$

Other coordinate systems

For a local Cartesian coordinate system embedded in a spherical polar coordinate system as shown in Figure 2a, the first- and second-order derivatives are related to corresponding derivatives with respect to the spherical coordinates, as follows:

$$\frac{\partial}{\partial x_1} = -\frac{1}{r}\frac{\partial}{\partial \theta}, \quad \frac{\partial}{\partial x_2} = \frac{1}{r \sin\theta}\frac{\partial}{\partial \lambda}, \quad \frac{\partial}{\partial x_3} = -\frac{\partial}{\partial r}; \tag{13}$$

$$\begin{aligned}
\frac{\partial^2}{\partial x_1^2} &= \frac{1}{r}\frac{\partial}{\partial r} + \frac{1}{r^2}\frac{\partial^2}{\partial \theta^2} \\
\frac{\partial^2}{\partial x_1 \partial x_2} &= \frac{\cot\theta}{r^2 \sin\theta}\frac{\partial}{\partial \lambda} - \frac{1}{r^2 \sin\theta}\frac{\partial^2}{\partial \theta \partial \lambda} \\
\frac{\partial^2}{\partial x_1 \partial x_3} &= -\frac{1}{r^2}\frac{\partial}{\partial \theta} + \frac{1}{r}\frac{\partial^2}{\partial \theta \partial r} \\
\frac{\partial^2}{\partial x_2^2} &= \frac{\cot\theta}{r^2}\frac{\partial}{\partial \theta} + \frac{1}{r}\frac{\partial}{\partial r} + \frac{1}{r^2 \sin^2\theta}\frac{\partial^2}{\partial \lambda^2} \\
\frac{\partial^2}{\partial x_2 \partial x_3} &= \frac{1}{r^2 \sin\theta}\frac{\partial}{\partial \lambda} - \frac{1}{r \sin\theta}\frac{\partial^2}{\partial \lambda \partial r} \\
\frac{\partial^2}{\partial x_3^2} &= \frac{\partial^2}{\partial r^2}
\end{aligned} \tag{14}$$



Gravity, Gradiometry, Figure 2 Local Cartesian coordinates relative to (**a**) spherical polar coordinates and (**b**) ellipsoidal coordinates.

with corresponding Laplacian operator

$$\nabla^2 = \frac{\partial^2}{\partial x_1^2} + \frac{\partial^2}{\partial x_2^2} + \frac{\partial^2}{\partial x_3^2} = \frac{\partial^2}{\partial r^2} + \frac{2}{r}\frac{\partial}{\partial r} + \frac{1}{r^2}\frac{\partial^2}{\partial \theta^2} + \frac{\cot\theta}{r^2}\frac{\partial}{\partial \theta} + \frac{1}{r^2 \sin^2\theta}\frac{\partial^2}{\partial \lambda^2}. \tag{15}$$

Usually the Earth is approximated by a rotational ellipsoid, generated by rotating an ellipse with linear eccentricity, E, about its semi-minor axis, identified as the polar axis. Corresponding ellipsoidal (spheroidal) coordinates, (u, δ, λ), are shown in Figure 2b, where surfaces of constant u are confocal ellipsoids and surfaces of constant δ are hyperboloids of revolution of one sheet. As for spherical coordinates, surfaces of constant longitude, λ, are half-planes containing the polar axis. The local first- and second-order derivatives with respect to Cartesian coordinates (where the x_3-axis is orthogonal to the confocal ellipsoid that passes through the origin of the local system) are related to the corresponding derivatives with respect to the ellipsoidal coordinates, as follows:

$$\frac{\partial}{\partial x_1} = -\frac{1}{w}\frac{\partial}{\partial \delta}, \quad \frac{\partial}{\partial x_2} = \frac{1}{v \sin\delta}\frac{\partial}{\partial \lambda}, \quad \frac{\partial}{\partial x_3} = -\frac{w}{v}\frac{\partial}{\partial u}; \tag{16}$$

$$\begin{aligned}
\frac{\partial^2}{\partial x_1^2} &= \frac{1}{w^2}\left(\frac{uv^2}{w^2}\frac{\partial}{\partial u} + \frac{E^2 \sin 2\delta}{2w^2}\frac{\partial}{\partial \delta} + \frac{\partial^2}{\partial \delta^2} \right) \\
\frac{\partial^2}{\partial x_1 \partial x_2} &= \frac{1}{wv \sin\delta}\left(\cot\delta \frac{\partial}{\partial \lambda} - \frac{\partial^2}{\partial \delta \partial \lambda} \right) \\
\frac{\partial^2}{\partial x_1 \partial x_3} &= \frac{v}{w^2}\left(-\frac{u}{w^2}\frac{\partial}{\partial \delta} + \frac{E^2 \sin 2\delta}{2w^2}\frac{\partial}{\partial u} + \frac{\partial^2}{\partial \delta \partial r} \right) \\
\frac{\partial^2}{\partial x_2^2} &= \frac{\cot\delta}{w^2}\frac{\partial}{\partial \delta} + \frac{u}{w^2}\frac{\partial}{\partial u} + \frac{1}{v^2 \sin^2\delta}\frac{\partial^2}{\partial \lambda^2} \\
\frac{\partial^2}{\partial x_2 \partial x_3} &= \frac{1}{w \sin\delta}\left(\frac{u}{v^2}\frac{\partial}{\partial \lambda} - \frac{\partial^2}{\partial \lambda \partial u} \right) \\
\frac{\partial^2}{\partial x_3^2} &= \frac{1}{w^2}\left(-\frac{E^2 \sin 2\delta}{2w^2}\frac{\partial}{\partial \delta} - \frac{uE^2 \sin^2\delta}{w^2}\frac{\partial}{\partial u} + v^2 \frac{\partial^2}{\partial u^2} \right)
\end{aligned} \tag{17}$$

where

$$v^2 = u^2 + E^2, \quad w^2 = u^2 + E^2\cos^2\delta. \tag{18}$$

The Laplacian operator is

$$\nabla^2 = \frac{1}{w^2}\left(v^2\frac{\partial^2}{\partial u^2} + 2u\frac{\partial}{\partial u} + \frac{\partial^2}{\partial \delta^2} + \cot\delta\frac{\partial}{\partial\delta} + \frac{w^2}{v^2\sin^2\delta}\frac{\partial^2}{\partial\lambda^2}\right). \tag{19}$$

Invariants

Being a second-order tensor, the gradients change under a rotation of Cartesian coordinates from system s to system t according to $\Gamma^t = C_s^t\Gamma^s C_t^s$, where C_s^t is the matrix of appropriate direction cosines. For any arbitrary Cartesian system, s, there exists a rotation that diagonalizes the tensor, Γ^s:

$$\begin{pmatrix} \lambda_1 & 0 & 0 \\ 0 & \lambda_2 & 0 \\ 0 & 0 & \lambda_3 \end{pmatrix} = \Gamma^t = C_s^t\Gamma^s C_t^s. \tag{20}$$

The diagonal elements, λ_j, are the eigenvalues of the gradient tensor and are called invariants (with respect to coordinate rotations). They are real numbers because the tensor is real and symmetric. All combinations of eigenvalues are also invariants.

Given the tensor, Γ, in some coordinate system, the eigenvalues are roots to the following characteristic equation (det = determinant):

$$\begin{aligned} \det(\lambda I - \Gamma) &= (\lambda - \lambda_1)(\lambda - \lambda_2)(\lambda - \lambda_3) \\ &= \lambda^3 - I_0\lambda^2 + I_1\lambda - I_2 = 0, \end{aligned} \tag{21}$$

from which it is easy to show that, with the gradient elements as designated in Equation 5,

$$I_0 = \lambda_1 + \lambda_2 + \lambda_3 = \Gamma_{11} + \Gamma_{22} + \Gamma_{33},$$

$$\begin{aligned} I_1 =& \lambda_1\lambda_2 + \lambda_2\lambda_3 + \lambda_3\lambda_1 = \Gamma_{11}\Gamma_{22} \\ &+ \Gamma_{22}\Gamma_{33} + \Gamma_{11}\Gamma_{33} - \Gamma_{12}^2 - \Gamma_{23}^2 - \Gamma_{31}^2, \end{aligned} \tag{22}$$

$$I_2 = \lambda_1\lambda_2\lambda_3 = \det\Gamma; \tag{23}$$

and, therefore, these quantities are invariants with respect to rotation. For example, Poisson's Equation 6 implies $I_0 = -4\pi G\rho$.

From Equations 22, we have $I_0^2 = \lambda_1^2 + \lambda_2^2 + \lambda_3^2 + 2I_1$. If $I_0 = 0$ (e.g., above the Earth's surface), then $I_1 < 0$. Pedersen and Rasmussen (1990) show that

$$0 \le I \equiv -\left(\frac{I_2}{2}\right)^2 \Big/ \left(\frac{I_1}{3}\right)^3 \le 1; \tag{24}$$

and call I an indicator of two dimensionality. $I = 1$ implies that the source of the gradients is like a monopole and $I = 0$ implies that the generated field is invariant in some direction, which means that the source is two dimensional and can be described by a cross section.

Finally, we note that both Γ_H (Equation 9) and $\Delta\kappa$ (Equation 10) are horizontal invariants, that is, independent of the azimuthal orientation of the local frame.

Models and modeling

As will be quantified later in this section, the gravitational gradients, being second-order derivatives of the potential, reflect primarily the short-wavelength, local features of the Earth's crust. For this reason, the forward modeling of gradients due to sources has largely concentrated on formulating the gradient signals of polyhedra of constant density, which by suitable assemblage can simulate the local crust, specifically the local topography. Given a regular distribution of elevation data for a particular region, the topography may be modeled as a collection of right-rectangular prisms whose vertical dimension is defined by an elevation data point and whose base has dimensions equal to the horizontal resolution of the data. Other options to model the topography include triangular prisms (using a triangulation of the elevation data) and any of several numerical integration methods applied to (from Equation 2)

$$\Gamma_{jk}(\boldsymbol{x}) = G\int_v \rho(\boldsymbol{x}')\frac{\partial^2}{\partial x_j\partial x_k}\frac{1}{|\boldsymbol{x} - \boldsymbol{x}'|}dv. \tag{25}$$

The purposes of modeling gravitational gradients range from validation of gradiometer accuracy to introducing constraints on the geophysical inverse problem. As new gradiometer systems are developed, particularly airborne systems, determining their accuracy is aided by flying over regions with well-known topographic elevations and density contrasts. Comparing the measurements to gradients forward modeled from the topography calibrates the noise level and enables tuning of appropriate data filters. Conversely, detecting subsurface geologic features, such as kimberlites (for diamond prospecting), from gradiometric surveys is facilitated by knowing what to look for in terms of a particular gradient signature. Thus, even in the inversion of gradiometric data to infer sources, forward modeling of structures plays an important role.

The gradients generated by constant-density, right-rectangular prisms follow from Equation 25. If the prism has dimensions bounded by Cartesian coordinates, $a_1 \le x_1' \le a_2, b_1 \le x_2' \le b_2, c_1 \le x_3' \le c_2$, the gradients for points outside the prism are given by

$$\Gamma_{jk}(\boldsymbol{x}) = -G\rho\ln(x_\ell - x_\ell' + r)\Big|_{x_1'=a_1}^{a_2}\Big|_{x_2'=b_1}^{b_2}\Big|_{x_3'=c_1}^{c_2}, \tag{26}$$

$$\Gamma_{jj}(\boldsymbol{x}) = G\rho\tan^{-1}\frac{(x_k - x_k')(x_\ell - x_\ell')}{(x_j - x_j')r}\Big|_{x_1'=a_1}^{a_2}\Big|_{x_2'=b_1}^{b_2}\Big|_{x_3'=c_1}^{c_2}, \tag{27}$$

where $r^2 = (x_1 - x_1')^2 + (x_2 - x_2')^2 + (x_3 - x_3')^2$ and where (j,k,ℓ) is a cyclic permutation of $(1,2,3)$. Using these formulas to model the gradients associated with the local topography is analogous to a numerical integration of Equation 25 using the rectangular rule.

To take advantage of various other numerical integration techniques based on a discretization of the topographic surface, $h(x_1', x_2')$, over an area, A, one first integrates Equation 25 with respect to the vertical, x_3':

$$\begin{aligned} \Gamma_{jk}(\boldsymbol{x}) &= G\rho \iint_A T_{jk}(\boldsymbol{x}; x_1', x_2')\, dA \\ &\approx G\rho \sum_{i_1} \sum_{i_2} T_{jk}\left(\boldsymbol{x}; (x_1)_{i_1}, (x_2)_{i_2}\right) \Delta A_{i_1,i_2}, \end{aligned} \tag{28}$$

where the functions,

$$T_{jk}(\boldsymbol{x}; x_1', x_2') = \int_0^{h(x_1', x_2')} \frac{\partial^2}{\partial x_j \partial x_k}\left(\frac{1}{r}\right) dx_3', \tag{29}$$

have well-defined analytic expressions (Jekeli and Zhu, 2006). The discretization indicated by Equation 28 then may take any number of forms.

For example, it may also be desirable to express T_{jk} as a Taylor series in h, in which case Equation 28 becomes a series of two-dimensional convolutions on the plane:

$$\Gamma_{jk}(\boldsymbol{x}) = G\rho \iint_A \left(\sum_n \frac{1}{n!} \frac{\partial^n}{\partial h^n} T_{jk}\big|_{h=0} h^n \right) \mathrm{d}x_1' \mathrm{d}x_2' \,, \tag{30}$$

where it is noted that T_{jk} is a function of $x_1 - x_1'$ and $x_2 - x_2'$ (besides x_3 and h). Discretized, such convolutions can be evaluated rapidly using fast algorithms for the discrete Fourier transform (Forsberg, 1985), provided the variable, x_3, remains constant (which is a limitation of the method). Similar Fourier transform methods have also been developed by (Parker, 1972), but found to be less suitable (Jekeli and Zhu, 2006).

Other fast methods transform the volume integral (Equation 25) to surface and line integrals along the theory of Gauss (divergence theorem, etc.); Petrovic (1996) and Tsoulis and Petrovic (2001) have developed corresponding formulas for arbitrary polyhedra. In all these cases, the underlying coordinate system is Cartesian. Modeling gravitational gradients in spherical coordinates that account for the convergence of coordinate lines of a data grid, as well as the convergence of radial (height) lines has not received much attention (see Smith et al., 2001) since the gradients are influenced primarily by very local topography.

Spectral models of the gravitational gradients can be derived directly from corresponding models of the gravitational potential, which exist in abundance for the global field. The Legendre spectrum, $\{(GM/R)C_{nm}\}$, of the potential, V, on a sphere of radius, R, represents its eigenvalues with respect to surface spherical harmonic functions, $\bar{Y}_{nm}(\theta,\lambda)$; and because the potential satisfies Laplace's Equation 8 in free space, the potential for $r \geq R$ is given by

$$V(r,\theta,\lambda) = \frac{GM}{R} \sum_{n=0}^{\infty} \sum_{m=-n}^{n} \left(\frac{R}{r}\right)^{n+1} C_{nm} \bar{Y}_{nm}(\theta,\lambda), \tag{31}$$

assuming no masses exist outside the sphere of radius, R, and total mass, M. The spherical harmonic functions are defined by

$$\bar{Y}_{n,m}(\theta,\lambda) = \bar{P}_{n,|m|}(\cos\theta) \begin{cases} \cos m\lambda, & m \geq 0 \\ \sin|m|\lambda, & m < 0 \end{cases} \tag{32}$$

where the functions, $\bar{P}_{n,m}$, are associated Legendre functions of the first kind, fully normalized so that

$$\frac{1}{4\pi} \iint_\sigma \bar{Y}_{n',m'}(\theta,\lambda) \bar{Y}_{n,m}(\theta,\lambda) d\sigma = \begin{cases} 1, & n' = n \text{ and } m' = m \\ 0, & n' \neq n \text{ or } m' \neq m \end{cases} \tag{33}$$

Typically, a spherical harmonic model is given with a limited spectrum up to maximum degree, $n_{\max}$. The gradients, Γ_{jk}, corresponding to this model in a local coordinate system, as shown in Figure 2a, can then be determined using Equation 14. However, the spectrum with respect to the surface spherical harmonics does not exist for all the gradients. Specifically, any of the derivatives in latitude destroy the orthogonality of the basis (eigen-) functions on the sphere. It is easy to see that the radial derivatives possess Legendre spectra.

Similarly, for a given ellipsoidal harmonic model with coefficients, C_{nm}^e (Jekeli, 1988a),

$$V(u,\delta,\lambda) = \frac{GM}{R} \sum_{n=0}^{\infty} \sum_{m=-n}^{n} \frac{\bar{Q}_{n|m|}(iu/E)}{\bar{Q}_{n|m|}(ib/E)} C_{nm}^e \bar{Y}_{nm}(\delta,\lambda), \tag{34}$$

where $\bar{Q}_{nm}$ is the fully normalized associated Legendre function of the second kind, the gradients in a local coordinate system are obtained using the derivatives in Equation 17. None of the derivatives of the potential have a Legendre spectrum with respect to the eigenfunctions, $\bar{Y}_{nm}(\delta,\lambda)$ because the geometry of the ellipsoid does not admit to a decomposition formula for the Legendre polynomials of $\cos\delta$.

Usually, a local Cartesian coordinate system suffices to model the spectrum of the gradients. In this case, the spectra of all gradients may be derived from the spectrum of the potential. Starting with the representation of the potential in terms of its Fourier spectrum, $\upsilon(f_1,f_2)$, on a plane $(x_3 = 0)$ and including the harmonic extension into free space $(x_3 > 0)$, we have

$$V(x_1,x_2,x_3) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \upsilon(f_1,f_2)e^{-2\pi f x_3}e^{i2\pi(f_1x_1+f_2x_2)}df_1df_2, \tag{35}$$

where $f = \sqrt{f_1^2+f_2^2}$ and f_1, f_2 are spatial, cyclical frequencies. The Fourier spectrum, $\mathcal{G}$, of each gravitational gradient on the x_3-plane is obtained by applying the appropriate derivative. We have

$$\begin{aligned}
\mathcal{G}_{11}(f_1,f_2;x_3) &= -4\pi^2 f_1^2 \upsilon(f_1,f_2)e^{-2\pi f x_3},\\
\mathcal{G}_{12}(f_1,f_2;x_3) &= -4\pi^2 f_1 f_2\, \upsilon(f_1,f_2)e^{-2\pi f x_3},\\
\mathcal{G}_{13}(f_1,f_2;x_3) &= -i4\pi^2 f_1 f\, \upsilon(f_1,f_2)e^{-2\pi f x_3},\\
\mathcal{G}_{22}(f_1,f_2;x_3) &= -4\pi^2 f_2^2\, \upsilon(f_1,f_2)e^{-2\pi f x_3},\\
\mathcal{G}_{23}(f_1,f_2;x_3) &= -i4\pi^2 f_2 f\, \upsilon(f_1,f_2)e^{-2\pi f x_3},\\
\mathcal{G}_{23}(f_1,f_2;x_3) &= 4\pi^2 f^2\, \upsilon(f_1,f_2)e^{-2\pi f x_3}.
\end{aligned} \tag{36}$$

These relationships can be used to determine any gradient from any other gradient or from any derivative of the potential. For example, the gradient, Γ_{13}, at altitude, x_3, is the inverse Fourier transform of $2\pi f\gamma(f_1,f_2)e^{-2\pi f x_3}$, where $\gamma(f_1,f_2) = -2\pi f\, \upsilon(f_1,f_2)$ is the Fourier transform of the vertical derivative of V (the gravitational acceleration) at ground level. In such transformations, due care must be exercised when calculating the higher frequencies of the gradients if the original data have noise and are limited in resolution due to finite data spacing.

Reference field and power spectral density

The first-order approximation of the Earth's gravity potential is the "normal potential," which includes the centrifugal component due to Earth's rotation and whose defining property is that it is constant on a co-rotating ellipsoidal model for the Earth. It may be expressed by the spherical harmonic expansion,

$$\begin{aligned}
U(r,\theta,\lambda) = &\frac{GM}{r}\left(1-\sum_{n=1}^{\infty}J_{2n}\left(\frac{a}{r}\right)^{2n}P_{2n}(\cos\theta)\right)\\
&+\frac{1}{2}\omega_e^2 r^2\sin^2\theta,
\end{aligned} \tag{37}$$

where a is the semi-major axis of the ellipsoid, ω_e is Earth's rotation rate, and the coefficients are given by

$$J_{2n} = (-1)^{n+1}\frac{3e^{2n}}{(2n+1)(2n+3)}\left(1-n+5n\frac{J_2}{e^2}\right), \tag{38}$$

where e is the first eccentricity of the ellipsoid, and J_2 is the dynamical form factor related to the difference in principal moments of inertia of the Earth, or also the polar flattening of the ellipsoid (Heiskanen and Moritz, 1967; Hofmann-Wellenhof and Moritz, 2005). The series (37) is usually truncated at $n = 5$ with entirely sufficient accuracy. For values of the defining parameters, GM, a, J_2, ω_e, of the current and past reference fields, see entry on *Gravity Field of the Earth*.

The normal gravity potential, U, does not depend on longitude due to the rotational symmetry of the ellipsoid; and in view of Equation 14, only the local gravity gradients, Γ_{11}, Γ_{13}, Γ_{22}, and Γ_{33} include a normal component. A standard approximation for the normal gradient, $\Gamma_{33}^{(U)}$ is $\Gamma_{33}^{(U)} \approx 3086\times10^{-9}\mathrm{s}^{-2}$, based on just the first term in Equation 37. The common unit of measure for gravity gradients is the Eötvös ($1\ \mathrm{E} = 10^{-9}\mathrm{s}^{-2}$), in honor of the Hungarian geophysicist, Loránd Eötvös, who invented the torsion balance (see *Gravity, Gradiometry*).

The residual potential, called the disturbing potential, then gives rise to disturbing gradients, which may in some instances attain an order of magnitude similar to the reference part, especially in very mountainous areas (e.g., Hein, 1977).

Globally, the power spectral density (psd) of the potential, defined on the sphere of radius, R, is given in terms of its spherical spectrum by (Jekeli, 2010)

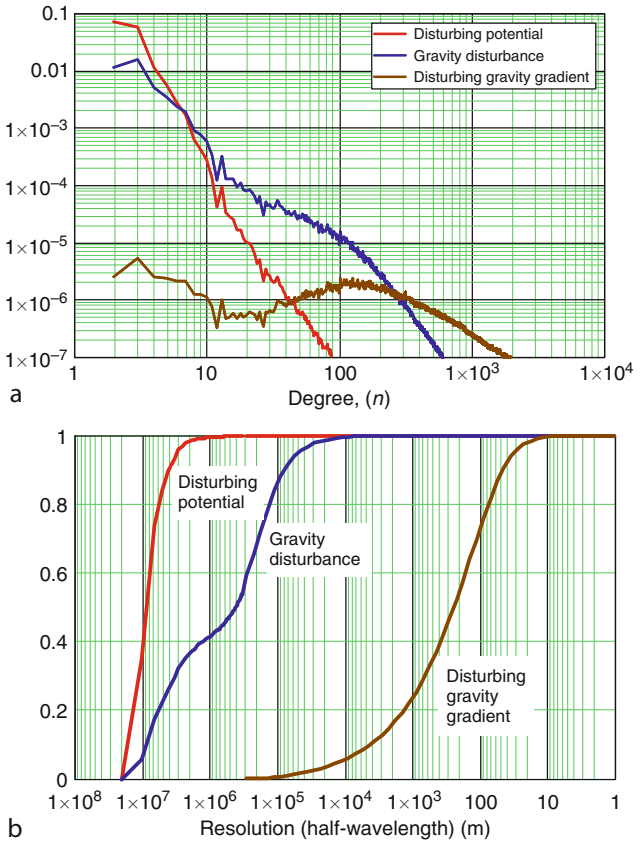
$$\Phi_n = \frac{1}{2n+1}\left(\frac{GM}{R}\right)^2\sum_{m=-n}^{n}C_{nm}^2. \tag{39}$$

Corresponding radial derivatives have psd's scaled by fixed powers of the degree, meaning that they emphasize the higher degrees or shorter wavelengths of the field. Figure 3a shows the psd's of the disturbing potential and its first two radial derivatives (relative to the normal field) according to the Earth Gravitational Model 2008 (EGM08, Pavlis et al., 2008).

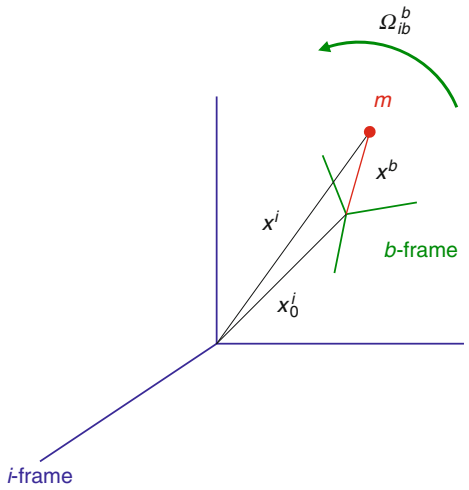
Also shown (Figure 3b) is the cumulative contribution of the disturbing field and its radial derivatives up to a given degree, n, or resolution, where spatial resolution (half-wavelength) in kilometers is given by $\Delta s = 6,371\pi/n$, 6,371 km being the mean Earth radius. While about 99.3% of the disturbing potential is defined by the field with wavelengths longer than 2,000 km, the gravity disturbance (first radial derivative) comprises only about 41.4% up to these wavelengths, and the disturbing gradient barely has any (relative) power at wavelengths longer than 200 km. Here, it is noted that the cumulative contribution of the disturbing gradient is highly dependent on the local field and is only an illustrative example. As another example, Jordan (1978) provided a psd model wherein 99.995% of the power of the disturbing gradient is due to the density variations in the upper 150 m of the crust, while this regime contributes 89% to the gravity disturbance, and only 7% to the disturbing potential.

Measurement error analysis

All practical gravity gradiometers measure "gradients" by differencing in one form or another the inertial accelerations sensed by linear or angular accelerometers. In the



Gravity, Gradiometry, Figure 3 (**a**) Power spectral densities of radial derivatives of the Earth's disturbing potential normalized by the respective total variance. (**b**) Cumulative relative power of each radial derivative as function of spatial resolution of the field.



Gravity, Gradiometry, Figure 4 The geometry for the lever-arm effect on the acceleration of m in the b-frame rotating with respect to the i-frame.

limit of infinitesimal separation, the model with linear accelerometers can be used to derive the theoretical equation for gravity gradiometers in this case, which also offers a general interpretation of measured gradients on a moving platform. We start with the lever-arm equation (Jekeli, 2000) for the output of an accelerometer (Figure 4)

$$\boldsymbol{a}^b = \boldsymbol{a}^b_0 + \left(\boldsymbol{g}^b_0 - \boldsymbol{g}^b\right) + \dot{\Omega}^b_{ib}\boldsymbol{x}^b + \Omega^b_{ib}\Omega^b_{ib}\boldsymbol{x}^b, \tag{40}$$

where $\mathbf{a^b}$ is the inertial acceleration of a test mass, m, in a frame (the b-frame) that rotates with respect to the inertial frame (i-frame) with angular rate given by the vector, $\boldsymbol{\omega}^b_{ib} = (\omega_1\ \omega_2\ \omega_3)^{\mathrm{T}}$, expressed in terms of a cross product as

$$\left[\boldsymbol{\omega}^b_{ib}\times\right] = \Omega^b_{ib} = \begin{pmatrix} 0 & -\omega_3 & \omega_2 \\ \omega_3 & 0 & -\omega_1 \\ -\omega_2 & \omega_1 & 0 \end{pmatrix}. \tag{41}$$

The acceleration of the b-frame in the i-frame is $\boldsymbol{a}^i_0$ and the location of the test mass (the lever-arm) in the b-frame is $\boldsymbol{x}^b$. The gravitational acceleration of the b-frame (in b-frame coordinates) is $\boldsymbol{g}^b_0$ and that of the test mass is $\boldsymbol{g}^b$. The last two terms of Equation 40 represent Coriolis and centrifugal accelerations due to the frame rotation.

Taking the spatial derivative of Equation 40, analogous to differencing the inertial accelerations of two test masses in the b-frame, we obtain

$$\frac{\partial \boldsymbol{a}^b}{\partial \boldsymbol{x}^b} = -\frac{\partial \boldsymbol{g}^b}{\partial \boldsymbol{x}^b} + \dot{\Omega}^b_{ib} + \Omega^b_{ib}\Omega^b_{ib}. \tag{42}$$

The measured acceleration gradient is the combination of the gravitational gradient and angular accelerations. Thus, a gravity gradiometer must either be stabilized against rotations with respect to the inertial frame or some other realizable frame, or these rotations must be measured independently with gyroscopes. An analysis of the required accuracy of these measurements (or, equivalently, of the stabilization) was conducted by Jekeli (2006) and is summarized in Table 1. Each row of this table corresponds approximately to commensurate sensor errors (gradiometer and gyroscope). For typical airborne gradiometer systems with noise levels in the range $1-10\,\mathrm{E}/\sqrt{\mathrm{Hz}}$, conventional high-accuracy gyroscopes are sufficient to separate the gravitational gradients from the non-gravitational components.

Due to the symmetry of the gravitational tensor, $\Gamma^b = \left(\partial \boldsymbol{g}^b/\partial \boldsymbol{x}^b\right)$, and the anti-symmetry of Ω^b_{ib}, the measurement of the full matrix, $\left(\partial \boldsymbol{a}^b_m/\partial \boldsymbol{x}^b\right)$, permits some simplifications, such as

$$\Gamma^b = -\frac{1}{2}\left(\frac{\partial \boldsymbol{a}^b}{\partial \boldsymbol{x}^b} + \left(\frac{\partial \boldsymbol{a}^b}{\partial \boldsymbol{x}^b}\right)^{\mathrm{T}}\right) + \Omega^b_{ib}\Omega^b_{ib}. \tag{43}$$

The next section offers further details on the measurement of gravity gradients.

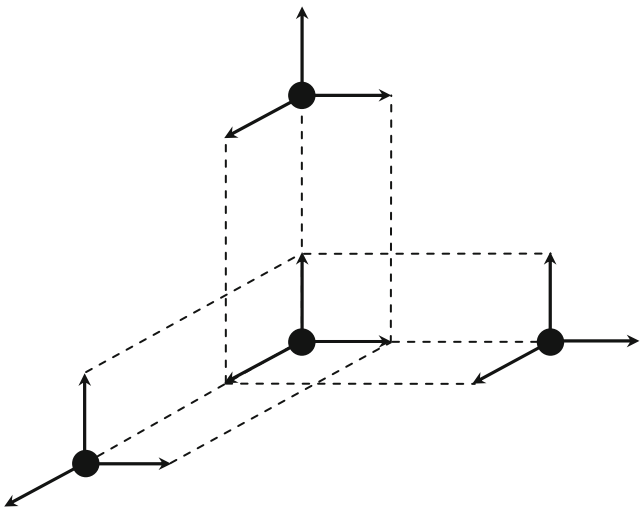
Gradiometry

Whereas the gravity meter, or any other accelerometer, senses the inertial reaction of a single test mass to an applied force, the (gravitational) gradiometer senses the difference of reactions from two test masses. In general terms, one may think of a gradiometer as the juxtaposition of two accelerometers and the sensed gradient as the ratio of the acceleration difference to the baseline length between them. As such, the gradiometer measures only an approximation of the gradient at a point, which is adequate for sufficiently small baselines. Measuring the entire tensor of gradients (a "full-tensor gradiometer") requires a minimum of 12 accelerometers as shown in Figure 5, although because some gradients share an accelerometer in this configuration, the errors between them may be correlated. Completely independent measurements of all nine tensor elements, therefore, require 18 accelerometers. On the other hand, taking advantage of the tensor symmetry and Laplace's field Equation 8 brings the minimum to five accelerometer pairs.

Most gradiometers actually are designed to sense components of the differential curvature of the field (Equation 12), and thus, they rely on Laplace's equation to determine the individual diagonal components. Specifically, imagine that a gradiometer senses $\Gamma_{22} - \Gamma_{11}, \Gamma_{12}$ in the instrument frame. Combining three such devices with mutually orthogonal orientation within the instrument system (Figure 6) thus yields in addition to $\Gamma_{12}, \Gamma_{23}, \Gamma_{31}$, the components $\Gamma_{22} - \Gamma_{11}$, $\Gamma_{33} - \Gamma_{22}$, and $\Gamma_{11} - \Gamma_{33}$. The latter always sum to zero (except for measurement errors) and cannot by themselves separate the diagonal elements of the tensor. Nevertheless, it is common to refer to this as a full-tensor gradiometer (FTG), even though effectively only five of the nine tensor elements are sensed independently.

Gravity, Gradiometry, Table 1 Roughly commensurate (per row) sensor errors in mobile gravity gradiometry. Emphasized entries represent typical calibrated error levels for high-accuracy components

Gradiometer white noise	Orientation error	Gyro bias	Gyro white noise
$30\,\mathrm{E}/\sqrt{\mathrm{Hz}}$	20°	0.5°/h	$3°/\mathrm{h}/\sqrt{\mathrm{Hz}}$
$\mathbf{10\,E}/\sqrt{\mathbf{Hz}}$	6°	0.15°/h	$1°/\mathrm{h}/\sqrt{\mathrm{Hz}}$
$1\,\mathrm{E}/\sqrt{\mathrm{Hz}}$	0.6°	**0.015°/h**	$\mathbf{0.1°/h/\sqrt{Hz}}$
$0.1\,\mathrm{E}/\sqrt{\mathrm{Hz}}$	**0.06°**	**0.0015°/h**	$\mathbf{0.01°/h/\sqrt{Hz}}$
$0.01\,\mathrm{E}/\sqrt{\mathrm{Hz}}$	**0.006°**	0.00015°/h	$0.001°/\mathrm{h}/\sqrt{\mathrm{Hz}}$



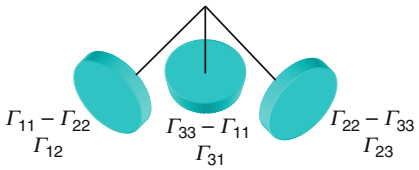
Gravity, Gradiometry, Figure 5 Conceptual minimal configuration for a full-tensor gradiometer.

The first instrument specifically designed to measure the gravity gradient was the torsion balance, invented by the Hungarian geophysicist, Lorand von Eötvös (1848–1919), at the end of the nineteenth century. Prolific in many endeavors of exploration geophysics, one of his passionate goals was to design an instrument that could sense all gravity gradients (he left the vertical-vertical gradient to others, since it would not be possible for his apparatus) (Szabó, 1998). (We make the distinction in geodesy between "gravitation" and "gravity," where the latter refers to measurements on the Earth's surface and is the vector sum of acceleration due to mass attraction (gravitation) and the centrifugal acceleration associated with Earth's rotation.)

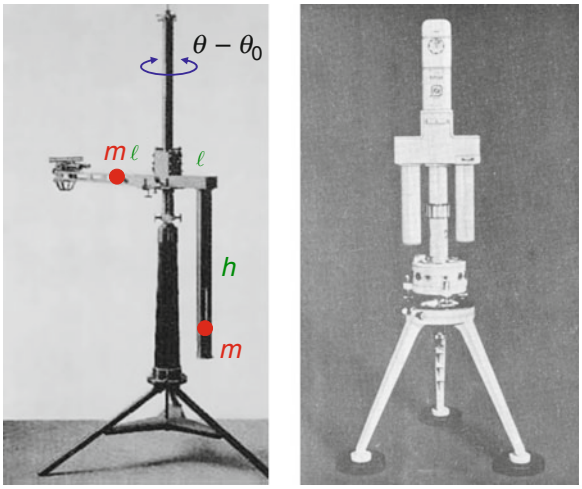
Eötvös adapted the concept of Coulomb's torsion balance (designed to sense electrostatic forces) to measure gravitational gradients. After several initial prototype instruments, including the curvature variometer, which was sensitive to the differential curvature components (Equation 12), and the horizontal variometer, which measured the horizontal gradients (Γ_{13}, Γ_{23}), the final product combined these into one instrument, shown in Figure 7. Two equal masses, m, are attached to the ends of a beam of length, 2ℓ, which is suspended by a platinum-iridium (or, tungsten) wire that may twist about the vertical axis in response to the curvature of the gravitational field. If both masses were at the same height ($h = 0$, in Figure 7), the instrument would be the curvature variometer. With the vertical offset of one mass, the instrument is also sensitive to the horizontal gradients.

Assuming the beam has negligible mass, the torque on the beam is

$$\boldsymbol{L} = \boldsymbol{r}_A \times m\boldsymbol{g}_A + \boldsymbol{r}_B \times m\boldsymbol{g}_B, \tag{44}$$



Gravity, Gradiometry, Figure 6 Mutually orthogonal gradiometer sensors in the "umbrella configuration."



Gravity, Gradiometry, Figure 7 Eötvös's original torsion balance (*Left*, from Szabó, 1998, reprinted with permission, Eötvös Lorand Geophysical Institute of Hungary.) and the more modern version manufactured by the Eötvös Loránd Geophysical Institute of Hungary, Budapest in the 1950s. (*Right*, from Badekas, 1967.)

where $\boldsymbol{r}_A = (-x, -y, 0)$ and $\boldsymbol{r}_B = (x, y, h)$ are the position vectors of the masses in a north-east-down coordinate system with origin at the instrument center, and $\mathbf{g}_A$, $\mathbf{g}_B$ are the gravity vectors at these points. The torque component about the vertical is

$$L_3 = mx(g_2(x,y,h) - g_2(-x,-y,0)) + my(g_1(-x,-y,0) - g_1(x,y,h)). \tag{45}$$

To first-order approximation, the gravity components are

$$g_1 = \Gamma_{11}x + \Gamma_{12}y + \Gamma_{13}z, \tag{46}$$

$$g_2 = \Gamma_{21}x + \Gamma_{22}y + \Gamma_{23}z, \tag{47}$$

which yields

$$L_3 = 2m(x^2 - y^2)\Gamma_{12} + 2mxy(\Gamma_{22} - \Gamma_{11}) + mh(x\Gamma_{23} - y\Gamma_{13}). \tag{48}$$

Here, the Γ_{jk} are gravity gradients as opposed to the gravitational gradients of the previous sections, as noted above.

We may introduce the azimuth, α, of the instrument with respect to north, such that $x = \ell\cos\alpha$ and $y = \ell\sin\alpha$. Then using the angular form of Hooke's law, $L_3 = -\tau(\theta_\alpha - \theta_0)$, Equation 48 becomes

$$-\tau(\theta_\alpha - \theta_0) = m\ell^2((\Gamma_{22} - \Gamma_{11})\sin 2\alpha + 2\Gamma_{12}\cos 2\alpha) + m\ell h(\Gamma_{23}\cos\alpha - \Gamma_{13}\sin\alpha), \tag{49}$$

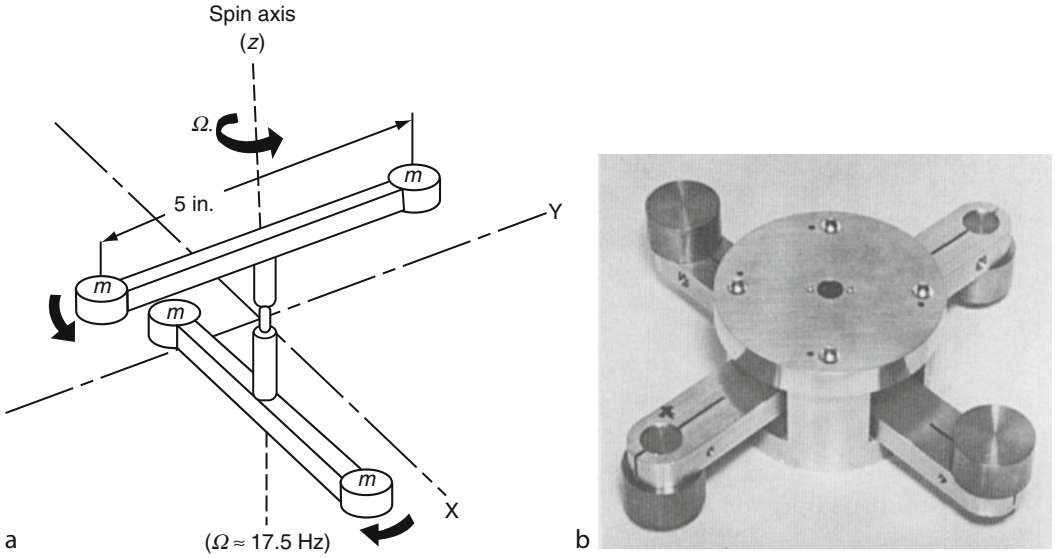
where τ is the torsion coefficient of the wire; θ_0 is the torsion-free, zero-direction of the beam; and θ_α is the angle of the beam relative to the zero-direction when the instrument (casing) is placed at azimuth, α. Measurements at several azimuths are required to determine all unknown quantities: θ_0, $\Gamma_{22} - \Gamma_{11}$, Γ_{12}, Γ_{13}, Γ_{23}.

Eötvös designed several other versions, such as the double torsion balance (two opposing beams) that he used to study the equivalence of inertial and gravitational mass (which Einstein postulated as intrinsically true for his general theory of relativity; see Applications). Though quite laborious and extremely sensitive to nearby masses in the field, the torsion balance (several versions built by various manufacturers) was widely used for geophysical prospecting of oil and gas in the early twentieth century both in Europe and in the USA. Ultimately, it gave way to the more efficient and equally accurate land gravity meter (Nettleton, 1976; Chapin, 1998).

Gravity gradiometry did not regain significant attention until the dawn of the space age since only gradiometers on planetary probes can make in-situ measurements of the gravitational field. Early developments of moving-base gradiometers mimicked the torsional sensing apparatus, similar, in principle, to Eötvös's horizontal variometer, but in a smaller package (thus sensing only $\Gamma_{22} - \Gamma_{11}$ and Γ_{12} in a local frame; Equation 49 with $h = 0$). In addition, by rotating the device about the axis perpendicular to the mass baseline, the sensed gradients are modulated by twice the rotation rate due to the symmetry of the mass-baseline configuration. In this way, some of the errors (such as accelerometer scale mismatches and misalignments) that modulate at once the rotation rate, Ω, can be separated in the frequency domain from the gradient signal that is modulated at twice this rate. That is, demodulation of the output signal at frequency, 2Ω, effectively filters these errors.

One of the earliest modern gradiometers was developed by Hughes Aircraft Research Laboratories for a lunar orbiter mission, the Hughes Rotating Gravity Gradiometer (RGG) (Forward, 1981). Figure 8 shows a schematic of the device that senses the relative torques on the two arms that are coupled to the base by torsion pivots. Two dumbbells are required to distinguish the gravitational gradients from torques on the case in a dynamic environment. Furthermore, the rotation rate of the device is designed to be half its mechanical resonant frequency so as to amplify sensed gradients. A demonstration model of the RGG (which was never put into operation) had a diameter of 14 cm and an accuracy of 1 E for a 10 s integration time (Forward, 1981).

The Charles Stark Draper Laboratory of Cambridge, Massachusetts, using its leading expertise in gyroscope technology, also devised several gradiometer concepts for moving-base applications. The "floated gradiometer," pictured in Figure 9a, was derived from the floated gyroscope whose buoyant/viscous/magnetic support system is virtually insensitive to high levels of acceleration and vibration. In this case, the device, like Eötvös's torsion balance, had two anomalous masses at different heights (skewed mass configuration). If, for example, $\alpha = -90^\circ$



Gravity, Gradiometry, Figure 8 Concept (From Heller, 1977) and breadboard model (From Forward, 1981) of the Hughes Aircraft Rotating Gravity Gradiometer.

is substituted in Equation 49 (maintaining the north-east-down coordinate system and indicating that the first axis of the device points west, toward $-x_2$), then the measurement is the applied restoring moment, M, in response to a deflection due to the gradients:

$$M = \tau(\theta_\alpha - \theta_0) = 2m\ell^2\Gamma_{12} - m\ell h\Gamma_{13}, \tag{50}$$

where ℓ is the radius of the device.

On a stabilized platform with axes constrained to the local north-east-down directions, a cluster of three such devices (Figure 9b) yields measured moments:

$$\begin{aligned} M_1 &= 2m\ell^2\Gamma_{12} - m\ell h\Gamma_{13} \\ M_2 &= 2m\ell^2\Gamma_{12} + m\ell h\Gamma_{13} \\ M_3 &= -2m\ell^2\Gamma_{12} + m\ell h\Gamma_{23} \end{aligned} \tag{51}$$

which can be combined to yield the horizontal gradients, Γ_{13} and Γ_{23}. Derived from the differences of corresponding torques (as shown), these measured gradients are insensitive to angular accelerations about the vertical axis, the direction about which a north stabilized platform is least accurate. Later designs used electrostatically suspended spheres, with anomalous masses, that in an appropriate triad configuration would constitute a full-tensor gradiometer (with Laplace's constraint) and be less susceptible to platform jitter effects (Wells, 1984). Like the Hughes Aircraft instruments, the Draper Lab gradiometers did not reach the production stage, but did demonstrate very good performance in the laboratory.

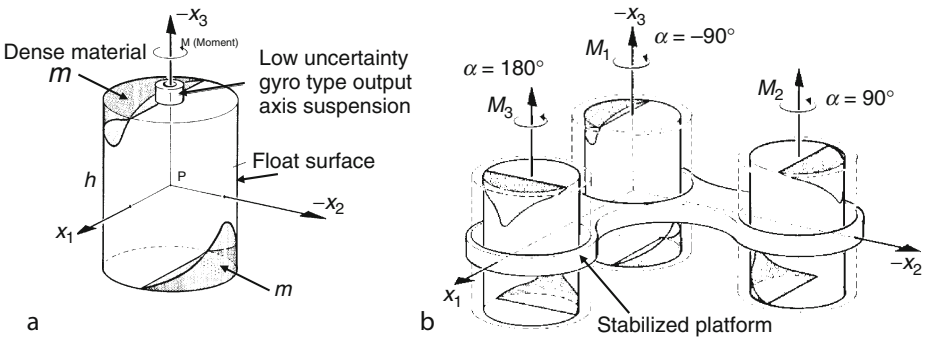
Another concept that utilized device rotation to separate the gradient signal from noise sources in the frequency domain was the gravity gradiometer instrument (GGI) of Bell Aerospace. The instrument consisted of pairs of accelerometers mounted on a rotating disk as shown in Figure 10, left. The input axes are perpendicular to the radius of the disk and thus, in analogy to the Hughes Aircraft RGG, their measurements may be thought of as proportional to torques about the spin axis. Substituting $\alpha = \Omega t$ and $\alpha = \Omega t + \pi/2$ for the respective pairs of accelerometers and $M = mr(a_1 + a_2)$ and $M = mr(a_3 + a_4)$ for the respective torques into Equation 49 (with $h = 0$), the measurement equation, therefore, is given by

$$\begin{aligned} &a_1(t) + a_2(t) - (a_3(t) + a_4(t)) \\ &\quad = 2r(\Gamma_{22} - \Gamma_{11})\sin 2\Omega t + 4r\Gamma_{12}\cos 2\Omega t, \end{aligned} \tag{52}$$

where Ω is the spin rate of the disk and t is time. The factor of 2 on the right side comes from the dual pairs of accelerometers. This instrument has been used for military and commercial applications and today's version (acquired by Lockheed Martin, Figure 10, right) has four pairs of accelerometers per disk, thus, in essence, further doubling the signal amplitude in the output (Schweitzer et al., 2000). However, three GGIs are still needed (e.g., in the configuration of Figure 6) to obtain all elements of the gradient tensor.

The Bell Aerospace (Lockheed Martin) gradiometer is currently operated for various geophysical and geodetic applications by Fugro (the erstwhile BHP Falcon single-disk system, Figure 11) and by Bell Geospace (full-tensor gradiometer, with the original four-accelerometer disks). The Falcon system is used primarily for airborne surveys, while the Bell Geospace system is deployed on aircraft and ocean vessels.

Satellite in-situ gravitational field measurements are limited fundamentally to gradiometry. Aside from small atmospheric drag forces and solar radiation (and Earth



Gravity, Gradiometry, Figure 9 Floated gradiometer geometry of the Charles Stark Draper Laboratory; (**a**) single unit, (**b**) cluster of three units on a stabilized platform (Both diagrams after Trageser, 1970, reprinted with permission, Draper Laboratory.)

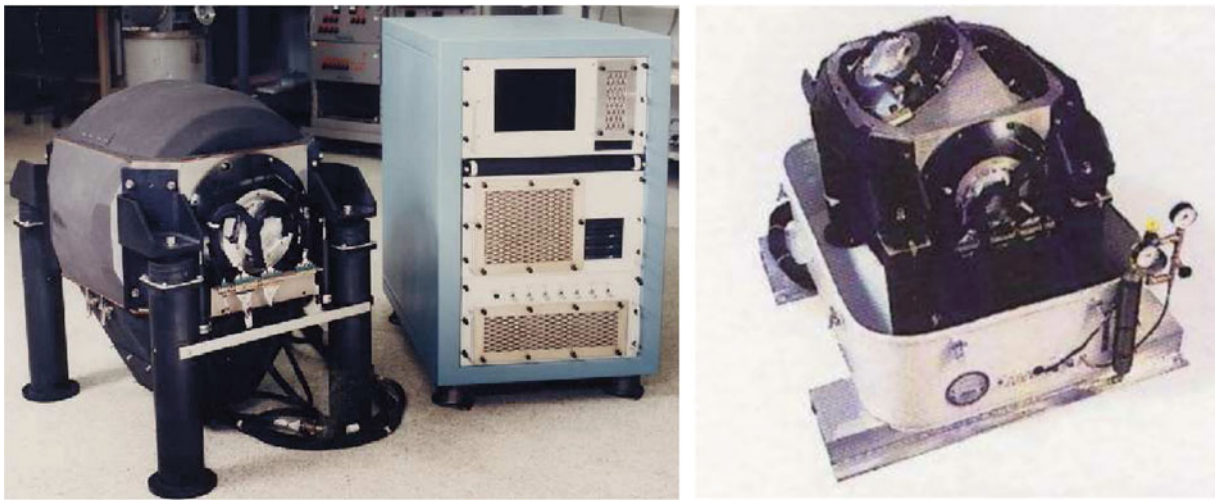
albedo) pressure, an Earth-orbiting satellite is in free fall. Accelerometers on a satellite sense only the non-gravitational forces, but a gradiometer, as on any moving platform, senses the gravitational gradient (Equation 42). Satellite gradiometry has a long, interesting, and ultimately successful history. Besides the Hughes RGG (which did not fly on a satellite), a major effort was undertaken by NASA to put a superconducting gravity gradiometer (SGG) into low Earth orbit in the 1980s. The SGG was developed by the University of Maryland (Moody et al., 1986; Paik et al., 1988) as an outgrowth of the technology of highly sensitive gravity wave detectors. Based on accelerometers that use the magnetic flux exclusion principle of superconducting bodies, the SGG was designed primarily to sense the in-line gradients. Referring to Figure 12, left, as the gap between the superconducting proof mass and the sensing coil changes due to acceleration, the magnetic flux is forced out of the sensing coil and into the input coil of a superconducting quantum interference device (SQUID), which is able to sense extremely small changes in the flux. The system was not flown on a satellite but did contribute to physics experiments involving the search for non-Newtonian gravitational effects (see Applications).

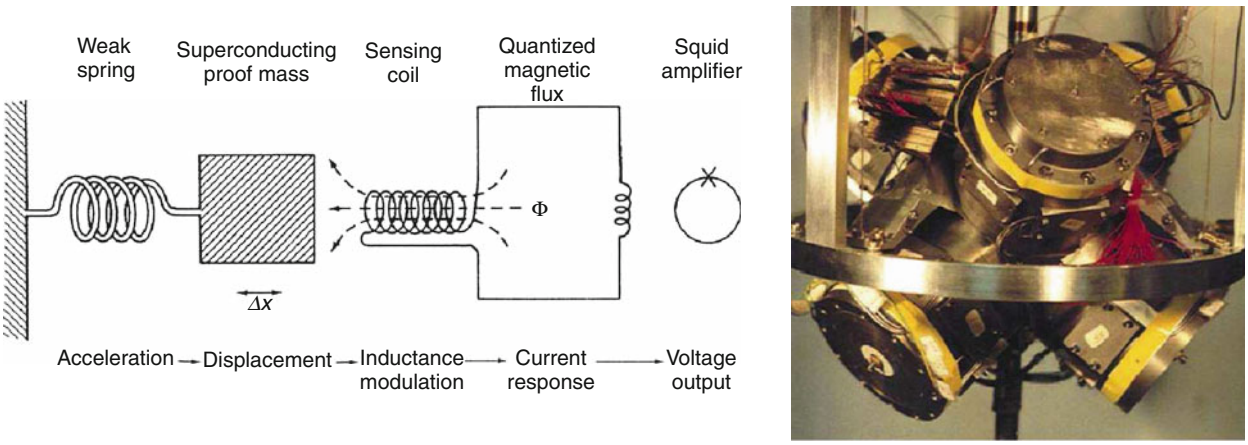
In March 2009, the first satellite-borne gravity gradiometer was launched by the European Space Agency (ESA) into low Earth orbit (altitude = 255 km) for a 20-month mission to map the Earth's gravitational field globally to a resolution of 100 km, or better (Drinkwater et al., 2003). The *Gravity field and steady-state Ocean Circulation Explorer* (GOCE) gradiometer is a true full-tensor device (Figure 13), based on three pairs of three-axis accelerometers, separated pair-wise by 0.5 m, thus in principle measuring all nine elements of the tensor, $\partial \boldsymbol{a}^b / \partial \boldsymbol{x}^b$ (Equation 42).

However, each accelerometer has one weakly calibrated axis, due to the earthly 1-g laboratory environment. As a consequence, the in-line components, $\partial a_1/\partial x_1$, $\partial a_2/\partial x_2$, $\partial a_3/\partial x_3$, and the cross components, $\partial a_1/\partial x_3$, $\partial a_3/\partial x_1$ are most accurate. The latter allow an accurate determination of the angular velocity, ω_2, about the normal to the orbital plane, which is greatest in magnitude (Earth-pointing stabilization), since from Equation 42 and the symmetry of the gravity gradient tensor, we have

$$\frac{\partial a_1}{\partial x_3} - \frac{\partial a_3}{\partial x_1} = 2\dot{\omega}_2. \tag{53}$$



Gravity, Gradiometry, Figure 11 Bell Aerospace (Lockheed Martin) GGI used on current terrestrial gradiometer systems. *Left*, the Fugro Falcon single-axis system (Previously BHP Billiton, from van Leeuwen, 2000, reprinted with permission, Society of Exploration Geophysics.); *right*, the full-tensor 3 GGI system of Bell Geospace (Murphy, 2004; reproduced with permission, Bell Geospace). Both systems are shown on inertially stabilized platforms.

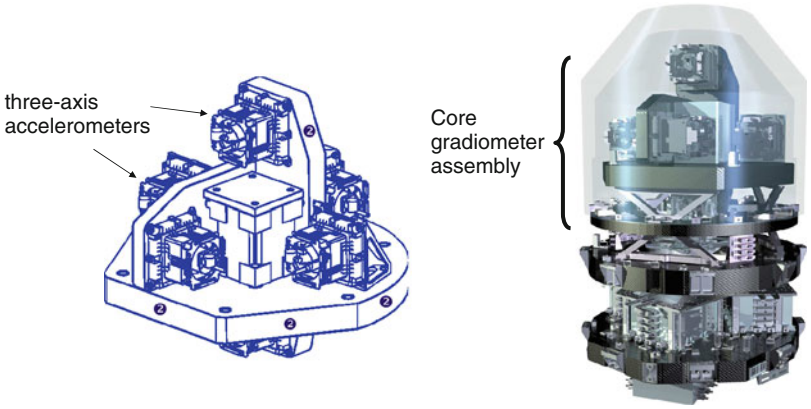


Gravity, Gradiometry, Figure 12 *Left*, the accelerometer concept of the superconducting gravity gradiometer of the University of Maryland (Reprinted with permission from Moody et al., 1986). Copyright (1986), American Institute of Physics). *Right*, a three-axis system that senses the three in-line gradients. (Paik, 2004; reprinted with permission of author.)

As a consequence and since ω_1 and ω_3 are comparatively small, the most accurate gravity gradients obtained by the GOCE gradiometer are the in-line gradients and the cross gradient, Γ_{13}.

Other types of gradiometers may be found discussed in the literature and are at various stages in their development. For example, a cryogenic gradiometer based on the same principle as the Hughes Aircraft RGG was constructed and tested by the Canadian company, Gedex (Tryggvason et al., 2004). Stanford University has investigated a gradiometer using dual cold-atom interferometer accelerometers (McGuirk et al., 2002). And, MEMS (micro-electro-mechanical systems) technology is being applied to the manufacture of miniature gradiometers (Flokstra et al., 2009). The reader is referred also to the review by Difrancesco (2007).

Designing and using a gravity gradiometer system requires consideration of several significant sources of error. Gradiometers on a moving platform must detect a very small differential gravitational signal buried in a large-amplitude acceleration environment. An accuracy of 1 E over an accelerometer baseline of 0.1 m implies better than 7×10^{-11} m/s^2 accuracy in the sensed accelerations, a resolving power that is challenging for most accelerometers. Rotation of the gradient sensor has been a key development to separate signal from noise in the



Gravity, Gradiometry, Figure 13 GOCE core gradiometer assembly (*left*) and total instrument (*right*).

frequency domain. Cryogenics is another solution, as is the dynamically quiet environment of a space vehicle.

Essential error sources for accelerometer-based gradiometers include the scale factor and bias stability of the accelerometers, as well as the degree to which their scale factors are matched and their sensitive axes are aligned. These all determine how well the common linear acceleration is rejected in the difference that ideally leaves only the gravitational gradient (with proper stabilization). Often, specialized electronic or mechanical devices or procedures (rotation and induced shaking) are used to eliminate or calibrate these erroneous effects. A particularly important calibration is the self-gradient of the vehicle that carries the gradiometer. Since the platform is stabilized (e.g., in the local level frame), the rotation of the vehicle about the platform creates a varying gradient field due to the changing attitude of the vehicle masses. This field must be calibrated, often using elaborate procedures that place the vehicle in varying attitudes while the gravitational field is constant (i.e., the vehicle is stationary) – see (Jekeli, 1988b).

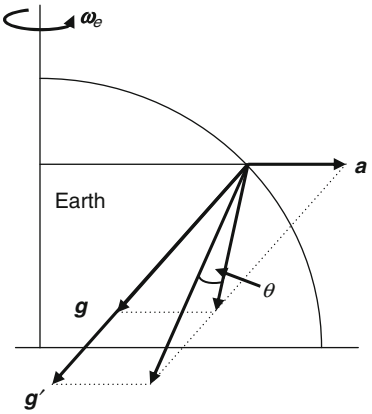
In summary, the development of instruments that measure gravitational gradients spans over 100 years; and, despite a variety of system advancements, mostly to make gradiometry mobile, many modern sensor concepts have strong analogies to the original Eötvös curvature variometer – they measure differential curvature parameters. In-line differential accelerometers are only just being deployed on a satellite system (GOCE) or are in development for future systems. The 1 E accuracy of the Eötvös torsion balance rivals or still bests the terrestrial mobile systems of today, but the latter have improved the integration time vastly from many hours to tens of seconds, or better. In principle, gradiometry relies primarily on the technology of inertial sensors, and the theoretical limit in measurement precision in many cases has not yet been reached at the operational level. It is clear that gravity gradiometry is the holy grail of precision gravimetry on moving platforms – the future will see many more ideas and prototype sensors added to the existing repertoire of instruments.

Applications

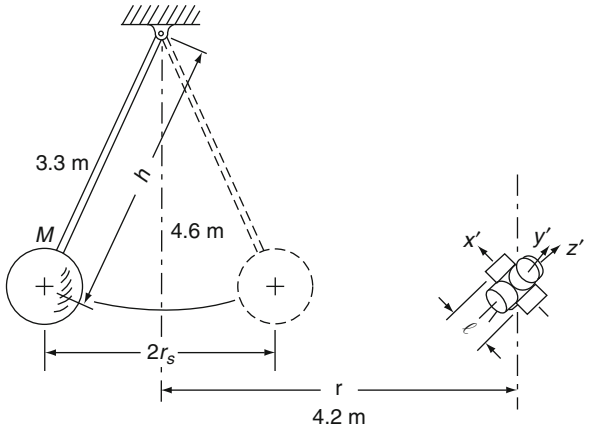
One of the more interesting applications of the torsion balance was Eötvös's experimental validation of the equivalence of inertial and gravitational mass, assumed by Einstein in his theory of general relativity. Inertial mass is the proportionality factor between velocity and linear momentum (or, between acceleration and *applied* force); while, gravitational mass is the proportionality factor between gravitational acceleration and gravitational force. Conceptually, the acceleration caused by the gravitational attraction of a mass body need not be indistinguishable from the acceleration caused by a force, such as propulsion, friction, or similar physical action. Yet the assumption of their equivalence led Einstein to his very successful theory.

Eötvös experimented already in the 1890s with the question of dependence of gravitational attraction on the composition of mass (continuing with Galileo's experiments that showed no such dependence). The idea of his experiment is illustrated in Figure 14 showing that different types of test masses on the beam of the torsion balance might yield different gravitational accelerations that in combination with the unchanging centrifugal acceleration due to Earth's rotation would yield a measurable deflection. Eötvös et al. (1922) found no deviation at the 5 part-per-billion level. If indeed, such a deflection is detected, it could also be interpreted as evidence of a non-constant gravitational constant, or an additional non-Newtonian force (Fischbach et al., 1986; Fischbach and Talmadge, 1992).

Another experimental test of Newton's law of gravitation involving gravitational gradients considers the sum of in-line gradients, which for a Newtonian field must sum to zero (Figure 15) in a vacuum (Laplace's Equation 8). Moody and Paik (1993) used a swinging pendulum in the laboratory to induce modulated in-line gradients that were measured with their superconducting gradiometer (see *Gravity, Gradiometry*). The sum of the measured gradients was zero with a statistical variation ($\sigma = 3 \times 10^{-4}$ E) that placed further limits on any local departure from Newton's law of gravitation.



Gravity, Gradiometry, Figure 14 Eötvös's experiment to determine if different types of mass experience different gravitational accelerations (**g** versus **g**′) that could be measured as a deflection, θ, with respect to the constant centrifugal acceleration, **a**.



Gravity, Gradiometry, Figure 15 Experimental setup to test Laplaces's equation by measuring the sum of in-line gradients modulated by the changing gravitational field induced by a swinging pendulum. (From Paik, 2004; reprinted with permission of author.)

The principal utility of the torsion balance and later the gravity gradiometer was and is in geophysical exploration. The Eötvös torsion balance (and its successors) played a significant part, with over a hundred in operation worldwide, in the exploration for oil and gas reservoirs in the early twentieth century, 1918–1940. The achievable accuracy was as good as 1–3 E, but the measurements were arduous, requiring up to 6 h per station. Thus, the torsion balance quickly lost ground when the more portable and robust, as well as sufficiently accurate spring-type gravimeters were developed in the 1930s and 1940s.

Gravity gradiometry in modern times is conducted almost exclusively with mobile systems, in order to take advantage of the increased resolution capability and avoid the difficulty of separating the kinematic and inertial accelerations, required in mobile gravimetry systems (Jekeli, 2000). Submarine gradiometers are used to compensate inertial navigation systems for the effects of gravity, and shipborne gradiometers have been used for marine gravity surveys. A significant investment has been made by a number of commercial exploration companies to use airborne gradiometers to map the gravitational field at high resolution in search for minerals, such as diamonds found in kimberlite pipes (Liu et al., 2001).

A long-standing goal of the space exploration agencies (NASA, ESA, among others) for half a century has been the gravitational mapping of the Earth (and other bodies of the solar system) using a satellite-borne gradiometer. This was realized finally starting in 2009 with the launch of the GOCE satellite whose 2-year mission will provide the highest resolution (100 km) global gravitational model derived solely from a satellite (see *Gravity, Gradiometry*). Such a detailed model of the global field will advance the earth sciences in many fields, from oceanography to regional tectonics and the dynamics of the upper mantle and crust, and to polar ice sheets and glaciology.

GREAT EARTHQUAKES

Roger M. W. Musson
Earthquake Seismology, British Geological Survey, Edinburgh, Scotland, UK

Definition

Any earthquake with magnitude over 8 Mw. Alternatively, any earthquake famous for one reason or another.

Introduction

Under the technical definition, one can find some very obscure "great" earthquakes – a magnitude 8 earthquake in the Southern Ocean is likely to go wholly unremarked by the world's media. Also, given the inherent imprecision in magnitude scales, it is possible for an earthquake with a magnitude of 8.0 to be successively promoted to and demoted from the canon of greatness with each successive revision.

If one took a sample of educated laymen and asked them to name any earthquakes they could think of, one

could be sure to get a few of the most recent high-profile calamities; further back, the results might vary from country to country. In the central USA, probably many are aware of the 1811 New Madrid earthquakes; in central Europe, the name of the 1356 Basel earthquake might come up, and so on. But probably not many could name correctly the largest earthquake ever known, the 1960 Valdariva, Chile, earthquake, which reached 9.6 Mw in magnitude, a value many seismologists suspect to be a physical upper limit of earthquake size. This devastating earthquake also produced a huge tsunami, which, on the Chilean coast, pitched boats up to 3 km inland. (See box-out: Ten Largest Earthquakes).

The title "largest earthquake ever" gives the 1960 Valdariva event an indisputable claim to greatness by any reckoning. Other earthquakes are famous for a variety of reasons: their place in history, the lessons learned from them, their significance in the development of seismology, or their sheer excessive destructiveness. The earthquakes of 1356 and 1811 mentioned above are both important for the same two reasons – they demonstrate that significant earthquakes can still occur well away from plate boundaries, and also that the historical record can reveal potential threats in places not much remarked for seismicity today.

The 1556 Shaanxi earthquake bears the record for being the most deadly earthquake, with about 830,000 dead. The figure of one million dead in one earthquake has not yet been reached (contrary to some sources, the 20 May 1202 earthquake in the Levant did not kill this many; Ambraseys and Melville, 1988), but, with several current megacities dangerously exposed, it is feared that it is only a matter of time. (See box-out: Ten Deadliest Earthquakes).

There are probably three earthquakes that stand out as the most unquestionably great earthquakes of history. Firstly, the 1755 Lisbon earthquake: not only was this (with its accompanying tsunami) one of the most deadly and devastating earthquakes in European history (not forgetting its impact on North Africa), but it sent shockwaves throughout the whole of Western culture. Second, the 1906 San Francisco earthquake so ingrained itself into history that the very name of San Francisco conjures earthquakes to mind; to which must be added the important role this event played in the development of seismological theory. Lastly, the 2004 Sumatra earthquake, staggering in its immensity, changed both the popular and professional understanding of earthquakes.

1 November 1755: the advance of rationalism

Of all great earthquakes, the one with the most lasting impact is certainly the Lisbon earthquake of 1755. Not only did it destroy what was then one of the most important cities in the world, the capital of the Portuguese empire, it shook up the very development of Western philosophy. Furthermore, it continues to be controversial amongst seismologists to this very day.

The first of November is the feast of All Souls, one of the most solemn occasions in the calendar of the Catholic Church. It was on the morning of this day that a massive earthquake struck somewhere off the coast of Portugal. Damage occurred over a wide area across Portugal and western Spain; significant damage occurred even in Morocco. The shaking was perceptible throughout the Iberian Peninsula and into France. Even beyond France, long-period waves caused the agitation of water in ponds and lakes at great distances – as far away as Scotland (Loch Ness was disturbed) and Scandinavia.

The worst damage, however, occurred in Lisbon. The churches, many of which collapsed, were packed with worshippers when the quake struck, and casualties were heavy. The sea then mysteriously withdrew, leaving fishes floundering in the mud. Many ventured out from curiosity, or to collect some of the fish. Shortly afterward the tsunami roared in, surged up into the semi-ruined city, collapsing many buildings that had already been damaged by the earthquake.

All Europe was shocked, and not just by the scale of the destruction. It was axiomatic in Christian thinking that all prodigious events such as earthquakes were of divine origin. The milder ones were sent as a warning of God's displeasure, the more severe ones were a punishment to send mankind back on the path of righteousness. Furthermore, this was true whether or not it was appreciated that such events had natural causes, as many printed works of the previous century explicitly argued: God works through, and controls, the natural world. Whether or not earthquakes were due to natural causes (the dominant explanation at the time was the Aristotelian view that earthquakes were due to subterraneous winds), the timing and location was divinely ordained (Walsham, 1999).

But the injustice of the destruction of Lisbon strained this train of thought to breaking point. Not only did the earthquake occur on one of the holiest days of the Christian year – the godly citizens who were marking the occasion by attending mass were killed, whereas sinners who chose to spend the morning in playhouses or brothels by and large escaped. If this was God's judgment, it was a very strange one. The earthquake was seized upon by Voltaire as a means of attacking the optimistic school of philosophy characterized by Leibniz (Kendrick, 1956). In Lisbon, a decree was issued that anyone found preaching that the earthquake was sent by God, should be put to death.

For modern study of the 1755 earthquake, there are several sorts of information that can be used to try and understand which fault produced it. Firstly, there is the distribution of earthquake effects; for most historical earthquakes, analysis of the distribution of intensity is the predominant means of location, though this is markedly less easy for offshore events. Secondly, for tsunamigenic earthquakes like 1755, the time and run-up of the tsunami at different locations can be inverted to estimate the parameters of the engendering fault rupture. Thirdly, some use can be made of information from

aftershocks. Since these are generally much smaller than the main event, they are usually felt only at short distances. Lastly, in the case of a major earthquake, there should be some geological trace of the structure that produced it.

In terms of available geological structures, there are two main candidates, and a possible third. The first, and most obvious, is the Gorringe Bank, a segment of the offshore plate boundary between Europe and Africa. This was identified as the source of the 1755 earthquake by Johnston (1996); it was also the location of a large earthquake in 1969, and the intensity distribution of the 1969 event resembled to some extent a scaled-down version of the pattern observed from the 1755 event (Levret, 1991).

The second candidate is a more recent discovery – a fault off the coast of Portugal trending NNE-SSW showing signs of recent activity (Baptista et al., 1998). This was named the Marquês de Pombal Thrust in honor of the man who oversaw the reconstruction of Lisbon. This fault provides a good fit to the analyses of tsunami arrivals on the Portuguese coast (Baptista et al., 2003). However, it doesn't seem very likely that an earthquake on this fault would have caused damage in Morocco.

The third is a controversial suggestion by Gutscher et al. (2002) and Gutscher (2004) that the causative feature was an N-S aligned subduction zone in the Gulf of Cadiz, dipping eastward under Gibraltar. Apart from the fact that the very existence of such a feature is disputed, if this was the source, it is hard to understand why Lisbon was destroyed in place of Cadiz. The earthquake is well described in Gibraltar itself, and damage was insignificant.

There are still more problems though. Given that the magnitude of this great earthquake must have been around 8.7 (Johnston, 1996), none of the faults described seem long enough to host such a great earthquake. Recent suggestions to account for this propose multiple near-simultaneous earthquakes: Baptista et al. (2003) and Baptista and Miranda (2005) propose a composite source involving the Marquês de Pombal Thrust and a fault segment on the southern flank of the Guadalquivir Bank; while Vilanova et al. (2003) have the second earthquake on a fault in the Lower Tagus Valley, close to Lisbon. The issue is still unresolved and controversial; the source of this great earthquake is still an enigma.

18 April 1906: the archetype of earthquakes

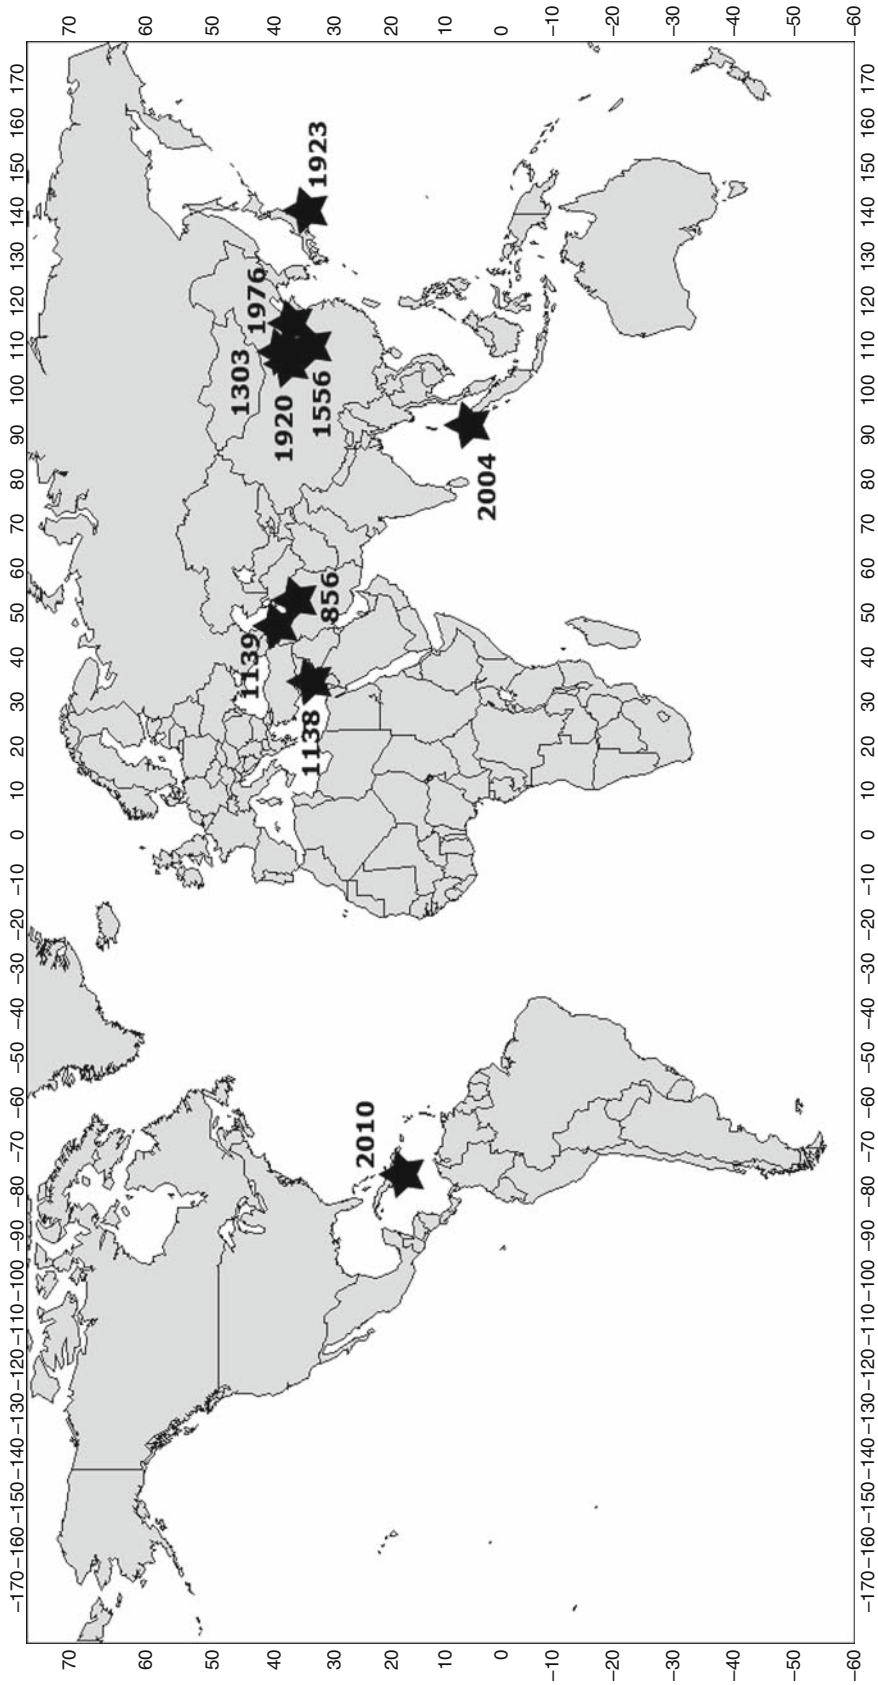
The San Francisco earthquake of 18 April 1906 is of all earthquakes, probably the most iconic in popular culture; the one earthquake that practically any layman can mention. As Davison (1927) remarked, "If the Californian earthquake were the only shock known to mankind, the attention paid to it could hardly have been more exclusive." Not only was it a major disaster in a romantic locale, it even had a celebrity cast – Caruso being in the city at the time. Thanks to the telegraph, the news spread quickly round the world, much faster than had been the case in 1755.

As with the Lisbon earthquake, fire was a contributor to the damage; but this time, the major contributor. Earthquakes are great fire starters, upsetting stoves, breaking gas pipes. But they also hinder fire-fighting efforts. As the fire gripped the city, much of which consisted of wooden buildings, it was found that the water supply system was also damaged by the quake. Unable to use hosepipes, the city authorities resorted to trying to control the fire with a system of firebreaks. Unfortunately, this was carried out somewhat ineptly. The black powder that was used often simply set fire to the building being blasted; and where it didn't, it blew houses into clouds of matchwood that easily ignited – the firebreaks being often created too close to the advancing flames. Furthermore, no attempt was made to check what the buildings marked for demolition actually contained. One such building, belonging to the Viavi pharmaceuticals company, contained a huge store of spirit alcohol. The resulting fireball so exacerbated the fire that probably another 50 blocks in the northern part of the city were destroyed as a result (Fradkin, 2006).

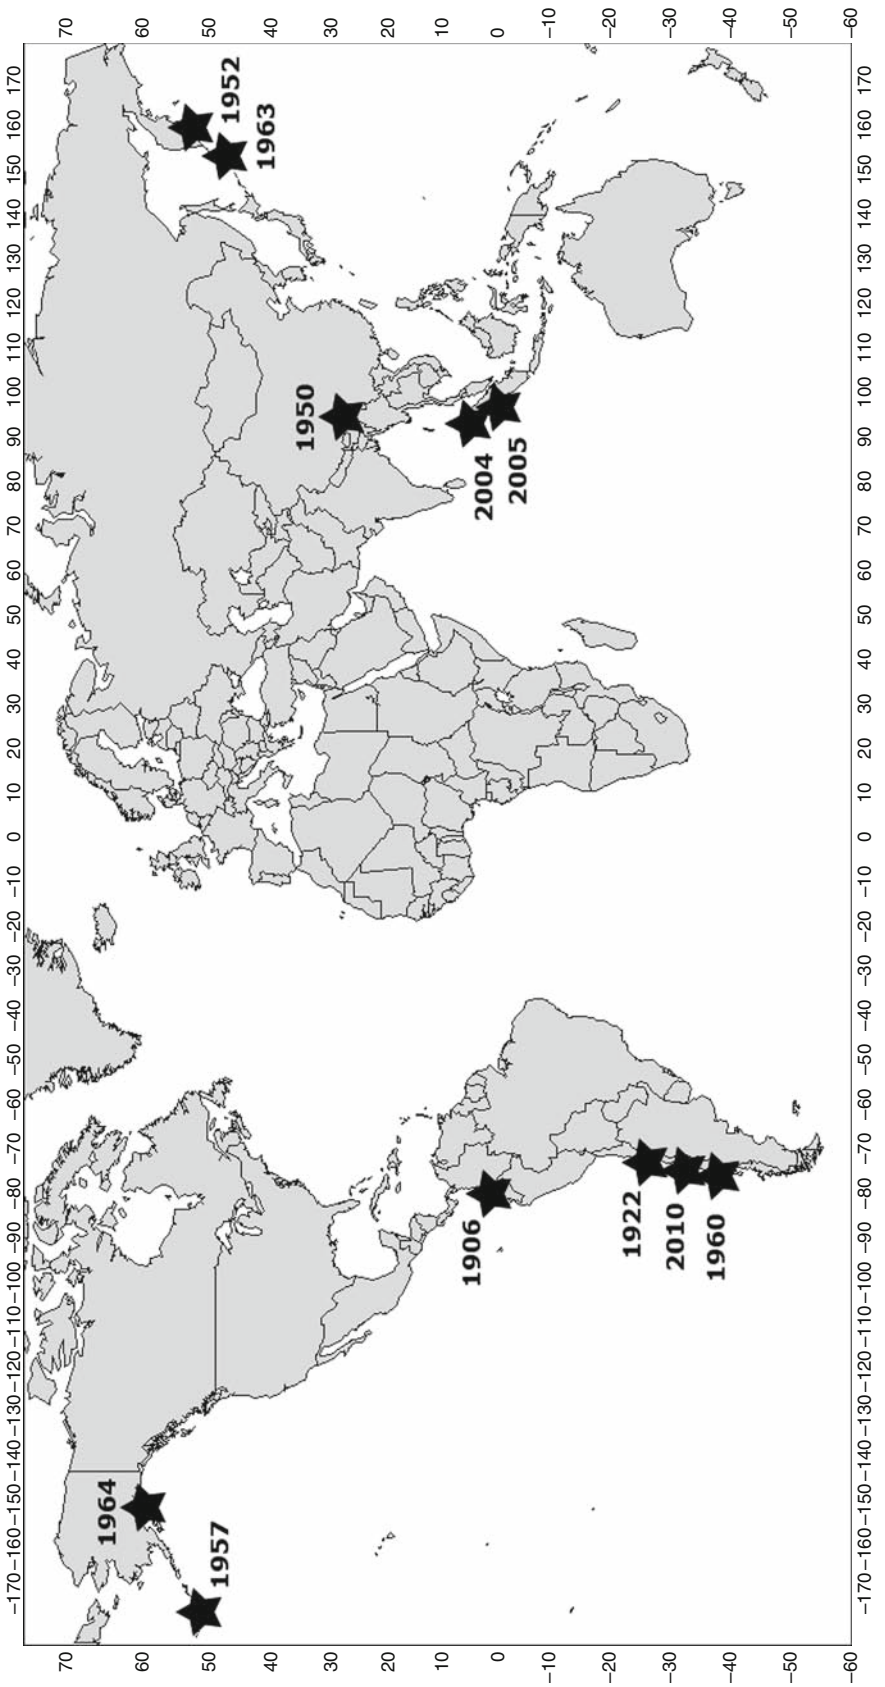
The final death toll is a matter of dispute; initial figures of around 700 are clearly underestimates, partly for propaganda purposes (reporters were encouraged to call it the Great San Francisco Fire and play down mention of the earthquake). Current estimates are about 3,000 dead (Stover and Coffman, 1993).

From a seismological point of view, the 1906 earthquake is rather more straightforward than the 1755 event. The fault it occurred on is not just known, it is perhaps the most famous fault in the world: the San Andreas, forming the plate boundary between the North American and Pacific plates. This is a right-lateral strike-slip fault; the fault rupture extended probably around 430 km including the offshore extension, with a slip of over 6 m in places (Lawson, 1908–1910; Segall and Liskowski, 1990; Stover and Coffman, 1993). Since strike-slip faults are limited in width to the thickness of the crust, this gives a magnitude of only around 7.8 Mw. The felt area was much less than that of the Lisbon earthquake, covering only California and extending partially into Nevada and Oregon (attenuation of seismic shaking is higher in California than in Iberia).

The dislocation of fence posts across the fault trace made it very obvious that the earthquake was due to fault displacement. It was studying the 1906 rupture that led Reid (1910) to develop the theory of elastic rebound, which still underpins basic seismological theory today – that a fault gradually deforms due to the build-up of crustal stresses, until a locking asperity breaks, releasing energy as the fault violently snaps. The connection between earthquakes and faulting was well-known at the time; Hoernes (1878) held that the majority of earthquakes were tectonic in origin, due to displacement along fractures related to mountain building. As early as 1855, Lyell identified repeated earthquake-related faulting in New Zealand (Lyell, 1856), but it is not clear that he understood that the fault produces the earthquake and not vice versa. The earliest statement that dislocation on a fault actually



Great Earthquakes, Figure 1 Map of the ten deadliest earthquakes in history.



Great Earthquakes, Figure 2 Map of the ten largest earthquakes since 1900 (actually 11 due to a tie for the tenth place).

causes earthquake shaking seems to be Mallet (1851), but he was ahead of his time.

However, Reid's fundamental understanding began a new era in seismology, opening the door to the interpretation of seismograms in terms of fault mechanics (Wald et al., 1993; Agnew, 2002).

26 December 2004: cataclysm

Although most of the world's subduction zones are around the Pacific, there are two in the Indian Ocean: on the Makran coast of Iran and along the south coast of Sumatra (extending to Burma in the north and bending round to Java in the east). While the historical seismicity of Sumatra (including a major event in 1833) was by no means unknown (Newcomb and McCann, 1987), it was not generally considered high on the list of potential localities for catastrophe before the earthquake of Boxing Day 2004. The epicenter was off the Sumatran coast at the northern end of the island, near Bandeh Aceh, and the rupture propagated almost entirely northward, for a staggering distance of 1,600 km (Nalbant et al., 2005), reaching up to the Andaman Islands. The northern part of the rupture zone, where the plate boundary is extremely oblique to the direction of convergence, was almost north–south in orientation. The resulting tsunami, instead of heading off into the southern Indian Ocean as occurred in 1833, headed due east and west, hitting crowded tourist beaches in Thailand about 15 min later (shortly after 8 a.m. local time) and India and Sri Lanka 2 h after that.

The effect was literally a cataclysm (Gr: down-washing), as the waves swept inland up to about the 30 m mark in some places, causing immense destruction. About 230,000 lost their lives, of which 167,000 were in Indonesia. It tends to be the case that most high-fatality earthquakes kill local people in substandard housing; this event was exceptional in killing large numbers of foreign tourists, which accounts in part for the great impact of the event on public consciousness in the West. (For a while afterward, journalists would enquire of seismologists "will there be a tsunami?" even in cases for earthquakes in central Russia.)

The result was a sudden impetus toward installing tsunami warning systems in different parts of the world, though perhaps not always with the understanding that technical solutions are of limited use without the practical means to evacuate people at risk in a timely fashion.

Given that no earthquake anything like as large had occurred anywhere in the world since the 1960s, in the following days, the analysis of the earthquake tested the methods of modern seismology in new ways. The shock waves circled the globe, being distinctly recognizable even on the third pass, and even altered the rotation of the planet itself, the length of day dropping by up to −5μs (Bizouard, 2005). The pole itself shifted by up to 2 mas (milli-arc seconds) toward 90°E (Bizouard, 2005; 1 mas equals an equatorial shift at the Earth's surface of 3.1 cm). The difficulty for analysts was caused by the excessive duration of the rupture; the unidirectional propagation of the rupture took about 10 min to reach its terminus. This complicated the seismic records as waves propagating from different parts of the rupture at different times over-wrote each other. The immediate impact was the underestimation of the earthquake's magnitude – immediate press releases giving values of 8.5 or 8.7. Initial attempts to model the slip distribution could only manage the southernmost part of the rupture (Ji, 2004). The first complete slip models were made by Ammon et al. (2005) from a combination of body waves, intermediate period waves and long period waves, and Vigny et al. (2005) using an inversion of GPS data (the two models disagree extensively).

Previously, it had been thought that such a large earthquake was impossible on this part of the Sunda thrust system, on tectonic grounds, and due to parts of the system having already broken in previous large earthquakes. The fact that the 2004 earthquake ruptured through segments that had already recently ruptured has caused seismologists to reassess the risk of great thrust earthquakes in other areas (e.g., Suárez and Albini, 2009).

It was speculated at the time that the movement due to the earthquake would increase the stress on the Great Sumatran Fault, a strike-slip fault running the length of the island, and bring this close to failure (Nalbant et al., 2005). As of the time of writing, the expected event on this fault has not yet occurred. Instead, a remarkable cascade of events occurred on segments of the thrust zone south of the 2004 rupture, including further great earthquakes on 25 March 2005 and 12 September 2007 with magnitudes $\geq$8.5 Mw. Current estimates (e.g., Megawati and Pan, 2009) are that there is still a potential slip in this part of the system to make further great earthquakes on the coast of Sumatra a continuing threat.

The ten deadliest earthquakes

A number of lists have appeared over the years purporting to give the ten earthquakes with the highest number of fatalities. Many of these are prone to easily avoidable errors, such as perpetuating fake earthquakes like the notorious 1737 Calcutta event (see Bilham 1994 for the refutation of this) or the 893 Ardabil (Iran) earthquake. However, compiling an accurate list is difficult, since for even relatively modern earthquakes, death tolls are often inaccurate, given the sheer difficulty of making a body count in the aftermath of a major disaster (as witness the difficulty of estimating the death toll in the 2010 Haiti earthquake). The problem is greatly multiplied for historical earthquakes, where sources are vague, unspecific, or exaggerated, and in most cases, there was no census to begin with. The earthquake generally agreed to be the deadliest of all time is the 1556 Shaanxi earthquake, with 830,000 deaths. This great earthquake (M ~ 8) affected an area where many people were living in loess caves, which collapsed, burying the inhabitants.

The second deadliest is probably the 1976 Tangshan disaster. The death toll from this event has been a matter of controversy; the earthquake occurred during the Cultural Revolution in China, when news about disasters was generally suppressed. Shortly after

the earthquake, a suspiciously accurate figure of 655,237 deaths appeared in the Hong Kong media (South China Morning Post, 5 January 1977). The official death toll later released was 242,419 (Chen, 1988), though Marza (2004) suggests the true figure may have been over a million.

There are a number of earthquakes with death tolls in the region of 200,000–300,000 that are hard to discriminate between. Willis (1928) attributes 260,000 deaths to the Syrian earthquake of 115, but a comprehensive review of the sources by Ambraseys (2009) shows that while the death toll must have been very high, the total figure is unknown. There are several candidates for third place. The 1920 Ningxia earthquake killed 235,502 according to Utsu (2002) and 160,000 according to Tiedemann (1992). The official death toll of the 26 December 2004 (9.2 Mw) Sumatran earthquake is 227,898, mostly from the tsunami. The 1139 earthquake in Ganjak, Azerbaijan is considered by Ambraseys and Adams (1989) to have killed 230,000, a figure rejected by Guidoboni and Comastri (2005) as exaggerated (considering the total population of the affected area). Finally, the 12 January 2010 Haiti earthquake, at the time of writing, is believed to have killed around 220,000–230,000.

Events with death tolls around 200,000 include another Chinese earthquake, in Shanxi province in 1303, with a death toll around 200,000 (Fu et al., 2005), and the 856 Qumis earthquake in Iran, believed to have killed around 200,000 (Ambraseys and Melville, 1982).

Next highest is undoubtedly the 1923 Kanto (Japan) earthquake with 143,000. The only other earthquake (leaving aside events with very doubtful high death tolls) with attributed deaths over 100,000 is the 1138 Aleppo earthquake, but this is another case where, according to Ambraseys (2009), the actual figure is quite unknown (Ambraseys, 1962 gives 130,000).

If one removed 1138 and 1139 from the list as too doubtful, the next two events would be the Sichuan earthquake of 2008 with 87,587, and the 1908 Messina earthquake in Southern Italy (82,000).

This gives us the following list (all magnitudes are moment magnitude, Mw):

1.	23 January 1556	~8	Shaanxi (830,000)
2.	27 July 1976	7.5	Tangshan (240,000)
3.	16 December 1920	7.8	Ningxia (235,000)
4.	26 December 2004	9.2	Sumatra (230,000)
5.	12 January 2010	7.0	Haiti (230,000)
6.	17 September 1303	~8	Shanxi (200,000)
7.	22 December 856	~7	Qumis (200,000)
8.	25 September 1139	~7	Azerbaijan (high)
9.	1 September 1923	7.9	Kanto (143,000)
10.	15 October 1138	~7	Aleppo (130,000)

Numbers of fatalities are rounded to the nearest 1,000; the precise ranking is obviously conjectural, as the figures are really only indicative of general loss levels. The distribution is shown in Figure 1.

The ten largest earthquakes

Listing the ten largest earthquakes presents different problems. For the period since 1900, it is possible, at least in theory, to provide indisputable magnitude values from instrumental data, although figures are not precise for the very largest events. For the pre-instrumental era, the situation is much harder. Early attempts to convert historical data into estimates of magnitude tended to rely on maximum intensity; however, this rapidly saturates in large earthquakes. More sophisticated methods based on intensity data fields are available (e.g., Sibol et al., 1987) but these are unlikely to be accurate for very large events (the lack of calibration is one problem).

Earthquakes around the 9.0 Mw mark are necessarily subduction events – only large subduction thrust planes can provide large enough rupture areas to accommodate the vast energies required. Estimation of magnitude from noninstrumental data in such cases cannot rely on intensity distribution, which is liable to be incomplete, but really needs to be based on estimating rupture area and displacement. It was possible, for instance, on the morning of 26 December 2004, to see at once that the great Sumatran earthquake was at least 9 Mw just by looking at the huge extent of the aftershock distribution, which stretched for over 1,000 km.

Since 1900, one can at least be certain that the catalog for very large earthquakes is complete. Taking the Centennial Catalogue of Engdahl and Villaseñor (2002) as a basis, one can list the ten largest earthquakes since 1900 as follows (all magnitudes are moment magnitude, Mw):

1.	22 May 1960	9.6	Chile
2=.	28 March 1964	9.2	Alaska
2=.	26 December 2004	9.2	Sumatra
4.	9 March 1957	9.1	Andreanof Islands
5.	4 November 1952	9.0	Kamchatka
6=.	31 January 1906	8.8	Colombia-Ecuador
6=.	27 February 2010	8.8	Chile
8=.	11 November 1922	8.7	Chile
8=.	25 March 2005	8.7	Sumatra
10=.	15 August 1950	8.6	Assam-Tibet
10=.	13 October 1963	8.6	Kuril Islands

The 2005 Sumatra earthquake, while not strictly an aftershock of the 26 December 2004 event, was certainly triggered by it. It was a very strange experience to be telling journalists that it was "only" 8.7 and small in comparison to the Boxing Day earthquake. It is somewhat remarkable that all the magnitude nines in the twentieth century, accounting for most of the seismic energy release of the whole century, occurred in the space of just 12 years, from 1952 to 1964. The years 2004–2010 appear to be making a similar spike in the energy release record.

The distribution is shown in Figure 2, which shows a very different pattern from Figure 1. The 2004 Sumatra earthquake is the only one to appear on both lists. This should emphasize that the deadliness of an earthquake generally owes more to its location with respect to population centers, than to its size.

Acknowledgments

The author would like to thank Professor N.N. Ambraseys and Dr. D.J. Kerridge for helpful reviews of the text.

Definition

Continental heat flow is the flux density of heat being conducted to the surface of continents. It is expressed as mW m^{-2}. Heat flow is calculated as the product of temperature gradient (mK m^{-1} or °C per km – a scale appropriate to the dimensions of geological formations) and thermal conductivity (W m^{-1} K^{-1}).

Introduction

Terrestrial heat flow, Q, is estimated from the product of temperature gradient (Γ) and thermal conductivity (K), according to:

$$Q = K.\Gamma \tag{1}$$

In practice, Γ is derived from point measurements of temperature at two or more discrete depths. K can be determined in situ, but for routine determinations of heat flow, the most practical approach is to measure it on the surface, either in the field or in a laboratory.

Beardsmore and Cull (2001) reviewed the various options for applying equation 1. These usually involve combining the harmonic mean thermal conductivity and temperature gradient over discrete intervals of the temperature profiles. Where there is significant thermal conductivity stratification, the "Bullard plot" is a useful method for calculating average heat flow (see Figure 1). In this method, temperature is plotted against integrated thermal resistance, R, where $R = z/K$, z being the thickness of the interval with mean conductivity K. If heat flow is constant with depth, the relation is linear and the slope of the line is the heat flow.

Uncertainty is inherent in heat flow determinations:

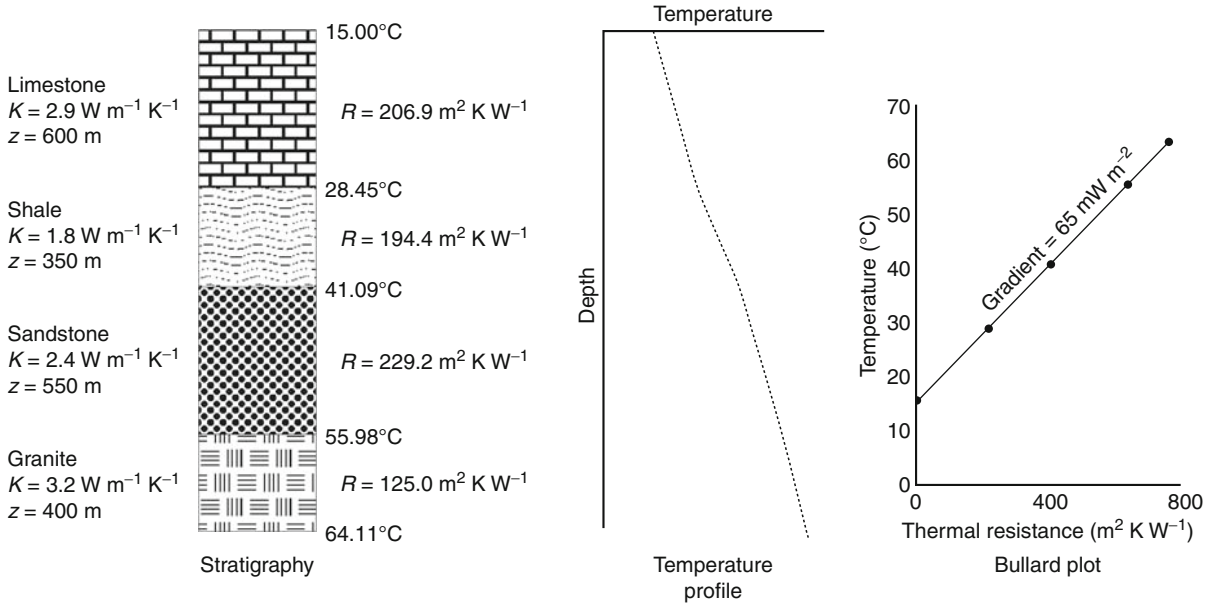
- As thermal gradient estimates become more precise with increasing depth, thermal conductivity estimates become less precise.
- The average thermal gradient and the average thermal conductivity must be determined over the same depth interval for a precise determination of heat flow.
- Because it is rarely practical to measure thermal conductivity over an entire depth interval, assumptions must be made as to how representative the measured samples are of the entire depth interval.
- The thermal disturbance due to seasonal surface temperature cycles may extend to a depth of several tens of meters, so meaningful results can be obtained only at greater depths.
- The diffusion of step changes in surface temperature (e.g., from the retreat of glaciation) may affect heat flow measurements down to hundreds of meters or more.
- Continental heat flow measurements, especially when compared to measurements of heat flow beneath the oceans, are complicated by significant lateral and temporal variations in surface temperature.
- Surface heat flow on the continents is more likely than oceanic heat flow to be distorted by near-surface variations in geological structures and topography.

Derived heat flow values may vary depending on the depth and sampling strategy of the survey, so careful thought should precede the design of any survey aimed at quantifying regional terrestrial heat flow.

Temperature

The earliest measurements of temperature beneath the earth's surface were obtained from mines and tunnels. As exploratory drilling for petroleum and minerals

Harsh K. Gupta (ed.), *Encyclopedia of Solid Earth Geophysics*, DOI 10.1007/978-90-481-8702-7,



Heat Flow Measurements, Continental, Figure 1 A hypothetical rock sequence with thermal properties and unit thicknesses. The thermal resistance, *R*, of each unit is equal to its thickness, *z*, divided by its thermal conductivity, K. A temperature–depth profile through the sequence is nonlinear, but a Bullard plot of temperature versus integrated thermal resistance is linear with slope equal to the conductive heat flow. Heat flow in this example is 65 mW m^{-2}.

became widespread, temperature profiles obtained in boreholes became the most common means of determining temperature gradients within the earth. Almost exclusively, electronic thermometers deployed on a wire line are currently used to measure temperatures within the earth.

Temperature and depth measurements for heat flow determinations need to be precise and accurate. Best practice calls for a precision of ~0.001°C at ~1 m intervals over several hundred meters. Common transducers include the following types:

- Thermistors: A thermistor is a bead of sintered metallic oxide, commonly germanium. It has a large negative temperature coefficient of resistance (typically −4% per K), and is precise and accurate to 1 mK using simple, unsophisticated readout devices like off-balance Wheatstone bridges and 4½ digit multimeters (DMMs) (McGee and Thomas, 1988). Thermistor probes for use in "normal" geothermal environments usually have a resistance of between 3 and 100 KΩ at 25°C and provide useable readouts between about 0°C and 80°C, above which their temperature sensitivity drops off because of low resistance. Thermistors must be individually calibrated.
- Platinum Resistance Elements (RTDs): Platinum RTDs have a small, positive temperature coefficient of resistance and depending upon their construction and configuration, can operate successfully up to 500°C (see Tew and Strauss, 2001, for principles and standards). Millidegree accuracy can be obtained with RTDs if 6½ digit DMMs are employed as readouts. RTD probes for geothermal applications typically have a resistance of 1 or 2 KΩ at 20°C. One advantage over thermistors is the interchangeability of RTD probes within a batch without the need for individual calibration.
- Diodes: Effective temperature sensors can be constructed from ordinary semiconductor diodes. Such sensors have a linear voltage or current response with temperature, are of relatively small size, operate over a limited temperature range (typically −40°C to +120°C), are of low cost, and are quite accurate if individually calibrated. Diode temperature sensors tend to be less robust (electrically and physically) than other sensor types, which tends to rule them out of most logging applications. For stationary applications, however, commercial semiconductor sensors are available that provide an output signal as a voltage, a current, a resistance, or as digital data.
- Fiber Optics: Distributed fiber-optic measurement of temperature using the phenomenon of backscattering is possible using commercially available instruments with temperature resolution down to 0.01°C (Selker et al., 2006). Instantaneous records of temperature distribution along entire lengths of fiber-optic cable at intervals of ~1 m up to 30,000 m can be obtained at time intervals of fractions of a minute. Temperature resolution increases relative to the length of time over which each measurement is recorded. This technology holds great promise for repeated temperature profiles in a well recovering from drilling-associated thermal

transients, or for monitoring the thermal effects of pumping or injection in "Hot Dry Rock" applications. Förster et al. (1997) presented a comparison between fiber-optic and conventional temperature logs.

Temperature Tools include the following types:

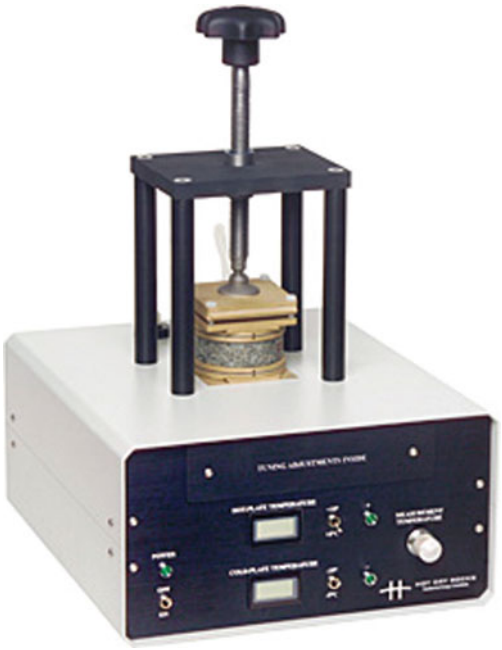
- Four-conductor connection to the surface. This mode provides for accurate measurement of the resistance of the temperature transducer. It requires that the leakage resistance between conductors be effectively infinite, a specification that can be met by manufacturers of geophysical logging cables. Significant leakage between conductors is usually manifested as noise on the detector. The relatively high resistance of thermistors with respect to typical logging cable makes them the most suitable transducers for these tools.
- Down-hole oscillator with single-conductor transmission. Where suitable multi-conductor cables are not available, the resistance element can be incorporated into an oscillator circuit with temperature–frequency dependence, independent of leakage between conductors (Doig et al., 1961).
- "Memory tools." With or without onboard pressure gauges, memory tools are deployed on a wire line. They record down hole and store data in onboard memory. The data are downloaded and read on the surface (Suto et al., 2008).
- Fiber-optic cables: Henninges et al. (2005) described the deployment of fiber-optic cables for both synoptic temperature logs and long-term monitoring of temperature.

Thermal conductivity

There are two basic approaches for thermal conductivity measurement:

1. Steady State (divided bar)
2. Transient (point-, line- or plane- source)

The concept of the divided bar was originally introduced by Prof. C.H. Lees in the nineteenth century. The device is essentially a vertical "stack" within which the temperature drop across a standard substance is compared with that across a disc of unknown thermal conductivity. Early versions were introduced in the 1930s by Prof. E.C. Bullard at Cambridge and by Prof. Francis Birch at Harvard. These adaptations featured a constant heat source at the top of the "stack" and an isothermal sink at the base. Adoption of a constant temperature difference resulted in more rapid measurements (Beck, 1957). Substitution of Peltier devices for the constant temperature water baths usually used provides hitherto unattainable portability, economy and speed of measurement (Antriasian, 2010; Figure 2). In the late 1960s, the divided bar was adapted to the measurement of the thermal conductivity of rock fragments, by far the most common source of material (Sass et al., 1971).



Heat Flow Measurements, Continental,
Figure 2 A commercial divided bar utilizing Peltier devices as heat source/sink. (Photo courtesy of Hot Dry Rocks Pty Ltd, Australia.)

Transient heat source methods can be applied in a permanent laboratory, in mobile field laboratories, or in certain circumstance within boreholes. In these techniques, the rock is heated, and the temperature-time curve of the heater element or a nearby point is analyzed to obtain the thermal conductivity. In general, higher conductivity rocks conduct heat away from the heater at a greater rate and suppress the increase in temperature.

Line- or cylindrical- source methods present difficulties in characterizing uniaxial (e.g., vertical) conductivity because they conduct heat radially, rather than linearly, away from the source. In homogenous sequences, conductivity is the same in all directions, but the values may be significantly different in heterogeneous sequences. Point source methods overcome this to some extent but require higher operating power and may initiate convection (thus negating the assumption of pure conduction).

J.C. Jaeger pioneered the concept of line- and cylindrical heat sources for the measurement of thermal conductivity. Early attempts at implementation of his models called for ingenuity in the use of analog recording devices of fairly low sensitivity. Line-source methods in common use include variations on the "needle probe" and half-space techniques; e.g., Showa Denko (Ito et al., 1977) and GeoForschungZentrum (GFZ) line-source units, see e.g., Pribnow and Sass (1995), which also has a description of the United States Geological Survey (USGS) divided bar apparatus. Both units are available commercially. K. Horai (1971) adapted the line-source

technique to measurements on fragments. The USGS versions of line-source techniques were described in detail by Sass et al. (1984).

Optical scanning

In the 1980s, Yuri Popov developed a rapid, nondestructive method for measuring the thermal conductivity of large numbers of rocks using an optical scanning technique. Flat and black-painted rock faces are aligned with a known standard material along a track. A device containing a laser heat source and an infrared radiometer temperature sensor moves at a constant speed across the surface of the samples. The radiometer measures the rise in temperature of the samples due to the applied laser pulse, and the temperature rise is then related back to the thermal conductivity of the rocks. This method was initially met with skepticism in many laboratories, but a three-way comparison among Popov's method, the USGS divided bar, and the GFZ line-source half-space apparatus resulted in remarkable agreement over a large range of thermal conductivity and a variety of crystalline rock types (Popov et al., 1999).

In situ thermal conductivity measurement in boreholes

The in situ measurement of thermal conductivity in vertical boreholes generally presents great experimental and logistical difficulties. In anisotropic rocks, it also measures conductivity in the wrong direction so that independent measurements of anisotropy on core are required to calculate vertical conductivity. Conductivity was measured in situ over a ~2 m interval of the KTB pilot core hole (Burkhardt et al., 1990) as a demonstration of the feasibility of the method.

During the boom in geothermal exploration in the mid- to late 1970s, the importance of determining heat flow, as well as temperature gradients became apparent. This was coupled with concerns over the security of exploration wells in competitive lease areas. To address these issues, the Geothermal Studies Project of the U.S. Geological Survey developed a method for determining temperature gradient, thermal conductivity, and thus, heat flow in situ over discrete intervals during the drilling process (Sass et al., 1981)

Details of the technology can be found in Sass et al. (1979) with the caveat that the electronics and computer hardware described in that reference have since been superseded.

More recently, Freifeld et al. (2008) have demonstrated thermal conductivity profiling of entire boreholes by coupling a down-hole line-source heating loop with a distributed fiber-optic temperature system.

Sampling

Thermal conductivity can rarely be practically measured over the full interval of interest. Certain sampling protocols must be devised and followed to estimate the conductivity over significant depth intervals. This may involve:

- Characterizing the conductivity of individual geological formations where these are largely homogenous
- Selecting samples from evenly spaced intervals as a "random" sampling strategy
- Measuring mixtures of chips from sequential depth intervals

Conductivity is temperature dependent and values measured in the laboratory should be corrected for in situ conditions especially for very deep wells, and in geothermal areas with high temperature gradients.

When no rock samples are available for measurement of thermal conductivity, estimates can be obtained from empirical relations between conductivity and well-log parameters or by choosing a "flux plate", a layer of more than a few meters thickness composed of a rock type whose conductivity has been characterized by measurements elsewhere. (See Blackwell and Steele, 1989 for a review of these methods.)

Summary

Heat flowing from the surface of the continents cannot be measured directly. It is calculated as the product of the temperature gradient (most often measured in boreholes) and the thermal conductivity of the formation within which the temperature gradient was measured. Thermal conductivity can be measured in situ, but by far the majority of measurements are made on rock samples from the borehole, or from nearby outcrops of the relevant formations.

Temperatures are usually measured by electronic transducers deployed on multi-conductor electrical cables or incorporated into "memory tools," which are lowered into the borehole on steel or alloy wires. Fiber-optic cables can also be inserted into boreholes to provide synoptic temperature profiles or a time series of profiles.

A variety of techniques, based on both steady-state and transient heat flow, can be used to characterize the thermal conductivity of rock specimens. Optical scanning methods provide rapid estimates of thermal conductivity and are valuable reconnaissance tools complementary to the conventional techniques.

Definition

Heat flow. The outward flow of thermal energy by conduction from within the Earth through the solid surface of the Earth.
Continental heat flow. Heat flow from the continental crust or lithosphere, which are those portions of the plates that are not directly formed by seafloor spreading at mid-ocean ridges and are not generally subducted.

Introduction

Heat flow is a fundamental property of the Earth. The Earth is a heat engine that drives plate tectonics and intraplate processes such as hot-spot volcanism unrelated to plate margins. Heat flow, the outward flow of thermal energy from within the Earth through the solid surface of the Earth, is a measure of the thermal energy that drives this heat engine. In addition, temperature in the Earth, which is closely related to heat flow, is a primary parameter controlling physical properties of materials within the Earth. In general, areas of high heat flow are underlain by higher temperatures, at least at shallow depth, than areas of low heat flow. We seek therefore to know the distribution of heat flow from the surface of the Earth and to understand the factors that control its variations.

The primary factor controlling the distribution of heat flow is the type of lithosphere, continental or oceanic. Continental lithosphere is generally relatively old (>500 Ma) and the dominant mechanism of heat transfer through this lithosphere is conduction. A significant portion of heat flow from this lithosphere is generated by radiogenic heat production in the continental crust. In contrast, oceanic lithosphere is young (<200 Ma), heat is convected into this lithosphere as it is formed at mid-ocean ridges and it has very little internal radiogenic heat production (see *Heat Flow, Seafloor: Methods and Observations*). A variety of

geologic processes modify continental lithosphere and most of these processes also modify the thermal regime. In addition, the upper continental crust commonly hosts moving groundwater that redistributes heat in the upper crust. Thus, the long and complex history of continental lithosphere, significant and lateral variability in radiogenic heat generation, and redistribution of heat by groundwater combine to make continental heat flow heterogeneous.

Fourier's law

Under conditions of steady state, heat flow, q, is a function of thermal conductivity, K, and temperature, T, given by Fourier's law:

$$q = -K\nabla T, \tag{1}$$

where ∇ is the gradient operator. This equation assumes that thermal conductivity is isotropic, that is, it does not change with direction. In general, spatial changes in thermal conductivity and anisotropy must be considered. The negative sign in the equation recognizes that heat flows from higher temperatures to lower temperatures and that flow of heat is in the opposite direction to the temperature gradient. On average, Earth heat flow is primarily vertical and the vertical component of heat flow, q_z, is commonly quoted:

$$q_Z = -K\frac{\partial T}{\partial z}, \tag{2}$$

where z is depth. In practice, the subscript and negative sign are commonly omitted:

$$q = K\,\partial T/\partial z. \tag{2a}$$

The working units of q, K, and $\partial T/\partial z$ are $\mathrm{mW\,m^{-2}}$, $\mathrm{W\,m^{-1}\,^{\circ}C^{-1}}$ or $\mathrm{W\,m^{-1}\,K^{-1}}$, and $\mathrm{^{\circ}C\,km^{-1}}$, respectively.

Under transient conditions the heat conduction equation in one dimension becomes:

$$\frac{\partial T}{\partial t} = \kappa\frac{\partial^2 T}{\partial z^2}, \tag{3}$$

where t is time and κ is thermal diffusivity, given by $\kappa = K/\rho c$, where ρ is density and c is specific heat. The general working units for t and κ are s and $\mathrm{mm^2\,s^{-1}}$, although Ma and $\mathrm{km^2\,Ma^{-1}}$ are also sometimes used.

If heat generation, A, is also included, the heat flow equation becomes:

$$\frac{\partial^z T}{\partial z^z} - \frac{1}{\kappa}\frac{\partial T}{\partial t} + \frac{A}{K} = 0. \tag{4}$$

The working units for radiogenic heat generation, A, are $\mu\mathrm{W\,m^{-3}}$.

Geothermal gradient

The rate of increase in temperature with depth, $\partial T/\partial z$, is the *geothermal gradient*. This term is usually reserved for zones over which heat is transferred by conduction and the rate of increase in temperature with depth is linear (see *Heat Flow Measurements, Continental*), but if detailed temperature data are not available or gradients are estimated from oil-well bottom-hole temperatures, an approximate average geothermal gradient may be given. The profile of temperature plotted as a function of depth is the *geotherm*.

Geothermal gradients range from very low to near zero in fore-arc regions, the zones between subduction zones and their associated volcanic belts where heat is convected downward by the subducting lithosphere. Similarly, low gradients are found in zones of groundwater recharge. Gradients in excess of $20{,}000^{\circ}\mathrm{C\,km^{-1}}$ have been measured at one location in the upper few meters of the sediments beneath Yellowstone Lake inside the caldera of Yellowstone National Park, Wyoming, USA (Morgan, et al., 1977), but such high gradients are buffered by the boiling point curve of water as soon as temperatures reach the boiling temperature at depth. Thus, there is a very wide range of geothermal gradients in the upper continental crust. Temperatures are ultimately controlled by the boiling point curve of water in the uppermost crust and then the solidus curves of the crust and mantle lithosphere, and temperatures at depth generally do not range as widely as shallow geothermal gradients might suggest. Thermal conductivity varies by a factor of about 5 in the main rock types that comprise the continental crust (see *Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat*): there is some variation in heat flow associated with changes in thermal conductivity, but the most significant variations in heat flow are accompanied by changes in geothermal gradient.

Sources of heat

There are two sources of heat contributing to continental heat flow, heat that enters continental lithosphere from below, and heat generated within the continental lithosphere (see *Energy Budget of the Earth*). Although the Earth beneath the lithosphere has thermal energy that must ultimately be lost to the surface either through the lithosphere or in the process of the formation of new oceanic lithosphere at mid-oceanic ridges, there is no requirement where or when that heat must be lost, that is, there is no constant basal heat flux that flows into continental lithosphere. The thermal boundary condition at the base of the lithosphere is probably more accurately described as a constant temperature boundary, and this constant temperature may be maintained either by small-scale convection and/or lateral flow in the asthenosphere. Heat flow into the base of the lithosphere is then determined by the thermal conductivity structure of the lithosphere, the thickness of the lithosphere, heat production within the lithosphere, and its surface temperature. The resulting thermal profile is disrupted during major deformation of the lithosphere or changes in its boundary conditions.

By far the largest source of heat within the lithosphere is radiogenic heat production from the decay series of

the unstable isotopes ^{232}Th, ^{235,238}U, and ^{40}K. These isotopes all have half-lives of the same order as the age of the Earth and thus remain sufficiently abundant to be significant and continue to decay at a rate that is significant in terms of heat production (see *Radiogenic Heat Production of Rocks*). Other radiogenic isotopes are important for age dating, such as ^{87}Rb, ^{147}Sm, and ^{187}Re (see *Absolute Age Determinations: Radiometric*), but the heat produced by the decay of these isotopes and other isotopes used for age dating is insignificant. Uranium, thorium, and potassium are incompatible elements and tend to be concentrated in silicic magmas. Hence, they are depleted in the mantle during crustal formation and generally concentrated in the crust in silicic rocks. Heat flow data show that their concentrations in large silicic plutons are relatively predictable from surface measurements (Roy et al., 1968), but their distributions are less predictable in metamorphic and sedimentary terrains (see *Lithosphere, Continental: Thermal Structure*). Measurements indicate that from as little as less than 20% to as much as 80% of heat flow may be derived from crustal radiogenic heat generation. Typical values of heat production for crustal rocks range from $<0.1\ \mu W\,m^{-3}$ for basic igneous rocks to $>6\ \mu W\,m^{-3}$ for radiogenic granites.

Other crustal heat sources include frictional heat from faults and heat from chemical reactions. Attempts to measure heat associated with active faults have generally failed to detect heat or produced inconclusive results. The primary chemical reaction that has been observed as a heat source is the oxidation of pyrite, but any exothermic metamorphic or weathering reaction is a potential heat source. However, friction and chemical heat sources are likely to be only local in extent and minor in terms of the total continental thermal budget.

Mechanisms of heat transport

In stable continental crust, the primary mechanism of heat transfer is conduction as described by Fourier's law (Equations 1 and 2). In the mantle, the effects of radiative heat transfer may be significant as olivine has a significant component of radiative heat transfer above a temperature of about 500°C. This radiative component may be included in Fourier's law by substituting a temperature-dependent value of thermal conductivity that includes a correction for radiative heat transfer.

Even in stable regions, heat may be redistributed in the upper few kilometers by groundwater flow. In stable regions the geothermal gradient is seldom high enough to drive free convection (see below), and groundwater flow is driven by differences in elevation of the piezometric surface (water table). Heat transferred by the forced vertical flow of groundwater, q_{gw}, may be approximated by:

$$q_{gw} = \bar{v} c_w |dT|, \tag{5}$$

where $\bar{v}$ is the equivalent vertical velocity if the porosity were 100%, c_w is the specific heat of water, and $|dT|$ is the absolute temperature drop over the vertical extent of the water flow. Heat transfer will be in the direction of water flow and heat flow is decreased in areas of recharge and increased in areas of discharge. This type of convection is termed forced convection or advection.

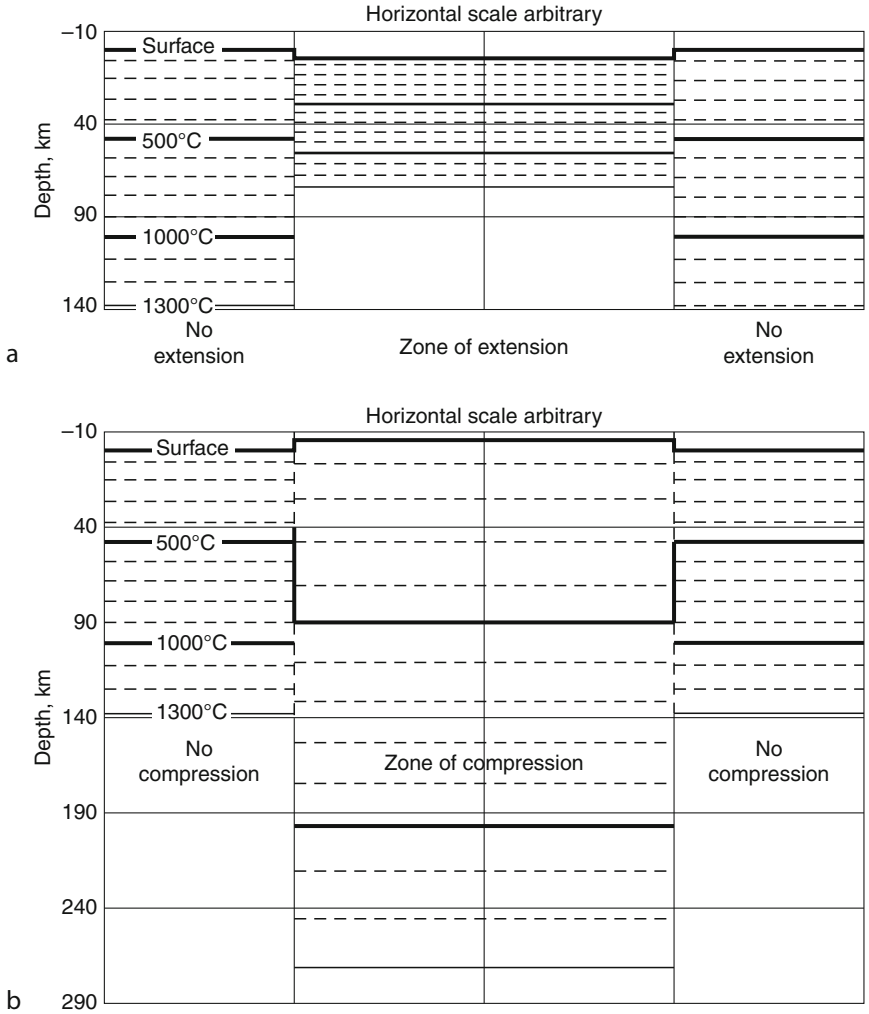
If the geothermal gradient is sufficiently high, water flow may be driven by thermal buoyancy forces. The magnitude of the gradient required for the onset for thermal convection depends on the geometry of the heat source and the medium in which convection occurs (e.g., Turcotte and Schubert, 2002, p. 393 et seq.). For a homogeneous porous layer of permeability $k\,m^2$ and thickness b km heated uniformly from below, the minimum thermal gradient, $(\partial T/\partial z)_{min}$, required for convection to occur is given by:

$$\left(\frac{\partial T}{\partial z}\right)_{min} = \frac{4.2x10^{-10}}{kb^z}. \tag{6}$$

This minimum gradient may not sustain convection and a higher gradient may be required for continuous convection. Convection driven by thermal buoyancy forces is termed free convection.

Heat will also be convected when there are net vertical movements within the lithosphere associated with deformation or changes in either the top or bottom boundaries of the lithosphere. In general, extensional deformation causes thinning of the lithosphere resulting in a net upward movement of the material in the lithosphere relative to its surface and a compression of the isotherms, or horizons of equal temperature within the lithosphere (Figure 1a). In contrast, compressional deformation causes thickening of the lithosphere resulting in a net downward movement of the material in the lithosphere relative to its surface and an increase of the spacing of the isotherms within the lithosphere (-Figure 1b). For simplicity, deformation in Figure 1 is shown to be 100% by pure shear and uniformly distributed throughout the lithosphere, a highly unlikely distribution of geological strain. As shear strength changes from brittle to ductile laterally and with depth throughout the lithosphere, the strain distribution is always much more complex: zones of simple shear, imbricated layers, and other complexities typically characterize lithospheric deformation. However, at a lithospheric scale, the net material movements and compression and extension of the geotherms illustrated in Figure 1 are valid.

Stable continental lithosphere has a relatively low heat flow corresponding to a low geothermal gradient and strong lithosphere. These conditions are not favorable for deformation. Observations indicate that deformation commonly occurs in lithosphere that is still recovering from a previous thermal event or has experienced a preceding thermal event. This thermal event may be manifested in the form of volcanism in which heat is advected in the lithosphere by ascending magmas. Heat transfer by magmas is conceptually similar to heat transfer by groundwater described by Equation 5, if the specific heat of magma is substituted for the specific heat of water. Additional heat is released from a magma during



Heat Flow, Continental, Figure 1 Diagrammatic examples of the effects of instantaneous pure shear deformation on lithospheric isotherms. Both diagrams have the same thermal conditions in undeformed lithosphere (no extension and no compression) calculated for a 35 km thick crust with a surface heat flow of 40 mW m^{-2}, a surface heat production of 2 μW m^{-3}, and a crustal thermal conductivity of 2.5 W m^{-1} K^{-1}. The crustal heat production is assumed to decay exponentially with depth with a depth parameter of 10 km, and the mantle is assumed to have a heat production of 0.084 μW m^{-3} and a temperature-dependent thermal conductivity appropriate for olivine. The base of the lithosphere is assumed to be the 1,300 °C isotherm. (**a**) shows the effect of thinning the lithosphere by a factor of 2 by extending the lithosphere by a factor of 2. (**b**) shows the effect of doubling the thickness of the lithosphere by compressing the lithosphere by a factor of 2.

solidification, and this heat is represented by the latent heat of solidification. Many analytical solutions for conductive modeling of magma intrusions may be found in Carslaw and Jaeger (1959) and other references, and these processes may also be modeled numerically. Magma generation may be initiated from below the lithosphere by the ascent of hot material to the base of the lithosphere (mantle plumes?) generating magmas by pressure-release melting and raising the temperature at the lower boundary of the lithosphere. Additionally magmas may be generated within the lithosphere by pressure-release melting and the melting of lower-melting temperature components within the lithosphere.

Once deformation is initiated additional magma generation will be initiated. The net upward movement of material during extension may trigger pressure-release melting, especially if the lithosphere has been preheated by pre-deformation magmatism. During compression, there is a net syn-deformational lowering of the geotherm. However, thickening of the crustal layer of radiogenic heat-producing elements will generally cause the geothermal gradient to return to a higher value than its initial value. This higher geotherm may result in melting of the thickened crust and crustal derived magmatism, the results of which are commonly observed in belts of compressional deformation. Thus, magmatic

convection of heat is an important heat transfer mechanism that commonly accompanies heat convection by tectonic deformation.

Finally, there is heat convection associated with changes at the Earth's surface. In discussing deformation and magmatism, the effects of these processes on surface elevation were ignored. Cooling oceanic lithosphere as it ages away from oceanic ridges results in a relatively simple change in depth of the ocean floor (see *Heat Flow, Seafloor: Methods and Observations*). A similar, but more complex relation exists for the thermal and density structure of continental lithosphere (Lachenbruch and Morgan, 1990; *Isostasy, Thermal*). Changes in surface elevation are generally accompanied by either erosion or sedimentation with the net result that the material in the lithosphere has a net movement either up or down relative to the surface, respectively. If the rates of erosion or sedimentation are known, a correction may be applied for these effects. If erosion creates three-dimensional topography, a terrain correction may also be applied. Not strictly a heat transfer mechanism, but changes in surface temperature associated with past climate change or changes in land use may also change surface heat flow and a correction may be applied for these perturbations.

The duration of a thermal disturbance associated with thermal convection in the lithosphere depends primarily on the stable thickness of the lithosphere and its thermal diffusivity. There is no standard for defining this duration as temperatures relax asymptotically to their stable values, and the form of this return depends on the structure of the thermal disturbance, which may be highly variable and very complex in continental deformation with magmatism. However, a useful guideline for the duration of the thermal disturbance, τ, is:

$$\tau = \frac{L^z}{4\kappa} \tag{7}$$

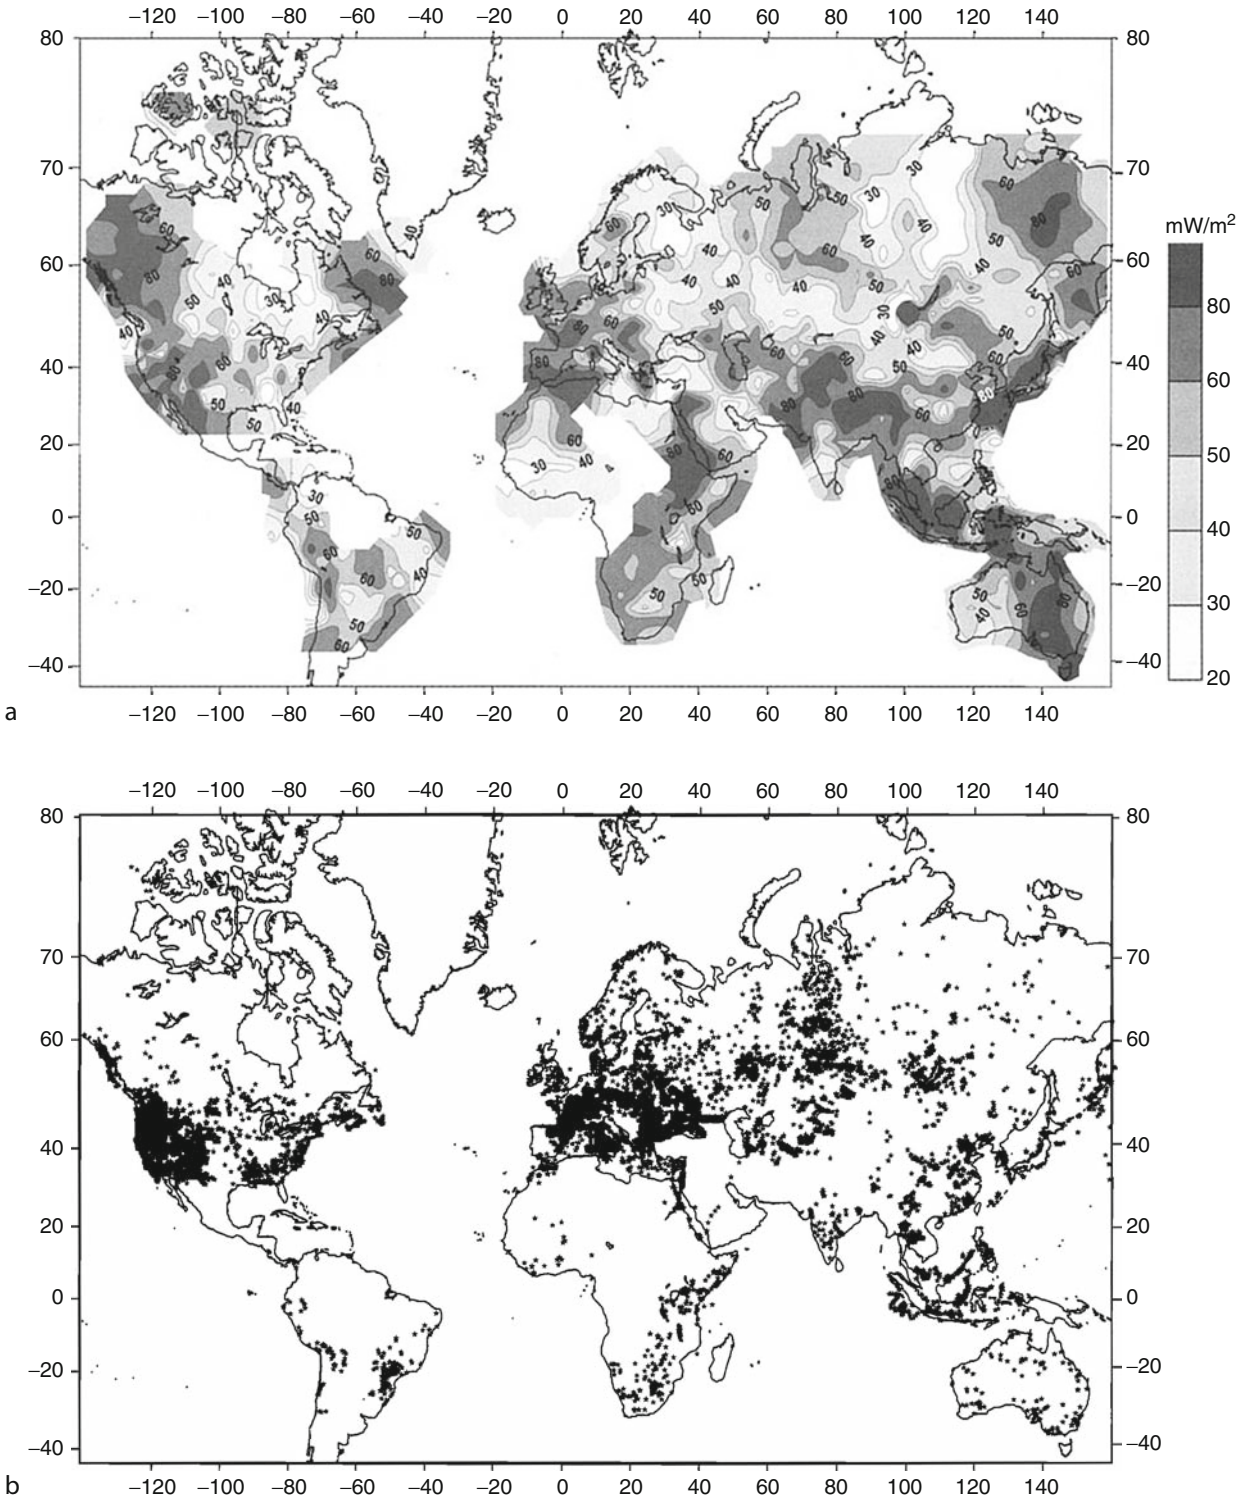
where L is the stable thickness of the lithosphere and κ is its thermal diffusivity. For example, using an average thermal diffusivity of 32 $km^2\ Ma^{-1}$ and a thickness of 100 km for stable oceanic lithosphere, the calculated duration of the thermal disturbance is about 78 Ma. Oceanic crust is observed to flatten at about 70–80 Ma. For continental lithosphere, if the stable thickness of this lithosphere is 100 km, the duration of the thermal disturbance would be about 78 Ma; if the stable thickness were 150 km, the duration would be ~175 Ma; if the thickness were 200 km, the duration would be ~310 Ma; and if the stable thickness were 250 km, the duration would be ~500 Ma. These durations are from the start of stabilization: if a deformation and magmatism event were followed by significant erosion or sedimentation, the duration of the thermal stabilization would not begin until the end of the erosion or sedimentation. However, as the effects of sedimentation and erosion are relatively minor, their measurable effects would probably be dissipated before the end of the formal disturbance duration.

Global distribution of continental heat flow

The global distribution of continental heat flow is shown in Figure 2a. The density of data is far from uniform (Figure 2b), but there are sufficient data that some generalizations about the heat flow distribution may be made. In general, high heat flow corresponds with zones of active seismicity, which in turn correlate with plate margins. Where the zones of seismicity are diffuse, such as the western US and the Himalaya, the plate margin deformation is distributed and the zones of high heat flow are extensive. Some portions of active plate margins are associated with low heat flow, such as the western margin of South America and the Pacific Northwest of the USA, west of the volcanic Cascade Range. These areas overlie subducting oceanic lithosphere where heat is being convected down into the mantle. Associated with these low heat flow zones is a rapid lateral transition to high heat flow in the active volcanic zones of the subduction zones. In addition, plate margins are generally associated with elevated topography, which received more precipitation than low elevations and in which heat flow is generally more variable because of redistribution of heat by forced and free groundwater convection.

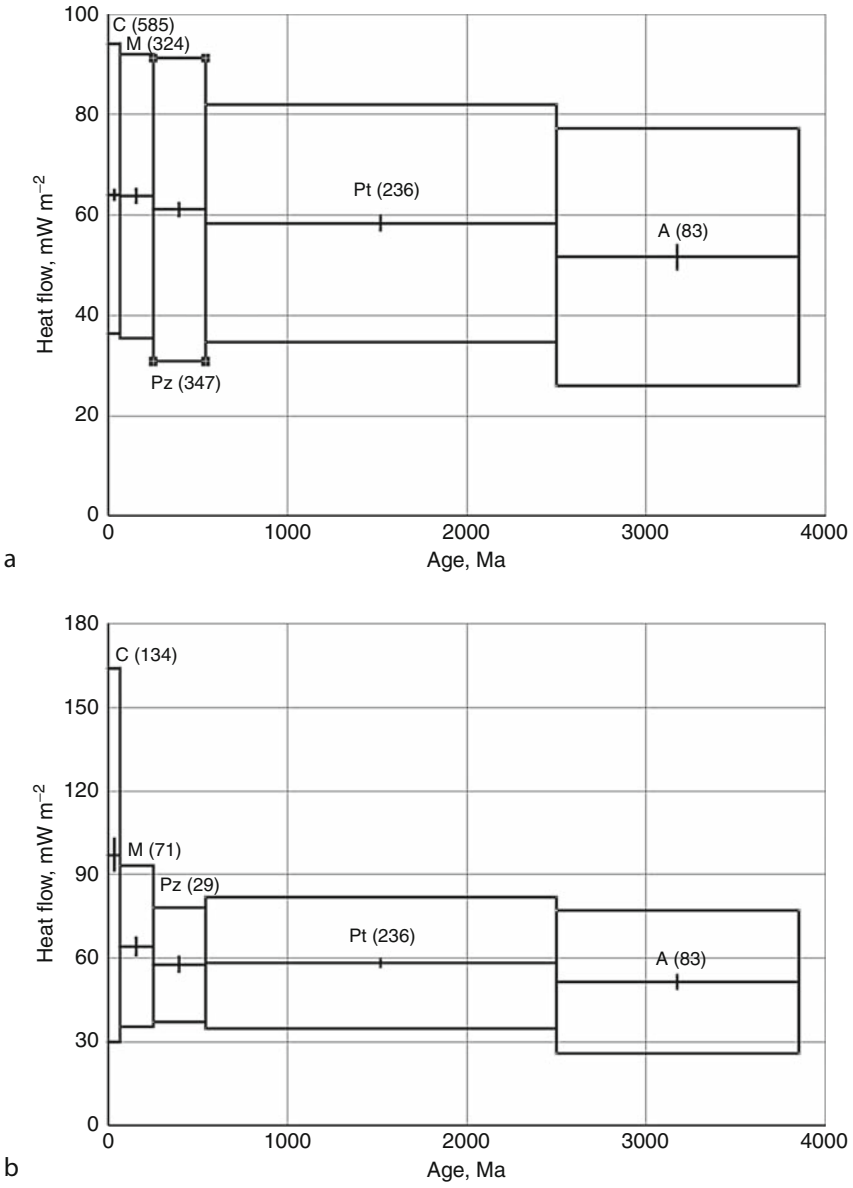
The association of high and low heat flow with active plate margins is demonstrated in a plot of mean heat flow as a function of age of heat flow site (Figure 3). Data are shown for sedimentary and metamorphic sites in Figure 3a and igneous sites in Figure 3b. The data for sedimentary and metamorphic sites (Figure 3a) show a small decrease from Cenozoic and Mesozoic to Paleozoic sites and from Paleozoic to Proterozoic sites, and a larger decrease from Proterozoic to Archean sites. This result suggests that the plate margin disturbances are relatively minor in the Phanerozoic sedimentary and metamorphic site data. In the igneous site data (Figure 3b), however, there is a significant decrease in both the mean and standard deviation from both Cenozoic to Mesozoic and from Mesozoic to Paleozoic sites. There is almost no difference in the mean from Paleozoic to Proterozoic sites. The data are the same for Proterozoic and Archean sites as Figure 3a. The igneous site data clearly show thermal perturbations with ages extending into Mesozoic age sites relative to older sites. This result is consistent with a continental lithospheric thickness of the order of 200 km. The observation that the igneous site data show a perturbation at young ages but there is only a small signal in the sedimentary and metamorphic site data suggests that the sedimentary and metamorphic site data are dominated by sedimentary sites and that these sites are either distant from plate boundaries or high heat flow is suppressed at these sites by downward advection of heat by advection during sedimentation.

The difference between the mean heat flow at Proterozoic and Archean sites has be commented upon from previous compilations of global heat flow data (Morgan, 1985) in addition to this data set (Artemieva and Mooney, 2001). To explain this difference as a transient effect would require a lithosphere of the order of 500–600 km



Heat Flow, Continental, Figure 2 (**a**) Distribution of continental heat flow, based on the data of Pollack et al. (1993) and subsequent updates, presented with a 10° × 10° interpolation (Artemieva and Mooney, 2001, Figure 3). (**b**). Locations of continental heat flow measurements used in constructing Figure 2(**a**) (From Artemieva and Mooney, 2001, Figure 4).

in thickness, which is probably unrealistic. However, a mean heat flow difference of 7 $mW\,m^{-2}$ may be explained in terms of a difference in the contributions of the mean heat production of Proterozoic and Archean crusts to their heat flows. Assuming an average crustal thickness of 35 km, an average difference of 0.2 $\mu W\,m^{-3}$ would explain the difference between the mean measured heat flow at Archean and Proterozoic sites. This difference is not universally observed in all areas (Jaupart and Mareschal, 1999; *Lithosphere, Continental: Thermal Structure*), but it is consistent with bulk observations of the differences in chemistry between the upper crust of Proterozoic and Archean terrains (McLennan et al., 2006). Archean upper crust is statistically depleted in the heat-producing elements relative to younger crust. In addition, xenolith data indicate that Archean lithosphere is statistically distinct from younger lithosphere so the upper crustal thermal observation may indicate that Archean lithosphere is statistically thermally distinct (Griffin et al., 2009).



Heat Flow, Continental, Figure 3 Continental heat flow as a function of age of data site. Widths of boxes and bars indicate age range. Heights of boxes indicate ± one standard deviation about the mean; short vertical line indicates ± one standard error about the mean. Ages of sites are grouped as C – Cenozoic, M – Mesozoic, Pz – Paleozoic, Pt – Proterozoic, and A – Archean. Numbers in parentheses are the number of 1° by 1° blocks represented in each age group. (**a**) shows sedimentary and metamorphic sites for Phanerozoic data. (**b**) shows igneous sites for Phanerozoic data. Data re-plotted from Pollack et al. (1993).

In summary, the global distribution of continental heat flow is complex. Neglecting measurement errors (see *Heat Flow Measurements, Continental*), variations associated with surface temperature changes, uncorrected topographic effects, and anomalies induced by changes in surface cover, heat flow may be described as steady state or transient. At any site, near-surface heat flow may be redistributed by groundwater flow, but this is most likely at sites with high elevation and rugged topography that are likely to have experienced relatively young (Cenozoic or Mesozoic) mountain building and/or igneous activity. Transient thermal perturbations in the lithosphere associated with tectonic deformation and/or igneous activity will dissipate with time and are likely to be restricted to heat flow sites in lithosphere with Cenozoic or Mesozoic tectonic or thermal ages. To distinguish tectonic and igneous ages from sedimentary ages, the term *tectonothermal age* is commonly used to describe the age of heat flow sites. Data from sites with tectonothermal ages Paleozoic and older are generally expected to be in steady state unless erosion or sedimentation are significant.

Igneous activity always heats continental lithosphere but deformation may either raise or lower the geothermal gradient (Figure 1). There is therefore no predictable anomaly for continental lithosphere at or near plate margins. The wide range in observed heat flow measured at young sites is in part associated with redistribution of heat by groundwater flow, but also associated with the real range in anomalies, both positive and negative, generated by deformation.

Whether the heat flow and geotherm be transient or steady state, significant variation among sites may occur associated with crustal radiogenic heat generation. Heat generation in the upper crust is very variable being generally low in mafic rocks and high in silicic rocks. Its contribution may vary from $<20\%$ to $>70\%$ of heat flow, and much of the range in heat flow represented in the standard deviations about the means of heat flow in Figure 3 are probably associated with chemical heterogeneity in the continental crust resulting in lateral variations in the contributions of radiogenic heat production to heat flow.

Paleo-heat flow

The discussion above has been restricted to heat flow measured at present although there is some lag in heat flow measured at the surface as it is conducted from depth: the order of that time lag may be estimated from Equation 7. This heat flow and associated temperatures are appropriate for most use for geophysical parameters, such as seismic wave velocities, electrical conductivities, and density calculations, but the time lag may be significant in some area where temperatures at depth in the lithosphere are changing. However, for some geological observations, including most techniques of radiometric age dating, the former temperature of a rock or mineral are preserved in a chemical or radiometric system when the rock cools as it is brought to the surface. This process may allow the temperature and sometimes the geothermal gradient of a site to be reconstructed at the time the rock was uplifted and this general topic is sometimes referred to as paleo-heat flow.

The rates of most chemical reactions increase at higher temperatures. For example, the maturation of organic material in sediments roughly follows the Arrhenius' equation, which describes the velocity of the reaction, r, as:

$$r = \lambda \exp(-E/RT_K) \tag{8}$$

where λ is the frequency factor, E is the activation energy, R is the gas constant, and T_K is temperature in Kelvin (Stegena, 1988). The combination of the frequency factor and temperature gives a time-temperature index that, together with composition of the organic matter, provides a useful predictor of hydrocarbon maturation. Temperatures in sedimentary basins are usually estimated by the increase in coal rank of carbonaceous matter in the sediments as measured by its vitrinite reflectance (e.g., Suggate, 1998), and time may be estimated by the sedimentation history of the basin. Vitrinite reflectance measures the maximum temperatures attained by the sediments, which may exceed modern temperatures.

Radiometric methods for age dating (see *Absolute Age Determinations: Radiometric*) do not determine rock ages but the time at which the radiometric system on which the age determination is based cools through its closure temperature, the temperature at which the age is set. Thus, radiometric ages may be used for the additional purpose of determining the thermal history of a rock, especially if some estimate of the depth at which the age was set may be determined (see below). Radiometric systems do not close at a single temperature but follow the Arrhenius' equation; at high temperatures cooling is generally relatively rapid. Examples of approximate mineral-closure temperatures for the uranium-lead method are monazite $>1{,}000°C$, zircon $>1{,}000°C$, titanite 650–600°C, apatite 500–450°C, and rutile 450–400°C (Flowers, 2005). Examples of approximate mineral-closure temperatures for the potassium-argon system are hornblende $530 \pm 40°C$, muscovite $\sim 350°C$, and biotite $280 \pm 40°C$ (McDougall and Harrison, 1999). Different dates from these minerals may be used to calculate rates of erosion or exhumation of terrains. However, young ages may also indicate reheating for minerals with relatively low-temperature closure temperatures.

The minerals used for some radiogenic systems have geologically very low closure temperatures. For example, the fission track technique is based on radiation damage (tracks) in different minerals caused by the spontaneous fission of ^{238}U (Garver, 2008). Closure of this system is by thermal annealing of the fission tracks, which occurs at $>120°C$ for apatite, $\sim 200°C$ for zircon, and $\sim 300°C$ for sphene. At these low temperatures, a geothermal gradient is usually assumed and the fission track ages are commonly used to indicate recent uplift/erosion rates (uplift/erosion rate = closure temperature/[fission track age × assumed geothermal gradient]).

Finally, paleo-thermal conditions are preserved by metamorphism, and in particular in mineral systems called geothermometers. Geothermometers are typically pairs of minerals in which concentration of one element in one of the minerals has a strong temperature dependence but is essentially pressure independent; the other mineral, which must be in intimate contact with the first mineral grain, acts as a reservoir for this element and allows the first mineral to be in thermal equilibrium with the element. Geothermometers tend to equilibrate rapidly at high temperatures but re-equilibrate slowly as the temperature decreases, so if cooling and exposure at the surface is relatively rapid, the geothermometer records peak thermal conditions. Geobarometers also exist in which the concentration of an element in the first mineral is strongly pressure (depth) dependent but insensitive to temperature. If mineral pairs representing a geothermometer and a geobarometer occur in the same outcrop, then temperature and depth may be estimated allowing calculation of the paleo-geothermal gradient and heat flow at the time of peak thermal conditions.

Studies of paleo-thermal gradients from metamorphic terrains suggest that, on average, geothermal gradients were higher than modern average geothermal gradients. However, although global heat flow was almost certainly higher in the past than at present (see *Energy Budget of the Earth*), these observations do not demonstrate that conclusion for the following reasons: (1) only peak or near-peak thermal conditions are preserved resulting in an overestimation of average continental heat flow; (2) peak preserved geothermal gradients are no higher than geothermal gradients measured today – modern geothermal gradients are buffered in the uppermost crust by the water boiling point curve and at greater depths by the crust solidus, and the same conditions would have applied in the earliest Earth preserved in the continental crust; and (3) if there were zones of low temperature/high pressure metamorphism (blueschist) in the Archean/Early Proterozoic, they are unlikely to be preserved because a geotherm required to maintain these metamorphic conditions requires active subduction. With the cessation of subduction, the geotherm would relax to a warmer geotherm, and blueschist metamorphism is likely to be overprinted. Similarly, low temperatures would not be recorded by geothermometers as the lithospheric temperatures increase.

Summary

Continental heat flow is a complex, but fundamental parameter that, together with oceanic heat flow, constrains the energy budget of the Earth heat engine. It is particularly complex because continents are complex and heterogeneous. It has components from beneath the lithosphere and radiogenic heat production within the lithosphere. Heat is advected into and within the lithosphere by magmatic activity, and heat is redistributed by lithospheric deformation associated with plate tectonics and at relatively shallow depths by groundwater flow. Changes in surface conditions also modify heat flow in the shallow crust. The time constant of thermal relaxation of continental lithosphere is of the order of 300 Ma for stable lithosphere 200 km in thickness. Typically heat flow data from igneous sites of Cenozoic and Early Mesozoic ages reflect transient thermal conditions; data from sites of older ages do not. However, continental heat flow remains very variable even at Precambrian sites because of lateral variability in crustal radiogenic heat production.

Definition

Heat flow. The rate of thermal energy transfer in a medium driven either conductively along a thermal gradient or advectively via mass transport. The standard unit is watts, W. The term is also used to describe a subdiscipline of geophysics, as in the title of this entry.

Conductive heat flux. The heat flow per unit area diffusing by conduction along a thermal gradient, determined as the product of the thermal gradient and thermal conductivity. The standard unit is W m^{-2}. The term *heat flow density* has been used correctly as a synonym; the term *heat flow*, traditionally but inexactly used as a synonym for heat flux, more strictly applies to the integrated heat flux over a specified area or region (watts).

Advective heat flux. The rate of heat transfer per unit area carried by a moving medium, proportional to the velocity and the heat capacity of the medium. The standard unit is W m^{-2}.

Thermal conductivity. The quantity that defines the ability of a medium to transfer heat by steady-state diffusion. The standard unit is W m^{-1} K^{-1}.

Hydrothermal circulation. Large-scale pore-fluid convection driven by thermal buoyancy, in which fluid flux and advective heat flux are strongly influenced by the permeability structure of the host formation.

History of observations

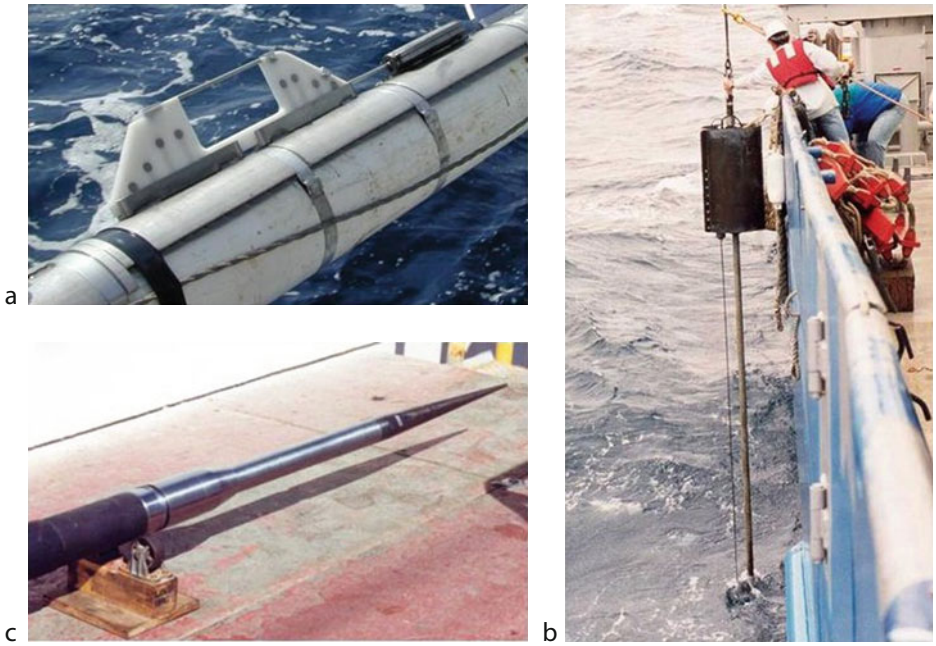
Pioneering measurements of temperature below the seafloor (e.g., Petterson, 1949; Revelle and Maxwell, 1952; Bullard, 1954) were made to compare the thermal state of the ocean crust with that of continents and thus to improve the knowledge of the present-day heat loss from the Earth. The early data demonstrated that gravity-driven probes and corers that penetrated a few meters into seafloor sediments could provide meaningful geothermal gradients, and they provided a foundation for the marine heat flow discipline. Methods for measuring the seafloor thermal gradient and thermal conductivity (the product of which is conductive heat flux) improved in subsequent years, the number and geographic distribution of determinations increased, and patterns of seafloor heat flux were gradually revealed. Initially, the average seafloor heat flux appeared to be similar to that through continents, despite the contribution from crustal radiogenic heat production, which is significant in the continental crust but not in the oceanic crust. Heat-flux values over midocean ridges were found to be significantly higher on average than in the flanking basins, but locally, values were often inexplicably scattered (Von Herzen and Uyeda, 1963; Lee and Uyeda, 1965). Higher heat flux at midocean ridges was consistent with emerging ideas about seafloor spreading, although the values measured were lower than expected from early theoretical models for the formation of ocean lithosphere. For nearly 2 decades, regionally low and scattered seafloor heat-flux values remained unexplained.

By the 1970s, studies began to be done with improved navigation, and with more closely spaced measurements made in the context of local sediment and igneous crustal structure. Results provided a sound basis for the hypothesis that hydrothermal circulation in the igneous crust and advective loss through unsedimented igneous outcrops caused both the scatter and the lower-than-expected values in young areas (Lister, 1972). Further improvements to instrumentation and observational strategies, in particular the development of probes that could be used with great efficiency for multiple measurements during a single instrument lowering, and the practice of making measurements in the context of geologic structure, led to the use of heat flux in the study of the process of hydrothermal circulation itself (Williams et al., 1974). With this new knowledge, it was possible to decipher the variability in measurements in a way that could lead to a better quantification of deep-seated heat flux, the goal of the original marine heat flow studies, and to understand the hydrologic processes behind the perturbations. Thus began a diverse range of applications of marine heat flow over a broad range of scales. A summary of the suite of tools currently in use for these studies is provided in the next section, along with a brief description of how heat-flux determinations are made. This is followed by a few examples of data from specific studies that illustrate how data are used, and a summary of some of the major conclusions that have been made through such studies.

Methods

Shallow measurements in marine sediments

Heat flux through the seafloor is often determined using temperatures measured with a series of sensors mounted on the outside of gravity-driven corers (Figure 1a), and thermal conductivities measured on the recovered sediment cores. Depths of penetration in excess of 10 m can be achieved in soft sediment, providing a valuable check on potential perturbations from bottom-water temperature variations, although accuracy is often limited by physical disturbances caused by the coring process, by changes in the physical properties of the recovered material, by



Heat Flow, Seafloor: Methods and Observations, Figure 1 Sensors and probes for measuring temperatures and thermal conductivity in marine sediments, including (**a**) outrigger temperature sensors mounted to the outside of a sediment corer (core barrel is 12 cm diameter), (**b**) a devoted heat-flux probe for measuring sediment temperatures and thermal conductivities (total length is 4.5 m), and (**c**) a high-strength probe that extends below a drill bit for bottom-hole temperature measurements (length is 1.2 m, tip diameter 1 cm).

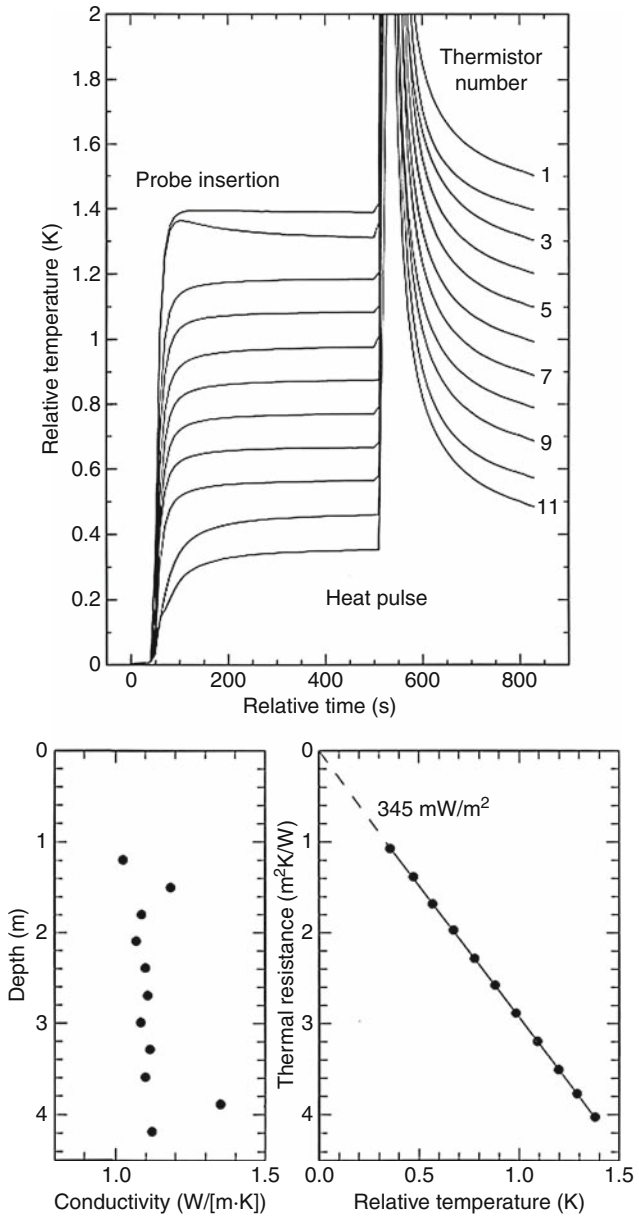
incomplete recovery, and by the imperfect depth registration between the cores and the intervals between the temperature sensors. Probes devoted exclusively to heat-flux measurements are typically limited to lengths of a few meters, but they have several distinct advantages. They allow thermal conductivity to be measured under in situ conditions and at depths that are co-registered with temperature measurements, and they allow transects of many measurements to be made efficiently during single instrument lowerings. A typical multipenetration heat-flux probe (Figure 1b) employs a heavy strength member that resists bending during repeated penetration and withdrawal from the sediment, and a small-diameter, rapidly responding tube containing thermistor sensors and a linear heater element. In situ temperatures are estimated by extrapolating transient decays following probe penetration, and conductivities are determined from the rate of change of temperature following steady or impulsive activation of the heater. A typical data record is shown in Figure 2, as are the resulting determinations of temperature and thermal conductivity. Heat flux is determined as the linear regression fit of temperature versus cumulative thermal resistance, R:

$$R = \sum [\Delta z / \lambda(z)]$$

where λ is thermal conductivity measured at a series of depths, z, and Δz is the depth interval assumed to be represented by each measurement. This is equivalent to calculating heat flux as the product of thermal gradient and the harmonic mean of thermal conductivity between temperature measurements, as was done in early marine heat flow studies. Errors associated with possible bottom-water temperature variations are evaluated by examining systematic deviations from linearity as a function of the number of thermistors included in the fit, working progressively up toward the shallowest measurement point. Complete descriptions of instruments and discussions of data reduction methods can be found in Lister (1979); Hyndman et al. (1979); Davis (1988), Wright and Louden (1989), and Villinger and Davis (1987).

Deep borehole measurements

Where observations are needed in hard formations or at depths greater than can be penetrated with a gravity-driven device, drilling is required. For research objectives, this has been done primarily through the Deep Sea Drilling Project, the Ocean Drilling Program, and the Integrated Ocean Drilling Program. In relatively unconsolidated sediments (typically the uppermost 50–100 m below the seafloor), hydraulically driven piston corers are deployed from the bottom of the drill string, and temperatures are measured at the tip of the core barrel (Horai and Von Herzen, 1985). At greater depths below the seafloor, high-strength probes can be pushed in with the weight of the drill string sufficiently far below the bottom of the hole (c. 1 m) to gain an unperturbed measurement (Uyeda and



Heat Flow, Seafloor: Methods and Observations, Figure 2 Typical data (upper panel) collected with a marine heat-flux probe like that shown in Figure 1b. Thermal conductivities are determined from the rates of decay following the metered pulse of heat, and natural sediment temperatures are determined by extrapolating the transients following probe insertion. In this example, high conductivities associated with two turbididic sand layers are present.

Horai, 1980; Davis et al., 1997a) (Figure 1c). Deeper than a few hundred meters in sediment, or at any level in crystalline rock, bottom-hole measurements are not feasible; instead, long-term borehole measurements are required to discriminate the natural formation thermal state from the commonly large and long-lived perturbations from drilling and subsequent fluid flow into or out of the hole. The most reliable method for determining the natural thermal state of crustal rocks has been to seal holes and install thermistor strings for long-term monitoring (Davis et al., 1992) (Figure 3).

Example studies

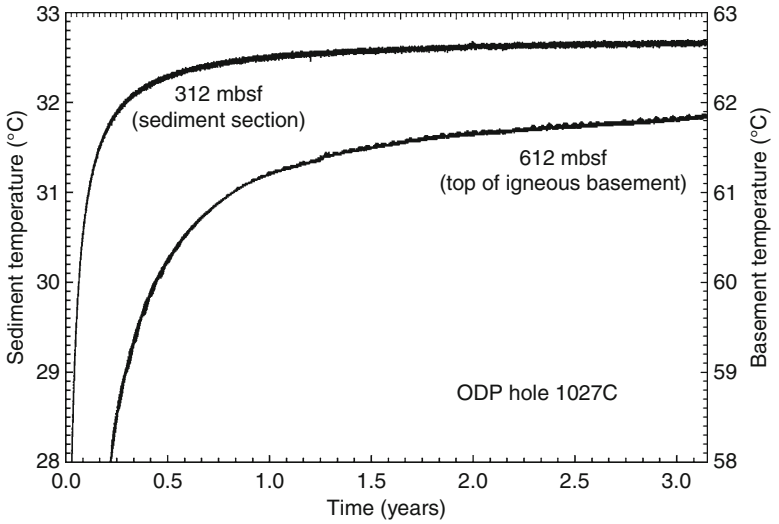
Bottom-water temperature perturbations

Seafloor heat-flux measurements rely on the assumption that both long- and short-term bottom-water temperature variations are small; the volume of ocean bottom water is very large and the temperature of the source in polar regions is regulated by the formation of sea ice. Many early measurements were made with temperatures determined at only three depths over a span of a few meters, however. Good checks on the validity of this assumption were not possible until temperature observations began to be made in deep-sea boreholes and long records of bottom-water temperature were acquired (Hyndman et al., 1984; Davis et al., 2003). An ideal suite of observations that would allow errors associated with bottom-water temperature variations to be quantified throughout the world's oceans – one that is broadly distributed both geographically and with ocean depth – does not yet exist, but the available data show that gradients measured a few meters below the seafloor generally do permit accurate determinations of heat flux in large areas of the oceans where depths are greater than ~2,000 m. One example where errors are demonstrated to be small is illustrated in Figure 4, where closely colocated seafloor probe and borehole observations are compared. Significant bottom-water temperature variations are ruled out by the linearity of the plots of temperature versus cumulative thermal resistance, and by the agreement between the shallow probe and deep borehole determinations. This illustration also shows the importance of precise colocation when doing such a comparison, given the local spatial variability of heat flux as defined by neighboring probe measurements.

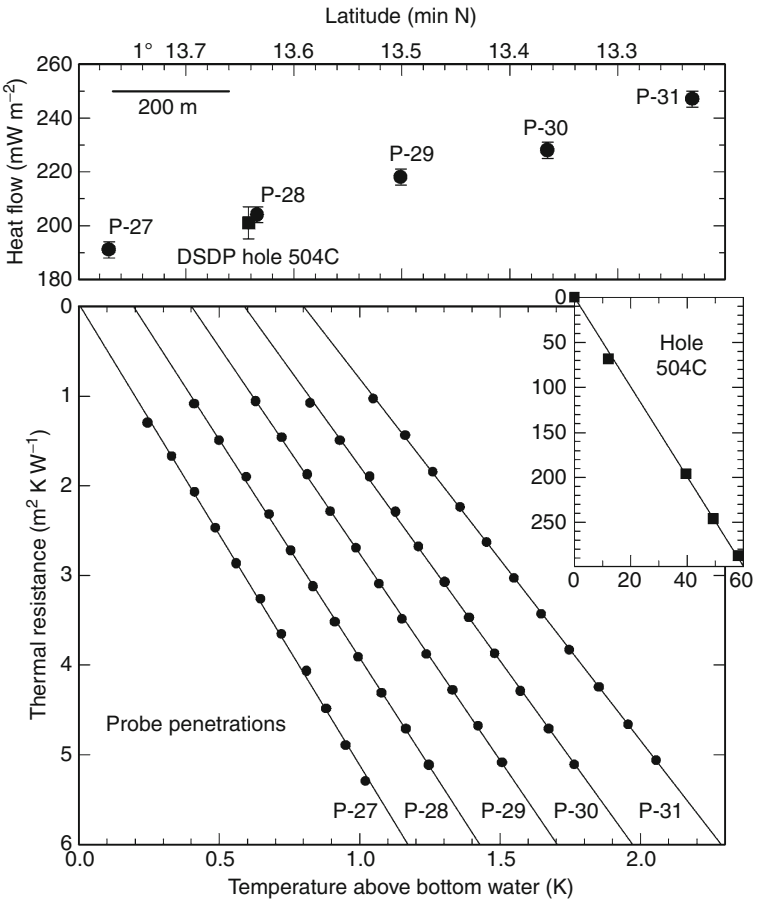
A more direct approach uses observations of bottom-water fluctuations. An example from a 5,000-m-deep site in the western Atlantic (Figure 5a) shows that in this area, oceanographic perturbations might have a modest influence on measured gradients. Estimated gradient perturbations at depths of less than 2–3 m below the seafloor range up to 10 mK m^{-1} (Figure 5b), that is, up to 20% of the geothermal gradient if the heat flux were 50 mW m^{-2}. A second example from a 2,600-m-deep site in the eastern Pacific shows smaller variability (Figure 5c), although perturbations estimated at a depth of 2 m could still result in a heat-flux determination error of up to 10%. Observations like these are clearly useful for guiding measurement strategy (e.g., depth of penetration) wherever heat flux is low and precise determinations are required.

Heat-flux signals from hydrothermal circulation

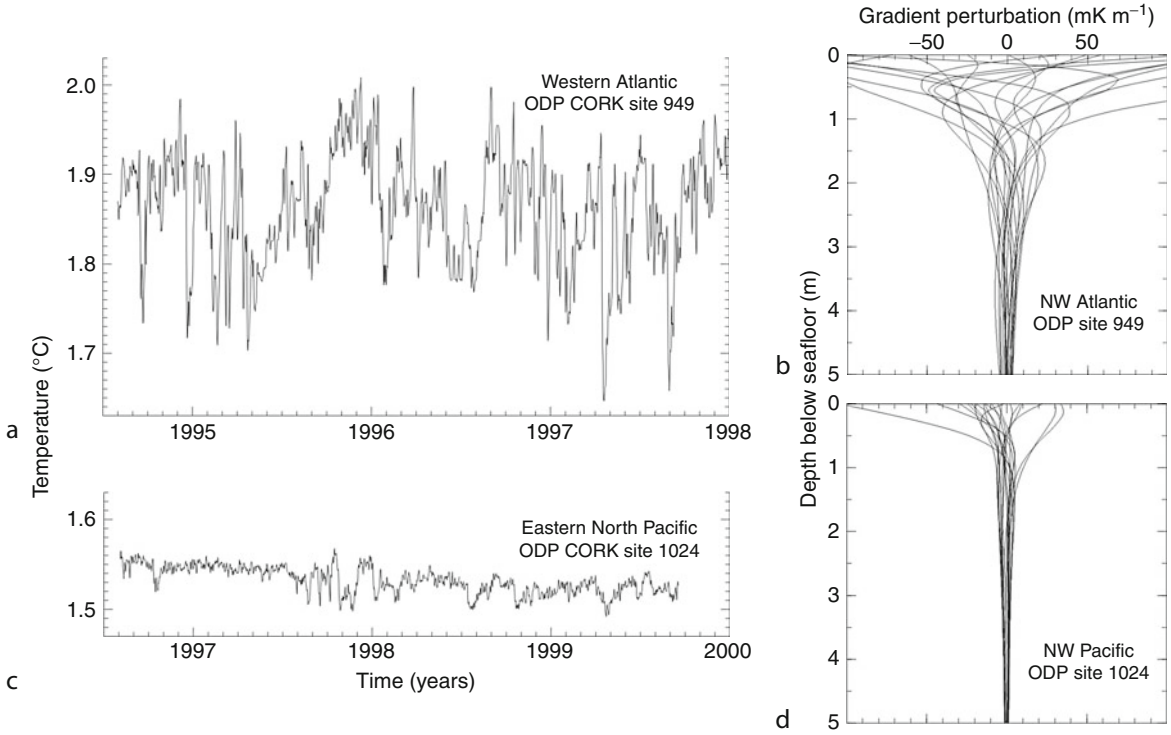
Hydrothermal circulation is a major source of error when determinations of deep-seated heat flux are sought, but it



Heat Flow, Seafloor: Methods and Observations, Figure 3 Two records from a 10-thermistor cable suspended in a borehole that penetrates a c. 600-m-thick sediment layer and into the underlying uppermost igneous oceanic crust. The longer recovery time at the deeper level reflects the large volume of water that invaded the uncased and permeable igneous section during the 5 days between the time of drilling and when the hole was sealed and instrumented.



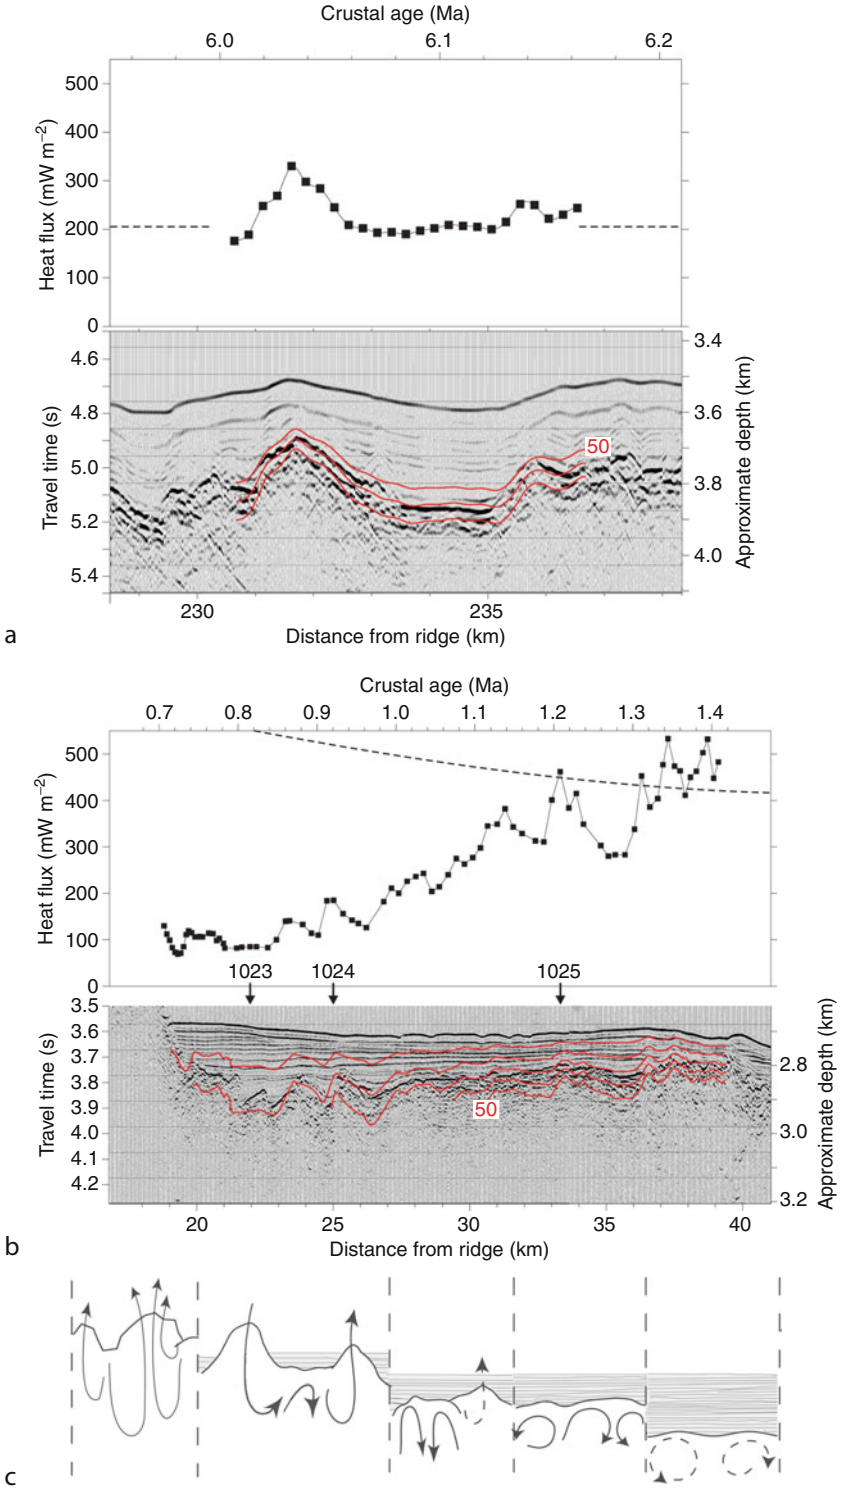
Heat Flow, Seafloor: Methods and Observations, Figure 4 Comparison of colocated seafloor probe and borehole heat-flux observations. Variations in probe measurements along the transect adjacent to the borehole site illustrate how carefully such comparisons must be done.



Heat Flow, Seafloor: Methods and Observations, Figure 5 Bottom-water temperature variations observed in the Atlantic (**a**) and Pacific Oceans (**c**), and estimated perturbations of the geothermal gradient as a function of depth (**b** and **d**) stemming from the variations, calculated at an evenly distributed suite of times during the temperature time series.

is also an important geological process. Hence it has been the focus of a large number of studies. Instructive examples of the influence of hydrothermal circulation are shown in Figure 6, where closely spaced measurements were made along transects striking perpendicular to basement structure. The first (Figure 6a) is in an area where sediment cover is continuous over a broad region spanning several tens of kilometers. Locally, heat flux varies inversely with sediment thickness. Such variations are common in areas of young seafloor, but can occur across relatively old seafloor as well (Embley et al., 1983; Von Herzen, 2004; Fisher and Von Herzen, 2005). They are the consequence of thermally efficient, local convection in permeable igneous rocks beneath low-permeability sediment cover. If the permeability of the igneous "basement" formation is high, vigorous convective flow maintains nearly constant temperatures at the sediment/basement interface despite variations in the thermal resistance of the overlying sediment layer. In this instance, the average seafloor heat flux is close to that expected from the underlying lithosphere, suggesting that from a thermal perspective, the circulation in the upper igneous crust is sealed in by the extensive sediment cover. The second transect (Figure 6b) crosses a sediment-covered area immediately adjacent to an area of outcropping igneous crust (where measurements are impossible). Local variations like those in Figure 6a are present, but even more apparent is a systematic variation of a larger scale, with heat flux increasing with distance from the area of basement outcrop, opposite to the expected trend of decreasing heat flux with increasing seafloor age. Temperatures estimated at the top of the igneous section increase systematically as well, suggesting that heat is transported laterally by fluid circulation and mixing in the sediment-sealed igneous crust. Heat exchange between the well-ventilated and sediment-sealed areas, indicated by the heat-flux deficit in this example, suggests a lateral heat-transfer scale of 20 km. Examples elsewhere suggest that the effects of advective heat loss may be felt laterally as far as 50–100 km (e.g., Fisher et al., 2003).

Ever since the early work of Lister (1972), the mere presence of local variability has been used as a diagnostic indicator of hydrothermal circulation in both young and old areas (e.g., Figure 6c), but with widely spaced observations, neither of the signals exemplified in Figure 6a and b could be resolved coherently; values were simply scattered and averages were often low. When systematic, detailed transects of observations began to be completed in context of colocated seismic data, the vigor of the convection could be inferred quantitatively from the nonconductive thermal regime (Fisher and Becker, 1995; Davis et al., 1997b), and the amount of heat lost



Heat Flow, Seafloor: Methods and Observations, Figure 6 Transects of heat flux on the flanks of the Costa Rica Rift (**a**) where an extensive sediment cover is present, and Juan de Fuca Ridge (**b**) striking away from an area of extensive basement at the left end of the figure. Both show the effects of hydrothermal circulation on conductive seafloor heat flux and on the crustal thermal regime. Heat flux estimated on the basis of the local lithosphere age (see text) is shown as the dashed lines. Temperatures estimated below the seafloor are shown at intervals of 10 °C. The cartoons in (**c**) show the influence of sediment burial on hydrothermal circulation and advective heat loss under a variety of burial states.

from the crust by fluid advection could be estimated with growing confidence (e.g., Anderson and Skilbeck, 1980; Stein and Stein, 1994; Harris and Chapman, 2004).

Two major lessons are learned from detailed observations like these for drawing conclusions about deep-seated heat flux. First, to ensure that observations do not suffer from the bias caused by convective ventilation, it must be demonstrated that there are no exposures of permeable rock at faults or volcanic edifices within distances of several tens of kilometers. Second, large numbers of closely spaced observations must be made, ideally colocated with seismic reflection data, so that the local variability can be understood and meaningfully averaged, and the locally relevant lateral transport scale can be assessed (e.g., Sclater et al., 1976; Davis et al., 1999).

Lessons learned about the way that the seawater interacts with the oceanic crust are far-reaching and continuously expanding. Estimates for the temperatures of circulation, the chemistry of the fluids, the volumetric rates of exchange between the crust and the ocean, and the consequent effects on crustal alteration and ocean chemistry have become reasonably well understood (e.g., Mottl and Wheat, 1994; Elderfield and Schultz, 1996). Studies of the actual distribution of crustal permeability, the percentage of rock affected by hydrothermal alteration, and the potential for chemosynthetic microbial populations are the focus of current investigations.

Dependence of heat flux on age and the global average

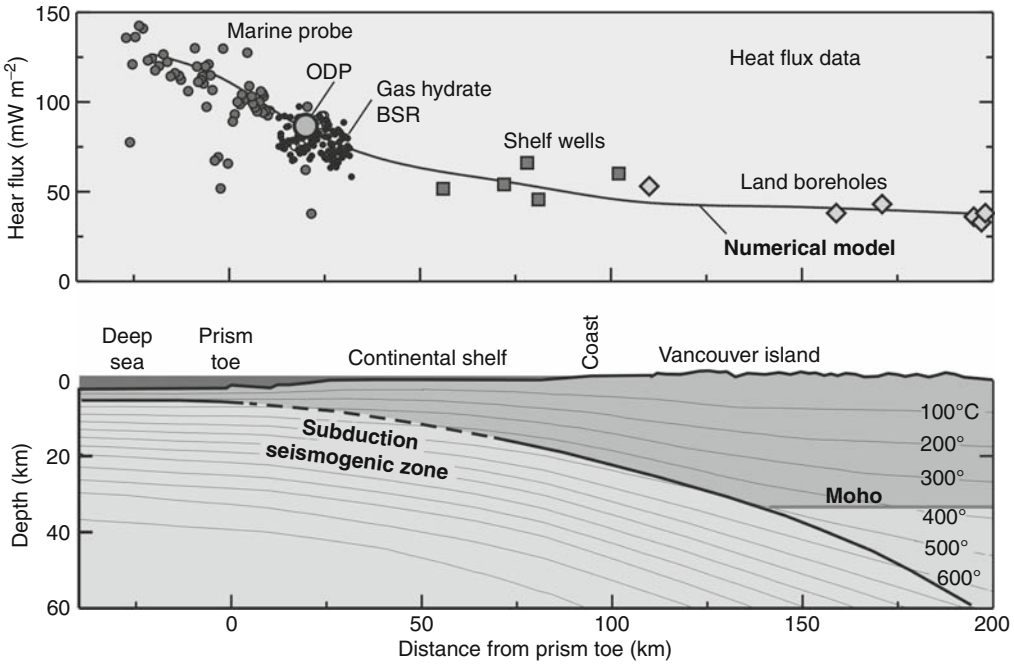
With the potentially large influence of hydrothermal circulation in mind, it is clear that a simple compilation of heat-flux data will provide a deceiving view of global heat loss. Except in old ocean basins, values are likely to be scattered and low relative to the heat loss expected from the underlying lithosphere. But by taking only those measurements that are sufficiently far from known permeable crustal outcrops and sufficiently numerous to provide a reliable local average, a subset of data can be gathered that provides a reliable determination of deep-seated heat flux. When considered in the context of lithospheric age, the results have been found to be consistent with both the characteristics of age-dependent seafloor subsidence and with simple lithospheric cooling theory (see *Lithosphere, Oceanic: Thermal Structure*). In young areas, heat flux is found to decline linearly with the inverse square root of age, following the simple relationship $Q = \mathrm{C}\, t^{-1/2}$ (where Q is heat flux in $\mathrm{mW\,m^{-2}}$, t is age in Ma, and C is a constant estimated between 475 and 510; Lister, 1977; Harris and Chapman, 2004). High-quality observations in older regions ($>$100 Ma) are generally uniform, in the range of 45–50 $\mathrm{mW\,m^{-2}}$ (Lister et al., 1990), suggesting that the thermal structure of the lithosphere may become stabilized in a state regulated either by the convectively supplied heat flux from the underlying asthenosphere, or by the combination of a compositionally established lithospheric thickness and the relatively uniform temperature of the vigorously convecting asthenosphere.

With the relationship between heat flux and age thus defined, the problems of the unknown bias and large scatter in young areas and the sparse distribution of measurements in large portions of the oceans can be overcome. A reliable estimate for the total heat flow through the floor of the ocean can be had by using the area/age relationship for the oceans defined by seafloor magnetic anomalies (e.g., Parsons, 1982; Wei and Sandwell, 2006), along with a robust heat-flux/age relationship. Several such estimates have been made (e.g., Williams and Von Herzen, 1974; Sclater et al., 1980; see summary in Jaupart et al., 2007), and all fall in a relatively narrow range centered around 32 TW (with contributions from marginal seas and hotspot swells included). This yields an average seafloor flux of roughly 107 $\mathrm{mW\,m^{-2}}$, a number that has little physical significance, but is considerably greater than that estimated in the early days of marine heat flow, and greater than the average though continents (c. 67 $\mathrm{mW\,m^{-2}}$), particularly when the latter is adjusted for the contribution of continental crustal radiogenic heat (c. 33 $\mathrm{mW\,m^{-2}}$).

With the total heat flow thus constrained, the heat lost advectively by ventilated circulation can be estimated from the difference between this and the age-binned average of unfiltered observations. Such estimates of this "heat deficit" fall in the neighborhood of 10 TW (Stein and Stein, 1994; Harris and Chapman, 2004). Most of this deficit occurs in seafloor less than 8–10 Ma in age, and it becomes insignificant on average by an age of 65 Ma. The actual age at which advective loss becomes insignificant is locally variable, depending primarily on the continuity of accumulating sediments that bury the igneous crust (Anderson and Skilbeck, 1980; Harris and Chapman, 2004), and the associated increase in spacing between basement outcrops that are essential for hydrothermal recharge and discharge on older ridge flanks (Fisher and Wheat, 2010).

The signature of subduction

Marine heat flux is used extensively to constrain deep thermal structure in studies of continental margins and marginal basins. A transect crossing the forearc prism of the Cascadia subduction zone illustrates one such application (Figure 7). This transect begins with standard gravity-driven probe measurements over the incoming plate and outermost accretionary prism, where bottom-water temperature variability is small. Where the seafloor is shallower than 1,500–2,000 m, other measurement techniques are used, including borehole measurements and estimates made using the depth to a bottom-simulating seismic reflector (BSR), which marks the limit of methane-hydrate stability. This reflector defines a unique set of pressure-temperature conditions, and with constraints on seismic velocity and thermal conductivity of the section above the BSR, the thermal gradient and heat flux can be estimated. Alternatively, a small set of seafloor



Heat Flow, Seafloor: Methods and Observations, Figure 7 Structural and heat-flux transect across the Cascadia subduction forearc, with temperatures estimated from a numerical model for underthrusting and sediment thickening, constrained by the heat-flux data (following compilation of Hyndman and Wang, 1993).

heat-flux measurements can be used as a "calibration." In either case, the travel-time depth to BSRs can serve as a widespread proxy for thermal data (e.g., Yamano et al., 1982). This technique is valuable where bottom-water temperature variability is too large to permit accurate heat-flux determinations with shallow probes, where sediments are too hard to allow probe penetration, or where there are few conventional measurements. Observations like these allow the thermal structure to be inferred deep within subduction zones, providing a critical constraint on the rheology of the rocks and the potential for seismogenic slip along the subduction thrust interface. In the example shown (Figure 7), the seafloor heat flux is variable locally, but regional values and trends are consistent with the expected thermal state of the thickly sedimented subducting plate.

In another study of the subducting Cocos Plate seaward of the Middle America Trench, variations in the thermal state of the plate are strongly influenced by regional differences in hydrothermal heat loss, and these correlate with differences in seismic processes occurring at depth (Newman et al., 2002; Fisher et al., 2003). One part of the plate is extensively cooled by hydrothermal circulation before the Cocos Plate is subducted, and earthquakes observed within the subduction wedge in this area are relatively deep (>20 km). Earthquakes tend to be shallower (<20 km) along an adjacent segment of the subduction zone, where there is no evidence for regional advective heat extraction. One explanation for the different earthquake depths is that cooling of part of the Cocos Plate slows dewatering and the transition of smectite to illite in subducting sediments (Spinelli and Saffer, 2004). Illite-rich sediments are more likely to undergo brittle deformation at depth, so the delay in heating associated with hydrothermal circulation in the crust prior to subduction causes a landward shift of the locked region where earthquakes are most likely to occur.

Summary

Seafloor heat flux can be measured with high accuracy in most deep-ocean settings with gravity-driven probes that penetrate a few meters into seafloor sediment. Improvements in heat-flux measurement technology, improvements in navigation, and integration with swath bathymetric, seismic, and other data that provide geological context for heat-flux measurements have greatly advanced our understanding of many global, regional, and local heat flow processes. Comparison of seafloor and borehole data has demonstrated that measurements made with short probes are accurate, provided that bottom-water temperature variations are relatively small. Compilations of global heat-flux data show that heat flux tends to vary systematically with seafloor age, following a $t^{-1/2}$ relation, at least until seafloor age exceeds 100 Ma, after which heat flux tends to become relatively constant. Determining the deep-seated lithospheric heat flux requires quantification of the potentially large influence of hydrothermal circulation in the permeable igneous rocks of the upper oceanic crust. This is best accomplished

through closely spaced transects of heat-flux measurements colocated with seismic reflection profiles that constrain the hydrologic structure, and regional maps that allow identification of basement outcrops. This approach has been applied in numerous settings, providing valuable constraints on the flow of water within the oceanic crust, the exchange of water, heat, and solutes between the crust and the oceans, the formation of hydrothermal mineral deposits, the accumulation of gas hydrates, and the development and maintenance of a subseafloor microbial biosphere. Individual heat-flux measurements and transects of measurements can be extended across broad regions using the depth to bottom-simulating seismic reflectors. These and other applications were never imagined by those who developed the original techniques for acquisition of seafloor heat-flux data 6 decades ago, but they illustrate how acquiring this kind of data has remained valuable for multidisciplinary studies of thermal, hydrogeologic, tectonic, and microbiological conditions and processes within the lithosphere.

IMPACT CRATERS ON EARTH

Richard A. F. Grieve[1], Gordon R. Osinski[2]
[1]Earth Sciences Sector, Natural Resources Canada, Ottawa, ON, Canada
[2]Department of Earth Sciences/Physics and Astronomy, University of Western Ontario, London, ON, Canada

Definition

Impact crater. An approximately circular or polygonal depression formed by the hypervelocity impact of an interplanetary body (asteroid or comet) on a planetary surface.

Shock metamorphism. Irreversible changes to rocks and minerals, resulting from the passage of a shock wave produced by a hypervelocity impact.

The terrestrial record

Introduction

The results of planetary exploration have demonstrated that impact cratering is a ubiquitous process that has occurred throughout solar system history. On bodies that have retained portions of their early crust, such as the Moon, older surfaces are dominated by impact craters, attesting to the importance of impact cratering in early surface and crustal evolution. The Earth is the most geologically active of the terrestrial planets and is constantly renewing its surface. As impact craters are surface features, the net result of this high level of endogenous geological activity is that most of the original population of Earth's impact craters have been destroyed. What is left is a small preservation sample. The terrestrial record, however, is invaluable in the understanding of impact processes for it is the only source of ground-truth data on the three-dimensional structural and lithological character of natural impact craters.

Since the time of the Apollo missions in the 1960s, the ground-truth data supplied by terrestrial impact craters has served as analogues in understanding cratering processes on the other terrestrial planets; however, impact was generally not regarded as important to Earth's evolution. This changed in 1980, with evidence for a major impact as the cause of the mass extinction event at the Cretaceous-Paleogene (K-Pg) boundary ~65.5 million years ago. The actual crater, the ~180 km diameter Chicxulub crater, was identified in 1991, underneath ~1 km of sediments in the Yucatan peninsula, Mexico. The terrestrial impact record currently stands at ~180 craters or crater fields, with the largest being the ~300 km diameter Vredefort structure, South Africa. Evidence of distal ejecta from over two dozen impact events, some of which can be linked to their source craters, is also recorded in the stratigraphic record. They include four strewn fields of impact glasses known as tektites, which can occur over considerable areas, for example, the Australasian strewn field, which has currently no known source crater, is in excess of 50×10^6 km^2.

Distribution

The basic properties of known terrestrial impact craters are listed at http://www.unb.ca/passc/ImpactDatabase. The spatial distribution of known terrestrial impact structures is not random, with concentrations on the geologically stable cratons of the Australian, European, and North American continents. They are areas with relative tectonic stability and low rates of erosion, that is, they are the best available surfaces for the preservation of terrestrial impact craters. These are also the regions where there have been active programs to study impact craters. Terrestrial processes, such as differential erosion, can result in terrestrial impact craters evolving from an originally negative to a positive landform, that is, by definition, no longer a "crater." Thus, it is more appropriate to use the term

Harsh K. Gupta (ed.), *Encyclopedia of Solid Earth Geophysics*, DOI 10.1007/978-90-481-8702-7,

terrestrial impact "structure," which is not limited to a particular landform. Approximately one-third of the known terrestrial impact structures are buried by post-impact sediments. Detected initially as geophysical anomalies, their identity was confirmed by drilling. There are a number that are now underwater and several that were formed underwater, on relatively shallow continental shelves. At present, no impact structures are known on the true ocean floors, reflecting their relatively young age and the poorer geologic knowledge of this realm.

At large (>20 km) diameters, the cumulative size-frequency distribution of terrestrial impact structures is similar to that on the other terrestrial planets. This likely represents some form of steady-state condition between the formation of impact structures and their removal by terrestrial geologic processes. At smaller diameters, however, there is a deficit in the number of known terrestrial impact structures. This is due to the crushing of small impacting bodies during atmospheric passage, the relative ease with which smaller structures can be removed by erosion or buried, and the intrinsic difficulties in recognizing smaller structures. There is also a bias in the ages of known terrestrial impact structures, with most being <200 Ma old, which also reflects the problems of preservation in the terrestrial environment.

Morphology

Unless buried almost immediately, the forms of terrestrial impact structures are generally modified from their original. There is, however, the same overall progression in form, with increasing diameter, as on the other terrestrial planets. Smaller structures have the form of a bowl-shaped depression, with an upraised rim, and a depth of ~1/6 the diameter, and are termed simple structures (Figure 1). The exposed rim, walls, and floor define what is called the apparent crater. Beneath the apparent floor is an allochthonous breccia lens, which is roughly parabolic in cross section and floored by parautochthonous fractured target rocks. This breccia lens–parautochthonous target rock boundary defines what is called the true crater, with a depth of ~1/3 the rim diameter (Figure 1). For simple structures, the rim diameter is ~10 times that of the impacting body.

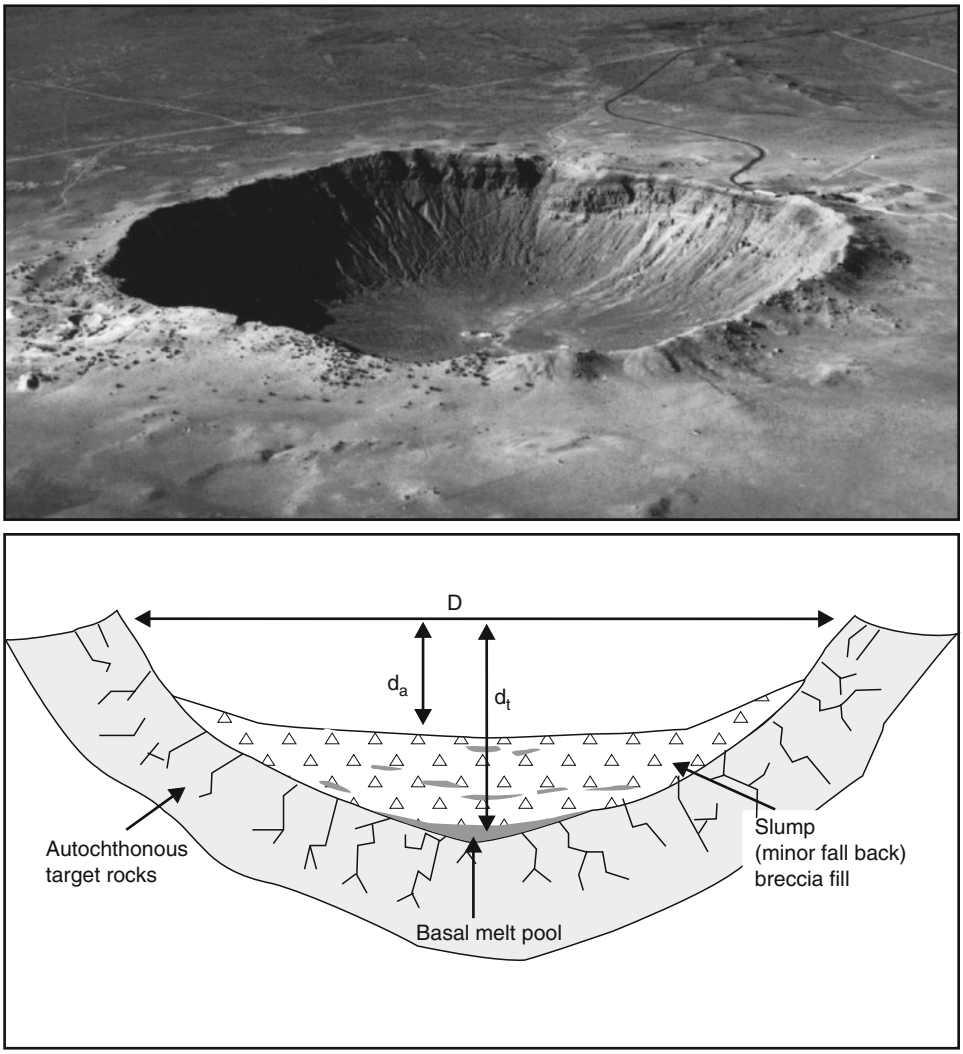
As the diameter increases, there is a change in form, with increasing wall and rim collapse, as simple structures evolve into complex impact structures, with rims consisting of structurally faulted terraces (Figure 2). Interior to the rim is a down-faulted annulus or trough, which is partly filled by allochthonous breccias and/or rocks melted by the impact. At the center is a structurally complex central peak of parautochthonous target rocks, which is the topographic manifestation of a more extensive volume of uplifted target rocks that lie beneath the floor in the center (Figure 2). The transition diameter from simple to complex structures appears to be an inverse function of planetary gravity and target rock strength, with the transition occurring at a diameter of ~4 km in crystalline and ~2 km in sedimentary target rocks, in the terrestrial environment. A number of relatively young (i.e., only slightly eroded) terrestrial complex structures – Haughton, Canada; Ries, Germany; Zhamanshin, Kazakhstan – lack an emergent central peak. These structures are in mixed targets of sediments overlying crystalline basement, with the lack of a peak most likely due to target strength effects. For complex structures, the rim diameter is ~20 times that of the impacting body.

With still increasing diameter, a fragmentary inner ring appears, marking the transition from a central peak structure to peak-ring basin. The larger impact structures in the terrestrial environment, however, tend to be older, eroded structures that have been modified, with their current elements being structural features rather than topographic features. Chicxulub is the best-preserved large terrestrial impact structure, due to burial. As such, however, the definition of its morphological elements depends on the interpretation of geophysical data. It has an interior topographic peak-ring, a terraced rim area, and exterior ring faults and, thus, appears to correspond to the definition of a multi-ring basin, as on the Moon. Details of the physics of cratering mechanics and impact, in general, can be found in Melosh (1989).

Geology of impact structures

Only small, young simple impact structures, where the atmosphere has partially slowed the impacting body, have physical evidence of the impacting body in the form of spalled fragments of iron or stony-iron meteorites, which are relatively quickly destroyed by weathering. (Equivalent-sized, weaker stony meteorites are generally crushed during atmospheric passage.) Larger impacting bodies (>100 m in diameter) impact the Earth with largely undiminished velocity. The average impact velocity of an asteroidal body is 20–25 km s^{-1} and cometary impacts have even higher velocities. Upon impact, most of the impacting body's considerable kinetic energy is partitioned into the target by means of a hemi-spherical propagating shock wave, which sets the target rocks in motion (kinetic energy) and compresses them (internal energy). A cratering flow-field is established in the target, leading to the excavation of target materials. During compression, a considerable amount of pressure-volume work is done. Not all this mechanical work is recovered on decompression to ambient pressure and the excess is manifested as waste heat. This leads to melting and even vaporization of some of the target rocks and the destruction of the impacting body.

The transient compression, decompression, and heating of the target rocks lead to shock metamorphic effects, which record pressures, temperatures, and strain rates well beyond those produced in terrestrial regional or contact metamorphism. The exact physical conditions recorded depend of the peak pressure on impact, as determined by the impacting body's impact velocity and density, and distance from the point of impact. Given the



Impact Craters on Earth, Figure 1 *Top*: Oblique aerial photograph of the classic example of a terrestrial simple impact structure: The 1.2 km diameter Barringer or Meteor Crater, Arizona, USA. *Bottom*: Schematic cross section of a terrestrial simple impact structure, showing various lithological, structural, and morphologic attributes. highly transient nature of shock metamorphic processes, disequilibrium and metastable equilibrium are common. The nomenclature of shocked rocks or impactites (various melt rocks, breccias, and shocked target rocks) and the pressures required to generate particular shock metamorphic effects are summarized in Stöffler and Grieve (2007). Examples of impactites and shock metamorphic effects are well illustrated in French (1998).

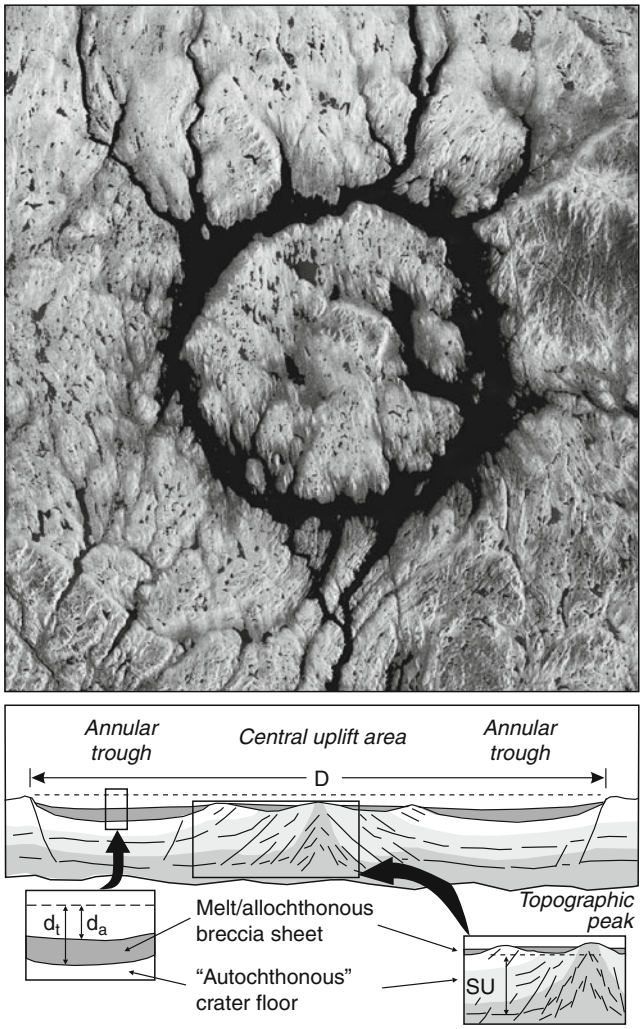
The highest shock metamorphic effect preserved at impact structures is impact-melted material, which results from shock pressures >60 GPa, and takes the form of glass clasts in breccias, melt dikes in the floor of the structure, and lenses and coherent sheets of impact melt rock within the crater interior (Figure 3). When crystallized, impact melt rocks have an igneous-looking matrix and are often charged with mineral and lithic debris. Compositionally, these melted lithologies can be modeled as a mixture of target lithologies, in geologically reasonable proportions. Isotopic systems, such Sr, Nd, and Pb, mirror those of the initial ratios of the target rocks, while others (e.g., Ar) can be reset and record the time of impact. In some cases, siderophile-element enrichments above target rock levels occur, reflecting an admixture of material from the impacting body. In some cases, their relative abundances have identified the type of impacting body, for example, C-1 chondrite. In a few cases, Cr and Os isotopes have also been used to identify the impacting body. At lower shock pressures (~60–30 GPa), selective mineral melting occurs. In addition, the shock wave can destroy the internal crystallographic order of feldspars and quartz and convert them to solid-state glasses, which still have the original crystal shapes. These are



Impact Craters on Earth, Figure 2 *Top*: RADARSAT image of the Manicouagan, Canada, complex impact structure. The annular lake is 65 km in diameter and is, in part, man-made, serving as reservoir for hydroelectric power generation. The original diameter of this partially eroded structure was ~100 km and the central peak (Mont de Babel) rises to 600 m above the level of the lake. *Bottom*: Schematic cross section of a terrestrial complex impact structure, indicating various lithological, structural, and lithological attributes. Example shown has a central peak and an annular ring, which may have been the original form of Manicouagan. *D* rim diameter, d_a apparent depth, d_t true depth, *SU* structural uplift, which is ~0.1 D.

"diaplectic" glasses (Figure 3), with the required pressures being 30–45 GPa for feldspar and 35–50 GPa for quartz (diaplectic plagioclase glass is also known as maskelynite). The extremely rapid compression and then decompression also produces metastable polymorphs, for example, coesite and stishovite from quartz and diamond and lonsdaleite from graphite.

The most-documented shock metamorphic feature is the occurrence of so-called planar deformation features, particularly in quartz (Figure 3), although they do occur in other minerals, for example, feldspar, zircon. Their utility is a function of the common occurrence and stability of quartz in terrestrial rocks and the relative ease with which they can be observed and measured by optical microscopy. When fresh, planar deformation features are parallel planes of glass, with specific crystallographic orientations as a function of shock pressures of ~10–35 GPa. The only megascopic shock features are shatter cones, which are distinctive, striated, and horse-tailed conical fractures ranging in size from millimeters to tens of meters (Figure 3). They are best developed in fine-grained, structurally isotropic rocks, such as carbonates and quartzites, but more poorly developed variants can occur in coarser-grained rocks. They are most common in rocks shocked to relatively low levels, ~2–6 GPa, but can occur in rocks recording pressures as high as ~25 GPa.

Geophysics of impact structures

For buried impact structures, a geophysical anomaly is the first indicator of their existence, although confirmation of their genesis requires drilling and the documentation of shock metamorphic effects. The most common geophysical anomaly is a localized low in the regional gravity field (Figure 4), due to lowering of rock density from brecciation and fracturing. In general, modeling of the gravity anomalies is consistent with the morphometric parameters of terrestrial impact structures, with the anomaly extending to the rim of the structure. The anomaly increases to a maximum of ~200–300 g.u. at rim diameters of 20–30 km (Pilkington and Grieve, 1992), with the lack of further increases in magnitude at larger diameters due to lithostatic pressure closing any deep-seated impact-related fracturing. The gravity signature can be complicated by erosion and variations in target rock densities. Larger complex impact structures tend to have a central, relative gravity high, which can extend out to approximately half the diameter of the structure. This central, relative gravity high is from the uplift of originally deeper (more dense) lithologies in the structural uplift.

Magnetic anomalies are more varied. Most commonly, they are a magnetic low, with the disruption of any regional trends in the magnetic field. This is due to an overall lowering of magnetic susceptibility and the randomizing of pre-impact lithologic trends in the target rocks. Larger structures commonly have high-amplitude, short wave-length anomalies in the center, due to changes to remanent magnetization in the target rocks from the effects of heat, shock, and/or post-impact hydrothermal alteration. Seismic velocities are reduced at impact structures, due to fracturing, and reflection seismic images are extremely useful in characterizing buried structures in sedimentary targets. Subsurface brecciation, fracturing, and incoherency of seismic reflectors increase toward the center of complex structures due to structural uplift, resulting in a central volume that is isotropic in terms of a reflection seismic signal. Electrical methods have been used less but,

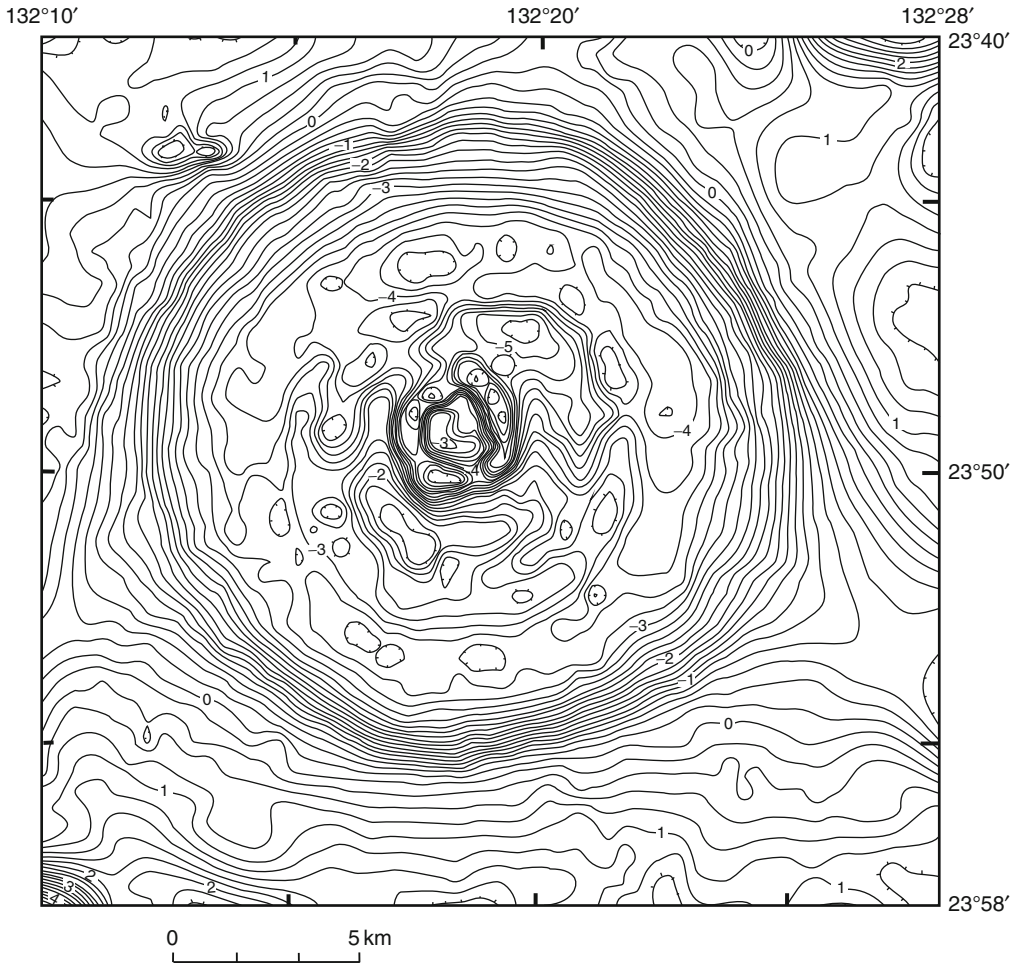
in general, there is a reduction in resistivity, which is related to fracturing. Resistivity contrasts can also delineate lithological contacts, for example, between allochthonous breccia deposits and the fractured target rock and/or post-impact sediments.

Impacts and Earth history

The formation of the terrestrial planets by the accretion of small bodies through collisions and subsequent growth to proto-planets includes potential collisions between these proto-planets. One such collision between the proto-Earth and a Mars-sized body is currently the best working hypothesis for the origin of the Moon. Such an impact would result in an Earth-orbiting accretionary disk of material from the impacting body and proto-Earth, which was the source of volatile- and siderophile-depleted material for building the Moon. The consequences for the proto-Earth include massive remelting and the loss of any original atmosphere. Without a Moon and lunar tides, there would be little or no littoral zone, which is the most important area in the terrestrial ecosystem, to Earth's oceans. With no littoral zone, the development and evolutionary path of Earth's biosphere would have been very different. Following planetary formation, the subsequent high rate of bombardment is attested to by the heavily



Impact Craters on Earth, Figure 4 Residual Bouguer gravity anomaly at the 22-km diameter Gosses Bluff impact structure, Australia, which is in the form of a symmetric gravity low, with a central, short-wave anomaly due to structural uplift. The target was a flat-lying sequence of sedimentary rocks and the simplicity in the form of the anomaly results from the lack of major asymmetric lithological/density contrasts. Contour interval is 1 g.u.

cratered lunar highland crust and the formation of the very large (up to 2,500 km in diameter) multi-ring impact basins. The Earth, however, has a larger gravitational cross section and will capture more incoming interplanetary bodies than the Moon. Thus, it has been subject to a greater number of impacts than the Moon throughout geological time, including the basin-forming impacts in the period of heavy bombardment. There have been speculation as to the potential effects of such impacts (e.g., Grieve et al., 2006), but no rocks are preserved from this period of the early Earth. Such impacts would retard any development of life on Earth but once they had subsided smaller impact events may have been beneficial for microbial life, with the generation of fertile hydrothermal systems, impact crater lakes, and new habitats within shocked rocks and minerals.

The temporal association of a large impact event (Chicxulub), world-wide ejecta, and a mass extinction at the K-Pg boundary is well established. As other large impact structures have not been linked to mass extinctions in the terrestrial biosphere, it may be that there was a unique characteristic to the Chicxulub event. Sulfate-bearing rocks occur at Chicxulub, raising the possibility of massive amounts of sulfur aerosols in the atmosphere after the impact. They would reduce light levels below those required for photosynthesis for the best part of a year, with the collapse of the food chain. Chicxulub-scale impacts occur every 100 ± 50 Ma. Smaller impacts occur on shorter timescales and loading of the atmosphere with dust from craters in the 20-km size-range would be global in scale. This would not produce a mass extinction but could severely disrupt or even destroy the relatively fragile infrastructure that supports human civilization.

Past-impacts have also been beneficial for the human condition. Approximately 25% of known terrestrial

impact structures have some form of natural resources, ranging from unexploited local deposits to world-class mining camps. For example, the ~1.5 billion tonnes of ores at the Sudbury impact structure, Canada, have so far produced over $ 300 billion worth of metals. Approximately 50% of impact structures in hydrocarbon-bearing sedimentary basins are producers. The world-class Campeche Bank oilfield in the Gulf of Mexico produces most of its hydrocarbon products (~ 12 billion barrels of oil and >3 trillion cubic feet of gas, since discovery) from Chicxulub-related breccias and has reserves exceeding the entire known reserves of the USA.

Concluding remarks

Although the first known recorded observations of impact craters was made by Galileo Galilei in 1609, it was not until the 1960s that the importance of impact cratering as a geological process began to be recognized. This came with the recognition of shock metamorphism and its effects on rocks and minerals and with impetus provided by the planned Apollo landings on the Moon. It is now widely acknowledged that impact cratering is one of the most important surface geological processes in the solar system. It has also become apparent that impact events have also played an important role throughout Earth's history, shaping the geological landscape, producing economic benefits, and affecting the evolution of life. The study of impact craters and related phenomena is relatively young when compared to other fields of scientific study and, as such, there is still considerable future potential for new and exciting discoveries.

Definition

Electrical survey. Mapping subsurface resistivity by injecting an electrical current into the ground.

Resistivity meter. An instrument used to carry out resistivity surveys that usually has a current transmitter and voltage-measuring circuitry.

Electrode. A conductor planted into the ground through which current is passed, or which is used to measure the voltage caused by the current.

Apparent resistivity. The apparent resistivity is the resistivity of an equivalent homogeneous earth model that will give the same potential value as the true earth model for the same current and electrodes arrangement.

Multi-core cable. A cable with a number of independent wires.

Introduction

The resistivity survey method is more than 100 years old and is one of the most commonly used geophysical exploration methods (Reynolds, 1997). It has been used to image targets from the millimeter scale to structures with dimensions of kilometers (Linderholm et al., 2008; Storz et al., 2000). It is widely used in environmental and engineering (Dahlin, 2001; Chambers et al., 2006) and mineral exploration (White et al., 2001; Legault et al., 2008) surveys. There have been many recent advances in instrumentation and data interpretation resulting in more efficient surveys and accurate earth models. In its most basic form, the resistivity meter injects a current into the ground through two metal stakes (electrodes), and measures the resulting voltage difference on the ground surface between two other points (Figure 1). The current (I) and voltage (V) values are normally combined into a single quantity, the apparent resistivity, which is given by the following relationship:

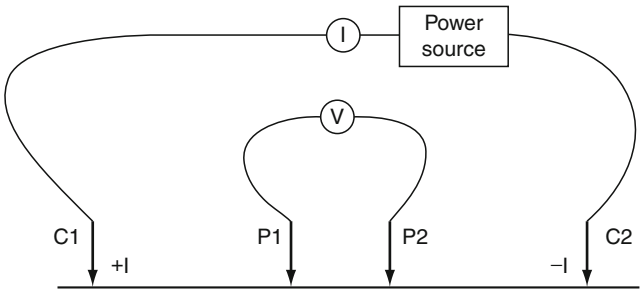
$$\rho_a = kV/I \quad (1)$$

The apparent resistivity is the resistivity of an equivalent homogeneous earth model that will give the same potential value as the true earth model for the same current and electrodes arrangement. The geometric factor k depends on the arrangement of the electrodes (see *Electrical Resistivity Surveys and Data Interpretation*). The flow of the current through the ground depends on the resistivity of the material (rocks) through which it passes and is reflected in the measured voltage values. Subsurface

resistivity distribution can be mapped by making measurements with the current and voltage electrodes at different positions.

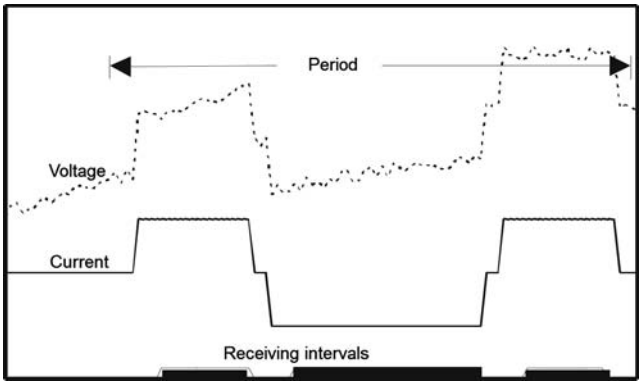
Basic resistivity instruments

The basic parts of a resistivity measurement system include a source of electrical current, a voltage measuring system, and the cables to connect these components to the electrodes. These components have undergone major modifications over the years to improve the efficiency of the survey procedure, the quality of the data, and to increase the depth of investigation. The power source for the current is typically a battery for shallow surveys. Some small portable resistivity meter systems (Figure 2a) for very shallow surveys of up to a few meters depth weigh less than a kilogram (Pozdnyakov et al., 2009). A typical system (with associated cables and electrodes) for environmental and engineering surveys that uses an internal battery is shown in Figure 2b. Such systems usually weigh between 10 and 50 kg. The current source and voltage measuring circuitry are integrated into a single unit (the resistivity meter). Such battery-based systems can provide currents of up to about 2 A and have been used for survey depths of up to about 200 m. For deeper surveys where currents of up to 10 A are used, a petrol/diesel engine–powered electric generator is usually used. Such systems can weigh several hundred kilograms, and are commonly used for induced polarization (IP) surveys in mineral exploration (White et al., 2001). The current transmitter is separate from the receivers that measure the potential signal (Figure 2c).



Instrumentation, Electrical Resistivity, Figure 1 Basic setup for an electrical resistivity survey. The current is injected into the ground through the C1 and C2 electrodes, and the resulting voltage difference is measured by the P1 and P2 electrodes.

(**b**) A typical system used for shallow environmental and engineering surveys (courtesy of Torleif Dahlin and Abem Instruments AB.), and (**c**) a schematic diagram of a system for deep surveys.



Instrumentation, Electrical Resistivity, Figure 3 Example of input current and resulting voltage signal. (Courtesy of Torleif Dahlin and Abem Instruments AB.)

In the interpretation of the survey data, it is assumed that a direct current (DC) is used. However, in practice, a low-frequency square-wave alternating current (AC) is normally used. The frequency is sufficiently low (typically less than 100 Hz) such that EM effects are negligible. Figure 3 shows an example of the shape of the input current used and the resulting voltage signal. The amplitude of the voltage signal is typically in the millivolt range, but smaller voltages can be resolved if the signal-to-noise ratio is sufficiently high or signal-stacking techniques are employed. A 24-bit ADC (analog-to-digital converter) is widely used in modern systems to digitize the voltage signal. In the absence of an input current, the ground has a natural self-potential (SP) voltage between different points on the surface. This can be caused by variations in the chemical properties of the soil or currents induced by changes of the geomagnetic field with time. The SP voltage can vary significantly with time. The voltage measuring system in the resistivity meter has a SP buck-out mechanism to remove the SP voltage signal. It usually also has notch filters (e.g., 50, 60, 16.7 Hz) to remove noise due to electric power lines and other technical infrastructure such as electrified railway systems.

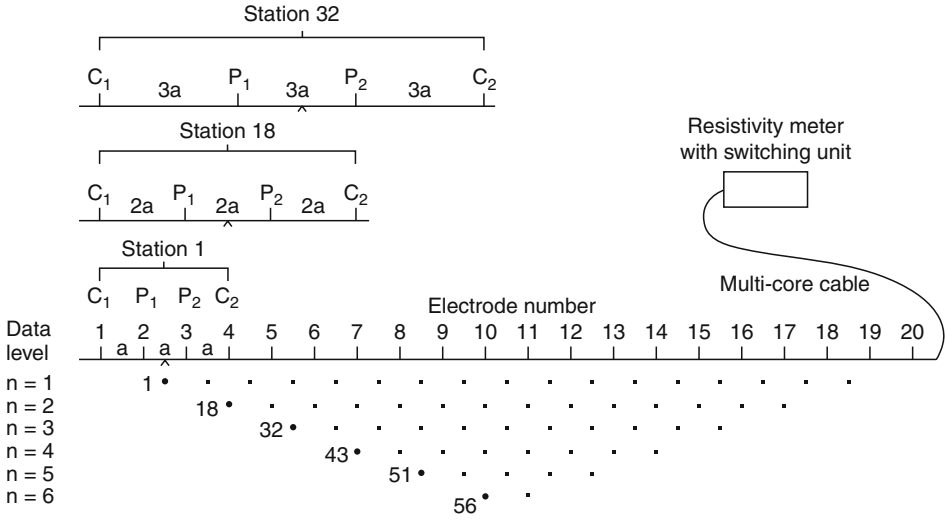
IP surveys are widely used in mineral exploration, and recently there has been increasing interest in the environmental and engineering sector (Aristodemou and Thomas-Betts, 2000; Dahlin et al., 2002). While both time and frequency domain (Telford et al., 1990; Reynolds, 1997) measurement techniques have been used in mineral exploration, the time domain method appears to be the norm for the less powerful equipment used in environmental and engineering surveys.

Electrode types

Metal stakes (Lu and Macnae, 1998) are commonly used for the current electrodes as well as the potential electrodes in resistivity surveys. For some ground conditions where it is difficult to insert a stake electrode, flat-base (or plate) electrodes have been used (Athanasiou et al., 2007; Tsokas et al., 2008); galvanic contact with the ground is achieved using an electrically conductive gel or mud at the base of the electrode. In IP surveys, nonpolarizable electrodes (Reynolds, 1997) are widely used as the potential electrodes to reduce SP noise. This makes it difficult to carry out IP surveys using multielectrode systems for 2-D (two-dimensional) imaging surveys. There has, however, been significant progress in using normal steel stakes as the potential electrodes (Dahlin et al., 2002; LaBrecque and Daily, 2008).

Multielectrode and multichannel systems

The development of multielectrode systems over the past 20 years has sparked a revolution in resistivity surveying. The advent of 2-D and 3-D (three-dimensional) resistivity tomography has opened up whole new application areas to electrical methods. Before early 1990s, the electrical resistivity method was mainly used in resistivity sounding, profiling, and mapping surveys (Telford et al., 1990). Quantitative interpretation was mainly confined to 1-D (one-dimensional) structure of the subsurface consisting of horizontal layers (Koefoed, 1979). The multielectrode systems made it practical to carry out 2-D imaging surveys that give a more accurate picture of the subsurface (Dahlin, 2001) in a routine manner. Unlike the conventional 4 electrodes system, a multielectrode system has about 25 or more electrodes connected to the resistivity meter via a multi-core cable (Figure 4). A switching circuitry controlled by an internal microcomputer within the resistivity meter automatically selects the appropriate 4 electrodes for each measurement. The system is usually programmable and almost any electrode array configuration can be used. Several variants of the multielectrode cable system exist, where the distinguishing factor tends to be the physical location of the switching circuitry. Some resistivity meters contain all the switching capability within the main unit, so that two or more long multi-core cables can be attached directly to the meter. The cables then merely serve as a physical extension between the switch and the electrodes, which have no other function than to act as a galvanic contact between the meter and the ground (also known as "dumb" electrodes). These systems have a practical limit on the number of electrode takeouts (commonly 32) in each cable. In the second type of system, an external switch box is connected to the main meter via a system bus. The switching capacity can then be extended by daisy-chaining switch boxes, each connecting to cable segments with multiple "dumb" electrodes. This design can vastly increase the possible number of electrodes available for simultaneous measurements, but it can also be less portable than the first arrangement, particularly in forested and rugged terrain. The third type of system uses "intelligent" electrodes, where the switching circuitry is decentralized and placed at individual electrodes. Even the actual voltage measurement and analog-to-digital conversion may be carried out locally in such systems, potentially reducing interference problems (Stummer and Maurer, 2001).



Instrumentation, Electrical Resistivity, Figure 4 Schematic diagram of a multielectrode system used for a 2-D electrical survey and an example sequence of measurements used to build up a pseudosection using the Wenner array.

A more recent development is multichannel capability for multielectrode systems that can greatly reduce the survey time. Only two electrodes can be used as the current electrodes at a single time, but the voltage can be measured between different pairs of potential electrodes. Commercial systems with 4–10 channels are available and some research systems have more than 100 channels (Stummer and Maurer, 2001).

Full-waveform systems

There has been considerable research on systems that record the full waveform of the potential signal in an effort to extract more information from the data and to improve the signal-to-noise ratio using signal processing techniques (Friedel and Jacobs, 1998; Storz et al., 2000; Matthews and Zonge, 2003; Rowston et al., 2003; Zhe et al., 2007). This is often the only practical approach for resistivity surveys in which large depths of investigation are required (such as, regional surveys or crustal studies) or where the nature of the target requires large dipole offsets (for example, investigations on volcanoes).

Towed systems for dynamic measurements

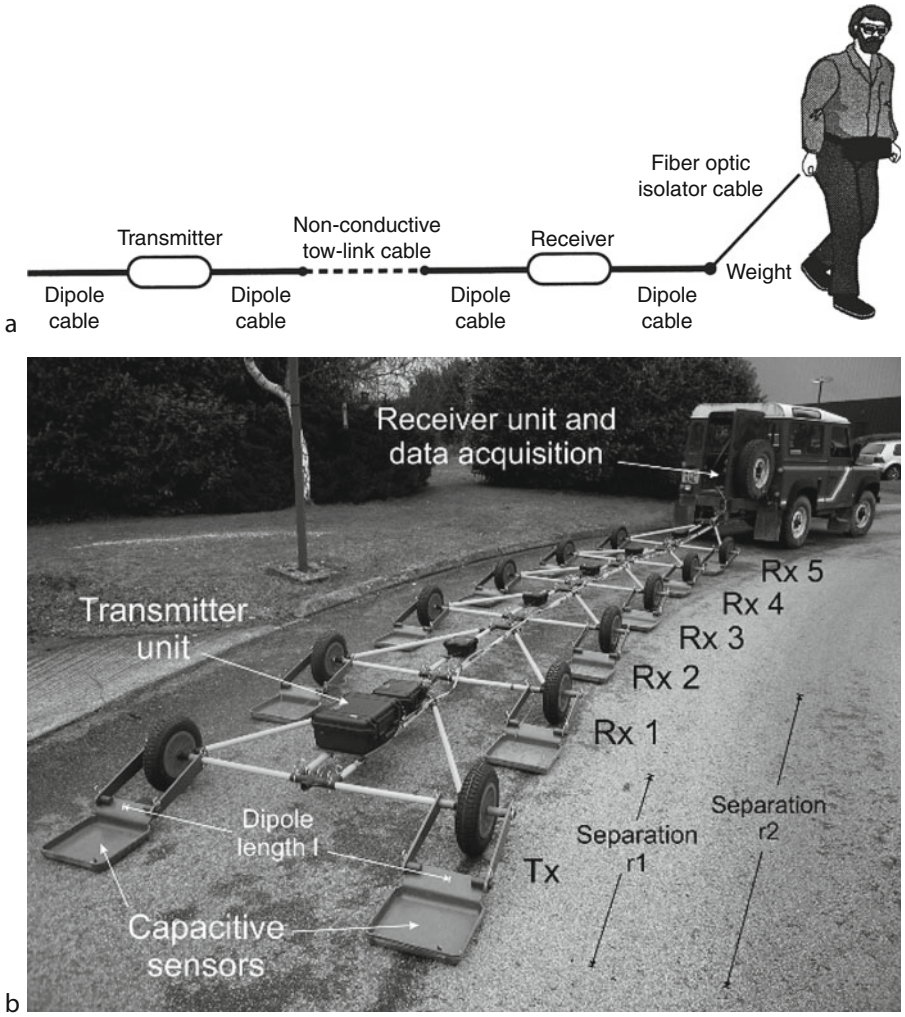
The multichannel multielectrode systems have been adapted for continuous profiling water-borne surveys using floating electrodes attached to a cable pulled by a boat (Loke and Lane, 2005; Mansoor and Slater, 2007; Goto et al., 2007). A PC coordinates the resistivity meter system data acquisition together with a GPS and water depth sounder. Continuous measuring systems for land surveys have also been developed. Some systems use cylindrical steel electrodes based on an in-line array geometry (Sørensen, 1996), while others use spiked wheels to achieve continuous galvanic contact with the soil (Panissod et al., 1998; Dabas, 2009).

Capacitively coupled systems

It is difficult or impossible to use conventional resistivity meter systems that inject a galvanic current into the ground in areas with very resistive surface materials or paved surfaces. Capacitively coupled systems can be used in such areas. These instruments use an oscillating, nongrounded electric dipole to generate current flow in the ground and a second similar dipole to measure the resulting potential distribution at the ground surface (Kuras et al., 2006). Two major configurations have been used in commercial and research instruments of this type. The first configuration (line antenna type) uses cylindrical transmitters and receivers, which are towed behind an operator (Figure 5a). It gives measurements that are comparable to the galvanically coupled in-line dipole–dipole array (Møller, 2001) and have maximum depths of investigation of 1–20 m, depending on the lengths of transmitter and receiver and the distance between them. The second type (electrostatic quadrupole) uses flat metallic conductors (Figure 5b) in an equatorial dipole–dipole configuration (Panissod et al., 1998; Kuras et al., 2007). This type has been used for survey depths of up to a few meters. Both configurations are dynamic measuring systems where the array configuration is fixed but the entire setup is moved during the survey for lateral coverage. 2-D and 3-D surveys with dense lateral coverage can be rapidly conducted with these systems (Kuras et al., 2007).

Automated resistivity monitoring systems

Automatic PC controlled monitoring systems have been developed for detecting transient phenomena such as water seepage from dams, landslides, and solute transport (Oldenborger et al., 2007; Sjödahl et al., 2008; Supper et al., 2008; Kuras et al., 2009). Monitoring systems are becoming increasingly sophisticated, and are now being



Instrumentation, Electrical Resistivity, Figure 5 Types of capacitively coupled systems. (**a**) Line antenna (courtesy of Geometrics Inc.) and (**b**) plate-wire capacitive sensors (electrostatic quadrupole) arranged in a towed array. (Courtesy of British Geological Survey, NERC.)

deployed remotely with permanently installed electrode arrays, telemetric control, and data transfer, supported by automated data management systems to handle the large data volumes generated through time-lapse data acquisition (Ogilvy et al., 2009).

Summary

There have been major advancements over the past few decades in the instrumentation for the electrical resistivity method. In addition to traditional 1-D surveys, the new multielectrode and multichannel systems have made it possible to efficiently carry out 2-D and 3-D imaging surveys that provide more accurate models of the subsurface geology. Computerized dynamic towed systems can map large areas on land and water rapidly. Capacitively coupled systems make it possible to survey areas with resistive surfaces where conventional galvanic systems cannot be used. Sophisticated PC controlled monitoring systems are now available to automatically detect and record transient phenomena.

nT Nanotesla, unit of magnetic flux density

Introduction

Here we look at instrumentation used for land and marine electromagnetic (EM) induction studies of Earth, which seek to characterize the electrical conductivity of the subsurface. Conductivity is driven by porosity and fluid content in the crust, temperature and mineralogy in the mantle, and minor proportions of highly conductive graphite, oxides, or sulfides in both. The principal tool for deep Earth conductivity sounding is the *magnetotelluric* (MT) method, in which time series measurements of the surface horizontal magnetic and electric fields are recorded and converted into a frequency-dependent transfer function. Loosely speaking, variations in the external magnetic field act as the input and induced electric fields in the earth act as the output. The frequency dependence of the amplitude and phase of the transfer function may be interpreted to recover electrical conductivity as a function of depth; longer periods propagate into deep structure while higher frequencies are absorbed in shallow structure.

A related method is called *geomagnetic depth sounding* (GDS), in which a transfer function between the vertical and horizontal magnetic fields is used in a similar manner. GDS data are mainly sensitive to lateral conductivity structure, although if assumptions are made about the morphology of the external magnetic source field, long-period data can be interpreted to recover conductivity as a function of depth in a similar manner to MT data. Alternatively, gradients in the magnetic field can become a proxy for the electric field, and an MT response calculated in this way.

When near-surface crustal geology is of interest, man-made sources of EM energy (transmitters) can be used to probe conductivity, using either current passed through a grounded wire (an electric field source) or current passed through a loop (or loops) of wire (a magnetic field source). Electric or magnetic fields are measured as a function of transmitter frequency (frequency domain sounding) or, alternatively, transmitter turn-off time (time domain, or transient, sounding). Transmitter–receiver position, separation, and geometry (orientation, etc.) are also survey parameters. Measurements of this type fall into the category of controlled-source EM (CSEM) methods, although particular configurations often have distinct names or even trade names (e.g., Turam, LoTEM, MTEM).

Electric field measurement

Electrodes are used to make contact with the ground (or, in the marine case, seawater) for the purpose of making a measurement of potential difference, which is usually then divided by the electrode separation to form an estimate of electric field. Even with high input impedance amplifiers, some small current must be drawn to make the measurement. The simplest electrode is a metal rod in contact with damp earth or water, which will act as a source or sink of electrons e^- through the reaction

$$\mathrm{M} \rightleftharpoons \mathrm{M}^+ + e^-$$

where M is the metal and M^+ is the metal cation. This is called an electrode of the first kind, and unless the metal cation is highly concentrated in the vicinity of the electrode, this reaction will not be reversible and the electrode will polarize, creating unwanted galvanic potentials and contributing to noise. This may be tolerable for high-frequency measurements, and simple metal rods are used for high-frequency MT measurements using man-made radio transmitters as the source field.

If the metal rod is immersed in a concentrated aqueous solution of a compatible salt, then the reaction is reversible and the electrode is nonpolarizing. The most commonly used electrode of this type is the copper–copper sulfate "porous pot." The "pot" containing the copper sulfate solution has a semipermeable barrier as its base, usually unglazed ceramic, which makes electrolytic contact with any moisture in the soil. Such electrodes are commonly used for "broadband" MT measurements in the frequency range of 1 mHz to 100 Hz.

Nonpolarizing electrodes of the second kind are made by coating a metal with a sparingly soluble salt and immersing in an aqueous electrolyte containing a compatible anion. The reaction here is

$$\mathrm{M} + \mathrm{A}^- \rightleftharpoons \mathrm{MA} + e^-$$

where A^- is the anion. On land the most commonly used electrode of this type is lead–lead chloride immersed in solution of potassium or sodium chloride (e.g., Petiau, 2000), and for marine work silver–silver chloride immersed in seawater, which contains about 30 g/l sodium chloride, is commonly used (e.g., Webb et al., 1985). These electrodes have lower temperature coefficients and higher stability than those of the first kind, and are preferred for long-period MT work on land and almost all MT studies in the marine environment. Silver–silver chloride electrodes are also favored for marine CSEM soundings, although polarizing, capacitively coupled, electrodes such as the carbon fiber sensors of Crona et al. (2001) have also been used.

Electrodes are separated by cables of order 100 m long on land to integrate the electric fields and provide a measurable potential difference. Contact impedance for electrodes can be as large as several kilohms, and so the input impedance of amplifiers should be large, but gain need not be very high since signals will be up to several millivolts across a 100-m antenna, and a reasonably well-designed amplifier will not contribute significantly to noise.

For marine measurements the situation is very different. The electrode contact impedance is much lower (around 10 Ω), the signal levels are much smaller (a few μV/m), and the antenna lengths are usually shorter as well (around 10 m). For long-period MT simple amplifiers with gains of about 100 are adequate, but for broadband MT and CSEM measurements at frequencies of 0.1 Hz and above,

capacitively coupled chopper amplifiers with very low noise and gains of 10,000 and higher are used (Webb et al., 1985).

Magnetic field measurement

Magnetic field sensors fall into two broad categories; total field magnetometers and vector magnetometers. Total field proton and nuclear precession devices are used for magnetic mapping, but for EM induction vector measurements are needed, either using induction coils or fluxgate sensors. Superconducting (SQUID) magnetometers have been used for induction studies, but so rarely that they will not be discussed here.

A simple loop of wire can be used as a magnetic sensor based on Faraday's Law, in which a time-varying magnetic flux of density B through area A will induce a voltage V in a loop of wire with N turns:

$$V = -NA\frac{dB}{dt} = -NA\mu\frac{dH}{dt}$$

where H is the magnetic field and μ is permeability, which for an air-cored loop is the free-space value of $4\pi \times 10^{-7}$ H/m.

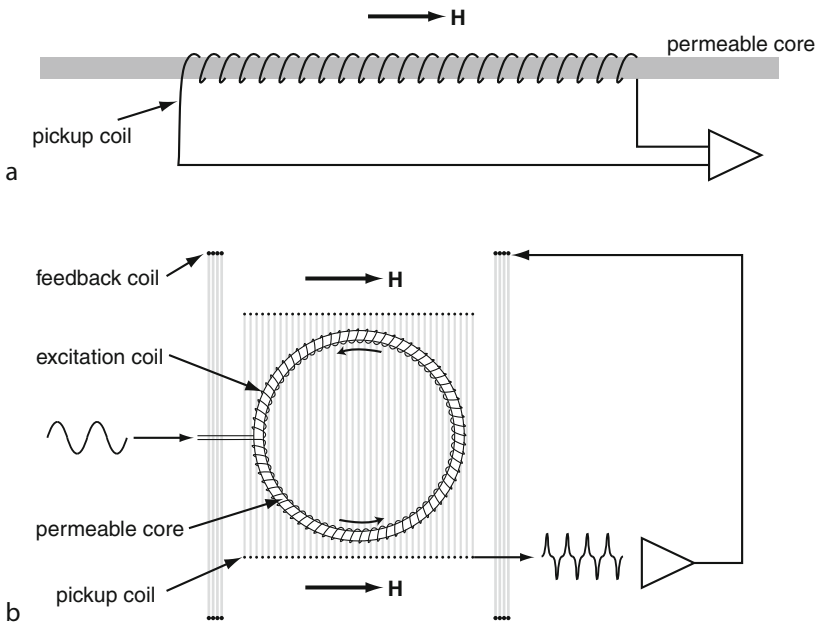
For CSEM operations at high frequencies (kilohertz range) the derivative term is large enough that an adequate signal may be measured in this way, particularly for single frequency CSEM in which lock-in amplifiers can be used. Alternatively, for time domain studies in which a large loop of wire is used as the transmitter, the area may be as much as 10^4 m^2 and it is possible to make measurements using the transmitter loop after switch-off. Normally however, induction coils (also called search coils, Figure 1a) are used, in which thousands of turns of wire are wound around a magnetically permeable core of soft ferrite or iron–nickel alloy (Permalloy or mu-metal). The core captures the magnetic field and multiplies the flux by an effective permeability, μ_e, determined by a combination of geometry and relative permeability, producing a voltage

$$V = -NA\mu\,\mu_e\frac{dH}{dt}.$$

For long, cylindrical, highly permeable cores of length L and diameter d the effective permeability depends only on geometry and is given approximately by (Tumanski, 2007):

$$\mu_e = \frac{(L/d)^2}{(\ln(2L/d) - 1)}.$$

We see that increasing length improves sensitivity, and typical broadband MT coils are of order 1 m long. The main source of noise for induction coils is the thermal (or Johnson) noise of the resistance in the wire windings, and so increasing N does not necessarily increase the signal to noise ratio (SNR) because it also increases resistance. Indeed, to a first approximation the SNR is proportional



Instrumentation, EM, Figure 1 (**a**) Schematic depicting the operation of an induction coil magnetometer. A coil of wire is wound around a permeable core. (**b**) The ring-core fluxgate magnetometer. An excitation coil drives the core into saturation in two different directions. The direction aligned with the external magnetic field will saturate sooner than the direction apposed to the field, creating a pulse of unbalanced flux twice per excitation cycle, which is detected by a synchronous amplifier tuned to twice the excitation frequency. In practice, fluxgates are often used as null sensors with the output of the pickup coil used to null the field using a feedback coil; the current in the feedback coil becomes the measurement.

to the mass of copper used in the windings. However, if weight is an issue, as it may be for marine instruments, aluminum windings can be used for a significant improvement in weight at a modest cost in resistance noise. The noise of a good-quality induction coil used for EM induction studies is around 10^{-9} nT^2/Hz at 1 Hz with a red $1/f$ type spectrum. Since motion in Earth's magnetic field can also produce a time-varying signal, on land induction coils are usually buried during operation to prevent movement. For marine MT and CSEM studies, the magnetometers must be stabilized by heavy anchors, usually made from concrete to avoid magnetic contamination.

Although integrating amplifiers or feedback can be used to flatten the frequency response of induction coils, the one-pole low-cut response of the dH/dt term is a fairly good match to the red spectrum of natural magnetic field variations. However, reasonable signal to noise performance for induction coils is still limited to periods shorter than several thousand seconds. For longer period MT and GDS studies, fluxgate magnetometers are preferred. Fluxgates use the principle that variations in magnetic flux may be generated for a fixed magnetic field by varying the permeability of the core material:

$$V = -NA\frac{dB}{dt} = -NA\mu\frac{d\mu_e}{dt}H.$$

This is achieved by winding the permeable core with an excitation coil that saturates the core in alternate directions using a sinusoidal or square wave current of around 1 kHz. A saturated core has an effective permeability of zero, since it is no longer influenced by the external field H, and so the excitation current generates the time-varying permeability required to get an inductive response.

Various core geometries can be used for fluxgates, but the most common type of geophysical sensor uses a ring-core geometry (Figure 1b). The excitation coil saturates the two sides of the core symmetrically in opposite directions; the side of the coil excited in the same direction as the external magnetic field saturates sooner, while the opposite side saturates later. This asymmetry produces a time-varying net flux at twice the excitation frequency, which is detected by a pickup coil wound around the core; the orientation of the detection coil determines the direction of sensitivity. A lock-in amplifier tuned to twice the excitation frequency will thus have an output proportional to the external field. However, this output is only linear over a range of several hundred nanotesla, and also will be sensitive to variations in μ_e caused by temperature; so most observatory quality instruments are operated as null sensors. The total magnetic field (usually the component of Earth's field aligned with the sensor) is canceled by a solenoid or Helmholtz coils. The output of the fluxgate is fed back to control the current in the nulling coils, and this current then becomes the measurement of low-frequency changes in the magnetic field.

The effective permeability of ring-core of diameter L and thickness d is approximately

$$\mu_e = \frac{L}{d}$$

for large L/d; ring-core sensors are usually about 2 cm in diameter and a millimeter or so thick, with quoted noise levels of order 10^{-4} nT^2/Hz at 0.1 Hz (Primdahl, 1979). By design, fluxgates sense the static magnetic field component in a given direction, which is typically 40 μT on Earth (possibly as large as 60 μT), and so the low-frequency response of fluxgates extends to DC. Excitation frequencies are high enough that variations up to a few tens of hertz can be recorded, but long-period MT instruments typically sample only at about 1 Hz, since the noise in fluxgates becomes higher than induction coils at a frequency of about 0.01 Hz. Also, making measurements of field variations in the presence of Earth's total field requires a large dynamic range, and even with 24-bit analog to digital conversion (ADC), the least count will be of order 0.01 nT, and resolutions of 0.1 nT are more typical. Least counts for induction coil sensors are of order 0.01 pT.

EM transmitters

Either a magnetic or electric field transmitter can be used for CSEM soundings. Electric transmitters consist of a long (hundreds of meters) wire grounded at both ends, through which a modulated current is driven. For large currents it is easier to switch square waves than generate sinusoidal waveforms, and if the switching is controlled rapidly then time domain measurements may be made. Alternatively, a swept or random sequence of binary pulses can be used and the receiver data deconvolved to generate a broadband response. For marine CSEM surveys, the high conductivity of seawater allows transmitter currents of up to a thousand amps to be used. Magnetic transmitters consist of large loops of wire through which a current is passed, and are mainly used for time domain studies on land.

Data acquisition systems

The science and technology behind EM sensors have not changed significantly for many decades, but development of modern electronics has revolutionized the way MT and CSEM data are collected. The advent of microprocessors; 24-bit ADC modules; low power, high capacity, static digital memory; and the global positioning system (GPS), which allows time to be measured with microsecond accuracy anywhere on the surface of Earth, together allow continuous, time-synchronized, measurements to be made using small, portable, low-power logging systems.

Time synchronization is important in MT data acquisition, since noise reduction in processing raw time series to frequency domain response functions depends on cross-spectra being estimated between two or more remotely separated sites. For CSEM soundings, synchronous stacking and estimation of phase lag between source and receiver both demand good timing for the transmitter and receiver. In the past this was done with wired or

wireless links between sites for both CSEM and MT. Now, all sites can be individually clocked with GPS timing for later synchronous processing, at least on land. Marine MT and CSEM receivers must have installed clocks that are reset using GPS time before deployment, and whose drift can be determined using GPS on recovery. In this way time accurate to better than a millisecond per day can be achieved. Since marine EM transmitters are attached to, and powered by, ships, GPS time can be used to control the output waveforms.

Similarly, in the past wired or wireless connections between the measurement equipment and bulky data acquisition and storage systems were needed, but now data can be stored site by site or even channel by channel, using integrated microprocessor-controlled acquisition and solid-state memory. Clearly, this has been of huge benefit to the collection of marine data, but land acquisition now also uses this approach.

Navigation

The GPS system, as its name suggests, provides highly accurate locations and makes surveying land MT and CSEM stations straightforward. For marine MT and CSEM, the positioning of seafloor receivers is more difficult, since during deployment they will drift 50–100 m from the release point as they sink down through currents in the water column. For MT surveys the release point may provide sufficient accuracy, but this is not the case for CSEM surveys. In this case accurate positions need to be derived from acoustic ranging from the survey ship, whose position is known from GPS. Short (1–10 ms), high-frequency (10–100 kHz) pulses of sound are emitted from the ship and transponders on the receiver instruments reply to these with similar "pings." The two-way travel time, along with estimates of sound speed in water derived from oceanographic tables or direct measurement, is used to calculated range. Two approaches are possible: long baseline surveys involve triangulation using ranges from three or more ship positions, and short baseline surveys use equipment that can estimate direction as well as range using multiple units or elements for the ship's transponders. For marine CSEM transmitter navigation, short baseline measurements are supplemented by depth, height, and possibly dead reckoning sensors on the transmitter.

On land the orientation of sensors is measured or set using levels and magnetic compasses during installation (fluxgate sensors can act as their own compasses). For seafloor measurements, orientation needs to be estimated using recording tiltmeters and compasses.

Summary

Recordings of natural or man-made variations in the magnetic field may be made with fluxgate sensors or induction coils, depending on the frequency of interest. In terms of signal to noise, the crossover between the two sensors is about 0.01 Hz, with induction coils used for measurements higher than 1 mHz and fluxgates for measurements lower than 1 Hz. Exact frequencies depend on the particular equipment and application. Electric field sensors are typically made using pairs of nonpolarizing electrodes to make contact with ground or water, separated and connected to amplifiers by 10–100 m of wire. At high frequencies simple metal rods may suffice as electrodes. Modern electronics and timing derived from the global positioning system have made data collection using autonomous loggers standard for both land and marine MT and CSEM data acquisition.

INTERNATIONAL GEOPHYSICAL YEAR

Ralph W. Baird
Baird Petrophysical International, Houston, TX, USA

Definition

The International Geophysical Year (IGY 1957–1958) was the most successful global effort to coordinate the measurement and collection of geophysical data from around the world during a period of anticipated maximum solar activity. It was also timed as a continuation of a series of international efforts to collect data at the poles, called the International Polar Years I and II (IPY 1882–1883 and IPY 1932–1933). The IGY actually was planned for 18 months, July 1, 1957, through December 31, 1958, and a follow-on International Geophysical Cooperation (IGC 1959) was necessary to complete the work and assemble the results, from January 1, 1959, through December 31, 1959.

During 2007–2009, there was a fourth international effort referred to as IGY-2 or IGY + 50, but instead of a coordinated singular management initiative, was organized as separate initiatives, the Electronic Geophysical Year (eGY 2007–2008), the International Polar Year (IPY 2007–2008), the International Heliophysical Year (IHY 2007–2009), and the International Year of Planet Earth (IYPE 2007–2009). To capture the work and materials from the IGY 1957–1958, organizers of the IHY created a legacy archive and recognition program entitled IGY Gold. During and after the IGY 1957–1958, the nonscience public joined the scientists with pamphlets, magazine articles, films, children's toys, games, and books, all aimed at encouraging exploration and discovery.

Introduction and concept

A lack of knowledge of natural Earth processes and the interest by thousands of Earth scientists to explore and discover relationships of the processes combined with modern communications and global transportation improvements inspired and motivated the organizers and participants of IGY in a postwar world (the early 1950s). The more measurements were studied, the more questions evolved. To get the answers, the world Earth science community needed to cooperate and collect data together and facilitate a means to share this new data to enable new Earth science discoveries.

The concept seems simple today in the twenty-first century: propose global efforts to collect physical and chemical measurements of the Earth on a semicontinuous basis over a specified period of time. In the early 1950s, this task was burdened with a lack of infrastructure and a lack of resources in all parts of the Earth, governed by separate regimes speaking hundreds of different languages, and recovering from wartime conflicts. Just getting from point A to point B was a time-consuming task. All this was about to change.

History

While in Maryland, James Van Allen (1914–2006) and his wife Abigail hosted a dinner on April 5, 1950, for British geophysicist Sidney Chapman (1888–1970), a theoretical physicist interested in the earth's magnetic phenomena and a participant in IPY II 1932–1933. Also present at dinner was Lloyd Berkner (1905–1967), a former radio-engineer who had been on Admiral Byrd's 1928–1930 Antarctic expedition. According to Van Allen, the dinner conversation ranged widely over geophysics and especially geomagnetism and ionospheric physics. Following dinner, as they were all sipping brandy in the living room, Berkner turned to Chapman and said, "Sydney, don't you think it is about time for another international polar year?" Chapman immediately embraced the suggestion, remarking that he had been thinking along the same lines himself (Van Allen, 1998).

The time was ripe. Technological improvements in instrumentation and rocketry had enabled scientists to probe much deeper into the atmosphere and deep into the Earth. In the process of enlisting support among the international scientific societies, Chapman and Berkner found a strong preference for a global program encompassing additional geographical regions and additional physical science disciplines.

Chapman first presented the idea for a third IPY to the constituent scientific unions under the International Council of Scientific Unions (ICSU). The unions, in turn, presented the proposal to the ICSU General Assembly, and ICSU, in turn, invited the World Meteorological Organization (WMO) to participate as well as the national organizations adhering to ICSU. By 1953, there were 26 countries signed up in what came to be known at the International Geophysical Year 1957–1958. The disciplines included practically all the earth, atmosphere, and oceanic sciences, covering many parts of the globe beyond the polar regions.

Scope

By 1954, the international IGY organizing committee (set up by ICSU in 1952) was known as CSAGI after its French name, Comité Special de l'Année Géophysique Internationale. The CSAGI set the priorities for IGY projects to have at least one of these characteristics:

- Problems requiring concurrent synoptic observations at many points involving cooperative observations by many nations
- Problems in the geophysical sciences whose solutions would be aided by the availability of synoptic or other concentrated work during the IGY
- Observations of all major geophysical phenomena in relatively inaccessible regions of the Earth that can be occupied during the IGY because of extraordinary effort during that interval (the Arctic and Antarctic)
- Epochal observations of slowly varying terrestrial phenomena

These were not arbitrary or unreasonable criteria. Based on this defined planning and framework, the scope of the IGY program materialized and an organization including field operations, data collection synchronization, data reporting, and assembly and archiving was begun.

Operations

When comparing the organization of IGY to today's professional and scientific working groups, the IGY was controlled by two separate bodies, the CSAGI and the ICSU. Areas of science emphasis covered:

Meteorology	Cosmic Rays	Gravity
Geomagnetism	Glaciology	Nuclear Radiation
Aurora and Air Glow	Oceanography	Latitude and Longitude
Ionosphere	Rockets and Satellites	World Days and Communication
Solar Activity	Seismology	

Participating countries represented in expeditions or contributing and sponsoring in-country data collection included:

Afghanistan	German Democratic Republic	Norway
Argentina	German Federal Republic	Pakistan
Australia	Ghana	Panama
Austria	Greece	Peru
Belgium	Guatemala	Philippines
Bolivia	Haiti	Poland
Brazil	Hawaii	Portugal
Bulgaria	Honduras	Rhodesia and Nyasaland
Burma	Hungary	Romania
Canada	Iceland	San Salvador
Ceylon	India	Saudi Arabia
Chile	Indonesia	Spain
China (Nationalist)	Iran	Sudan
China (People's Republic)	Ireland	Sweden
Colombia	Israel	Switzerland
Costa Rica	Italy	Thailand
Cuba	Japan	Tunisia
Czechoslovakia	Korea, Democratic Republic of	Turkey
Denmark	Libya	Union of South Africa
Dominican Republic	Malaya	Union of Soviet Socialist Republics
East Africa	Mexico	United Kingdom
Ecuador	Mongolia, People's Republic of	United States of America
Egypt	Morocco	Uruguay
Ethiopia	Netherlands	Venezuela
Finland	New Zealand	Vietnam, Democratic Republic of
France	Nicaragua	Vietnam, Republic of
		Yugoslavia

Achievements

General achievements of IGY were:

- Global cooperation for improved Earth physical and chemical measurements
- Improved awareness and understanding of Earth processes
- Coordinated collection and assembly of multidisciplinary data
- Archive and sustainable safekeeping of data collected and shared
- Inspiration and hope for future similar programs and initiatives

Some of the most significant IGY achievements were:

- Defining the system of mid-ocean ridges that encircle the globe, furthering our understanding of the Earth's crust and the theory of Plate Tectonics.
- Discovery of the Van Allen radiation belts. These belts surround the Earth at altitudes of hundreds and at thousands of kilometers above the surface and are significant to present-day electronic communications.
- Collection of synoptic data, a comprehensive overview of global physical phenomena. These achievements were accomplished through organization of various scientific fields under the International Council of Scientific Unions (ICSU). This union created a series of technical panels with scientific goals and facilitated international cooperation.
- Under the collection of synoptic data, special attention was given to the Antarctic Continent. Neither the race for the South Pole in the early 1900s nor the age of exploration in the 1930s brought the influx of humanity experienced during the IGY to the ice-covered continent.
- A new value for total abundance of water in the form of ice on the Antarctic continent. Ninety percent of the planet's ice is found on and around the continent, locking 68% of the world's fresh water in the Southern Hemisphere.
- Improved meteorological predictions by understanding the weather patterns of the Southern Hemisphere.
- Advancements in the theoretical analysis of glaciers.
- Seismology of the Southern Hemisphere.
- The scientific cooperation in Antarctica paved the way for the Antarctic Treaty. The treaty signed December 1, 1959, created a continent free from nuclear weapons and open to scientific research; the first truly international territory.
- Improved science and math education. Through implied competition among countries, IGY generated a new sense of the importance of math and science to competitive problem solving.
- Sputnik and satellite measurements. IGY provided the first peaceful use of previously military equipment and technology to enhance the measurement capability and later communications of people on Earth.
- World Days and Communication. During the IGY, a calendar was arranged to achieve simultaneous observations in most disciplines. During some periods, intensification in observations was considered and the World Days program was established. There were three classes of special days: Regular World Days (RWD) and World Meteorological Intervals (WMI) were picked in advance on the calendar. Special World Intervals (SWI) were designed day to day and broadcast by the World Warning agency (AGIWARN).
- World Data Centers. The IGY was predicated on full and open data exchange. The World Data Centers were created to provide equitable access for use by all qualified scientists for public good and for geophysical research as a tool for sustainability.
- World Gravity Map. Over 60,000 observations and additional 150,000 anomaly values results from the various IGY programs. The raw data were prepared for storage and further analysis on punched paper cards

for machine analysis. The final values was published as a monograph and supplied to the World Data Centers.
- Postage stamps, films, songs, and pamphlets. Outside of the scientists contributing, the new approach included outreach and generational attraction to science at all levels. These creative media and documentary projects contributed to the events during the IGY and continue through today to provide accounts and anecdotes about the progress made by participants in IGY.

INTERNATIONAL GRAVITY FORMULA

Hans-Jürgen Götze
Abteilung Geophysik, Institut für Geowissenschaften, Christian-Albrechts-Universität zu Kiel, Kiel, Germany

As a first approximation the Earth is a rotating sphere. As a second approximation it can be regarded as an equipotential ellipsoid of revolution. According to Moritz (1980), the theory of this equipotential ellipsoid was first given by P. Pizzetti in 1894. It was further elaborated by C. Somigliana in 1929 and served already as the basis for the International Gravity Formula adopted at the General Assembly of the International Union of Geodesy and Geophysics (IUGG) in Stockholm in 1930.

One particular ellipsoid of revolution, also called the "normal Earth" or "normal spheroid," is the one having the same angular velocity and the same mass as the actual Earth, the potential U_0 on the ellipsoid surface equal to the potential W_0 on the geoid, and the center coincident with the center of mass of the Earth. The Geodetic Reference System 1967 (GRS 67), Geodetic Reference System 1980 (GRS 80), and World Geodetic System 1984 (WGS 84) all are "normal Earth" models.

The normal or theoretical gravity is the gravity effect due to an equipotential ellipsoid of revolution. Approximate formulas are used widely even though we can calculate the exact theoretical gravity analytically. The conventionally used International Gravity Formula is obtained by substituting the parameters of the relevant reference ellipsoid. Helmert's 1901 Gravity Formula and International Gravity Formulas 1930, 1967, and 1980, correspond respectively to the Helmert 1906, International 1924, GRS 67, and GRS 80 ellipsoids. For example, the recent 1980 International Gravity Formula is (Moritz, 1980):

$$\gamma_{1980} = 978,032.7\left(1 + 0.0053024\,\sin^2\phi - 0.0000058\,\sin^2 2\phi\right)10^{-5}\ \mathrm{m/s^2}$$

where ϕ is the geodetic latitude.

The resulting difference between the 1980 International Gravity Formula and the 1930 International Gravity Formula is:

$$\gamma_{1980} - \gamma_{1930} = -16.3 + 13.7\sin\phi^2 \quad 10^{-5}\ \mathrm{m/s^2}.$$

Similarly, one can compare the 1967 formula to the 1980 formula in use today. The difference between the two is relatively small:

$$\gamma_{1980} - \gamma_{1967} = 0.8316 + 0.0782 \sin \phi^2 \quad 10^{-5}\ \mathrm{m/s^2}.$$

The first term of the International Gravity Formula is the value of gravity at the equator on the ellipsoid surface. Unfortunately, in the 1930s no one really knew what it was. The most reliable estimate at that time was based on absolute gravity measurements made by pendulums at the Geodetic Institute Potsdam in 1906. The Potsdam gravity value served as an absolute datum for worldwide gravity networks from 1909 until 1971. In the 1960s, new measurements across continents were made by precise absolute and relative gravity meters, and became the network of IGSN71 still in use today. A mean difference between the Potsdam datum and the IGSN71 reference has been found to be 14×10^{-5} m/s^2 (Woollard, 1979).

The theoretical gravity is the gravity effect due to an equipotential ellipsoid of revolution. Approximate formulas are used widely. In fact, the theoretical gravity at any position on, above, or below the ellipsoid surface can be calculated using closed-form expressions also. Such a closed-form expression for the theoretical gravity on the surface of the ellipsoid is given by the formula of Somigliana (Heiskanen and Moritz, 1967, p. 76).

The Somigliana–Pizetti formula gives the magnitude of normal gravity on the surface of a geocentric reference ellipsoid:

$$\gamma = \gamma_e \frac{1 + k \sin^2 \phi}{\sqrt{1 - e^2 \sin^2 \phi}}$$

where k is the normal gravity constant (not to be confused with the universal gravitational constant, G), γ_e is the normal gravitational acceleration at the equator and e^2 is the square of the first numerical eccentricity of the ellipsoid. Importantly, the geocentric latitude N, which is compatible with the GRS80, must be used in the Somiliana formula (Götze and Li, 2001; Hackney and Featherstone, 2003).

Parameters used to compute the normal gravity using the Somigliana–Pizetti formula are given values for the GRS80 ellipsoid from Moritz (1980) (Table 1).

International Gravity Formula, Table 1 Parameter definition and GRS80 values

a	Ellipsoid semi-major axis	6,378,137 m
b	Ellipsoid semi-minor axis	6,356,752.3141 m
γ_e	Equatorial normal gravity	9.780 326 771 5 m s^{-2}
γ_p	Polar normal gravity	9.832 186 3685 m s^{-2}
k	$(b\gamma_p/a\gamma_e) - 1$	0.001 931 851 353
e^2	$(a^2 - b^2)/a^2$	0.006 694 380 022 90
f	$(a - b)/a$	0.003 352 810 681 18
m	$(\omega^2 a^2 b)/\mathrm{GM}$	0.003 449 786 003 08
ω	Angular velocity	7292 115 $\times$ 10^{-11} rad s^{-1}
GM	Geocentric gravitational constant	3,986,005 $\times$ 108 m^3 s^{-2}

The normal gravity at any ellipsoid height h and any geodetic latitude N can also be given by a closed-form formula. Starting from the general formula of Heiskanen and Moritz (1967, p. 67–71) Lakshmanan (1991) derived the formula and published a result containing typographic errors. Later the derivation was repeated and corrected (Li and Götze, 2001).

INTERNATIONAL POLAR YEAR 2007–2008

David J. Carlson
British Antarctic Survey, IPY International Programme Office, Cambridge, UK

Concept

The International Polar Year 2007–2008 (IPY) was an intensive, internationally coordinated scientific research campaign in the Arctic and the Antarctic sponsored by the International Council for Science (ICSU) and the World Meteorological Organization (WMO). Working together through international projects, IPY researchers examined all aspects of polar regions. IPY highlighted the global importance of polar processes and the urgent need to understand and track extremely rapid changes occurring at high latitudes.

History

By most accounts, the 2007–2008 IPY represented the fourth IPY: 1882–1883, 1932–1933, 1957–1958 (that event grew from a Polar Year into a Geophysical Year – the IGY), and 2007–2008. Although topics and

technologies have changed over 125 years, the challenges and difficulties of working in polar regions have not, and the most recent IPY still adheres strongly to the original concept that substantial advances in polar science require, periodically, extraordinary levels of enhanced and focused international cooperation and coordination. With news of sea ice retreat, ice sheet collapse and threats to polar species almost constantly in media headlines, the scientific need for this IPY became obvious.

Scope

The IPY Framework Document (Rapley et al., 2004) specified four goals:

- Make major advances in polar knowledge and understanding.
- Leave a legacy of new or enhanced observational systems, facilities, and infrastructure.
- Inspire a new generation of polar scientists and engineers.
- Elicit keen interest and participation from polar residents, schoolchildren, the general public, and decision-makers worldwide.

IPY emerged as one of the most ambitious international research efforts in the past 50 years. It engaged the intellectual resources of thousands of scientists – many more than expected and often from nonpolar countries – representing an unprecedented breadth of specialties, from geophysical to biological to social sciences. IPY stimulated international and interdisciplinary collaboration with over 160 endorsed science projects assembled from the ideas of researchers in more than 60 countries. IPY stimulated substantial new funding for polar science – more than US$ 400 million, which coordinated with and supplemented ongoing polar research and monitoring programs.

Achievements

Major advances in polar knowledge and understanding

Major IPY-stimulated advances in polar science will emerge in the time period 2009–2015 and beyond, as IPY researchers explore, analyze, evaluate, and share their data sets. Already, we can see increased and more pervasive evidence of change in ice sheets and sea ice; we can see and foresee alteration, migration, and depletion of polar ecosystems; we can see hints of large changes in crucial polar components (sinks and sources) of global carbon cycles; and we can see the early impacts of relentless environmental, economic, and social changes on polar communities. We can predict with confidence, as a major advance in understanding, the increasing recognition of the global importance and impact of polar change.

Infrastructure legacy

This IPY has done a superior job of observing both polar oceans, through multiple ship voyages and extensive use of buoys, drifters, and autonomous gliders. It has produced, from spaceborne radars, lidars, and gravity sensors, unprecedented coverage and views of the polar ice masses. Four separate multinational teams made difficult traverses across Antarctica, covering some regions for the first time since IGY. Field stations around the Arctic upgraded their capabilities, established new networks, and supported twice and in some cases thrice as many researchers as in previous years.

A new generation

A new Association of Polar Early Career Scientists (http://www.apecs.is/) has brought vibrant and critical energy and ideas to this IPY and to polar science. Now incorporated, internationally endorsed and engaged in all aspects of polar research, and with their own funded Directorate, APECS represents one of IPY's most significant accomplishments. With more than 1,400 members from more than 40 countries, with the ability to do online posters and career development workshops almost anywhere in the world, APECS has clearly succeeded in shaping the future of polar research.

Excite and stimulate the public

Through international collaboration and cooperation, by careful cultivation of a global community of enthusiastic volunteers, and by creative use of free technologies, this IPY stimulated active and engaged networks of hundreds of teachers, media officers, journalists, and students. Working with those partners and networks, quarterly Polar Days were organized that engaged more than 500 individual and institutional partners from 50 countries in polar activities. Teacher's workshops, summer schools, polar science weekends, and student expeditions in both hemispheres were conducted. A Polar Resource Book documenting these and many other IPY activities was published. The polar community was expanded by leaving a legacy of polar information in many languages. This IPY has demonstrated that an effective, energetic, and enthusiastic team working full-time to promote science communication serves as the key partner in a science program's success.

Challenges ahead

The variety, breadth, and volume of IPY data highlight the fact that international science data infrastructure, largely a legacy of IGY, has for the most part not kept pace with the modern expectations and needs for data access and data preservation. A few national and disciplinary data systems demonstrate admirable capabilities, and new approaches, focused on open access and an information commons approach, such as the Polar Information Commons (http://www.polarcommons.org/), may stimulate a data transformation. Identifying and sustaining the essential elements of long-term observation and monitoring systems for polar regions, as those regions undergo rapid change, will represent a severe challenge, one

without obvious technical or resource solutions. A more urgent focus on integrated prediction skills and systems will provide improved structure and rationale for maintaining polar observational capabilities. The many science specialties in this IPY, and the wide variety of data, will make the task of synthesis extremely difficult, but they will also stimulate innovative integration processes and result in products of enormous impact and value.

Summary

Often the science community seeks to organize prominent "above and beyond" events, events that transcend business as usual and accelerate scientific processes. Presented as "Experiments" or "Observation Periods" or "Years," these events share ambitious goals of enhanced research, increased resources, heightened attention and, not coincidently, re-invigorated recruitment of new researchers. The IPY 2007–2008 succeeded in stimulating international and interdisciplinary cooperation. Through widespread international cooperation and extraordinary enthusiasm, it achieved (in large part) its research, resource, recruitment, and public attention goals, and will produce a positive legacy for participants, for science in general, and for the public.

International Year of Planet Earth

INTERNATIONAL YEAR OF PLANET EARTH

Eduardo F. J. de Mulder[1], Wolfgang Eder[2]
[1]NGU, Geological Survey of Norway, Trondheim, Norway
[2]Department of Earth Sciences, University of Munich, Munich, Germany

Definition

The "International Year of Planet Earth" (IYPE) was a joint initiative by the International Union of Geological Sciences (IUGS) and UNESCO and ran from 2007 to 2009.

Background and activities

When, in the year 2000, the International Union of Geological Sciences (IUGS) tried to match current scientific knowledge about Planet Earth against the application of such knowledge in daily life, it found a major discrepancy. The Indian Ocean tsunami in 2004 and hurricane Katrina in 2005 only confirmed the existence of that gap; knowledge about natural hazards existed, but it was not applied – or not applied adequately – to protect vulnerable societies from devastation.

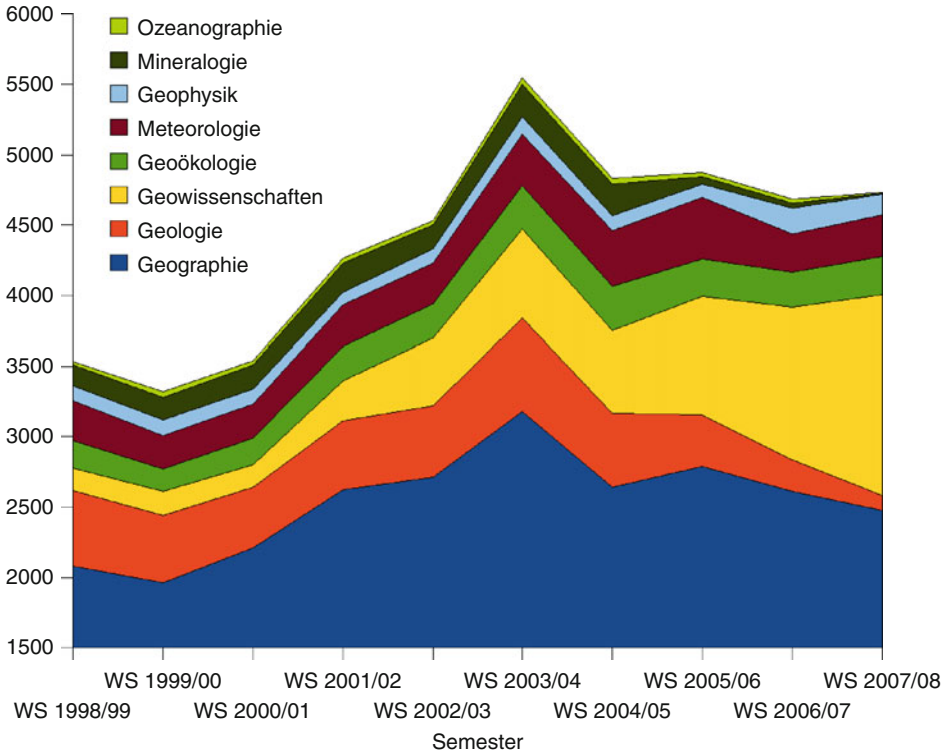
Another observation was that fewer and fewer future experts in geoscience had been recruited at universities since the early 1980s, despite the fact that society needs increasing numbers of them to help reduce the impact of such disasters and to assist governments in subsurface management issues. Today, industry needs more geo-experts to find the new earth resources for which the world is desperately searching. Those experts are the same ones that find innovative solutions to reducing the environmental impact of such necessary resource exploitation.

These observations motivated us to explore how the public and politicians could be urged to reverse these trends. We chose an international, rather than national, approach and began the long road toward the proclamation of an International Year of Planet Earth (IYPE) under the UN system. IYPE aims to capture people's imagination with the exciting knowledge about our planet, and to see that knowledge used more effectively to make the Earth a safer, healthier, and wealthier place for our children and grandchildren. That, we believe, can be achieved by building on the knowledge accumulated by the world's 400,000 Earth scientists, and is expressed by the IYPE subtitle: *Earth Science for Society.*

Two earlier events served as models. The *International Geophysical Year* (1957–1958) uncovered many facts about our planet, which was then seen for the first time from space. IGY attracted lots of public attention, and many youngsters were inspired to begin professional careers in Earth sciences. More recently, in 2002, the Germans celebrated their "Jahr der Geowissenschaften" with many public events and with an attractive logo that was later donated to the IYPE. That public exposure resulted in a much higher enrollment of German students in the Earth sciences in subsequent years (Figure 1). That information fuelled the outreach program of the International Year.

Soon after the inception of IYPE, UNESCO's (former) Earth Science Division joined in, followed by 25 Associate Partners and 11 Founding Partners. To achieve its aims and ambitions, and to collect public and political support for this issue, we then approached the United Nations system. That process went through various stages, beginning at UNESCO where the United Republic of Tanzania successfully launched the initiative in the Executive Board in April 2005, followed by the General Conference in October. In December 2005, the General Assembly of the United Nations adopted Resolution 192 proclaiming 2008 to be the *International Year of Planet Earth* (United Nations General Assembly, 2005).

Shortly afterward, the IYPE Corporation was registered as a not-for-profit 501 (c) (3) Corporation in the USA, consisting of a Board of Directors and a Secretariat based at the Norwegian Geological Survey in Trondheim. Although the International Year was proclaimed by the



International Year of Planet Earth, Figure 1 Student enrolment in the earth sciences in German universities between 1999 and 2007. Note the spike following the successful "Jahr der Geowissenschaften" (2002).

UN for 2008, its initiators expanded that into a Triennium, starting in early 2007 and closing in June 2010. A Triennium was considered the minimum needed to implement at least part of our ambitious plan.

After the UN proclamation, additional support for the IYPE grew rapidly. By December 2009, 36 International Partners were providing financial and other support. Simultaneously, geoscientific communities in individual countries began to establish IYPE National Committees (Figure 2) to a total number of 80 National and Regional Committees by the end of the IYPE Triennium. These countries are widely distributed across the globe.

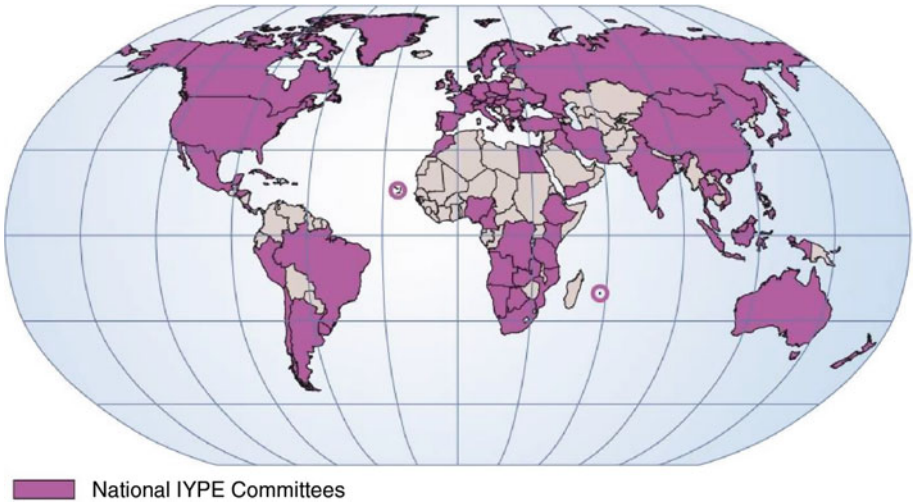
The main activities of the IYPE have been coordinated through Science and Outreach Programs. Both programs essentially operated in a "bottom-up" mode. The Science Program consisted of 10 broad, societal relevant, and multidisciplinary themes: health, climate, groundwater, ocean, soils, deep Earth, megacities, resources, hazards, and life. Brochures on each of these themes are available in hard copy or may be downloaded from IYPE's Web site: www.yearofplanetearth.org.

The Outreach Program has mainly been implemented at the national level. A global launch event was organized at UNESCO headquarters in Paris in February 2008. In addition, continent-wide launch events took place for Africa (in Arusha, Tanzania) and for Latin America (in Brasilia, Brazil). Finally, a closing event with perspectives for the future was organized in Lisbon, Portugal, in November 2009. On an international level, brochures and flyers were produced and the global IYPE web-portal was maintained. Moreover, numerous activities in many countries with IYPE National Committees were monitored and registered.

Education has been an essential element in the International Year of Planet Earth. Many of the national and international activities involved students and focused on participation by secondary and primary school pupils. An example of student involvement was the IYPE global launch event in Paris. In preparation for that event, 18–22-year-old students from around the world submitted essays and poems each dealing with one International Year theme. National Committees and the IYPE Secretariat evaluated them and selected the best. Through national and international sponsorship, some 200 winning students from almost every corner of the planet were awarded a free trip to Paris to participate actively in the launch event, including interacting with VIPs on pressing issues concerning Planet Earth. A comparable approach was taken for the Lisbon event, in 2009.

Legacy

The 80 National and Regional IYPE Committees belong to the most important legacy items of the IYPE. At



International Year of Planet Earth, Figure 2 Countries with an established national committee for IYPE (in *dark purple*). One regional committee for IYPE has been established for East and Southeast Asia.

national levels, they united key players of several, sometimes competing organizations into one joint ambition to raise awareness for the Earth sciences among decision makers and the public. An evaluation among the National Committees proved that this ambition was at least partly accomplished.

Since the onset of the IYPE Triennium in 2007, many thousands of activities all over the globe have taken place. A significant majority of these were related to education. Thousands of schools worldwide paid attention to the International Year of Planet Earth, each in their own languages and cultures.

Another IYPE legacy item was the creation of a Young Earth Science Initiative (YES). This provides a platform for young professionals in the Earth sciences. It started in 2007 and grew rapidly at the Global Launch Event of the IYPE in Paris (2008). From there the YES Initiative expanded, leading to a formal structure, a network of supporting organizations (including IYPE) and an invitation by the Chinese government hosting the first International YES Conference in October 2009 in Beijing (Figure 3). One month later, another gathering of some 200 students and young professionals from 70 countries took place in Lisbon with representation of YES.

At a political level, a flood of public statements were given by leading politicians pleading for implementation of the aims and ambitions of the International Year of Planet Earth: to base decision making more on science and knowledge of the Earth for safer, healthier, and more prosperous societies. The most common model for that has been the organization of a national launch event where politicians spoke in support of the IYPE often coupled with cultural performances by school kids highlighting the importance of the Earth and sustainable development for future generations.

OneGeology is another major IYPE legacy item. That initiative was positioned under the IYPE banner in 2007. The ambition of this project is to bring together geological data of all nations into a digital database and translate these into one single computer language. That should result into a digital map of the subsurface of the world and may eventually provide a third dimension to popular geographical Web sites, as Google Earth. By February 2010, 116 national Geological Surveys have embarked on this initiative.

Many more legacy items developed during the IYPE Triennium. For example, cross-country geological hiking tours through the Alps: ViaGeoAlpina; an elegant method to assist teachers with simple materials to explain often complex geological processes: EarthLearningIdea; the production of a series of state-of-the art scientific books on each of the ten IYPE Themes, by Springer Verlag; and an UNESCO initiative to measure the conditions of Earth sciences education in Africa and to develop tools to improve these.

It appears that student entries in the Earth sciences have been growing in a considerable number of countries since 2007. Although not all such positive developments may be attributed to the IYPE alone, the International Year of Planet Earth must have contributed at least to some extent to growth as growth is generally positively correlated with the level of IYPE activities in a specific nation.

Finally, a Report on the entire IYPE operation will be produced for the United Nations and the IYPE Initiators (IUGS and UNESCO) as a legacy item in 2010.

Perspectives

Spurred by the National and Regional IYPE Committees who considered the IYPE as an excellent opportunity to

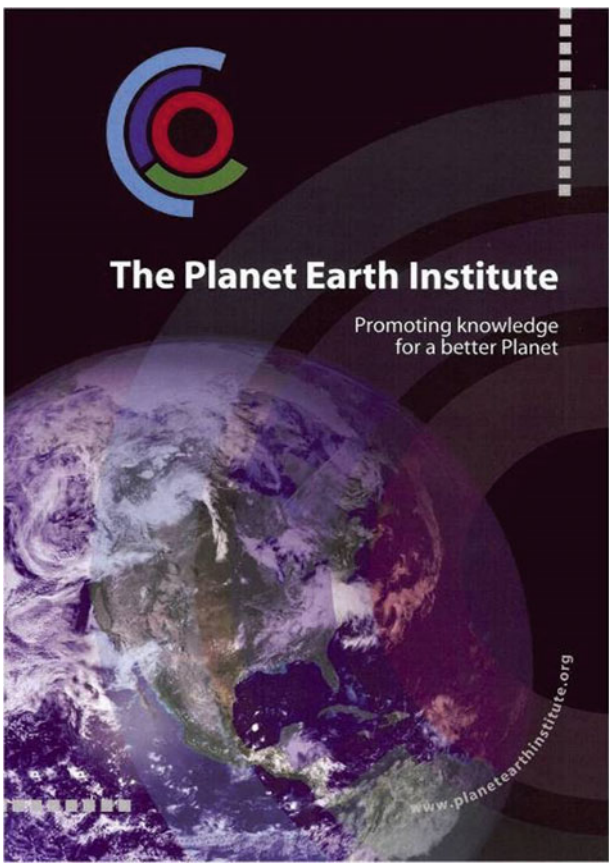
International Year of Planet Earth, Figure 3 The first international conference for Young Earth Scientists (YES) was held in Beijing, China, in October 2009.

raise public awareness to use knowledge of the Earth for better decision making and to encourage the youth to go for a professional career in the Earth sciences, and supported by the IYPE Board of Directors, some new initiatives have been discussed since early 2009. Two major new initiatives developed with the specific intention to build on the IYPE legacy are described here.

The Planet Earth Institute

The Planet Earth Institute's mission is to communicate with the general public the added value of Earth science information for society and is an international, non-governmental, non-profit organization. This (mainly virtual) Institute has been given as subtitle "Promoting knowledge for a better Planet." Implementation will be realized along three channels: through a wide variety of outreach activities, through its National Committees, and through its International Partners. Activities may include exposure through big screens in city centers, other mass media, publications, public events, education projects, cultural and artistic expressions, co-marketing, and projects (Figure 4).

National Committees shall constitute, too, the geographic backbone of the Planet Earth Institute. Current IYPE National Committees are invited to embark on the Planet Earth Institute to continue their (mainly outreach) activities. They will significantly benefit from revenues generated by international outreach activities. International Partners shall form the financial spine of the Planet Earth Institute. Current International IYPE Partners are invited to continue supporting the Planet Earth Institute activities once the IYPE Triennium has phased out. The Planet Earth Institute shall be financially self-supportive.



International Year of Planet Earth, Figure 4 Cover of the Planet Earth Institute folder.

Sponsors are invited to support the Foundation during its Initial Stage.

World-class science initiative

Another new initiative is aiming to identify or design "world-class" projects for a "Global Geoscience Initiative." This was explored by an ad-hoc group through a brainstorm meeting in July 2009, and the initiative was then presented to Earth scientific audiences at several major geoscientific gatherings around the world. It is envisaged that the theme(s) of a new world-class science initiative, its structure, and funding mechanism would have been determined by mid-2010.

Summary

The International Year of Planet Earth has been particularly successful in its outreach and education programs. As fundraising started to bear fruit quite late in the Triennium, not sufficient funds were available to properly support a (costly) science program. Moreover, several of the ten science themes of the IYPE were addressed at national levels through current university curricula and special programs. UN proclamation has been crucial for the success of the IYPE, in particular for national implementation of the aims and ambitions through the 80 National and Regional Committees. These have also been the drivers for developing a new initiative, the Planet Earth Institute.

INVERSE THEORY, ARTIFICIAL NEURAL NETWORKS

William A. Sandham[1], David J. Hamilton[2]
[1]Scotsig, Glasgow, UK
[2]Ateeda Limited, Edinburgh, UK

Introduction

Neural networks have been recognized for many years as a powerful tool for solving complex problems associated with pattern recognition, classification, and generalization, and have been used in geophysics in a large variety of different applications. The power of neural networks arises from their ability to emulate complex input/output mappings efficiently.

Comprehensive reviews may be found of all the major geophysical applications of neural networks in a number of excellent tutorial papers (Sandham and Leggett, 1998; Van der Baan and Jutten, 2000; Poulton, 2002). A number of books on the subject have also been published in the last decade (Poulton, 2001; Nikravesh et al., 2003; Sandham and Leggett, 2003).

In this present article, the fundamentals of geophysical inversion using neural networks are reviewed. In section "Geophysical inversion," the physics of geophysical inversion are described, together with a short mathematical formulation. In section "Artificial neural networks (ANNs)," the basics of artificial neural networks are discussed. This includes a review of the major types, the training strategies involved, and a discussion of issues such as data preprocessing and performance. In particular, the important case of the multilayer perceptron trained with the back-propagation algorithm is considered in some detail. In section "Geophysical inversion using artificial neural networks," geophysical inversion applications of neural networks are reviewed, including computation of velocity models, split shear-wave analysis, impedance inversion, pseudolog prediction, petrophysics, well logging, and potential field inversion.

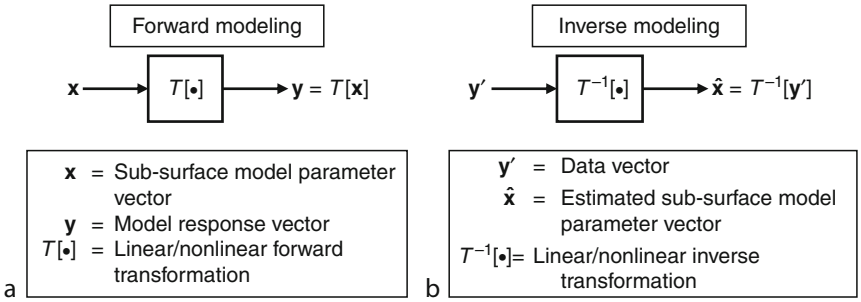
Geophysical inversion

Geophysical inversion, or inverse modeling, may be defined as the estimation of quantitative subsurface earth parameters using measured (observed) geophysical data (Treitel and Lines, 2001; Ulrych and Sacchi, 2005).

Generic definitions of forward and inverse modeling are given in Figure 1.

Mathematically, forward modeling may be described as the transformation $\mathbf{y} = T[\mathbf{x}]$, where $\mathbf{y}$ is the model response, $\mathbf{x}$ is a vector containing the set of subsurface model parameters, and $T[\bullet]$ is some transformation (linear or nonlinear) that describes an observed physical process. For example, in the seismic case, $T[\bullet]$ produces a model response in the form of a synthetic seismogram. Inverse modeling may be written as $\hat{\mathbf{x}} = T^{-1}[\mathbf{y}']$, where $\hat{\mathbf{x}} = T^{-1}[\mathbf{y}']$ is now a vector containing the set of estimated subsurface model parameters (the model space), derived from the data vector $\mathbf{y}'$ (the data space). The operator $T^{-1}[\bullet]$ then denotes the inverse transformation from data space to model space.

Unfortunately, analytical expressions for the inverse transformation seldom exist. Numerically, the inverse problem is solved using methods from mathematical optimization theory. A popular iterative solution is to assume an initial guess for a model, compute the model response $\mathbf{y}$, compare it with the observed response $\mathbf{y}'$, and then perturb the model with the hope of achieving a better fit. However, since the underlying physics in most cases is nonlinear, a straightforward inversion is, even under ideal conditions, inherently unstable. One possible solution is to try and linearize the inverse problem. Unfortunately, such methods are notoriously dependent on the choice of the initial guess for the model. Furthermore, the presence of noise in the data makes interpretation of the results



Inverse Theory, Artificial Neural Networks, Figure 1 (**a**) Forward modeling illustrating the derivation of a model response vector **y**, from the forward transformation $T[\bullet]$ of a subsurface model parameter vector **x**. (**b**) Inverse modeling illustrating the derivation of an estimated subsurface model parameter vector $\hat{\mathbf{x}}$ from the inverse transformation $T^{-1}[\bullet]$ of a data vector $\mathbf{y}'$.

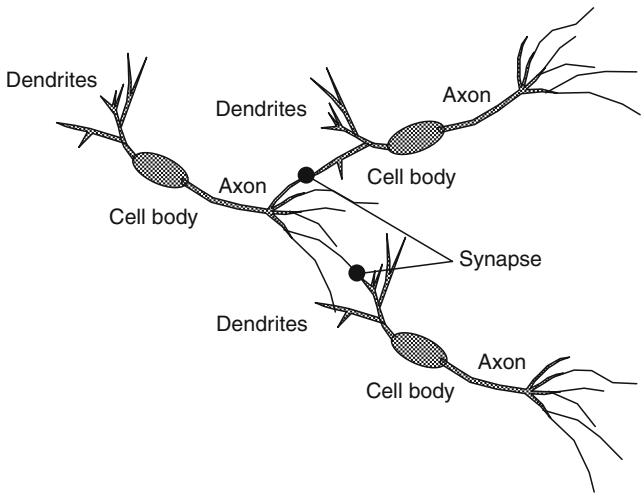
additionally difficult and circumspect. A possible alternative is to use stochastic methods like Monte Carlo (MC), simulated annealing (SA), or genetic algorithms (GA), all of which provide some insight into the statistical nature of the inverse relationships. Unfortunately, MC is extremely inefficient and computing intensive in multidimensional cases, and both SA and GA need subjective tuning parameters that determine the nature of the stochastic search. Most techniques also involve the assimilation of *a priori* knowledge during the inversion process, to constrain the result. All these techniques – linear and nonlinear – involve very expensive forward calculations and are necessarily specific to the particular data set used. Also, the solution is generally nonunique.

It is precisely these intractable features of geophysical inversion that have encouraged geophysicists to investigate solutions using artificial neural networks (ANNs).

Artificial neural networks (ANNs)

The expeditious pattern recognition and classification abilities of humans are a direct consequence of the human brain having a very large number of highly interconnected biological nerve cells or neurons. The basic anatomy of an individual neuron is shown in Figure 2.

It consists of a cell body or soma, the output of which is a long, branching fiber called the axon, which, on appropriate triggering by the cell, transmits an impulse. A human neuron "fires" when its electrical potential reaches a threshold. The output signal is transmitted by the axon and distributed to other neurons via connecting points termed synapses, located in the tree structure at the end of the axon, which modify the strength of the output signal. The input area of the cell is a set of branching fibers called dendrites. Input signals to the soma are attenuated with an increasing distance from the synapses to the soma. Since the human brain is a very dense neural network with a highly interconnected set of approximately 10^{11} neurons, the axon of each neuron is connected to around 10,000 other cells, resulting in approximately 10^{14} connections or synapses. It is this large number of interconnections, which is the basis for the human brain's immense computational power.



Inverse Theory, Artificial Neural Networks, Figure 2 Biological neural network showing three neurons, each of which consists of a cell body or soma, an output or axon, and a series of inputs or dendrites, with the connecting point between an axon and a dendrite termed the synapse.

As the name implies, an artificial neural network (ANN), or simply neural network (NN), is a mathematical or computational model that tries to emulate the structure and/or functional aspects of a biological neural network, and as such, represents a technology that is rooted in many disciplines, including neurosciences, mathematics, statistics, physics, computer science, and engineering. ANNs consist of an interconnected group of artificial neurons (programming constructs that mimic the properties of biological neurons), which process information using a connectionist approach to computation. In most cases, an ANN is an adaptive system that changes its structure based on external or internal information that flows through the network during a learning phase, realized via suitable training iterations. ANNs may either be used to gain an understanding of biological neural networks, or for solving artificial intelligence problems without necessarily creating a model of a real biological system. In the

latter case, they may be defined as nonlinear statistical data modeling tools, and can be used to model complex relationships between inputs and outputs or to find patterns in data. Indeed, the power of neural networks arises from their ability to emulate complex input/output mappings efficiently.

There are now some excellent general reviews of ANNs in the literature (Hush and Horne, 1993; Zhang, 2007; Wilamowski, 2009). A substantial number of books on the subject have also been published over the last 2 decades (McCord Nelson and Illingworth, 1991; Priddy and Keller, 2005; Haykin, 2009). The texts by Haykin (including earlier editions) are probably the most comprehensive and definitive.

The basic building block of an ANN is the (mathematical) perceptron, which was conceived almost 70 years ago by McCulloch and Pitts to mimic the behavior of a biological neuron. The perceptron is also known as an artificial neuron, neurode, processing element/unit (PE/PU), or simply unit. A schematic of a perceptron is shown in Figure 3a.

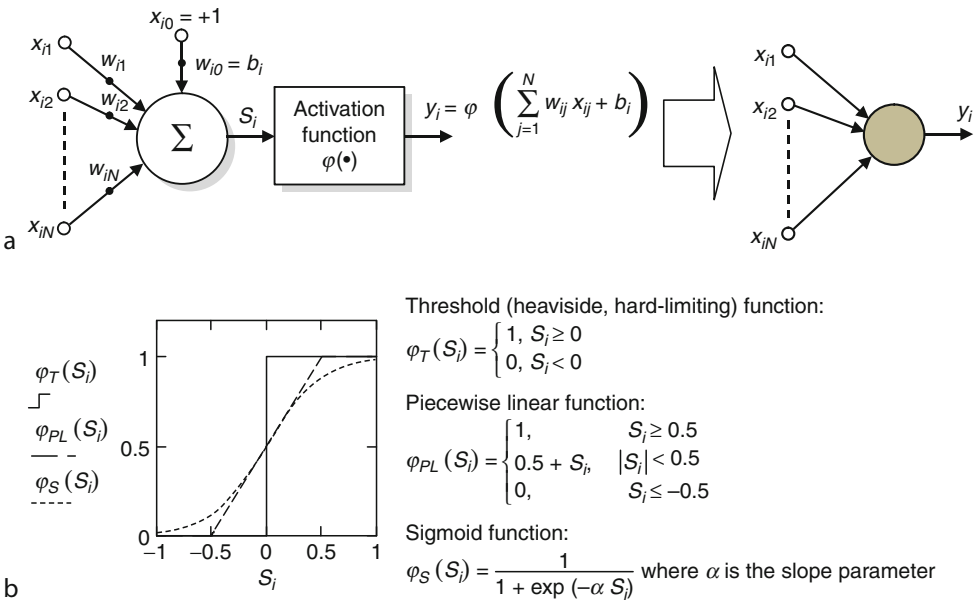
This depicts a number of inputs x_{ij}, analogous to the dendrites in a biological neuron, which are modified by corresponding weights w_{ij}, analogous to the synapses. The $w_{ij}x_{ij}$ products are then summed, along with bias b_i, and the result passed through a nonlinear activation function $\varphi(\bullet)$ to produce the final output y_i, analogous to the axon. The activation function transforms the weighted/summed input S_i to a neuron into its activation. Some major types of activation function are shown in Figure 3b. Historically, the threshold activation function was used. However, this particular function gives only a binary output (i.e., 1 or 0). Also, this particular function is not continuously differentiable and so the optimum weights were very difficult to estimate. A more popular activation function is the sigmoid, which is continuously differentiable and monotonically increasing.

An ANN is formed by connecting (usually many) PEs together in some fashion. Some of the major ANN paradigms are depicted in Figure 4.

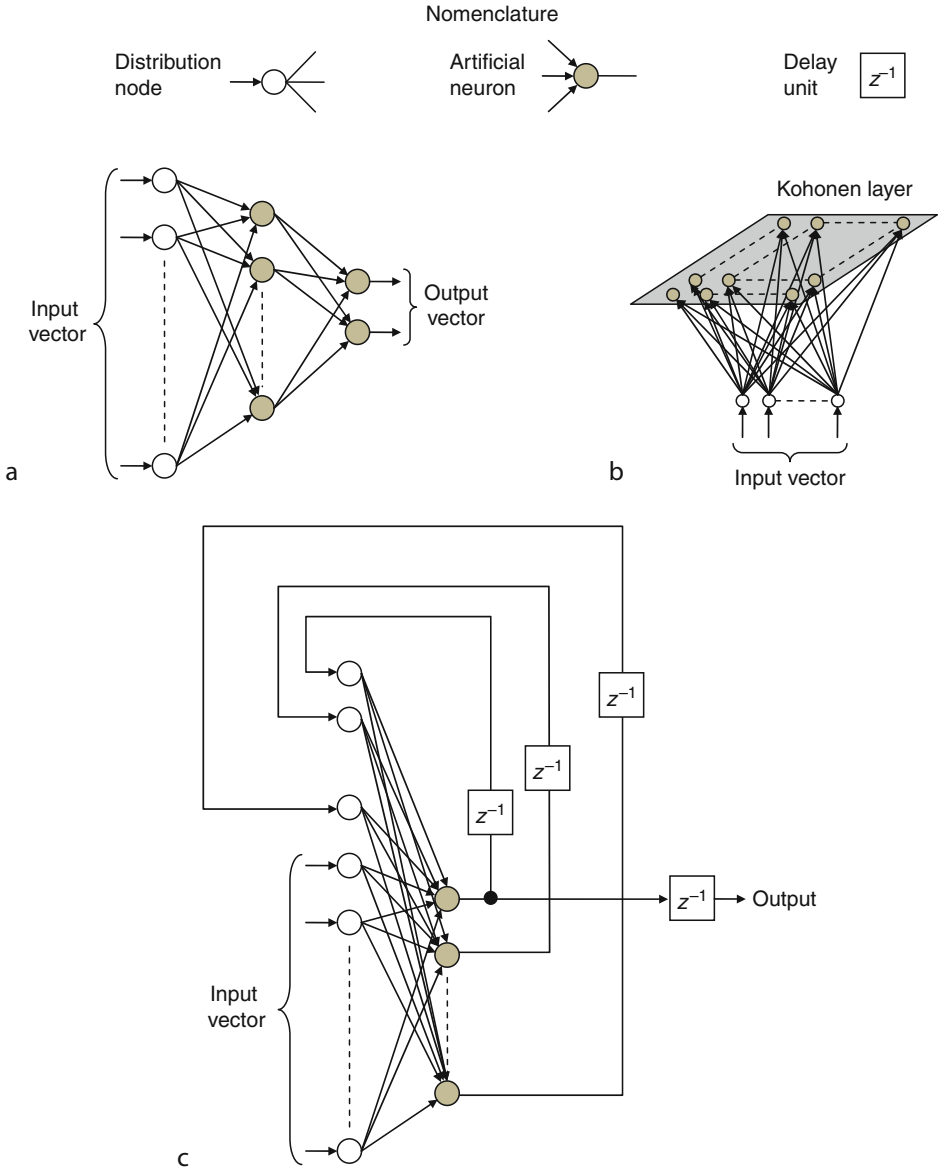
Once an ANN has been chosen, and the number of layers and neurons have been estimated, the various network weights w_{ij} have to be determined, through a network training procedure. Training can either be supervised or unsupervised – see Figure 5a and b.

Supervised training involves presenting target answers for each input pattern, whereas with unsupervised training, the network adjusts its weights in response to input patterns without target answers, effectively classifying the input patterns into similarity categories. After training has been carried out, network performance is assessed using input patterns that have not been used previously, that is, as training data – see Figure 5c. This will indicate whether the network has been over-trained and cannot generalize, and also whether the network has been trapped during training in a local minimum. Performance is dependent on the quality of data, preprocessing involved, training algorithm, network complexity, generalization, and implementation.

One of the most popular ANNs is the so-called multilayer perceptron or MLP (Figure 4a). This is a feedforward



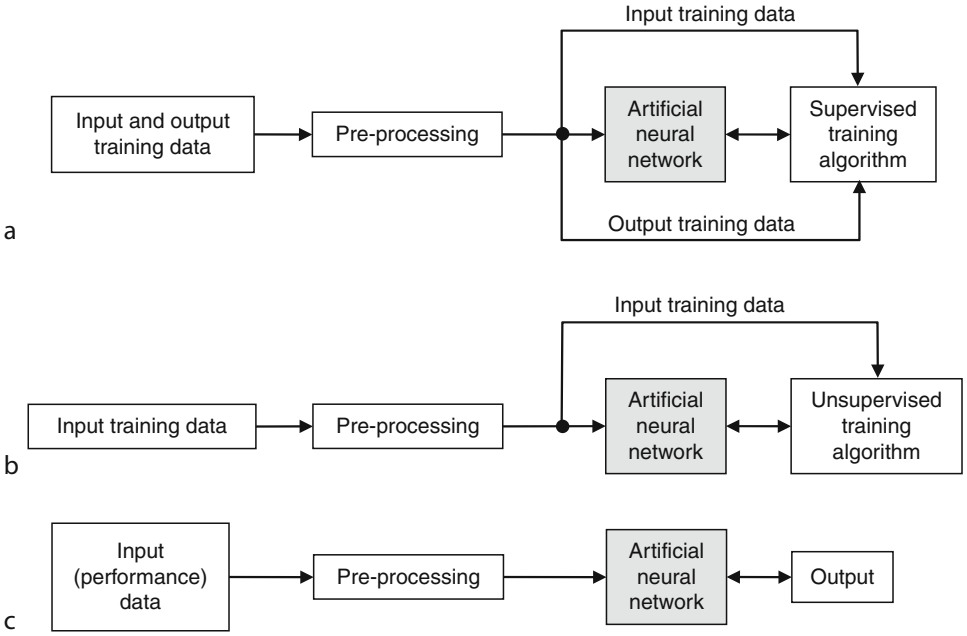
Inverse Theory, Artificial Neural Networks, Figure 3 (**a**) Schematic of an artificial neuron, which modifies inputs x_{ij} by corresponding weights w_{ij}, sums the products along with bias b_i, and passes the result through a nonlinear activation function $\varphi(\bullet)$ to produce the final output y_i. The diagram on the right is a concise way of depicting the neuron. (**b**) Common activation functions used in artificial neural networks. The range of activation functions is usually $0 \leq \varphi(S_i) \leq 1$, as defined here; however, it is sometimes desirable for the range to be $-1 \leq \varphi(S_i) \leq 1$.



Inverse Theory, Artificial Neural Networks, Figure 4 Some common neural network paradigms. (**a**) Fully connected multilayer perceptron (MLP) with one hidden layer and two output neurons. (**b**) Kohonen architecture trained using a self-organizing map (SOM) (unsupervised). (**c**) Fully connected recurrent network with one output neuron.

network consisting of a layer of input distribution nodes, a number of "hidden" layers of perceptrons, and an output layer. In a fully connected version, all distribution nodes and perceptrons are connected to perceptrons in the following layers. The network configuration should allow for an adequate description of the underlying statistical distribution of the spread in the data. Since the number of input nodes and output neurons is usually dictated by the problem, good network design relies on estimating an optimum number of hidden layers and numbers of neurons in each layer. These are usually determined through trial-and-error procedures. A supervised training algorithm called back-propagation (or back-error propagation), popularized in the mid-1980s by Rumelhart and McClelland, is usually used to train a MLP. This iterative, steepest-descent algorithm is outlined below.

Step 1: All w_{ij} set to small random values.
Step 2: Input presented together with target outputs t_i.
Step 3: Actual outputs y_i computed.
Step 4: Errors computed for all nodes in a layer.
Output Layer: $\delta_i = (t_i - y_i)\varphi'(S_i)$
Hidden Layer: $\delta_i = (t_i - y_i)\varphi'(S_i)$



Inverse Theory, Artificial Neural Networks, Figure 5 The two major network training strategies. (**a**) Supervised training. (**b**) Unsupervised training. (**c**) Post-training performance assessment.

Step 5: Update weights.

$$w_{ij}(t+1) = w_{ij}(t) + \eta\delta_i y_j + \alpha\left[w_{ij}(t) - w_{ij}(t-1)\right]$$

Step 6: Return to Step 4 or Step 2.

The weight update in Step 5 includes learning rate (η) and momentum (α) terms to improve performance of the algorithm. The selection of a learning rate is of critical importance in finding the true global minimum of the error distance. Back-propagation training with too small a learning rate will make agonizingly slow progress. Too large a learning rate will proceed much faster, but may simply produce oscillations between relatively poor solutions. Both of these conditions are generally detectable through experimentation and sampling of results after a fixed number of training epochs. Ideally, the largest learning rate should be used that still converges to the minimum solution. Use of a momentum term can be helpful in speeding algorithm convergence and avoiding local minima. This gives the system a certain amount of inertia since the weight vector will tend to continue moving in the same direction unless opposed by the gradient term. The momentum term (i) smooths the weight changes and suppresses cross-stitching, that is, cancels side-to-side oscillations across the error valley, (ii) amplifies the learning rate when all weight changes are in the same direction, causing a faster convergence, and (iii) enables escape from small local minima on the error surface. Typical values for the learning rate and momentum parameter are $0 < \eta, \alpha < 1$. The momentum term will allow a larger learning rate and thus speed convergence and avoid local minima. On the other hand, a learning rate of 1 with no momentum will be much faster when no problem with local minima or non-convergence is encountered. Other popular training algorithms include Quickprop and Cascade Correlation.

A very popular network that uses unsupervised training is Kohonen's Self-Organizing Feature Map or SOM (Figure 4b). This is a two-layered feedforward network consisting of a layer of input distribution nodes, and an output layer usually arranged as a 2-D map, which shows the natural relationships among the patterns presented to the network. Essentially, neighboring neurons compete in their activation by means of mutual lateral interactions, and develop adaptively into specific detectors of different input patterns. The unsupervised training algorithm is outlined below.

Step 1: All w_{ij} set to small random values.
Step 2: Input presented.
Step 3: Euclidian distances δ_i between each input node (j) and output node (i) computed.

$$\delta_i = \sum \left[x_j(t) - w_{ij}(t)\right]^2$$

Step 4: Select output node i^* with minimum distance.
Step 5: Update weights to node i^* and neighbors.

$$w_{ij}(t+1) = w_{ij}(t) + \eta(t)\left[x_j(t) - w_{ij}(t)\right], \mathrm{i} \in NE_{i*}(t)$$

Step 6: Return to Step 2.

Recurrent networks, which involve the inclusion of feedback loops such as the one depicted in Figure 4c, have a profound impact on the learning capability of the network and its performance.

Many other types of ANN exist, including Hopfield recurrent networks, those based on the adaptive resonance theory of Carpenter and Grossberg, probabilistic, modular, and radial-basis function ANNs, support vector machines, and more recently, networks including spiking ANNs and wavelet ANNs.

Geophysical inversion using artificial neural networks

ANNs offer many advantages to geophysicists for inversion applications, and this has made them an intensely active research area. Indeed, many ANN inversion algorithms are now sufficiently mature and are routinely employed in their respective application area. A number of good reviews of geophysical inversion using ANNs are available in the literature (Röth and Tarantola, 1994; Nunnari et al., 2001).

The basis of ANN geophysical inversion methods is illustrated in Figure 6.

First, a geophysical model is used to derive many simulated model response vectors $\mathbf{y}^{(i)}$ from a large number N of subsurface model parameter vectors $\mathbf{x}^{(i)}$, where $1 \leq i \leq N$. Next, the response vectors act as input data training sets to an ANN. In supervised training the model parameter vectors are used as the target vectors. Finally, after appropriate training, a new survey data vector $\mathbf{y}'$ is input to the ANN, and an estimated subsurface model parameter vector $\hat{\mathbf{x}}$ obtained, that is, geophysical inversion has been achieved. There are many variations of this basic technique.

It is important to emphasize that geophysical inversion using ANNs will only be successful if proper consideration and diligence are provided during the preprocessing and training phases. This is to ensure the prevention of over-training and local minima entrapment (Maiti and Tiwari, 2010).

There are many examples in the literature of ANNs being employed across the complete spectrum of geophysical inversion applications, and these publications, many of which are cited below under their respective application domains, should be consulted for further information.

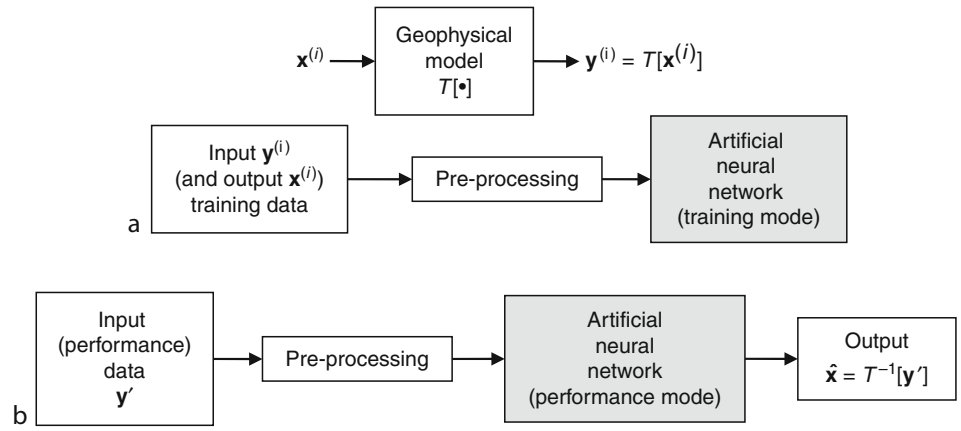
Summary

Geophysical inversion is an essential tool to help geophysicists solve practical environmental, engineering, or exploration problems. This is particularly relevant for situations



Inverse Theory, Artificial Neural Networks, Figure 6 Basis of geophysical inversion using ANNs. (**a**) A geophysical model is used to derive many simulated model response vectors $\mathbf{y}^{(i)}$ from subsurface model parameter vectors $\mathbf{x}^{(i)}$. The response vectors then act as input data training sets to an ANN. In supervised training the model parameter vectors are also used. (**b**) After appropriate training, a new survey data vector $\mathbf{y}'$ is input to the ANN, and an estimated subsurface model parameter vector $\hat{\mathbf{x}}$ obtained.

that require detailed quantitative subsurface information and data. Traditional approaches to inversion are many and varied, and include model perturbation/comparison, linearization usually of a nonlinear geophysical model, together with a variety of stochastic methods including Monte Carlo, simulated annealing, and genetic algorithms. These approaches do not perform well in the presence of noise, are very inefficient and computing intensive, require subjective tuning parameters and a priori knowledge, and/or produce results that are nonunique.

Alternative geophysical inversion methods, based on artificial neural networks (ANNs), have been investigated over the past 15–20 years, to try and overcome the disadvantages of the traditional approaches. These ANN inversion methods have now found considerable success across many different geophysical domains, including seismic attributes, velocity fields, and tomography, to potential field inversion, archaeology, and remote sensing.

With the continuous introduction of improved ANN paradigms and training algorithms, coupled with the ever-increasing power of digital computing hardware (including Field Programmable Gate Arrays [FPGAs]), there is no doubt that ANNs have a very positive future in the exciting and challenging world of geophysical inversion.

INVERSE THEORY, GLOBAL OPTIMIZATION

Mrinal K. Sen, Paul L. Stoffa
Department of Geological Sciences, UT Institute for Geophysics, Jackson School of Geosciences, The University of Texas at Austin, Austin, TX, USA

Definition

Inversion of geophysical data involves searching for optimal set(s) of earth model parameters that can be used to compute synthetic data that match with observations. The data misfit (or fitness) is often measured by a suitably defined objective function that is generally non-convex. Optimization methods search for a minimum (optimal) value of an objective function. In general, there can be solutions that are locally optimal.

Global optimization refers to finding the best set of parameters corresponding to the global minimum of a function of multiple parameters.

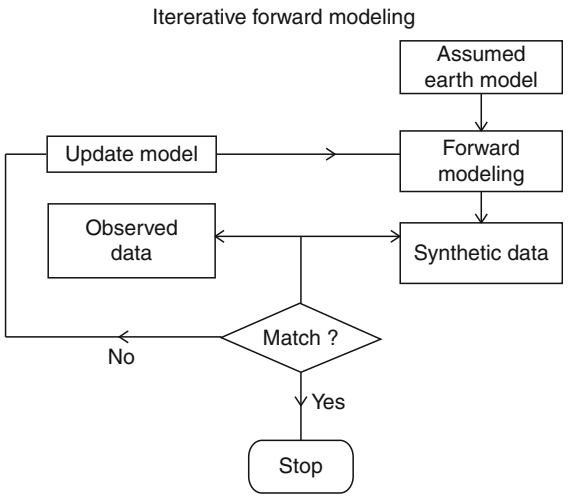
Introduction

The primary goal of geophysics is to determine the properties of the earth's interior from a finite set of remotely sensed measurements from instruments placed on the surface of the earth with perhaps a few in boreholes. The forward problem involves computation of theoretical data for a given set of earth model parameters. Typically, this requires numerical solution of a partial differential equation. The inverse problem whose goal is to estimate earth model parameters from observations is nontrivial due to the fact that data are almost always inadequate, inconsistent, and insufficient (Jackson, 1972). The direct inversion methods are formulated based on the physics of the forward problem by recognizing or designing a mathematical operator, which is applied to the observed data (sometimes recursively) to derive a model of the earth. Such methods are generally unstable due to the typical data problems of inadequacy.

In a *model-based inversion* approach, synthetic data are generated for an assumed model and compared with the observed data. If the match between observed and synthetic data is acceptable, the model is accepted as the solution, otherwise, the model is changed. The synthetics are recomputed and again compared with the observations. This iterative forward modeling procedure is repeated until an acceptable match is obtained between data and synthetics. Thus in this approach, inversion is viewed as an *optimization* process in which a model is sought that best explains the observations (Figure 1). Therefore, searching for a model that explains the field observation the best, comprises one of the major tasks of inversion.

Inversion is not restricted to just finding the so-called best-fit model since there can be multiple solutions. In other words, often we have nonunique solutions. Thus it is very important for a practitioner to have a clear understanding of the forward problem and to impose constraints and restrict the search for an optimal realistic solution within regions that are geologically meaningful. This can be addressed by a proper choice of an objective function. One approach to inversion may be termed "exploitation of model space" in which one simply seeks a best-fit model. Another approach may be termed "exploration of model space," which casts the inverse problem in Bayesian Framework (Tarantola, 1987) and constructs a posteriori probability density function (PPD) in model space.

Details of geophysical inverse theory with some examples of application can be found in the texts by Menke (1984), Tarantola (1987), Sen and Stoffa (1995), Aster et al. (2005), and Sen (2006). In the following, we will provide a summary of global optimization methods with some examples of application to geophysical inversion.



Inverse Theory, Global Optimization, Figure 1 Principle of model-based inversion by optimization.

Method

Background

The essential elements of a model-based inversion algorithm include data, model, forward problem, objective function, and optimization method. We will restrict ourselves to discrete data **d** and model **m** defined by the following vectors

$$\begin{aligned} \mathbf{d} &= [d_1\, d_2\, d_3 \ldots d_N]^T, \\ \mathbf{m} &= [m_1\, m_2\, m_3 \ldots m_M]^T. \end{aligned} \tag{1}$$

In general $N \neq M$. The forward problem can be represented by the following equation

$$d^{syn} = g(m), \tag{2}$$

where g is a nonlinear forward modeling operator that operates on the model vector to generate synthetic data vector $\mathbf{d}^{syn}$. The next step is to define an objective function that measures a misfit between the observed and synthetic data using a suitably defined norm. The data residual is given by

$$\mathbf{\Delta d} = \mathbf{d}^{obs} - \mathbf{d}^{syn}, \tag{3}$$

where $\mathbf{d}^{obs}$ is the observed data vector and the data misfit norm can be written as

$$\|\mathbf{\Delta d}\|_p = \left[\sum_{i=1}^{N} |\Delta d_i|^p\right]^{1/p}, \tag{4}$$

where p is an integer representing the order of the norm. The most commonly used norm is an L_2 norm for which $p = 2$ resulting in a minimization of the mean square error. This corresponds to the popular least squares minimization approach.

To address the issues of stability and nonuniqueness, constraints are incorporated by adding a model norm term, which can be used to impose smoothness, positivity, and bounds. A detailed description of this issue is beyond the

scope of this article. A fairly general objective function with such constraints using an L_2 norm can be written as

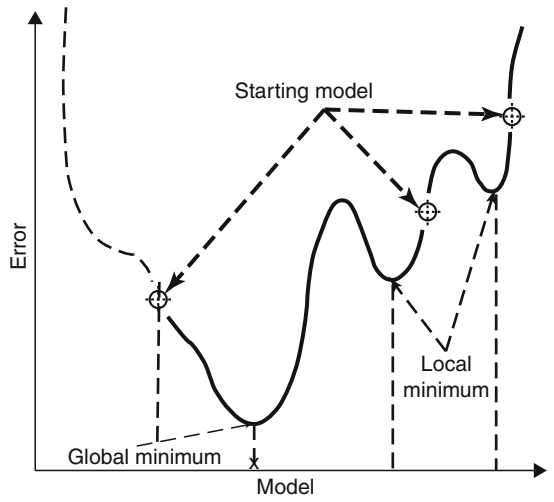
$$F(\mathbf{m}) = \left(\mathbf{d}^{obs} - \mathbf{d}^{syn}\right)^T \mathbf{W}_d \left(\mathbf{d}^{obs} - \mathbf{d}^{syn}\right) + \alpha \left(\mathbf{m} - \mathbf{m}^{prior}\right)^T \mathbf{W}_m \left(\mathbf{m} - \mathbf{m}^{prior}\right), \quad (5)$$

where $\mathbf{W}_d$ and $\mathbf{W}_m$ are the data and model weighting matrices, $\mathbf{m}^{prior}$ is the prior model, and α is a regularization weight. The misfit function given by Equation 5 is also called the objective function, cost function, error function, energy function, etc., in different applications.

Optimization

The goal of an optimization algorithm is to search for the minimum of an objective function such as the one defined by Equation 5. Note that the operator g in Equation 2 is, in general, a nonlinear operator. Therefore the objective function (Equation 5) is expected to be non-convex with multiple peaks and troughs (Figure 2). In other words, the objective function can have multiple local minima; the minimum of all the local minima is called a "global" minimum (e.g., Gill et al., 1981). In most applications, once an objective function has been defined, the goal is to find the global minimum of the objective function.

Optimization methods vary depending on the method of search for the minimum. They can be broadly classified into two categories: local optimization and global optimization. The local optimization methods generally use calculus-based rules to find an update in their search. In other words, they make use of local gradient and/or curvature of the objective function to compute an update. Most of these methods are deterministic in nature and the success of these methods is largely dictated by the choice of the starting model. Only if the starting model is close to the globally optimal model can we expect to reach the global minimum using local optimization methods. These techniques cannot generate or even use the global information needed to find the global minimum for a function with multiple local minima.



Inverse Theory, Global Optimization, Figure 2 A hypothetical error function as a function of model (the model is assumed to have only one model parameter) showing several minima. The iterative gradient method will find the global minimum only when starting at position 1. Others will end up in secondary minima of the error function.

The global optimization methods, on the other hand, are mostly based on stochastic rules and use more global information about the misfit surface to update their current position. The interaction between computer science and optimization has yielded new practical solvers for global optimization problems, called *meta-heuristics*. The structures of meta-heuristics are mainly based on simulating nature and artificial intelligence tools. Meta-heuristics mainly invoke exploration and exploitation search procedures in order to diversify the search all over the search space and intensify the search in some promising areas. Therefore, meta-heuristics cannot easily be entrapped in local minima. However, meta-heuristics are computationally expensive due to their slow convergence. One of the main reasons for their slow convergence is that they may fail to detect promising search directions especially in the vicinity of local minima due to their random constructions.

The convergence of these methods to the globally optimal solution is not guaranteed for all the algorithms. Only for some of the algorithms under certain conditions is convergence to the globally optimal solution statistically guaranteed. Also, with real observational data it is never possible to know whether the derived solution corresponds to the global minimum or not. However, our experience indicates that we are able to find many good solutions starting with only poor initial models using global optimization methods (Sen and Stoffa, 1995). They are less greedy than the well-known local optimization methods in that during iterative optimization worse solutions are occasionally accepted, which allow these algorithms to avoid local minima. There are several variants of global optimization methods; detailed descriptions of some of these approaches as applied to geophysical inversion can be found in Sen and Stoffa (1995). Here we will provide brief descriptions of a few commonly used global optimization methods, namely the *Simulated Annealing* (SA), *Genetic Algorithms* (GA), *Neighborhood Algorithms* (NA), and *Particle Swarm Optimization* (PSO).

Simulated annealing

Simulated annealing was first proposed by Kirkpatrick et al. (1983). It is analogous to the natural process of crystal annealing when a liquid gradually cools to a solid state. The SA technique starts with an initial model $\mathbf{m}_0$, with associated error or energy $E(\mathbf{m}_0)$. It draws a new model $\mathbf{m}_{\text{new}}$ from a flat distribution of models within the predefined limits. Note that each model parameter can be bounded by different limits. The associated energy (objective function value) $E(\mathbf{m}_{\text{new}})$ is then computed, and compared against $E(\mathbf{m}_0)$. If the energy of the new state is less

than the initial state, the new state is considered to be good. In this case, the new model is accepted and replaces the initial model unconditionally. However, if the energy of the new state is larger than the initial state, $\mathbf{m}_{\text{new}}$ is accepted with the probability of $\exp(-(E(\mathbf{m}_{\text{new}}) - E(\mathbf{m}_0))/T)$, where T is a control parameter called annealing temperature that controls if the "bad" model should be carried over to the new model. This completes one iteration. It is the rule of accepting with a probability that makes it possible for SA to be able to jump out of the local minima. The same process is repeated for a large number of times, with the annealing temperature gradually decreasing according to a predefined scheme. Hopefully with a carefully defined cooling schedule, a global minimum can be found. One may choose a linear, or a logarithmically decreasing cooling scheme. The tradeoff here is between the computation cost and the accuracy of the result. Fast cooling will fail to produce a crystal (the algorithm gets stuck in a local minimum), slow cooling takes a long time but may eventually find the global minimum.

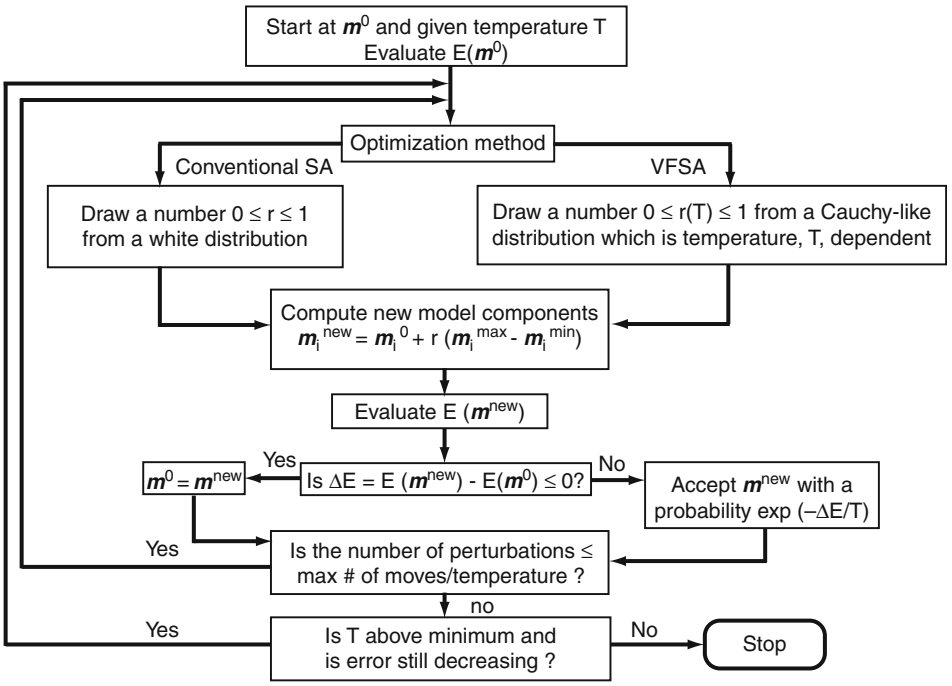
To speed up the annealing process without much sacrifice in the solution, a variant of SA, called Very Fast Simulated Annealing (VFSA) was proposed by Ingber (1989). VFSA differs from SA in the following ways. The new model is drawn from a temperature dependent Cauchy-like distribution centered on the current model (Figure 3). This change has two fundamental effects. First it allows for larger sampling of the model space at the early stages of the inversion when the temperature is high, and much narrower sampling in the model space as the inversion converges when the temperature decreases. Second, each model parameter can have its own cooling schedule and model space-sampling scheme. Therefore it allows for the individual control for each parameter, and the incorporation of a priori information. For many geophysical inversion applications, VFSA has been demonstrated to have excellent performance (Sen and Stoffa, 1995).

Genetic algorithm

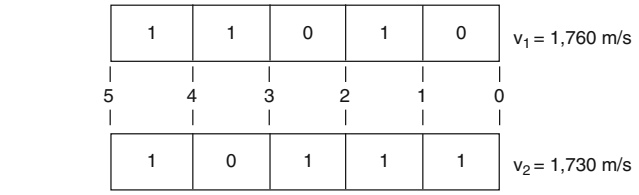
Genetic algorithms are so named because they emulate the biological processes of evolution and are based on the principle of survival of the fittest (e.g., Goldberg, 1989). In a simple GA, the model parameters are coded in binary form (Figure 4). The algorithm starts with a randomly chosen population of models called *chromosomes*. The second step is to evaluate the fitness values of these models. Note that unlike our preceding discussion on optimization in which we attempt to minimize an objective function, a GA searches for the maximum of a suitably defined fitness function that measures similarities between the observed and synthetic data. After the initial selection process, the three genetic processes of selection, crossover, and mutation are performed upon the models in sequence.

In *selection*, models are copied in proportion to their fitness values based on a probability of selection. Thus during this process, models with higher fitness values (lower error values) have a higher probability of getting selected.

Crossover acts on the selected pairs of models. This operation picks a crossover site within the paired strings and exchanges, based on a crossover probability, the bits

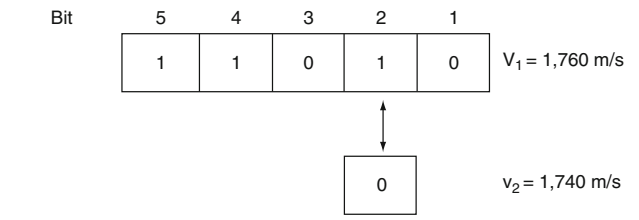


Inverse Theory, Global Optimization, Figure 3 A flowchart for global optimization by simulated annealing. Note that the VFSA draws models from a Cauchy-like distribution whose shape changes with iteration.



a

Crossover position	v_1 m/s	v_2 m/s
0	1,760	1,730
1	1,770	1,720
2	1,770	1,720
3	1,810	1,680
4	1,730	1,760
5	1,730	1,760



b

Mutation bit	v_1 m/s	v_2 m/s
1	1,760	1,770
2		1,740
3		1,800
4		1,680
5		1,600

Inverse Theory, Global Optimization, Figure 4 Genetic algorithms are based on binary coding of model parameters (**a**) and then processes of crossover(**a**) and mutation (**b**). Figure (**a**) shows bit representation of velocity values and the new values resulting from crossover at different crossover positions. Figure (**b**) demonstrates how the velocity changes with mutation at different mutation bits.

between the two models to the right of the crossover site (Figure 4). Thus the crossover process results in two new models (or children).

Mutation, which involves changing a bit at random based on a mutation probability, is applied to the models to maintain diversity.

After execution of these three processes, the new models are compared to the previous generation and accepted based on an update probability (Stoffa and Sen, 1991). The procedure is repeated until convergence is reached, that is, when the fitness of all the models becomes close to one another.

Note that the repeated applications of selection, crossover, mutation, and update do not necessary guarantee convergence to the global maximum of the fitness function. Nonetheless, the algorithm has been found to be successful in many optimization problems including those from Geophysics.

Neighborhood algorithm (NA)

NA was introduced by Sambridge (1999). The principal idea behind this algorithm is to generate a set of models, at each generation, whose sampling density is constructed from all previous models (Sambridge and Mosegaard, 2002). In other words, the proposal distribution to draw the models from is updated at each iteration. One other unique feature of the algorithm is that the algorithm involves portioning of the model parameter space into nearest-neighbor or Voronoi cells about each of the models, and thus the information in the previous model samples drives the search for new models. At regular intervals the approximation is updated, and sampling can concentrate in multiple regions.

Particle swarm optimization (PSO)

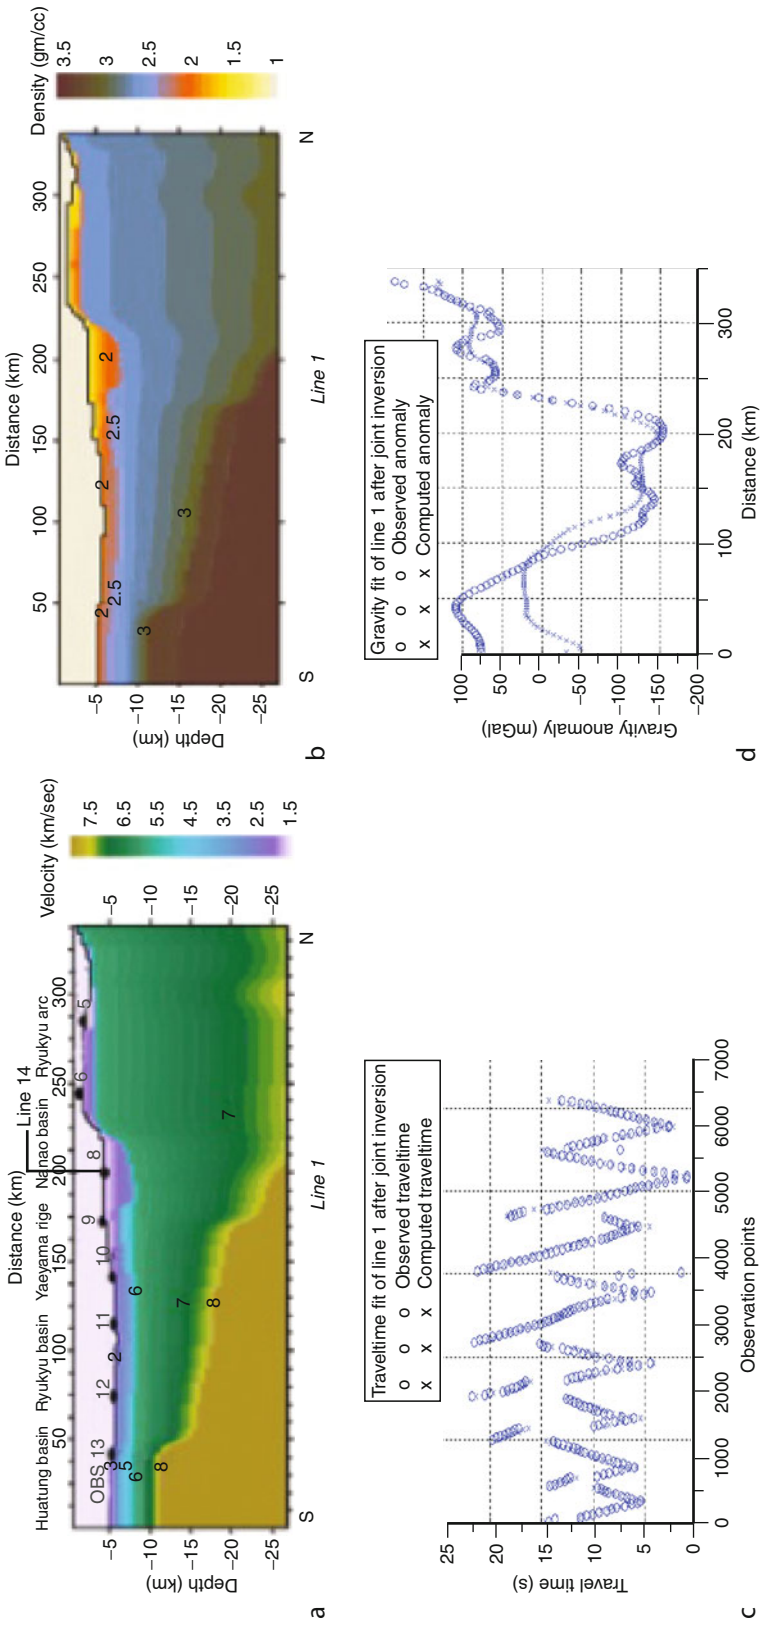
The particle swarm is a stochastic evolutionary computation technique (Kennedy and Kennedy and Eberhart, 1995) used in optimization, which is inspired by observation of social behavior of individuals (called particles) in nature, such as bird flocking and fish schooling. This has been successfully used in many different science and engineering fields including Geophysics (Shaw and Srivastava, 2007). PSO defines a swarm of particles (models) in an M-dimensional space. Each particle maintains memory of its previous best position, $\mathbf{p}_i$ and velocity, $\mathbf{v}_i$. At each iteration, a velocity adjustment of the particle is determined jointly by the previous best position occupied by the particle and the best position of the swarm. The new velocity is then used to compute a new position for the particle. The component of the velocity adjustment determined by the individual's previous best position has been termed as the *cognition*, and the component influenced by the best in the population is the *social* part. The velocity update formula is given by

$$\begin{aligned} \mathbf{v}_i^k &= \mathbf{v}_i^{k-1} + b.ran(.)\left(\mathbf{m}_i^l - \mathbf{m}_i^k\right) + c.ran(.)\left(\mathbf{m}_g - \mathbf{m}_i^k\right) \\ \mathbf{m}_i^{k+1} &= \mathbf{m}_i^k + a\mathbf{v}_i^k, \end{aligned} \tag{6}$$

where $\mathbf{m}_i^k$ is the current location; $\mathbf{v}_i^k$ is the current velocity; $\mathbf{m}_i^l$ is the best location so far; $\mathbf{m}_g$ is the best location achieved by the swarm prior to the kth iteration; *ran*(.) is a random number generator; and a, b, and c are constants. This algorithm is very intuitive and easy to program.

Applications

Several applications of global optimization to geophysical data can now be found in the literature. Due to space limitation, only two examples are included here, which are

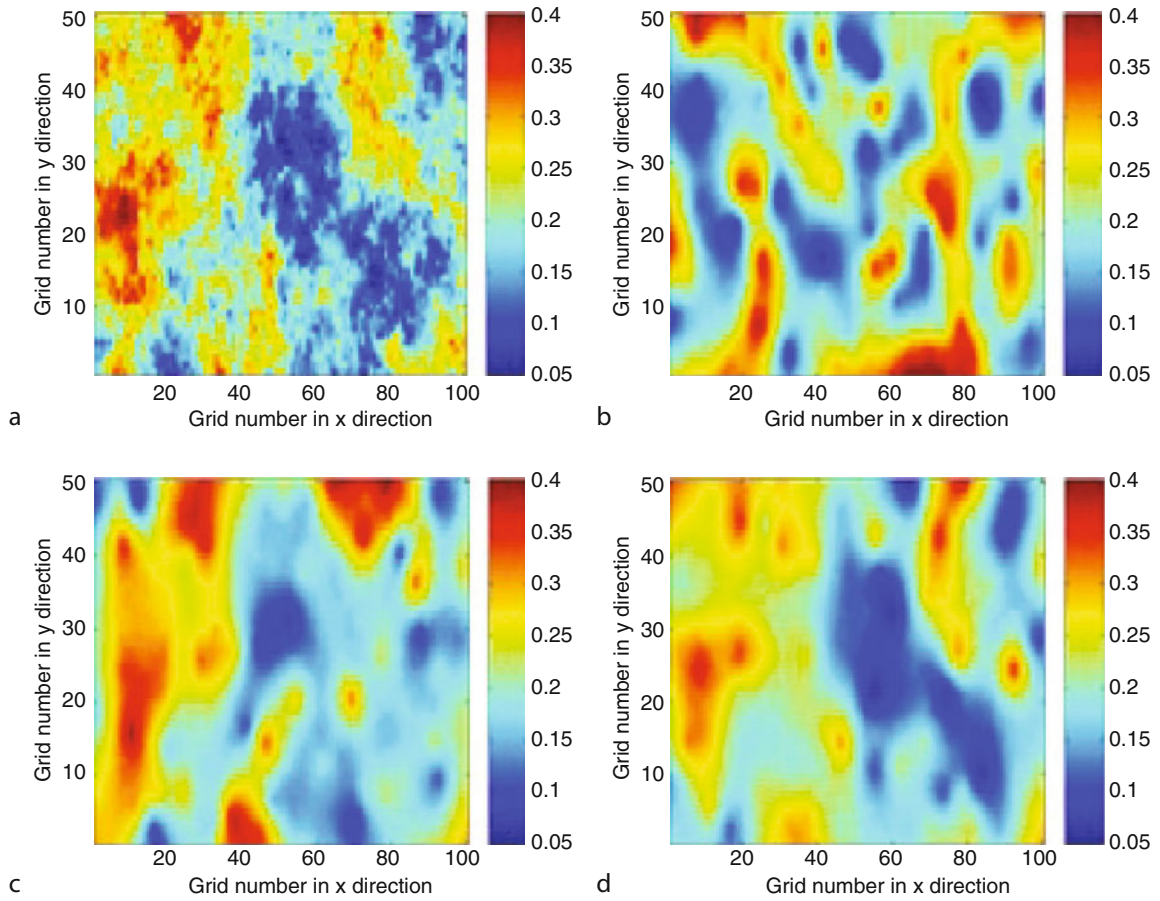


Inverse Theory, Global Optimization, Figure 5 Example of joint inversion of first arrival seismic travel time and gravity data (Modified from Roy et al., 2005): (**a**) the best-fit P-wave velocity (*top*) and (**b**) density (*bottom*) models for a 2D line marked line 1; (**c**) comparison between observed and predicted travel time at different OBS locations and (**d**) comparison between observed and predicted gravity anomalies at different locations (Figure reprinted with permission from IOP Publishing).

particularly intriguing since both of these applications address the issue of joint inversion of disparate datasets.

Roy et al. (2005) implemented a joint inversion of first arrival travel time and gravity data with application to field data from a geologically complex subduction zone. They employed a layer-based model description, in which interfaces (which may also be called iso-velocity lines) were defined by a summation of arc-tangent functions. Within each layer, the velocity is assumed to vary linearly with depth at each surface location. Because of the nonuniqueness of the gravity inversion, they used prior knowledge to relate velocity to density values. The nonlinear optimization problem was solved by a very fast simulated annealing (VFSA) technique. At each iteration, travel times were generated by the solution of the Eikonal equation while the gravity anomalies are computed using a standard formula. The objective function consists of two parts: one measures the misfit in travel time and the other measures the misfit of gravity anomalies. The technique was applied to field data collected over the Ryukyu subduction zone offshore Taiwan during an ocean bottom seismometer (OBS) experiment (called TAICRUST) conducted in the year 1995. An example of results from a profile along NS direction is shown in Figure 5. The left panel in Figure 5 shows the velocity and density models derived by joint inversion of travel time and gravity data. The fit between observed and synthetic data is shown in the right panel of Figure 5.

The second application (taken from Jin et al., 2009) is that of joint inversion of flow and seismic data for reservoir parameters. It is a challenging task in that these disparate datasets are sensitive to different physics and model resolutions for the forward problem. To overcome some of these challenges, Jin et al. (2009) developed a global optimization method based on very fast simulated annealing (VFSA) and a pilot-point-based model parameterization scheme. Reservoir simulation was used to create the saturation and pressure distribution with time. The simulation results were converted to seismic properties using an appropriate rock physics model. Seismic modeling was used to create the seismic response. The objective function was defined as a weighted sum of data misfit and model misfit and VFSA was used to derive optimal model parameters. Results from application to a synthetic dataset



Inverse Theory, Global Optimization, Figure 6 Joint inversion of time-lapse seismic and well production data obtained by pilot-point parameterization and very fast simulated annealing (Modified from Jin et al., 2009):true porosity (**a**); inversion result using only well data (**b**); inversion result using only seismic data (**c**); and inversion result using both seismic data and well data (**d**).

are shown in Figure 6. A comparison of results from using well data alone (top right panel), seismic data alone (bottom left panel), seismic and well data (bottom right) with the true model parameters (top left panel; a 2D porosity slice) shows marked improvement with the use of time-lapse seismic and well production data.

Summary

Most geophysical inverse problems are nonlinear in nature and require searching for the minimum of an objective function that is often multimodal. Although linearization of the forward problems and use of local optimization methods have been fairly successful in many applications, many complex problems show suboptimal results using these methods. The global optimization methods are not sensitive to the choice of the starting models and make no assumption on the shape of the objective function. These methods, however, require numerous forward model evaluations and are therefore, computationally expensive. With the advent of cheap fast computers with large memory, applications of these methods are becoming increasingly popular. In some applications, hybrid methods based on local and global optimization (e.g., Chunduru et al., 1997; Porsani et al., 2000) can be designed that can take advantage of both the approaches.

Introduction

The activity of solving inverse problems is all pervading. We perform this activity throughout our life right since birth. As a new born baby the first inverse problem we solve, albeit through pattern recognition, is identification of mother in a group of persons. In this vein, the geophysical inverse problems are just a member of the class of inverse problems encountered and studied in science. Formally, the inverse problem can be defined as an estimation of system parameters together with their uncertainties from the observed system response to a given source excitation. In contrast, the forward problem is defined as computation of response of the system for a given model of its properties and for a given source excitation. Most of the geophysical inverse problems are nonlinear by virtue of the system response being a nonlinear function of system parameters. However, a widely employed class of methodologies solves the nonlinear inverse problems through quasi-linearization whereby the nonlinear problem is recast into a sequence of linear problems that are solved iteratively using linear methodologies. Further, since bulk of the nonlinearity signatures in a geophysical inverse problem arise from geometry of the distribution of physical property, the problem can be recast, in some cases, to a linear problem when the model geometry is considered known. For example, in gravity studies, if the domain of study is divided into small cubes of known volumes and the unknowns are only the density of cubes, the corresponding inverse problem is linear. Similarly, in case of a layered earth model, the problem can be cast into

a linear one when the layer thickness is assumed to be known according to some criterion, for example, constant travel time in case of seismics, constant thickness in DC resistivity, or constant skin depth in case of magnetotellurics (Kunetz, 1972; Gupta et al., 1996, 1997). So, there exists an enormous interest in methodologies for solving the linear inverse problems. This article deals with general aspects of linear inverse theory, the description of well- and ill-posed problems, the least square, minimum norm, and generalized inverses of a matrix, the data and parameter resolution matrices, and the ways of handling noise in data. Lastly, the seminal method proposed by Backus and Gilbert (1967, 1968, 1970) for solving linear inverse problems is discussed in some detail. For rigorous readings on inversion theory one can refer the books by Aki and Richards (2002), Indira and Gupta (1998), Lines and Treitel (1984), Menke (1984), Scales et al. (2001), Sneider and Trampert (1999), Tarantola (2005), Tikhanov and Arsenin (1977), Twomey (1977), and Zhdanov (2002), while for numerical aspects of inverse problems one can refer the books by Bjorck (1996), Lawson and Hanson (1995), and Rao and Bhimasankaram (1992) and also the works of Rojas and Sorenson (2002) and Saltelli et al. (2006). For applications and case studies, one can refer Aki and Richards (2002) and Tarantola (2005) for seismological inverse problems, Borcea (2002) for electrical impedance tomography, Habashy and Abubakar (2004) for electromagnetic inversion, Mallat (2009) for signal processing, and Rawlinson et al. (2010) for seismic tomography. For general geophysical applications one can refer to Treitel and Lines (2001) and Oldenburg and Li (2004).

Linear inverse problems

The common linear inverse problems can be presented in the form of Fredholm's integral equations of first kind,

$$g(y) = \int_a^b K(x,y) f(x) \mathrm{d}x, \quad c < y < d. \tag{1}$$

Here, $K(x, y)$ is the kernel function that transforms the system parameter function, $f(x)$, into the observable function $g(y)$. A special class of linear problems is the convolution problem where the kernel function has the special form $K(y–x)$.

The problem of obtaining a function, $f(t)$, from its Fourier transform function, $F(\omega)$, can be looked upon as an inverse problem as stated below

$$F(\omega) = \int_{-\infty}^{\infty} f(t) \mathrm{e}^{-i\omega t} \mathrm{d}t. \tag{2}$$

Oldenburg (1976) studied this linear inverse problem using Backus–Gilbert method.

Another example, the gravity anomaly problem can be stated as

$$g_z(\mathbf{r}) = \iiint_{\mathbf{v}} \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|^3} d^3\mathbf{r}'. \tag{3}$$

Here, $\rho(\mathbf{r}')$ is the unknown density distribution and the remaining factor defines the kernel function. The anomaly $g_z(\mathbf{r})$ is a linear function of density $\rho(\mathbf{r}')$. It may be noted that it is a convolution type problem.

Similarly, in DC resistivity method, the apparent resistivity function, $\rho_a(r)$, is linearly related to the resistivity transform function, $T(\lambda)$, through the kernel function as

$$\rho_a(r) = \int_0^{\infty} T(\lambda) J_n(\lambda r) d\lambda. \tag{4}$$

Ghosh (1971a, b) transformed this problem to a convolution problem by transformation of independent variables.

The discrete equivalent of linear problems can be cast in the form of a matrix equation as

$$\mathbf{Ax} = \mathbf{b}. \tag{5}$$

Here, $\boldsymbol{A}$ is an $m \times n$ matrix, $\boldsymbol{b}$ is the m-dimensional observation data vector and $\boldsymbol{x}$ is the n-dimensional parameter variable vector to be determined.

The traditional solution of this problem exists only for the case where $m = n$ and the coefficient matrix is nonsingular so that its exact inverse exists. However, in such special cases also there exist serious problems. Consider the simple example

$$x + y = 2$$
$$x + 1.0001y = 2.0001$$

The solution of this problem is $x = y = 1$. However, if the right-hand side vector is an outcome of some observations where accuracy is only up to two decimal places, statement of the problem may become

$$x + y = 2$$
$$x + 1.0001y = 2.00$$

The solution will now be $x = 2$, $y = 0$. Such drastic change in the solution vector for a very small change in data vector is a reflection of the problem being an *unstable* one. Similarly, if our coefficient is an outcome of some computations where the accuracy is only up to two decimal places, assuming the data vector to be error free, the problem becomes

$$x + y = 2$$
$$x + 1.00y = 2.0001$$

In this case we find that the two equations are *inconsistent*.

Lastly, if in the previous case the data is also erroneous, the resulting equations are

$$x + y = 2$$
$$x + 1.00y = 2.00$$

Now there exist infinite solutions and the problem is *nonunique*.

These problems of instability, inconsistency and nonuniqueness invariably crop up while solving inverse problems. If a problem has any one of these features it is termed as an ill-posed problem. Hadamard (1902) formalized the definition of a well-posed problem in terms of the three conditions:

1. The solution exists.
2. The solution is unique.
3. The solution is stable.

Since in applied mathematics one is interested in obtaining the solution, another condition was subsequently added to this list of conditions for a problem to be termed as well posed, that is,

4. The solution is constructible.

A linear or linearized inverse problem, when cast in a matrix form, can be solved as a least square problem. Here, we shall be discussing various ways of solving the matrix equation in its generality. The various classifications of matrix equation 5 can be

1. Case when $m > n = k$, is known as strictly overdetermined.
2. Case when $n > m = k$, is known as strictly underdetermined.
3. Case when $m = n = k$, is known as evenly determined.
4. Case when $k < min(m,n)$ is known as underdetermined.

Here, k is the rank of matrix $\boldsymbol{A}$.

In any real problem the observed data is, in general, inadequate and inaccurate. As a result the resulting inverse problem is inconsistent, underdetermined, and most of the time unstable. Under such adverse conditions when the exact solution does not exist, the basic task in solving the matrix Equation 5 pertains to obtaining a solution that meets the desired objectives. Backus (1970, 1996), Backus and Gilbert (1967, 1968, 1970), Jackson (1972, 1979), and others studied these problems and developed methodologies to obtain a unique solution. It is inevitable that in such cases there would be a trade-off between the propagation of data error to parameter estimation and the parameter resolution. The inevitable nonuniqueness is removed by incorporating the available a priori information about the unknown parameter vector $\boldsymbol{x}$. The various methods differ in handling the a priori knowledge about data error and model and in controlling the trade-off between error propagation and parameter resolution.

To be able to solve Equation 5 one designs a matrix $\boldsymbol{A}^{\boldsymbol{g}}$, termed as generalized inverse, such that

$$\mathbf{x} = A^{\mathbf{g}}\mathbf{b}. \tag{6}$$

It is obvious that matrix $\boldsymbol{A}^{\boldsymbol{g}}$ will not possess all the properties of the exact matrix inverse, $\boldsymbol{A}^{-1}$, which can be defined only for non-singular matrix. For various cases mentioned above, the generalized inverse will possess only a subset of these properties. One of the important properties of exact inverse is $\boldsymbol{A}\boldsymbol{A}^{-1} = \boldsymbol{A}^{-1}\boldsymbol{A} = \boldsymbol{I}$. In case of a matrix $\boldsymbol{A}$ of order $m \times n$, the generalized inverse matrix, $\boldsymbol{A}^{\boldsymbol{g}}$, will lead to the product matrices, $\boldsymbol{S} = \boldsymbol{A}\boldsymbol{A}^{\boldsymbol{g}}$ of order $m \times m$ and $\boldsymbol{R} = \boldsymbol{A}^{\boldsymbol{g}}\boldsymbol{A}$ of order $n \times n$ and these, in general, will not be identity matrices. The former product matrix $\boldsymbol{S}$ is termed as *data resolution matrix* or *information density matrix*, while the latter product matrix $\boldsymbol{R}$ is known as *parameter resolution matrix*. These product matrices play an important role in the evaluation of quality of solution. Norms of the deviation of matrices $\boldsymbol{S}$ and $\boldsymbol{R}$ from respective Identity matrices provide quantitative measures of quality of information contained in data vector and of the degree of parameter resolution, respectively.

The matrix $\boldsymbol{A}^{\boldsymbol{g}}$ can be synthesized in several ways for a given type of coefficient matrix $\boldsymbol{A}$. The important approaches widely employed to solve the Equation 5 lead to

1. Least square inverse
2. Minimum norm inverse
3. Damped least square (DLS) inverse
4. Rao–Mitra generalized inverse
5. Moore–Penrose generalized inverse based on singular value decomposition (SVD)

All these approaches are briefly presented below followed by Backus–Gilbert method which also provides a solution of the linear inverse problem stated as Equation 1.

Generalized inverses

Least square inverse

The least square (LS) solution of a strictly overdetermined problem was first proposed by Gauss in 1795. The LS solution exists even for inconsistent system of equations. It is obtained by minimizing the L2 norm of misfit error vector, that is,

$$\left\{\begin{array}{c} \text{Minimize } \boldsymbol{e}^{\mathrm{T}}\boldsymbol{e} = (\boldsymbol{b}-\boldsymbol{A}\boldsymbol{x})^{\mathrm{T}}(\boldsymbol{b}-\boldsymbol{A}\boldsymbol{x}) \\ \text{Solution: } \boldsymbol{x} = (\boldsymbol{A}^{\mathrm{T}}\boldsymbol{A})^{-1}\boldsymbol{A}^{\mathrm{T}}\boldsymbol{b} \\ \text{Inverse: } \boldsymbol{A}^{\boldsymbol{g}} = (\boldsymbol{A}^{\mathrm{T}}\boldsymbol{A})^{-1}\boldsymbol{A}^{\mathrm{T}} \\ \text{Information density matrix: } \boldsymbol{S} = \boldsymbol{A}\boldsymbol{A}^{\boldsymbol{g}} \\ = \boldsymbol{A}(\boldsymbol{A}^{\mathrm{T}}\boldsymbol{A})^{-1}\boldsymbol{A}^{\mathrm{T}} \neq \boldsymbol{I}_{\boldsymbol{m}} \\ \text{Parameter resolution matrix: } \boldsymbol{R} = \boldsymbol{A}^{\boldsymbol{g}}\boldsymbol{A} \\ = (\boldsymbol{A}^{\mathrm{T}}\boldsymbol{A})^{-1}\boldsymbol{A}^{\mathrm{T}}\boldsymbol{A} = I_n \end{array}\right\} \tag{6}$$

The expressions of matrices $\boldsymbol{S}$ and $\boldsymbol{R}$ reveal that the data quality is not optimal while all the parameters are resolved exactly.

Minimum norm inverse

The minimum norm (MN) solution of a strictly underdetermined problem is obtained through constrained minimization of the L2 norm of the unknown vector $\boldsymbol{x}$.

$$\left\{\begin{array}{c}\text{Minimize } \boldsymbol{x}^{\mathrm{T}}\boldsymbol{x}\\ \text{Subject to the constraint } \boldsymbol{b}-\boldsymbol{A}\boldsymbol{x}=\boldsymbol{0}\\ \text{Solution: } \boldsymbol{x}=\boldsymbol{A}^{\mathrm{T}}(\boldsymbol{A}\boldsymbol{A}^{\mathrm{T}})^{-1}\boldsymbol{b}\\ \text{Inverse: } \boldsymbol{A}^{\boldsymbol{g}}=\boldsymbol{A}^{\mathrm{T}}(\boldsymbol{A}\boldsymbol{A}^{\mathrm{T}})^{-1}\\ \text{Information density Matrix: } \boldsymbol{S}=\boldsymbol{A}\boldsymbol{A}^{\boldsymbol{g}}\\ =\boldsymbol{A}\boldsymbol{A}^{\mathrm{T}}(\boldsymbol{A}\boldsymbol{A}^{\mathrm{T}})^{-1}=\boldsymbol{I}_{\boldsymbol{m}}\\ \text{Parameter resolution matrix: } \boldsymbol{R}=\boldsymbol{A}^{\boldsymbol{g}}\boldsymbol{A}\\ =\boldsymbol{A}^{\mathrm{T}}(\boldsymbol{A}\boldsymbol{A}^{\mathrm{T}})^{-1}\boldsymbol{A}\neq\boldsymbol{I}_{\boldsymbol{n}}\end{array}\right\} \tag{7}$$

The expressions of matrices $\boldsymbol{S}$ and $\boldsymbol{R}$ suggest that the data quality is optimal while all the parameters are not resolved exactly and there exists linear dependence amongst some components of the parameter vector.

Damped least square inverse

The DLS solution of an overdetermined problem when rank $k<min(m,n)$ was concurrently developed by Marquardt, Phillips, Tikhanov, and Twomey. It is obtained by minimizing the two objective functions defining norms of error $\boldsymbol{e}$ and of unknown vector $\boldsymbol{x}$, subject to the constraint of $\boldsymbol{x}$ satisfying the matrix equation 5.

$$\left\{\begin{array}{c}\text{Minimize } \boldsymbol{e}^{T}\boldsymbol{e}=(\boldsymbol{b}-\boldsymbol{A}\boldsymbol{x})^{\mathrm{T}}(\boldsymbol{b}-\boldsymbol{A}\boldsymbol{x}) \text{ and } \boldsymbol{x}^{\mathrm{T}}\boldsymbol{x}\\ \text{Subject to the constraint } \boldsymbol{b}-\boldsymbol{A}\boldsymbol{x}=\boldsymbol{0}\\ \text{Solution: } \boldsymbol{x}=(\boldsymbol{A}^{\mathrm{T}}\boldsymbol{A}+\lambda^{2}\boldsymbol{I})^{-1}\boldsymbol{A}^{\mathrm{T}}\boldsymbol{b}\\ =\boldsymbol{A}^{\mathrm{T}}(\boldsymbol{A}\boldsymbol{A}^{\mathrm{T}}+\mu^{2}\boldsymbol{I})^{-1}\boldsymbol{b}\\ \text{Inverse: } \boldsymbol{A}^{\boldsymbol{g}}=(\boldsymbol{A}^{\mathrm{T}}\boldsymbol{A}+\lambda^{2}\boldsymbol{I})^{-1}\boldsymbol{A}^{\mathrm{T}}\\ \text{or} \boldsymbol{A}^{\mathrm{T}}(\boldsymbol{A}\boldsymbol{A}^{\mathrm{T}}+\mu^{2}\boldsymbol{I})^{-1}\\ \text{Information density matrix: } \boldsymbol{S}=\boldsymbol{A}\boldsymbol{A}^{\boldsymbol{g}}\neq\boldsymbol{I}_{\boldsymbol{m}}\\ \text{Parameter resolution matrix: } \boldsymbol{R}=\boldsymbol{A}^{g}\boldsymbol{A}\neq\boldsymbol{I}_{\boldsymbol{n}}\end{array}\right\} \tag{8}$$

Here, the parameter λ is a control parameter that represents relative weighting given to the two objective functions. The expressions of matrices $\boldsymbol{S}$ and $\boldsymbol{R}$ suggest that neither the data quality nor resolution of parameters is optimal.

Weighted damped least square inverse

To incorporate any available information about the error characteristics of data and/or about smoothness characteristics of parameter vector, the two objective functions optimized in case of DLS inverse, can be redefined in terms of weighting matrices $\boldsymbol{W}_{\boldsymbol{e}}$ and $\boldsymbol{W}_{\boldsymbol{m}}$. $\boldsymbol{W}_{\boldsymbol{e}}$ is the data error covariance matrix and $\boldsymbol{W}_{\boldsymbol{m}}$ is the matrix defining smoothness characteristics of the desired model. $\boldsymbol{W}_{\boldsymbol{m}}$ can be constructed from the low order differences of parameter vector components.

$$\left\{\begin{array}{c}\text{Minimize } \boldsymbol{e}^{\mathrm{T}}\boldsymbol{W}_{\boldsymbol{e}}=(\boldsymbol{b}-\boldsymbol{A}\boldsymbol{x})^{\mathrm{T}}\\ \boldsymbol{W}_{\boldsymbol{e}}(\boldsymbol{b}-\boldsymbol{A}\boldsymbol{x}) \text{ and } \boldsymbol{x}^{\mathrm{T}}\boldsymbol{W}_{\boldsymbol{m}}\boldsymbol{x}\\ \text{Subject to the constraint } \boldsymbol{b}-\boldsymbol{A}\boldsymbol{x}=\boldsymbol{0}\\ \text{Solution: } \boldsymbol{x}=(\boldsymbol{A}^{\mathrm{T}}\boldsymbol{W}_{\boldsymbol{e}}\boldsymbol{A}+\lambda^{2}\boldsymbol{W}_{\boldsymbol{m}})^{-1}\boldsymbol{A}^{\mathrm{T}}\boldsymbol{W}_{\boldsymbol{e}}\boldsymbol{b} \text{ or}\\ \boldsymbol{x}=\boldsymbol{W}_{\boldsymbol{m}}^{-1}\boldsymbol{A}^{\mathrm{T}}(\boldsymbol{A}\boldsymbol{W}_{\boldsymbol{m}}^{-1}\boldsymbol{A}^{\mathrm{T}}+\lambda^{2}\boldsymbol{W}_{\boldsymbol{e}}^{-1})^{-1}\boldsymbol{b}\\ \text{Inverse: } \boldsymbol{A}^{\boldsymbol{g}}=(\boldsymbol{A}^{\mathrm{T}}\boldsymbol{W}_{\boldsymbol{e}}\boldsymbol{A}+\lambda^{2}\boldsymbol{W}_{\boldsymbol{m}})^{-1}\boldsymbol{A}^{\mathrm{T}}\boldsymbol{W}_{\boldsymbol{e}} \text{ or}\\ \boldsymbol{A}^{g}=\boldsymbol{W}_{\boldsymbol{m}}^{-1}\boldsymbol{A}^{\mathrm{T}}(\boldsymbol{A}\boldsymbol{W}_{\boldsymbol{m}}^{-1}\boldsymbol{A}^{\mathrm{T}}+\lambda^{2}\boldsymbol{W}_{\boldsymbol{e}}^{-1})^{-1}\\ \text{Information density matrix : } \boldsymbol{S}=\boldsymbol{A}\boldsymbol{A}^{\boldsymbol{g}}\neq\boldsymbol{I}_{\boldsymbol{m}}\\ \text{Parameter resolution matrix : } \boldsymbol{R}=\boldsymbol{A}^{\boldsymbol{g}}\boldsymbol{A}\neq\boldsymbol{I}_{\boldsymbol{n}}\end{array}\right\} \tag{9}$$

All the above inverses can be considered as special cases of the generalized inverse defined by Rao and Mitra (1971) which is discussed next.

Rao–Mitra inverse

Rao and Mitra (1971) put forth a definition of generalized inverse, $\boldsymbol{A}^{\boldsymbol{g}}$, as any matrix that provides a solution of matrix equation 5 as

$$\boldsymbol{x}=\boldsymbol{A}^{\boldsymbol{g}}\boldsymbol{b}. \tag{10}$$

It is evident that this inverse satisfies the relation

$$\boldsymbol{A}\boldsymbol{A}^{\boldsymbol{g}}\boldsymbol{A}=\boldsymbol{A}. \tag{11}$$

This condition leads to two more properties

$\mathbf{A}\mathbf{A}^{\mathbf{g}}$ is idempotent,

$\mathbf{A}^{\mathbf{g}}\mathbf{A}$ is idempotent.

It may be mentioned that idempotent matrices are those for which any power of the matrix is equal to itself.

Rao and Bhimasankaram (1992) presented a suit of algorithms for evaluating the generalized inverse using Gaussian elimination like steps based on elementary row and column operations that reduce the coefficient matrix to a Hermite canonical form.

An earlier definition of generalized inverse, $\boldsymbol{A}^{+}$, given by Moore (1920) and rediscovered by Penrose (1955), was based on SVD of matrix $\boldsymbol{A}$. It satisfies the conditions

$$\left\{\begin{array}{l}\boldsymbol{A}\boldsymbol{A}^{+}\boldsymbol{A}=biA\\ \boldsymbol{A}^{+}\boldsymbol{A}\boldsymbol{A}^{+}=\boldsymbol{A}^{+}\\ \boldsymbol{A}\boldsymbol{A}^{+} \text{ is idempotent}\\ \boldsymbol{A}^{+}\boldsymbol{A} \text{ is idempotent}\end{array}\right\} \tag{12}$$

Moore–Penrose inverse (MPI) is always unique while Rao–Mitra inverse (RMI) is, in general, not. In fact, MPI is one member of the set of all possible RMIs. To elaborate this point, it may be stated that for a given SVD of matrix $\boldsymbol{A}$,

$$\boldsymbol{A}=\boldsymbol{U}\Lambda\boldsymbol{V}^{\mathrm{T}}. \tag{13}$$

Here $\boldsymbol{U}$ and $\boldsymbol{V}$ are the modal matrices of orders $m\times m$ and $n\times n$, respectively and Λ is an $m\times n$ matrix whose leading k diagonal elements correspond to the nonzero singular values and all other elements are zero.

The MPI is given by

$$\boldsymbol{A}^{+} = \boldsymbol{V}\Lambda^{+}\boldsymbol{U}^{\mathrm{T}} \tag{14}$$

Here Λ^{+} is the $n \times m$ matrix whose first k diagonal elements correspond to the inverse of nonzero singular values and all other elements are zero.

In contrast, the RMI is given by

$$\boldsymbol{A}^{\boldsymbol{g}} = \boldsymbol{V}\Lambda^{\boldsymbol{g}}\boldsymbol{U}^{\mathrm{T}}. \tag{15}$$

Here matrix $\Lambda^{\boldsymbol{g}}$ is an $n \times m$ matrix whose leading $k \times k$ submatrix block is diagonal with nonzero diagonal elements corresponding to the inverse of nonzero singular values and all the other submatrices are arbitrary. This freedom of having arbitrary elements outside the main $k \times k$ block leads to the nonuniqueness of MRI. This, in turn, leads to nonunique solutions of matrix Equation 5, which can be derived from a given solution, $\boldsymbol{x}^{(1)}$, of Equation 5 as

$$\boldsymbol{x} = \boldsymbol{x}^{(1)} + (\boldsymbol{A}^{\boldsymbol{g}}\boldsymbol{A} - \boldsymbol{I})\boldsymbol{\xi} \tag{16}$$

$\boldsymbol{\xi}$ being an arbitrary vector. One possible vector $\boldsymbol{x}^{(1)}$ can be $\boldsymbol{x}^{+}$ the solution obtained using MPI.

Backus–Gilbert method

Backus and Gilbert (1967, 1968, 1970) studied in detail the problem of synthesizing solutions to a linear inverse problem expressible as a Fredholm's equation of first kind like Equation 1. The main feature of this methodology is the possible detailed study of the trade-off between parameter resolution and error propagation. The Backus–Gilbert method (BGM) is briefly described here both for continuous and discrete cases.

Continuous inverse problem

The solution of Equation 1 can be represented as

$$f(x) = \int_{c}^{d} G(x,y)g(y)dy, \quad a < x < b \tag{17}$$

For Equations 1 and 17 to coexist, it is essential that the functions $K(x,y)$ and $G(x,y)$ satisfy the relations

$$\int_{a}^{b} G(x,y)K(x,y')dx = \delta(y - y'), \tag{18}$$

and

$$\int_{c}^{d} G(x,y)K(x',y)dy = \delta(x - x'). \tag{19}$$

The function $\delta(r-r')$ is the transcendental Dirac-delta function.

Backus and Gilbert brought into focus the infinitely undetermined nature of the real continuous linear inverse problems represented by Equation 1. They emphasized that from the finite observations, it would never be possible to exactly determine the infinite unknowns constituting the sought model property function $f(x)$. They circumvented the problem by seeking not the exact solution but its approximation as a linear superposition of the observed data values.

Let the finite observation set comprise m values $g_i = g(y_i)$ with $c \le y_1 \le y_2 \le \ldots \le y_{m-1} \le y_m \le d$. Further let the unknown function $f(x)$ need be estimated at the n argument values $a \le x_1 \le x_2 \le \ldots \le x_{n-1} \le x_n \le b$. Now Equations 1 and 17 can be rewritten as

$$g_i = g(y_i) = \int_{a}^{b} K_i(x)f(x)dx, \quad \forall 1 < i < m \tag{20}$$

and

$$f_j = f(x_j) = \int_{c}^{d} G_j(y)g(y)dy, \quad \forall 1 < j < n \tag{21}$$

where

$$K_i(x) = K(x, y_i) \text{ and } G_j(y) = G(x_j, y). \tag{22}$$

Backus and Gilbert sought an approximation of Equation 21 as

$$f_j \cong \hat{f}_j = f(x_j) = \sum_{1}^{m} c_i(x_j)g_i \tag{23}$$

Substituting for g_i from Equation 20, we get

$$\hat{f}_j = \sum_{1}^{m} c_i(x_j) \int_{a}^{b} K_i(x)f(x)dx$$

For K_i and f being square integrable, the order of integration and summation can be interchanged and the equation can be rewritten as

$$\hat{f}_j = \int_{a}^{b} \left[\sum_{1}^{m} c_i(x_j)K_i(x)\right] f(x)dx = \int_{a}^{b} A(x,x_j)f(x)dx \tag{24}$$

where

$$A(x,x_j) = \sum_{1}^{m} c_i(x_j)K_i(x), \tag{25}$$

is termed by Backus and Gilbert as averaging kernel and is also known in literature as resolving kernel or scanning function.

From Equation 24, it is evident that for f_j to be exactly estimated, the averaging kernel should be the Dirac-delta

function $\delta(x–x_j)$. This equality is, in general, not achievable. In order to make $A(x,x_j)$ as close to $\delta(x–x_j)$ as possible, the coefficients c_i's are chosen to satisfy a judiciously chosen δ-ness criterion. One such criterion can be

$$q_j = q(x_j) = \int_a^b J(x,x_j)\left[A(x,x_j) - D(x,x_j)\right]^2 dx. \quad (26)$$

Several pairs of functions J,D have been used by different workers. Backus and Gilbert used $J(x,x_j) = 12(x–x_j)^2$ and $D(x,x_j) = \delta(x–x_j)$. They interpreted q_j as the half-width or spread of the resolving kernel A. Hence, c_i's are so chosen that these minimize q_j subject to the condition that A is unimodular, that is,

$$\int_a^b A(x,x_j)dx = 1 \quad (27)$$

Expressing Equations 24, 26, and 27 in matrix form, we get

$$\left\{\begin{array}{l} \hat{f}_j = \mathbf{c^T g} \\ q_j = \mathbf{c^T M c} + \mathbf{a}^{\mathrm{T}}\mathbf{c} + b \\ \mathbf{u}^{\mathrm{T}}\mathbf{c} = 1 \end{array}\right\} \quad (28)$$

with

$$M_{ij} = \int_a^b K_i(x)K_j(x)dx$$

$$a_i = -2\int_a^b K_i(x)J(x,x_j)D(x,x_j)dx$$

$$b = \int_a^b D^2(x,x_j)dx$$

$$u_i = \int_a^b K_i(x)dx$$

Using Lagrange's method of undetermined multipliers, the solution of Equation 28 is found to be

$$\boldsymbol{c} = \frac{\boldsymbol{M}^{-1}\boldsymbol{u}}{\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}^{-1}\boldsymbol{u}} \quad (29)$$

Substituting these c-values in Equation 23, one gets the estimate of unknown physical property function f_j at argument value x_j. All values $f_1,f_2,\ldots,f_n$ are obtained by repeating the above steps for each $x_1,x_2,\ldots,x_n$.

The quality of solution can be evaluated by analyzing the characteristics of the averaging kernel $A(x,x_j)$, which ideally should be the Dirac-delta function. Hence, the deviation of the center of $A(x,x_j)$ from x_j and the finite range of x over which $A(x,x_j)$ is nonzero may be taken as pointers to the quality of estimation.

The discussion till now was confined to error-free data. However, if the data is erroneous and its error covariance matrix is $\boldsymbol{E}$, the procedure need to be modified to get a solution. In such cases, the superposition coefficient vector $\boldsymbol{c}$ is obtained by minimizing besides q_j given by Equation 26 and the error propagation measure e_j given by

$$e_j = \boldsymbol{c}^{\mathrm{T}}\boldsymbol{E}\boldsymbol{c} \quad (30)$$

The two objective functions are combined into one as

$$r_j = \boldsymbol{c}^{\mathrm{T}}\boldsymbol{N}\boldsymbol{c},$$

where

$$\boldsymbol{N} = \lambda\boldsymbol{M} + (1-\lambda)\boldsymbol{E}, 0 \le \lambda \le 1. \quad (31)$$

The procedure described above can be followed after replacing matrix $\boldsymbol{M}$ by $\boldsymbol{N}$ and the resulting estimate of coefficient vector will then be

$$\boldsymbol{c} = \frac{\boldsymbol{N}^{-1}\boldsymbol{u}}{\boldsymbol{u}^{\mathrm{T}}\boldsymbol{N}^{-1}\boldsymbol{u}}. \quad (32)$$

Equations 20 and 21 make it obvious that for $\lambda = 1$, spread gets minimized but error propagation is uncontrolled while for $\lambda = 0$, the spread is unlimited and error propagation is minimized.

Discrete inverse problem

The implementation of BGM for the discrete case represented by Equation 5 was given by Gupta (1998) where it is shown that, for error-free case, if the unimodularity constraint is not applied the BG estimate is same as the minimum norm estimate. However, when this constraint is applied the BG estimate has an additional correction term.

The solution of matrix equation 5 is synthesized as

$$\boldsymbol{x} = \boldsymbol{A^g b}. \quad (33)$$

To synthesize $\boldsymbol{A^g}$ some norm of $(\boldsymbol{A^g A – I})$ is minimized. In particular, for L2 norm, we can minimize

$$\boldsymbol{u}^{\mathrm{T}}(\{\boldsymbol{A^g A} - \boldsymbol{I})(\boldsymbol{A}^{\mathrm{T}}\boldsymbol{A^{g^{\mathrm{T}}}} - \boldsymbol{I})\boldsymbol{u}.$$

Here $\boldsymbol{u}^{\mathrm{T}} = \mathbf{(1\ 1\ \ldots\ 1)}$. Minimization yields

$$\boldsymbol{A^g} = \boldsymbol{A}^{\mathrm{T}}(\boldsymbol{A}\boldsymbol{A}^{\mathrm{T}})^{-1}. \quad (34)$$

This will lead to the minimum norm solution $\boldsymbol{x_{min}}$.

When the unimodularity condition, asking for each row vector of the resolution matrix $\boldsymbol{R = A^g A = A^T(AA^T)A}$ to be of unit length, is imposed as constraint, the solution $\boldsymbol{x_{BG}}$ is found to be given as

$$\boldsymbol{x_{BG}} = \boldsymbol{x_{min}} + \frac{\boldsymbol{u} - \mathbf{Ru}}{\boldsymbol{u}^{\mathrm{T}}\mathbf{Ru}}(\boldsymbol{u}^{\mathrm{T}}\boldsymbol{m_{min}}) \quad (35)$$

Trade-off between resolution and error propagation

In Backus–Gilbert (BG) method Equation 31 demonstrates the trade-off between the two objective functions. For different values of λ one gets different solutions. Hence, it is expected that some value of λ will provide optimal trade-off solution. BG demonstrated in their paper of 1970 that when the values of objective functions q_j and r_j for each λ are plotted against each other, one gets an L-shaped curve. This curve reveals that for large value of λ, error propagation is uncontrolled and the spread is optimized while for small value of λ, error propagation is optimized and the spread is uncontrolled. The tip of the L-curve provides the optimal value of λ.

In case of DLS method, the same exercise can be carried out to obtain the optimal value of λ. Lot of research has been put in to devise the strategies to find optimal λ values. Most of these works analyze the dependence of solution on λ through eigenanalysis. For details, one can refer Calvetti et al. (2000), Hansen (1992), Reichel and Sadok (2008), and Rezghi and Hosseini (2009).

Summary

This article presents salient aspects of linear inverse problems. The LS formulations and the Backus–Gilbert formulation are discussed in brief. The information density and parameter resolution matrices and their importance are discussed. Finally, the methods for finding the optimal multi-objective optimization parameter λ are briefly mentioned. For more details on SVD one can refer to the article by A. Manglik, while for global optimization techniques for nonlinear inverse problems one can refer to the articles by M. K. Sen and by W. Sandham published in this series.

Definition

Monte Carlo method. A computational technique making use of random numbers to solve problems that are either probabilistic or deterministic in nature. Named after the famous Casino in Monaco.
Monte Carlo inversion method. A method for sampling a parameter space of variables representing unknowns, governed by probabilistic rules.
Markov chain Monte Carlo (McMC). A probabilistic method for generating vectors or parameter variables whose values follow a prescribed density function.

Introduction

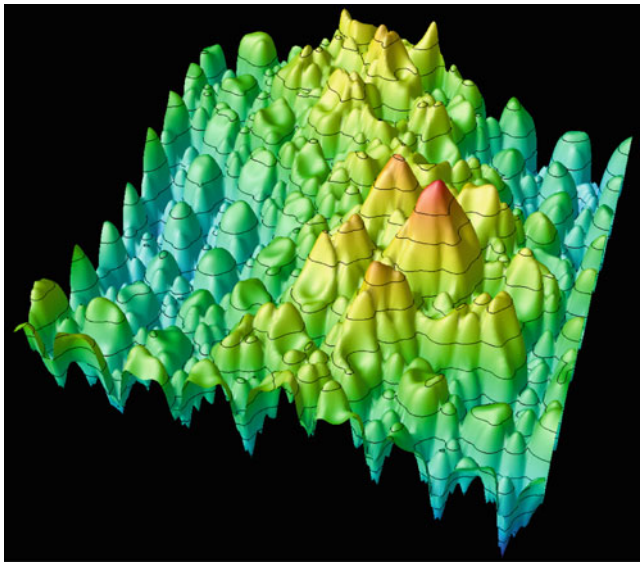
Because geophysical observations are made at (or very near) the Earth's surface, all knowledge of the Earth's interior is based on indirect inference. There always exists an inverse problem where models of physical properties are sought at depth that are only indirectly constrained by the available observations made at the surface. Geophysicists have been dealing with such problems for many years, and in doing so have made substantial contributions to the understanding of inverse problems.

Pioneering work on linear inverse problems in the 1960s arose out of the need to understand how to use new surface observables from seismology to constrain radial variations in geophysical properties at depth within the Earth. Data were few in number and attention was focused on the mathematical structure of the inverse problem and the ways in which reliable information could be recovered. This resulted in a series of important papers beginning with Backus and Gilbert (1967, 1968, 1970). Since that time the geosciences, like many other fields, have moved into a data-rich environment with increasing availability of computational power. Considerable progress has been made over 30 years utilizing the class of linear (typically least squares) parameter estimation algorithms, which are common to many areas of the physical sciences (Aster et al., 2005). In many of the inverse problems encountered the dependence of data on models is nonlinear and this must be taken into account for meaningful solutions. Often this is achieved by performing a local linearization and using *Inverse Theory, Linear*. As the mathematical relationship between data and unknowns becomes complex then linearized methods fail because they depend heavily on having a starting model for the iterative process which must be close enough to the solution for convergence.

Over the last 30 years there has been considerable progress in the solution of highly nonlinear inverse problems involving a limited number of parameters so that thorough exploration can be made of the character of models. Many algorithms have been devised, most of which make use of random numbers to make decisions, that is, in how to generate a set of values of the unknowns whose predictions can be compared to the available data. The original description of Monte Carlo methods by Hammersley and Handscomb (1964) is "the branch of experimental mathematics which is concerned with experiments on random numbers." By this definition all inversion techniques that make use of random numbers are Monte Carlo methods. Many of the *Inverse Theory, Global Optimization* inversion methods fall within the class. The particular approach known as Markov chain Monte Carlo is the primary focus of the present article.

Nonlinearity and multimodal fitness functions

Figure 1 shows a fitness surface from an inverse problem that arises in the analysis of infrasound array data. (Infrasound arrays are used by the United Nations Comprehensive Test Band Treaty Organization to monitor international adherence to the nuclear test ban treaty.) The height of the surface represents the degree of



Inverse Theory, Monte Carlo Method, Figure 1 A multimodal data fit surface arising from the mismatch between two oscillatory fields in the infrasound inversion problem (Kennett et al., 2003).

agreement between two oscillatory fields. There are just two unknowns in this case, which represent tuning parameters in the infrasound array. The object of the exercise is to best tune the array for sensitivity to incoming atmospheric signals, which means finding the point on the surface where the fitness is maximum. We see a curved rim of local maxima from background to foreground, with a broader valley of low fit to the left of the central maximum (red). The physics of the forward problem, that is, calculating the oscillatory field corresponding to a pair of tuning parameters, as well as the nature of the data itself result in a complicated 2-D fitness function.

The set of unknowns that gives the best fit (i.e., smallest misfit) to data corresponds to the global maximum of the multimodal function and to find it one must employ *Inverse Theory, Global Optimization* techniques such as model space search. In this example the global maximum (at the red central peak) was efficiently found with the neighborhood algorithm of Sambridge (1999), which utilizes ideas from the field of computational geometry. Optimization techniques based on local *Inverse Theory, Linear* would only be suitable once a trial solution is found within the vicinity of the global peak (shaded red). Adaptive Monte Carlo-based direct search approaches like genetic algorithms, simulated annealing, and the neighborhood algorithm (see *Inverse Theory, Global Optimization*) are able to solve this (two unknown parameters) problem relatively easily due to their ability to detect the variation of the fit and concentrate sampling where there is most benefit.

This example demonstrates the complexity of inverse problems in cases where the data are highly oscillatory waveforms, a common situation in fields such as acoustics and seismology, where the dimension of the problem is often much higher.

For the 2-D example in Figure 1, the objective is to tune a particular instrument for maximum sensitivity, and it is appropriate to seek a global maximum. More generally in inverse problems the fitness landscape would represent the difference between observations and predictions made by a mathematical model. In this case simply finding the best-fit solution is inadequate. One needs to characterize the uncertainty in the solution, for example, assess how noise in the data lead to errors and trade-offs in the estimated model. Linearized techniques (see *Inverse Theory, Linear*) could be used, but all uncertainty estimates are then based on the assumption of local linearity and do not truly reflect the global nature of the data constraint.

Another issue that often arises in inverse problems is that of nonuniqueness (see *Inverse Theory, Singular Value Decomposition*). In this case it is not possible to fully constrain the unknowns from the data. The model is unbounded and so best data fit solutions do not exist, and extra assumptions or independent information must be introduced to achieve a single optimal solution. In linearized inversion some form of regularization is used. An example is damping a solution back to some reference set of values (or model) (Aster et al., 2005). It is well known that in this case the details of the solution depend on the nature of regularization used. In addition, uncertainty estimates produced by linearized theory often reflect the choice of regularization. Typically, the least well-constrained components of the solution require the most regularization and resulting uncertainty estimates are severe underestimates of the real errors (Aster et al., 2005 for an example) potential leading to overconfidence in the results.

Bayesian inference

An alternative approach to inversion is Bayesian inference. Many textbooks and review papers are available. Discussions within a geophysical context can be found in Tarantola and Valette (1982), Duijndam (1988a, b), Sambridge and Mosegaard (2002), and Mosegaard and Sambridge (2002). In Bayesian inference, all information on the unknowns is represented in terms of probability density functions (PDF). Within this framework it is accepted that all inference is relative. What one learns from the data gets added to what is known prior to collecting the data and represented in terms of an a posteriori PDF. The most commonly used form of Bayes' rule is given below

$$p(m|d) = kp(d|m)p(m) \tag{1}$$

where $p(m|d)$ is the PDF of the model vector, m, containing the unknowns, given the data vector, d, containing the data; $p(d|m)$ is the likelihood function measuring the probability of the data, d, being observed given the model m; $p(m)$ is the a priori PDF on the model (which is known or assumed about m before the data are

collected), and k is a constant of proportionality. In a Bayesian framework, all information on the unknown variables in the model is represented by the posterior PDF, $p(m|d)$ and one usually sets about trying to generate an ensemble of candidate solutions to the inverse problem whose density is distributed according to this function. This is termed sampling the posterior PDF.

The posterior PDF is the product of the likelihood and the prior PDF. Only the former contains the data vector, d. The likelihood increases as the model fits the data better relative to the noise in the data. The form of the likelihood depends on the statistical character of the data errors. A simple example is a multidimensional Gaussian function characterized by a mean and a covariance matrix, both of which are usually known or assumed. The prior PDF represents information known about the model before collecting the data represented in a probabilistic manner, and may take a variety of forms. Again a multidimensional Gaussian is the most simple, but rarely is real information in this convenient form. Prior PDFs can be the most controversial component of Bayesian inference as there is always a degree of subjectivity in any choice, and the only way to represent no prior information is to not have a prior PDF. Comparisons of Bayesian and alternate approaches can be found in Malinverno and Parker (2005).

We see then that instead of seeking a single optimal solution, in a Bayesian framework many samples are sought. Assessment of the constraints placed on the model is achieved by examining collective properties. Typically, this is done by plotting the distribution of samples as a function of one or more subsets of unknowns, calculating credible intervals to represent uncertainty and covariance matrices to examine the trade-offs between parameters.

The main task to be carried out is then to generate random samples that follow the multidimensional posterior PDF $p(m|d)$arising from the inverse problem. McMC methods are practical tools for dealing with complicated probability distributions. Used correctly they result in (quasi)-independent samples whose density follows any target PDF. They have been the subject of much research in fields from Theoretical Physics to Computational statistics. For summaries, see Smith (1991), Smith and Roberts (1993), and Bernardo and Smith (1994). Below we describe the McMC method briefly and provide a simple illustrative example.

Markov chain Monte Carlo

Fixed dimension approach

McMC can be regarded as a combination of random Monte Carlo sampling and a Markov chain random walk strategy around the model space. The aim is to produce an ensemble of models from a probability distribution, that is, the posterior PDF, using only function evaluations. The basic approach was developed from the work of Metropolis et al. (1953), placed in a Bayesian framework by Hastings (1970), and a useful overview is given in Gilks et al. (1996). The practical applications lagged behind theoretical developments as a consequence of the need for many simulations. However, the increase in computing power over the last 15 years or so has led to a rapid increase in use of this methodology in geophysics and other fields of Earth Sciences (e.g., Mosegaard and Tarantola, 1995; Malinverno, 2002; Sambridge et al., 2006; Gallagher et al., 2009).

The algorithm is as follows: first we choose an initial model from the prior distribution, and calculate its likelihood. Then we generate a new model by making a random perturbation (Monte Carlo) to the current model. This new model is known as the proposed model and depends only on the values of the current model (Markov chain). The final stage is to decide whether we replace the current model with the proposed model, or stay at the current model and repeat the whole process. This important step is determined from the acceptance criterion, which is defined below

$$\alpha = \min\left\{1, \frac{p(m')p(d|m')q(m|m')}{p(m)p(d|m)q(m'|m)}\right\} \tag{2}$$

where m' and m are the proposed and current models, respectively, $q(a|b)$ is the probability of proposing model a, given a current model b, and the other distributions are as defined earlier. The decision to accept or reject a proposed model is made by comparing the value of α (which is always between 0 and 1) to a uniform (between 0 and 1) random number, u. If $u < \alpha$ then we replace the current model with the proposed model, if not we discard the proposed model and stay at the current model. We then continue the sampling process (perturb the new current model and so on) for many iterations.

The choice of the proposal function is not critical to the correctness of the sampler, but does affect the efficiency, performance, and convergence. A typical choice might be a normal distribution, centered on the current model, and then we need to tune the performance through the scale parameter of this distribution (e.g., the variance). If we choose too small a scale parameter, the proposed model will be very similar to the current model, their likelihoods will be similar, and we will almost always accept the proposed model. If we choose too large a scale parameter, the proposed model will tend to be very different to the current model, and lead to large changes in the likelihood, which are more likely to be rejected. In practice, both situations mean that we tend to move slowly around the model space. The proposal functions need then to be tuned for particular problems to achieve a reasonable balance between accepting and rejecting the proposed models. A reasonable rate of acceptance is around 30–40%. Generally, we can choose proposal functions that are symmetrical, so that $q(a|b) = q(b|a)$, so these terms cancel out in the acceptance criterion. Also, if we choose uniform prior distributions, then the prior terms also cancel. The acceptance criterion then reduces to the original Metropolis et al. (1953) algorithm.

After an initial period sampling (known as the burn-in), the current model from each iteration is taken as representing a sample from the posterior distribution (the sampling chain is then stationary). If the model space has N dimensions, and we are interested in the distribution on one of the parameters, m_i, for example, then formally we need to solve the following integral

$$p(m_i) = \int p(m_i, m_j) dm_j; \quad j = 1, .., i-1, i+1, ..., N \tag{3}$$

that is we need to integrate out the variation in all parameters except m_i. This is known as marginalizing and $p(m_i)$is the marginal probability distribution of m_i. Using the McMC samples, we can just plot all value of m_i as a histogram as the sampling effectively deals with the integration.

Also, it is straightforward to calculate estimates of the expected (or average) value for any parameter. Formally, we have the expected value for parameter m_i defined as

$$E(m_i) = \int p(m_i) m_i dm_i \tag{4}$$

Using the McMC samples, we simply average over all the samples accepted for that parameter, that is,

$$E(m_i) = \frac{1}{N_a} \sum_{j=1}^{N_a} m_i^j \tag{5}$$

where N_a is the number of samples accepted (post-burn-in) for model parameter m_i

Transdimensional approach

A major issue concerning most inverse problems, and the approaches used to solve them, is how best to balance the twin desires of fitting the observations and avoiding introduction of unjustified complexity in the resulting models. Green (1995) introduced a transdimensional form of McMC (referred to as Reversible Jump), in which the inversion procedure involves the inference of the model complexity (see also birth–death McMC Geyer and Møller, 1994). For finite dimension models (with a fixed number of unknowns) this then typically becomes a question of determining the dimension of the model. If we are dealing with two models with dimensions k and k', then acceptance criterion can be written as

$$\alpha = \min\left\{1, \frac{p(\mathrm{k}')p(m'|\mathrm{k}')p(d|m', \mathrm{k}')q(m|m')}{p(\mathrm{k})p(m|\mathrm{k})p(d|m, \mathrm{k})q(m'|m)}\right\} \tag{6}$$

Here we separate the prior on the number of dimension, $p(k)$, from the model parameter prior, $p(m|k)$. The proposal function $q()$ becomes more complex as we now want to propose models with different dimensions. Moreover, we need to allow for the transformation from one model to another to ensure that theoretical probability requirements are maintained. In dealing with a situation where we are simply increasing or decreasing the number of parameters, we can write

$$\alpha = \min\left\{1, \frac{p(\mathrm{k}')p(m'|\mathrm{k}')p(d|m', \mathrm{k}')g(u^{\mathrm{k}'})}{p(\mathrm{k})p(m|\mathrm{k})p(d|m, \mathrm{k})g(u^{\mathrm{k}})} |\mathrm{J}|\right\} \tag{7}$$

Here $u^{k'}$ and u^k are vectors of random numbers of length r' and r, respectively, and used to transform from one model to another, such that $r+k = r'+k'$, and $g(.)$ is the probability distribution used to generate these random numbers. The term $|J|$ is the Jacobian, and allows for the transformation between the two models, that is,

$$|\mathrm{J}| = \frac{\partial(m', u^{\mathrm{k}'})}{\partial(m, u^{\mathrm{k}})} \tag{8}$$

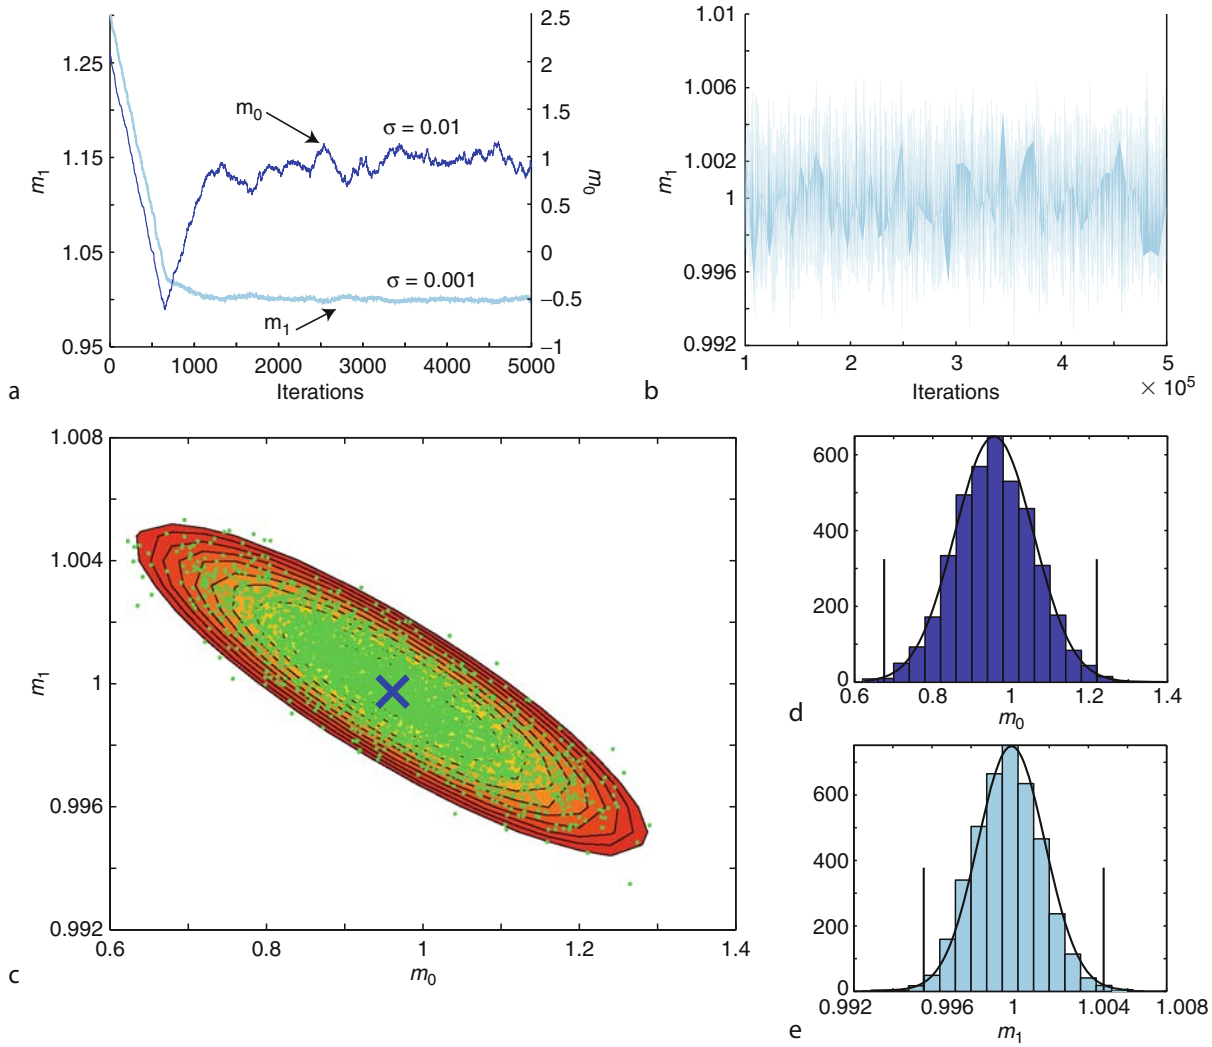
The last equation for α is actually a general form for the acceptance criterion, although for fixed-dimensional problems the Jacobian is generally 1, and the proposal functions are of the form as described earlier. The details of the reversible jump acceptance criterion are discussed in more detail by Green (2003), Malinverno (2002), and Sambridge et al. (2006) and examples of the implementation algorithms for variable dimension problems are given in Jasra et al. (2006), Bodin and Sambridge (2009), Charvin et al. (2009), and Hopcroft et al. (2009). One important characteristic of the Bayesian transdimensional formulation is that it is naturally parsimonious. For two models that fit the data equally well, it will tend to favor simpler models over complex ones as a consequence of the posterior probability effectively being penalized through the addition of more terms to the prior distribution.

A simple example

To demonstrate McMC in action, we choose a simple two parameter linear regression problem, that is,

$$y_i = m_0 + m_1 x_i + \varepsilon_i, i = 1, ..., N \tag{9}$$

where m_0 and m_1 are the model parameters, y is an observed/measured value, and ε is the data error. In a Bayesian formulation, this problem has an analytical solution for a uniform prior on the model parameters, assuming the data error is known (Lee, 1989, p. 180). We chose $m_0 = m_1 = 1$ and generated 100 synthetic data (y) for random values of x between 0 and 100, and added noise ($\varepsilon = 0.5$). We used Gaussian proposal distributions, with different scale parameters ($\sigma_{m_0} = 0.01$, and $\sigma_{m_1} = 0.001$). In Figure 2 we show the sampling for the two parameters, starting from a randomly selected model. Figure 2a shows that the sampler has not reached the stationary state until at least 1,500–2,000 iterations. Figure 2b shows the sampling for parameter m_1 for later iterations which is clearly stationary. The sampling resembles a white noise spectrum about the mean (or expected) value, lacking any internal structure as a function of



Inverse Theory, Monte Carlo Method, Figure 2 (**a**) Intitial 5,000 iterations for sampling of two parameters for the linear regression problem. (**b**) Post-burn-in iterations for parameter m_1. (**c**) The *green points* show the post-burn-in sampling, and the contours are the log likelihood function. The *blue cross* is the best solution (equivalent to the analytical maximum likelihood or least squares solution). (**d**) Marginal distribution for parameter m_0. The histogram is constructed from the post-burn-in accepted samples, and the curve is the analytical solution for the marginal distribution. The two vertical bars mark the upper and lower bounds on the 95% credible interval. (**e**) As (**d**) but for parameter m_1.

iteration. It is also clear that the sampler manages to move toward the upper and lower extreme values of the parameter range (determined by the posterior PDF and the proposal function scale parameter). These are diagnostic (but qualitative) characteristics of stationarity.

Figure 2c shows the 2-D distribution of samples of the post-burn-in accepted samples (here we thinned the chain taking every 100th sample), compared to the log likelihood function (which is proportional to the log of the posterior distribution as we use uniform priors). The density of the sampling increases around the high likelihood values, but there are still some samples from the lower likelihood regions. Figure 2d and e shows the marginal distributions for the two parameters as a frequency histogram, and also the analytical solutions (scaled to the same peak height). These are constructed simply by taking all the accepted values for a given model parameter, as the sampler effectively integrates out the other parameters. Also shown are the 95% credible interval ranges for each parameter. These are constructed by sorting all the samples for a given parameter in ascending order, and finding the indices for the credible values such that 2.5% of the samples are less than the lower credible value, and 2.5% of the values are greater than the upper credible value. Again, we can see that the sampler has managed to distribute itself across the distribution according to the posterior probability and these histograms are good representations of the marginal distributions.

Summary

Monte Carlo sampling, relying on random numbers, has been used in Geophysics for over 40 years, although the increase in computing power has seen a commensurate increase in applications in the last 15 years or so. This approach avoids the use of gradients, is robust to local minima, and so is suitable for nonlinear inverse problems which often have complex misfit (or fitness) surfaces in high dimensions. McMC, particularly when used in a Bayesian formulation, provides a means of sampling a model space according to the (unknown) posterior distribution for the model parameters. Transdimensional (or reversible jump) Markov chain Monte Carlo generalizes this approach to allow models of different dimensions to be considered, and provides a means of choosing between models of differing complexity. Quantifying the posterior distribution with McMC is then a solution to the inverse problem and various types of inference can be made from this distribution (e.g., expected values, marginal distributions, credible intervals) to characterize the model space.

Definition

Condition number. Ratio of the largest singular value to the smallest singular value of a matrix. For a singular matrix it is infinite and it is very large for an ill-conditioned matrix.

Description

Linear geophysical inverse theory (*Inverse Theory, Linear*) deals with solving a system of linear equations, represented in matrix form as

$$\mathbf{A}\mathbf{x} = \mathbf{b}, \tag{1}$$

where $\mathbf{A}$ is a $m \times n$ Jacobean matrix, $\mathbf{x}$ a $n \times 1$column vector of perturbations in unknown model parameters with respect to a reference model, and $\mathbf{b}$ the corresponding $m \times 1$ column vector of perturbations in observed responses. For a full rank square matrix ($m = n = p$: the rank of matrix $\mathbf{A}$), it is easy to find a unique inverse $\mathbf{A}^{-1}$ and estimate the model parameters as $\mathbf{x} = \mathbf{A}^{-1}\mathbf{b}$. However, geophysical inverse problems mostly deal with inversion of rectangular matrix $\mathbf{A}$ wherein m is either greater than n (over-determined system representing more number of observations than the unknown parameters, also known as least squares solution) or less than n (under-determined system representing less number of observations compared to the unknown parameters, also called minimum norm solution). For many geophysical problems the rank p of the matrix is less than m and n. In such situations, linear geophysical inverse theory aims at finding out a pseudo-inverse $\mathbf{A}^{-}$of $\mathbf{A}$ such that

$$\hat{\mathbf{x}} = \mathbf{A}^{-}\mathbf{b}, \tag{2}$$

where $\hat{\mathbf{x}}$ represents the column vector of the estimated model parameters. Moore (1920) and Penrose (1955), using a spectral decomposition form of matrix $\mathbf{A}$, showed that there exists a unique pseudo-inverse $\mathbf{A}^{-}$ of the matrix $\mathbf{A}$ such that (1) $\mathbf{A}\mathbf{A}^{-}\mathbf{A} = \mathbf{A}$, (2) $\mathbf{A}^{-}\mathbf{A}\mathbf{A}^{-} = \mathbf{A}^{-}$, (3) $(\mathbf{A}\mathbf{A}^{-})^{T} = \mathbf{A}\mathbf{A}^{-}$, and (4) $(\mathbf{A}^{-}\mathbf{A})^{T} = \mathbf{A}^{-}\mathbf{A}$, where superscript Tdenotes the transpose of matrix. Further details can be found in Inverse theory, linear.

Singular Value Decomposition (SVD) is a powerful tool to invert matrices that are either singular or numerically very close to singular (ill-conditioned system). Standard matrix equation solvers can fail in such situations. The advantage of SVD is that one need not a priori know the nature of the problem, that is, whether it is over determined, under determined, or partially determined. SVD is very general in the sense that it can be applied to any arbitrary size matrix. The technique was discovered independently by Beltrami in 1873 and by Jordan in 1874 as a tool to solve square matrices and was extended to rectangular matrices by Eckart and Young in the 1930s (Stewart, 1993). Its use as a computational tool dates back to the 1960s (Golub and Kahan, 1965; Golub and Reinsch, 1970). Golub and van Loan (1996) demonstrated its usefulness and feasibility in a wide variety of applications.

Following SVD, a matrix $\mathbf{A}$ of size $m \times n$ is factorized in the form

$$\mathbf{A} = \mathbf{U}\mathbf{\Lambda}\mathbf{V}^{T}, \tag{3}$$

where $\mathbf{U}$ is a $m \times m$ unitary matrix, $\mathbf{\Lambda}$ is a $m \times n$ diagonal matrix, and $\mathbf{V}$ is a $n \times n$ unitary matrix. The columns of $\mathbf{V}$ form a set of orthonormal vectors called parameter eigenvectors and the columns of $\mathbf{U}$ form a set of orthonormal basis vectors called data eigenvectors. For a special case of $m = n$, the matrix $\mathbf{\Lambda}$ has the form

$$\mathbf{\Lambda} = \begin{bmatrix} \sigma_1 & 0 & \cdots & 0 \\ 0 & \sigma_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \sigma_n \end{bmatrix}, \tag{4}$$

where $\sigma_1, \cdots, \sigma_n$ are called the singular values of matrix $\mathbf{A}$. The number of nonzero singular values is equal to the rank of $\mathbf{A}$. In the SVD representation, the singular values are arranged in the order of decreasing amplitude, that is,

$$\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_n. \tag{5}$$

For a real matrix, the columns of matrices $\mathbf{U}$ and $\mathbf{V}$ are orthogonal, that is, $\mathbf{U}^{T}\mathbf{U} = \mathbf{I}$ and $\mathbf{V}^{T}\mathbf{V} = \mathbf{I}$, where $\mathbf{I}$ is the identity matrix and $T$is transpose of matrix. For complex matrices transpose is replaced by complex conjugate.

Inverse of A

The expression for the inverse of $\mathbf{A}$ can be obtained by first substituting Equation 3 into Equation 1 to get

$$\mathbf{U}\mathbf{\Lambda}\mathbf{V}^{T}\mathbf{x} = \mathbf{b}. \tag{6}$$

and then applying the following orthogonal transformation

$$\mathbf{b} = \mathbf{U}\mathbf{b}'; \qquad \mathbf{x} = \mathbf{V}\mathbf{x}', \tag{7}$$

and multiplying Equation 6 by $\mathbf{U}^{T}$, which gives

$$\mathbf{\Lambda}\mathbf{x}' = \mathbf{b}'. \tag{8}$$

Since $\mathbf{\Lambda}$ is a diagonal matrix, we can easily get

$$\mathbf{x}' = \mathbf{\Lambda}^{-1}\mathbf{b}'. \tag{9}$$

From Equation 7 and Equation 9, and orthogonality property of data and parameter eigenvectors, we get

$$\mathbf{x} = \mathbf{V}\boldsymbol{\Lambda}^{-1}\mathbf{U}^T\mathbf{b}, \tag{10}$$

or the inverse of $\mathbf{A}$ can be written as

$$\mathbf{A}^{-1} = \mathbf{V}\boldsymbol{\Lambda}^{-1}\mathbf{U}^T. \tag{11}$$

Rank-deficient matrix and its inverse

The advantages of above spectral decomposition can be seen in the case of $\mathbf{A}$ being a singular matrix. Let us assume that only p of n singular values of $\mathbf{A}$ are nonzero. In this case, the data and parameter eigenvectors can be split into two sub-spaces representing nonzero eigenspace and null-space, respectively, that is,

$$\begin{aligned} &\boldsymbol{\Lambda} = \begin{bmatrix} \boldsymbol{\Lambda}_p & 0 \\ 0 & 0 \end{bmatrix}; \qquad \mathbf{U} = \left[\mathbf{U}_p, \mathbf{U}_0\right]; \\ &V = \left[V_p, V_0\right], \end{aligned} \tag{12}$$

then

$$\mathbf{A} = \left[\mathbf{U}_p, \mathbf{U}_0\right] \begin{bmatrix} \boldsymbol{\Lambda}_p & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} \mathbf{V}_p \\ \mathbf{V}_0 \end{bmatrix}^T, \tag{13}$$

which gives

$$\mathbf{A} = \mathbf{U}_p\boldsymbol{\Lambda}_p\mathbf{V}_p^T. \tag{14}$$

This indicates that matrix $\mathbf{A}$ can be reconstructed only from nonzero singular values and corresponding vector spaces. An inverse of a rank-deficient matrix can be written as:

$$\mathbf{A}^- = \mathbf{V}_p\boldsymbol{\Lambda}_p^{-1}\mathbf{U}_p^T, \tag{15}$$

by substituting Equation 12 into Equation 11.

Ill-condition matrix

Equation 15 assumes that the singular values of the system are either zero or positive scalars. If some of the singular values are very small then it is easy to see that the inverse of such values can be very large and, in the case of error in data, can lead to unstable solutions. Stability of the matrix inverse can be defined in terms of ratio of largest to smallest singular value, also called the condition number

$$\eta = \frac{\sigma_1}{\sigma_{\min}}. \tag{16}$$

The matrix is ill-conditioned if the condition number is very large. In such situations, the system can be stabilized by specifying a cutoff threshold η_0 for the condition number and ignoring all singular values that lead to the condition number larger than this threshold. Let there be p nonzero singular values arranged in decreasing order of their amplitudes of which only the first q singular values have the condition number smaller than η_0. Then $(q+1, \cdots, p)$ singular values can be reset to zero thus reducing the rank of the matrix to q. This can be understood as ignoring finer details of the parameter space, which are associated with small singular values. Geophysical inverse problems normally fall under this category.

For least square inverse problems, where an inverse of $\mathbf{A}$ is given by the expression

$$\mathbf{A}^- = \left(\mathbf{A}^T\mathbf{A}\right)^{-1}\mathbf{A}^T, \tag{17}$$

Marquardt (1963) suggested that an ill-conditioned matrix $\mathbf{A}^T\mathbf{A}$ may be stabilized by adding an arbitrary damping factor λ to its diagonal elements, that is,

$$\mathbf{A}^- = \left(\mathbf{A}^T\mathbf{A} + \lambda^2\mathbf{I}\right)^{-1}\mathbf{A}^T. \tag{18}$$

In terms of singular value decomposition, it amounts to boosting the small singular values of the matrix $\mathbf{A}^T\mathbf{A}$. This can be shown by expressing Equation 18 in terms of singular values decomposition of the matrix $\mathbf{A}$, which gives

$$\mathbf{A}^- = \mathbf{V}\mathrm{diag}\left(\frac{\sigma}{\sigma^2 + \lambda^2}\right)\mathbf{U}^T, \tag{19}$$

where diag(...) represents the elements of a diagonal matrix. Here, it can be seen that adding λ to small singular values stabilizes the inverse.

Sensitivity to errors in data

Field observations normally contain noise superimposed on the actual response. If we assume a noise vector $\boldsymbol{\varepsilon}$ then we observe $\mathbf{b} + \boldsymbol{\varepsilon}$ instead of $\mathbf{b}$. This leads to an error $\delta\mathbf{x}$ in the estimated model parameters. Therefore, for noisy data Equation 1 may be written as:

$$\mathbf{A}(\mathbf{x} + \delta\mathbf{x}) = \mathbf{b} + \boldsymbol{\varepsilon}. \tag{20}$$

Substituting from Equation 1, we get

$$\mathbf{A}\delta\mathbf{x} = \boldsymbol{\varepsilon}. \tag{21}$$

Expressing matrix $\mathbf{A}$ in spectral form and applying orthogonal transformation $\delta\mathbf{x}' = \mathbf{V}\delta\mathbf{x}$ and $\boldsymbol{\varepsilon}' = \mathbf{U}\boldsymbol{\varepsilon}$, Equation 21 gives

$$\delta\mathbf{x}' = \boldsymbol{\Lambda}^{-1}\boldsymbol{\varepsilon}. \tag{22}$$

This shows that in the case of small singular values small error in data yields large error in estimated model parameters. This problem of instability of estimated model parameters can be overcome by either truncating the small singular values or boosting these by adding a Marquardt damping factor, as discussed in the previous section. Such treatment nevertheless results in loss of finer details of the model parameters.

Resolution matrices

In linear inverse theory, the concepts of parameter resolution and data information density analyses are used to analyze the resolution of estimated model parameters and the

regions of data contributing maximum to these model estimates. These resolution matrices can be expressed in terms of data and parameter eigenvectors. Parameter resolution matrix for a rank-deficient system can be obtained by substituting Equations 1, 14, and 15 into Equation 2, which gives

$$\Re = \mathbf{V}_p \mathbf{V}_p^T. \tag{23}$$

For a well-resolved system $\Re$ is an identity matrix $\mathbf{I}$. For a rank-deficient system this matrix provides information about the equivalence of various model parameters.

Similarly, data information density matrix can be written as

$$\Im = \mathbf{U}_p \mathbf{U}_p^T, \tag{24}$$

by substituting Equations 2, 14, and 15 into Equation 1.

Jupp and Vozoff (1975) provided an elegant description of the concepts of stability of solution and resolution of model parameters for geophysical data contaminated by noise and Vozoff and Jupp (1975) showed its application to Direct Current (DC) electrical resistivity and Magnetotelluric (MT) data interpretation.

Summary

SVD is a powerful tool to solve geophysical linear inverse problems, which often deal with rank-deficient singular matrices. The advantage of SVD is that one need not a-priori know the nature of the problem, that is, whether it is over determined, under determined, or partially determined. It is very general in the sense that it can be applied to any arbitrary size matrix.

ISOSTASY

Anthony B. Watts
Department of Earth Sciences, University of Oxford, Oxford, UK

Synonyms

Isostacy – (Dutton, 1882)

Definition

Isostasy. A principle or general law (Heiskanen, 1931). Isostasy considers there is a certain surface within the Earth, known as the depth of compensation, on which the vertical stresses due to an overlying column of rock are equal (isos = Greek ισος "equal," stasis = Greek στάσις "a standing still"). Isostasy implies a state of hydrostatic equilibrium such that the Earth's crust and mantle float on their substrate and light regions have a greater elevation than dense regions.

Isostatic equilibrium. An idealized state that the outermost layers of the Earth tend toward following their disturbance by the addition or removal of loads associated, for example, with the waxing and waning of ice sheets, the growth and decay of volcanoes and the deposition, sliding and slumping of sediments.

Local isostasy. A hypothesis that the outermost layers of the Earth are weak such that the deformation caused by loading and unloading is localized, intense, and may involve faulting.

Regional (or flexural) isostasy. A hypothesis that the outermost layers of the Earth have an intrinsic strength such that they resist the deformation associated with loading and unloading and bend (or flex) over a broad area rather than break.

Thermal isostasy. A hypothesis that the outermost layers of the Earth form a cooling thermal boundary layer and that regional differences in topography are controlled by differences in the temperature structure such that hot regions have a greater elevation than cold regions.

Historical background

Isostasy is a principle that has played a major role in our understanding of the structure, morphology, and tectonic evolution of the Earth's outermost layers. The term was first coined by Dutton (1889), but there is evidence (Delaney, 1940; Vai, 2006) that the equilibrium state of the Earth's crust was being considered much earlier by, for example, the Italian scientists Leonardo da Vinci (1452–1519), who pondered the occurrence of marine fossils at high elevations in mountain ranges, and Luigi Fernando Marseli (1658–1730), who was puzzled about the juxtaposition of ocean deeps and mountains. J. F. W. Herschel (1792–1871) was one of the first to link subsidence in one area to uplift in another by some sort of subcrustal mantle flow and both C. Lyell (1797–1875) and C. Babbage (1790–1871) appreciated that the same area of the crust could experience both subsidence and uplift.

The breakthrough that led to the formulation of the principle of isostasy came following George Everest's pioneering geodetic work in India. Airy (1855) and then Pratt (1855) used Everest's deflection of the vertical data in northern India to address the question of how the Himalayan mountains were supported at depth. Fisher (1881), who favored Airy's hypothesis that the Himalaya were supported by a deep crustal "root," concluded that the Earth's crust was in a state of hydrostatic equilibrium and floated on its fluid substrate, much like an iceberg in seawater.

Today, we tend to think of isostasy as a restraining force rather than a plate tectonic driving force like ridge push or trench pull. Isostasy is a process that acts on the topography created at the plate boundaries by continental rifting, breakup, and mountain building so as to reshape it and redistribute the stresses that have built up. The existence of regions of large topographic relief, unusually thick and thin crust, and large-amplitude gravity anomalies are all pointers that isostatic equilibrium does not prevail everywhere. The main challenge in isostatic studies has been to quantify the degree to which the hydrostatic equilibrium of Earth's crust is achieved and the time and spatial scales over which it operates.

A number of isostatic models have been proposed, three of which are illustrated in Figure 1. Airy and Pratt are local models in which changes in the Earth's topography are supported by *either* changes in the thickness of a uniform density crust or by lateral changes in density of the crust and mantle. Both models imply that the crust and mantle responds to loads (e.g., volcanoes) or unloads (e.g., erosion) locally such that neighboring regions are not involved in their support or removal. They imply an intrinsically weak crust that responds to loads and unloads locally, intensely, and in some cases by faulting. Vening Meinesz, on the other hand, is a regional model in which loads and unloads are supported by a gentle bending or flexure over a wide area rather than by faulting.

It is important to remind ourselves that the models in Figure 1 are highly idealized and only represent the state that the Earth's outermost layers would tend toward in the absence of disturbing forces. These disturbing forces include many of the great cycles of geology such as the waxing and waning of ice sheets, the growth and decay of volcanoes, and sedimentation and erosion. Each of these processes is potentially a disturbing force that could act to delay or even prevent isostatic equilibrium from being achieved.

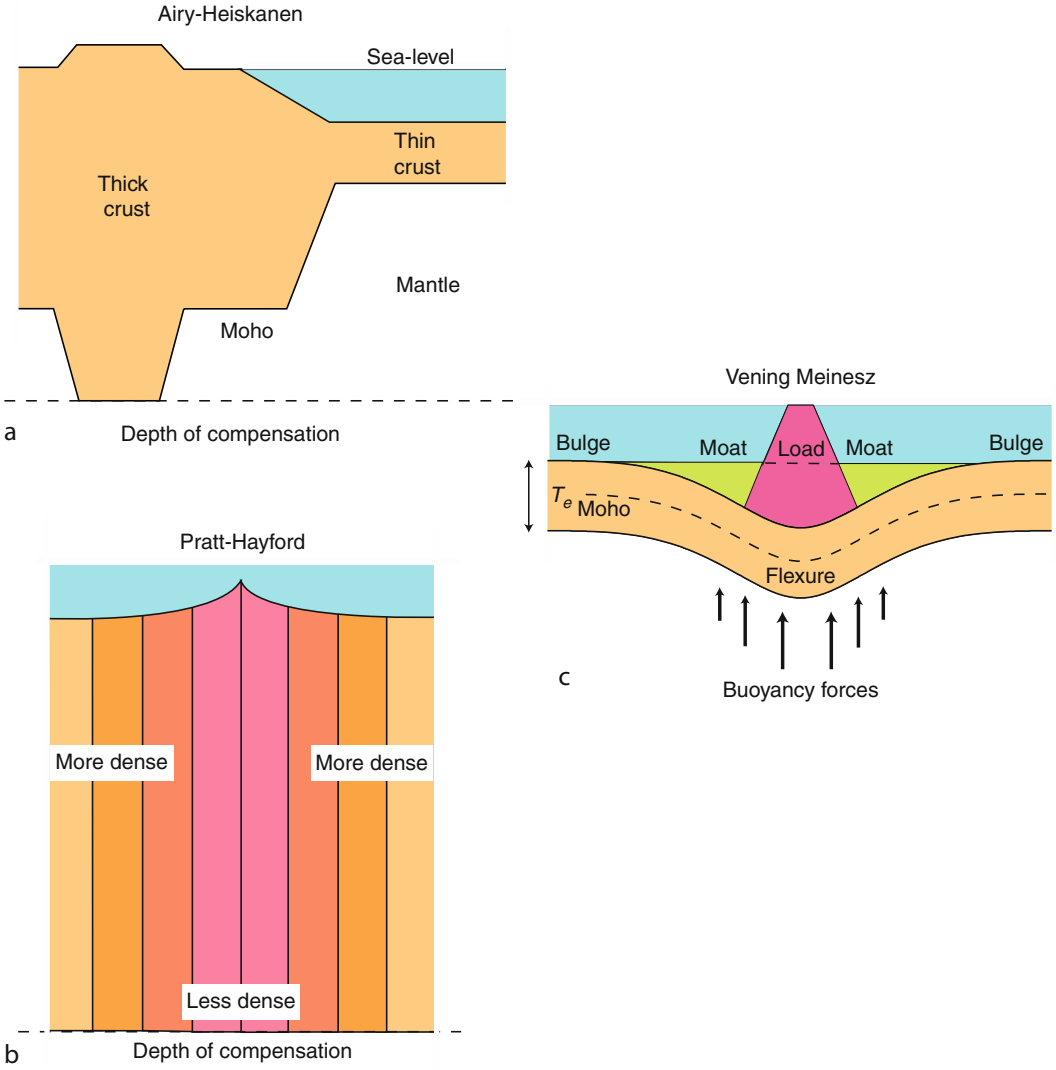
There is now a considerable body of work that indicates the Earth is a dynamic planet that is continuously being deformed. Isostasy, on the other hand, is a static concept that refers to a crust and mantle that has already moved and is now in equilibrium. It therefore appears at odds with current geodynamic views. But isostatic studies of the deformation that follows large earthquakes, late-glacial rebound, and volcano emplacement provide "snapshots" of the way that the crust and mantle responds to loads and unloads over certain temporal and spatial scales (Watts, 2007). Together, these "snapshots" provide information on lithosphere behavior and the clues as to how the crust and mantle would actually deform in response to continually applied loads and unloads.

A goal of isostatic studies is to determine the vertical motion history of the Earth's crust and mantle on short, through intermediate to long timescales. Therefore, isostasy is central to studies of environmental change, especially those that are aimed at determining the relative role of tectonics and sea-level change in controlling the position of the shoreline today and in the geological past. Most significantly, isostatic studies provide information on how the lithosphere responds to the load and unload shifts that occur during climate-driven glacial and interglacial cycles. We are presently in an interglacial, for example, yet the isostatic effects of the Last Glacial Maxima (LGM) are still clearly visible today in tide gauge and satellite Global Positioning System (GPS) data. Isostasy is a key to understanding the lithosphere on which we live and how it interacts with the asthenosphere below and the cryosphere, hydrosphere, and atmosphere above.

Concepts and applications

The isostatic models illustrated in Figure 1 imply different gravity anomalies and crustal and mantle structures. Airy and Pratt, for example, predict that free-air gravity anomalies will generally be small over elevated regions (e.g., volcanoes) because they are underlain by either a thick, uniform density, crustal "root" or a constant thickness low-density crust, the negative gravitational effect of which will compete with the positive effect of the volcano. Vening Meinesz, on the other hand, predicts a shallower depth to Moho than Airy or Pratt and, hence, the free-air gravity anomaly will be generally large over a volcano because its gravity effect will now dominate over that of the compensation.

Figure 2 shows the topography, free-air and isostatic gravity anomalies in the region of northern India where the early geodesists carried out their classical work. The isostatic anomaly has been calculated by subtracting

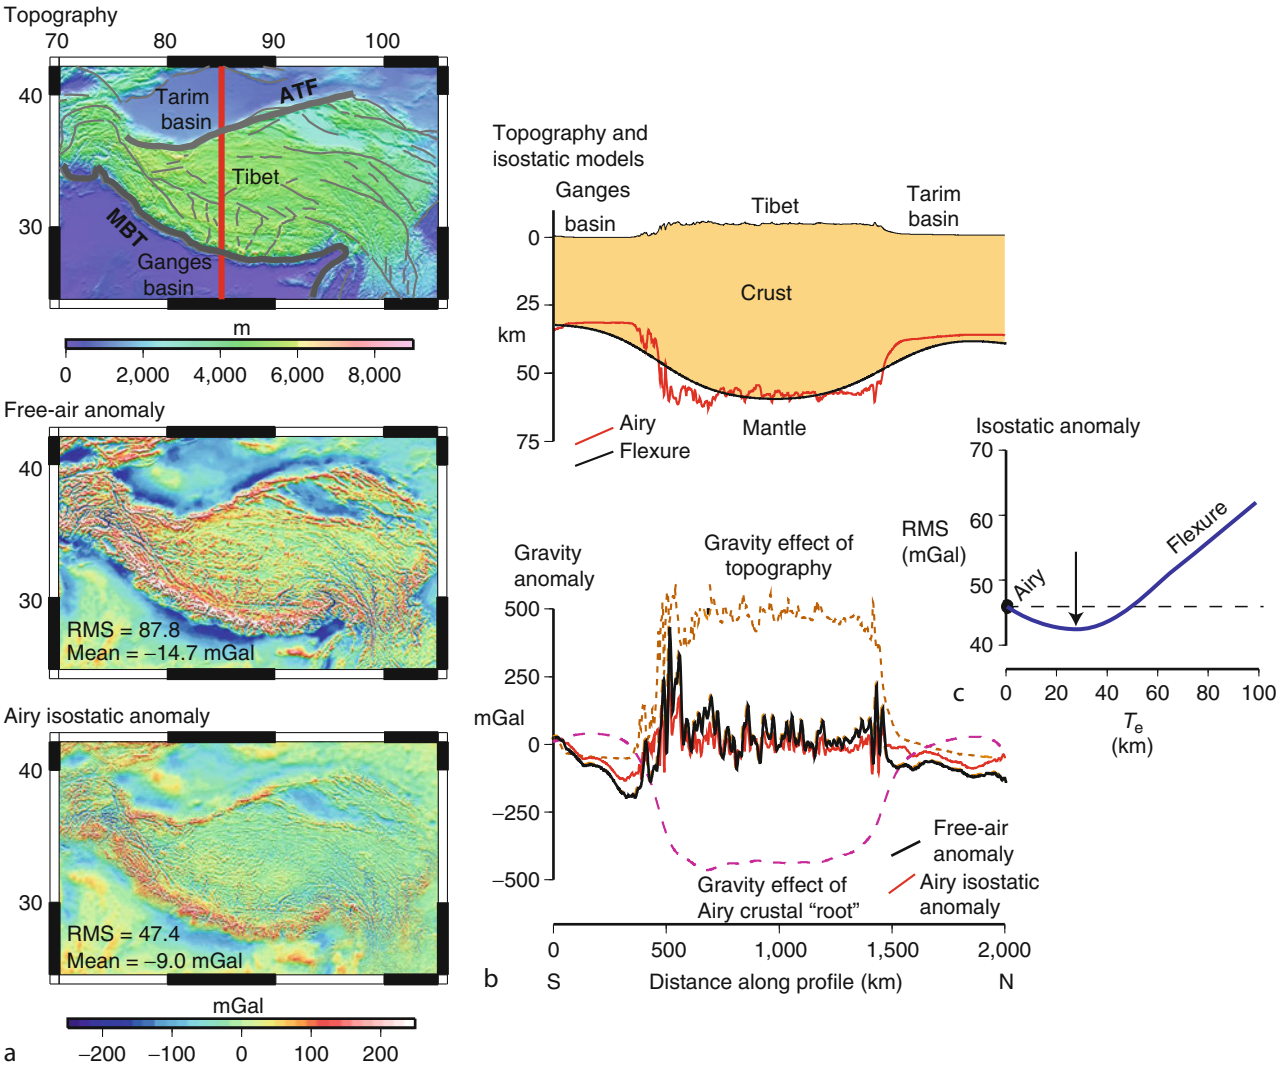


Isostasy, Figure 1 The main types of isostatic models. Each model implies a state of hydrostatic equilibrium such that the Earth's outermost layers are in a state of flotation on their more fluid substrate. The names (e.g., Airy-Heiskanen) refer to the workers who first conceived and quantified the models. Vertical (lithostatic) stresses are constant on the depth of compensation in the Airy-Heiskanen (Airy, 1855; Heiskanen, 1931) and Pratt-Hayford (Pratt, 1855; Hayford, 1909) models and vary laterally in the Vening Meinesz model (Vening Meinesz, 1931). (**a**) Airy model in which isostatic equilibrium is achieved by variations in the thickness of a uniform low-density crust that overlies a high-density mantle. (**b**) Pratt model in which isostatic equilibrium is achieved by lateral changes in the density. (**c**) Vening Meinesz model in which the topography is considered as a load and isostatic equilibrium is achieved by flexural downwarping and upwarping of the crust and mantle over a broad area. In this model, a load is supported by the strength of the lithosphere (which is determined by its effective elastic thickness, T_e) and the buoyancy of the underlying asthenosphere.

(and thereby removing) the positive gravity effect of the topography and the negative gravity effect of the Airy compensation from the observed free-air gravity anomaly. The Root Mean Square (RMS) of the free-air gravity anomaly variation about its mean is 87.8 mGal, while the RMS of the Airy isostatic gravity anomaly is 45.9 mGal. The RMS values show that the free-air gravity anomaly is substantially reduced after a correction for isostasy, and so we may conclude that equilibrium prevails to a significant degree in the northern Indian region.

Despite this success, Figure 2a shows that significant departures still remain in the Airy isostatic anomaly map. The most striking are the positive–negative anomaly "couples" that correlate with the edge of the Tibetan Plateau, particularly its boundary with the Ganges and Tarim foreland basins. The negative anomalies are usually on the basin side while the positive anomalies are on the plateau side, which implies that the Moho is deeper than expected for Airy on the basin side and shallower on the plateau side. Such a Moho geometry can be explained if we

assume that the load of the Himalaya and Kunlun mountains is supported by the strength of the underlying crust and mantle, which flexes over a broad region that extends beyond the mountains themselves. The Vening Meinesz model takes into account these ideas of loading and bending, and Figure 2c shows that when an elastic plate flexure model is used to compute the compensation rather than an Airy model, the RMS of the isostatic anomalies is reduced even further. A useful parameter in the Vening Meinesz model is the effective elastic thickness, T_e, since it is a proxy for the long-term strength of the lithosphere. Figure 2c shows that there is a well-developed minimum in the RMS of the isostatic anomaly for $T_e \sim 30$ km, suggesting this as the best fit T_e estimate for the region (see also Crosby, 2007 who found a similar best fit T_e for the northern Indian region). This is, of course, only an average and so there will be areas that are stronger and areas that are weaker than this. Indeed, Braitenberg et al.



Isostasy, Figure 2 Topography, free-air and isostatic gravity anomalies in the region of the Tibetan plateau. (**a**) *Upper panel*: Topography based on GEBCO (GEBCO, 2003). The map shows the plateau and the flanking Tarim and Ganges foreland basins, the major faults (ATF = Altyn Tagh Fault, MBT = Main Boundary Thrust) and the north–south profile (*thick red line*) plotted in (**b**). *Middle panel*: Free-air gravity anomaly based on the EGM2008 2.5 × 2.5 min grid (Pavlis et al., 2008). *Lower Panel*: Airy isostatic anomaly calculated by subtracting the gravity effect of the topography and its compensating "root" from the observed free-air gravity anomaly. Calculations assume a density of water, crust, and mantle of 1,030, 2,800, and 3,330 kg m^{-3}, respectively, and a zero elevation crustal thickness of 31.2 km. (**b**) Predicted crustal structure based on the Airy and flexure models and free-air and isostatic gravity anomaly profiles of the Tibetan plateau at longitude 85°E. (**c**) Root Mean Square (RMS) of the isostatic anomaly as a function of elastic thickness, T_e, which is a proxy for the long-term strength of the lithosphere. The Moho depth for $T_e = 0$ km corresponds to the predictions of an Airy model that implies a plate with no strength. The minimum RMS and hence the isostatic model that best explains free-air gravity anomaly data in the vicinity of the Tibetan plateau is for a flexure model with $T_e = 30$ km.

(2003) and Jordan and Watts (2005) have already shown, using inverse methods, that T_e is <30 km over the central and northern Tibetan Plateau and >30 km over the Ganges and Tarim foreland basins.

Another way to test isostasy on a regional scale is to compare compilations of the seismically constrained crustal structure directly to the predictions of isostatic models. Figure 3 shows, for example, an 18,000 km long transect crossing the Indian, Atlantic, and Pacific Oceans along which observed and calculated depths to Moho are compared. The observed Moho is based on CRUST2.0 (Bassin et al., 2000), a 2 × 2° grid of P-wave velocity and crustal thickness data derived from controlled source seismic data. The calculated Moho is based on Airy. The figure shows that the calculated Airy Moho tracks the observed seismic Moho well, especially at continental margins.

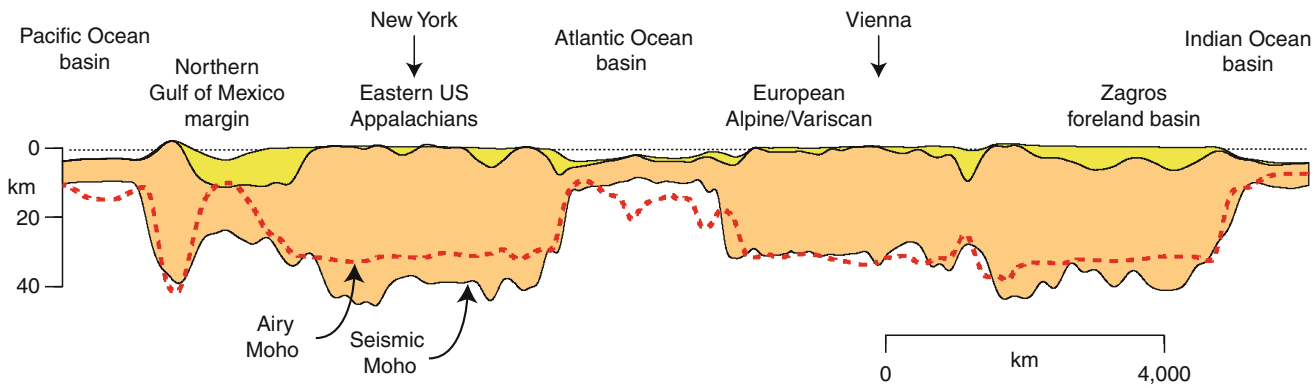
The main departures are in the Atlantic Ocean where the observed Moho depth is shallower than predicted by Airy and beneath the East Coast, U.S. margin and Persian Gulf where the observed Moho depth is deeper. The shallower depths can be explained by our assumption of a relatively high subcrustal oceanic mantle density (3,330 kg m^{-3}), which if reduced (e.g., to 3,180 kg m^{-3}) beneath a mid-ocean ridge would result in a shallower Moho depth and better agreement with the seismic Moho depths. The idea of a relatively low-density subcrustal mantle beneath the ridge suggests a Pratt rather than an Airy model of isostatic compensation. Indeed, Pratt has been assumed in thermal cooling models (Sclater and Francheteau, 1970) for the variation of seafloor depth and heat flow with age and the model may well apply to other cases of thermal isostasy, for example, at mid-plate oceanic swells (Nakiboglu and Lambeck, 1985).

The deeper depths than predicted by Airy are associated with thick sediments at the East Coast, U.S. coastal plain and the Zagros foreland basin. Here, flanking loads due to rifting and thermal contraction and thrusting and folding have flexed the Moho downward over a broad area such that Moho is deeper than would be expected for an Airy model.

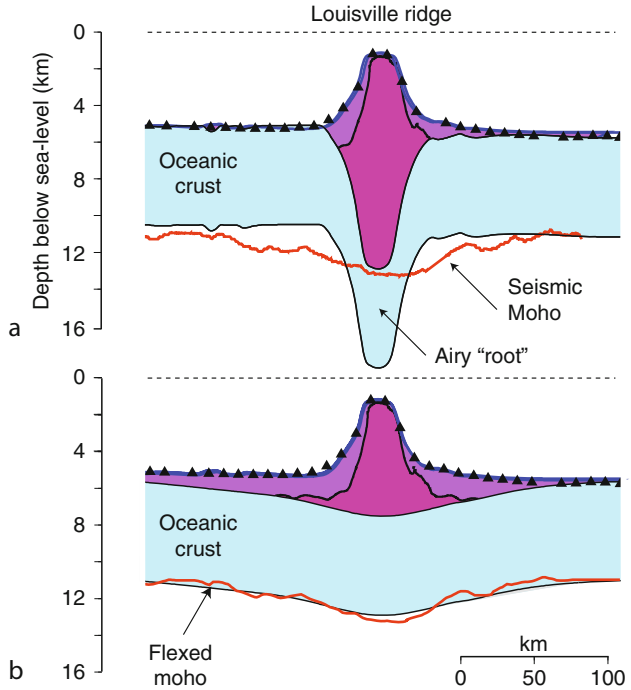
The role of flexure in contributing to crustal structure is well illustrated in Figure 4, which shows the results of a recent seismic reflection and refraction survey of the Louisville Ridge seamount chain near its intersection with the Tonga-Kermadec trench (Contreras-Reyes et al., 2010). The survey utilized a large-volume air gun source array and 39 ocean bottom seismometer receivers spaced 15 km apart were deployed. The source–receiver geometry was such that full ray coverage of the seamount and the underlying oceanic crust and uppermost ~10 km of the mantle was achieved. Figure 4a shows that the seismically constrained Moho cannot be explained by an Airy model that predicts too deep a Moho beneath the seamount and too shallow a Moho in flanking regions. The best fit between observed and calculated Moho depths (Figure 4b) is for a flexure model of isostasy with T_e =10 km. Such a model explains well the observed depth to Moho beneath *both* the seamount edifice and flanking regions.

Current investigations

One of the most important results to have emerged from isostatic studies over the past 40 years has been the link that has been made between the T_e derived from flexural modelling and the long-term strength of the lithosphere. Data from experimental rock mechanics, for example, suggest that the strength of oceanic lithosphere is limited by brittle deformation in its uppermost part and by ductile flow in its lowermost part (Goetze and Evans, 1979). This strength profile implies that loads applied to the surface (or base) of the lithosphere will be supported partly by the brittle and ductile strength of the lithosphere and partly by a central "core" that deforms elastically. It has been shown that oceanic T_e reflects the thickness of this "core," which will be small in regions of young crust, large loads, and high curvature of bending and high in regions of old



Isostasy, Figure 3 Comparison of the crustal structure based on seismic refraction data to the predicted crustal structure assuming an Airy model along an 18,000 km long great circle profile that extends from the Pacific Ocean in the west across the Atlantic Ocean to the Indian Ocean in the east. The seismic refraction data is based on CRUST2.0 http://igppweb.ucsd.edu/~gabi/rem.html and the Airy model is based on the same parameters as assumed in Figure 2.



Isostasy, Figure 4 Comparison of the observed crustal structure derived from seismic refraction data (Contreras-Reyes et al., 2010) to the predictions of an Airy and flexure model of isostasy along a NNE-SSW trending profile of the Louisville Ridge seamount chain, southwest Pacific Ocean. Black filled triangles indicate the location of the ocean bottom seismometers that were used to constrain the crustal structure. *Thick solid red lines* show the depth to the seismically constrained Moho. *Thin solid black line* separating the purple and pink filled regions show the 6.0 km/s P-wave iso-velocity contour. *Purple fill* = volcanoclastic material. *Pink fill* = volcano edifice. *Blue fill* = deformed oceanic crust. (**a**) Airy model based on the same parameters as assumed in Figure 2. (**b**) Flexure model with T_e =10 km.

crust, small loads, and low curvature (Watts and Burov, 2003). Oceanic T_e is in the range 0–40 km, and since the oceanic crust is only ~8 km thick we may conclude that not only the crust but also the mantle is involved in supporting long-term geological loads.

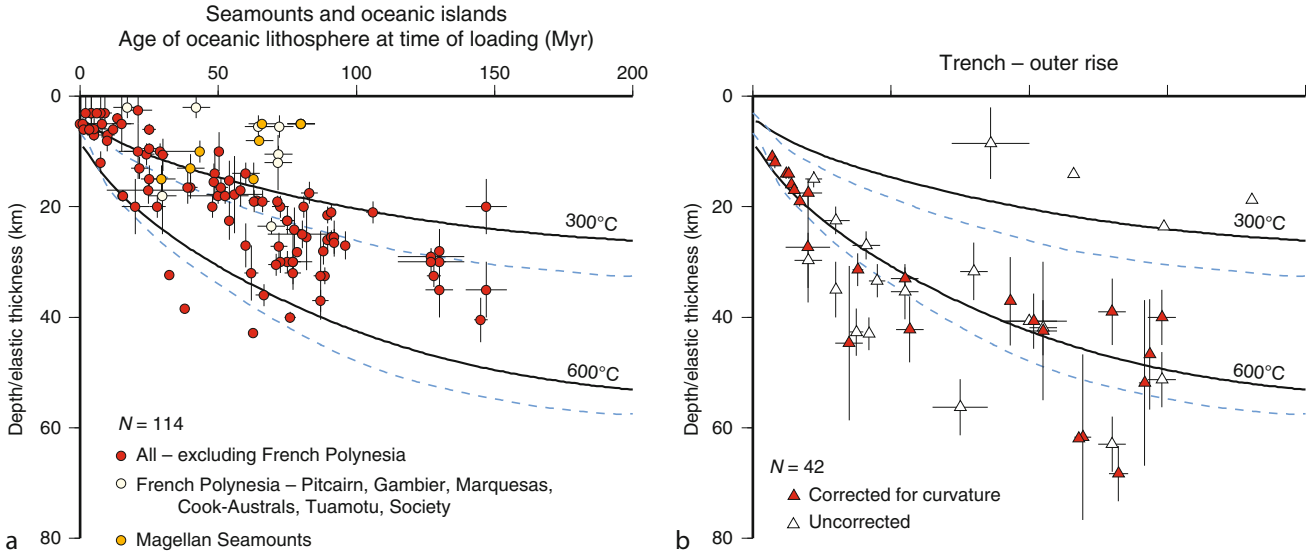
Figure 5 shows that T_e at seamounts and ocean islands and deep-sea trench and outer rise systems increases with the age of the lithosphere at the time of loading, being small at volcano and trench loads that form on young seafloor (e.g., on-ridge) and large at loads on old seafloor (e.g., off-ridge). Thus, as the oceanic lithosphere cools, subsides, and increases in age following its creation at a spreading center, it becomes more rigid in the way that it responds to loads. Interestingly, most seamount and oceanic island values fall within the 300–600°C isotherm envelope based on the cooling plate model of Parsons and Sclater (1977) while most trench and outer rise values require a higher controlling isotherm in the region 450–800°C. This difference in the range of controlling isotherm can be explained by difference in the load age, which is small (essentially present day) at deep-sea trench-outer rise and large (~1.5–100 Myr) at seamounts and oceanic islands. Indeed, a load age dependency explains much of the scatter in plots of T_e vs. the age of the lithosphere at the time of loading. Other possible contributors are uncertainties in load, infill, and mantle densities; thermal perturbations due to hot and cold spots; and yielding in regions of large loads and high curvature.

Most of the T_e estimates plotted in Figure 5 are based on a forward modelling approach in which the gravity or geoid anomaly, surfaces of flexure, or vertical motion history are calculated and compared to observations. The best fit T_e is then determined by a "trial and error" comparison of the observed and calculated. While forward modelling is a satisfactory way to estimate T_e, the number of sites where information on both load and plate age are available is limited.

Technological improvements in satellite radar altimetry and shipboard multibeam (swath) bathymetry data acquisition systems have led to a rapid increase in the number of T_e estimates. Watts et al. (2006), for example, used satellite-derived gravity data together with a reciprocal admittance technique to predict bathymetry for different values of T_e. By comparing observed and calculated bathymetry these workers obtained 9,758 individual estimates of T_e, 291 of which were at sites where both load and plate age were known. Bry and White (2007) used satellite-derived gravity and shipboard bathymetry data to determine T_e along a number of fixed length profiles of deep-sea trench-outer rise systems, while Kalnins and Watts (2009) used satellite-derived gravity and shipboard bathymetry data and an admittance technique to determine the T_e structure of the western Pacific region.

One problem with all these spectral methods is the influence of the analysis window size on the recovered T_e. Windows need to be large enough to resolve the largest T_e and small enough to avoid "contamination" from more than one type of geological feature. Watts et al. (2006) and Bry and White (2007), for example, found a greater than expected scatter in plots of T_e vs. the age of the lithosphere at the time of loading with no clear indication of a controlling isotherm. Kalnins and Watts (2009), however, used a moving window technique and found that the controlling isotherm varied regionally; this may explain some of the scatter in plots of T_e against load and plate age.

The physical meaning of T_e and its relationship to load and plate age is much less clear in the continents than it is in the oceans. Unlike oceanic lithosphere, continental lithosphere has a multilayered rheology (Burov and Diament, 1995; Meissner and Strehlau, 1982) and there may be more than one brittle and ductile layer that supports an individual load or unload. In this situation, T_e is not a particular depth in the lithosphere but a measure of its integrated strength. Continental T_e depends on both the curvature of flexure (which depends in turn on the size of the load or unload) and how well individual competent layers are coupled together, being low for high curvature



Isostasy, Figure 5 Plot of T_e vs. the age of the oceanic lithosphere at the time of loading. (**a**) Seamounts and oceanic islands and (**b**) deep-sea trench and outer rise systems. The data is based on Table 6.1 in Watts (2001) with the addition of Freedman and Parsons (1986), McQueen and Lambeck (1989), and 15 other studies carried out since 2000. *Solid and dashed lines* show the calculated depth of the 300°C and 600°C isotherms based on the cooling plate models of Parsons and Sclater (1977) and McKenzie et al. (2005), respectively.

and poorly coupled systems and high for low curvature and well coupled systems (Watts and Burov, 2003).

As in the oceans, continental T_e has been estimated using both forward and inverse modelling techniques. Most forward modelling estimates are based on fitting either the gravity anomaly or the surfaces of flexure (as inferred, e.g., from basement depth data) at rift-type, strike-slip, intra-cratonic, and foreland basins to model predictions. Sometimes, both gravity anomaly and depth to basement data are available and this yields the most reliable estimates (Haddad and Watts, 1999). Continental T_e estimates range from 5 to 100 km and no simple relationship has yet been found between T_e and load and plate age (Watts, 2001). The data is suggestive, however, of some age dependence. Archaen and Proterozoic cratons, for example, are generally associated with high T_e values ($>$70 km) while Phanerozoic and younger mountain belts generally have lower values (25–60 km) (Pérez-Gussinyé and Watts, 2005). Young rifted margins (e.g., South China Sea) appear to have lower T_e values than old margins (e.g., Amazon) (Watts et al., 2009) and this has been interpreted as the result of heating during continental breakup that weakens the lithosphere, and cooling following rifting that strengthens it (Burov and Poliakov, 2001). Plume-influenced rifts (e.g., Afar, North Atlantic) are associated with the lowest T_e values (Ebinger et al., 1989; Watts and Fairhead, 1997), but it is not known how much strength a weakened rifted lithosphere is capable of regaining.

According to the Wilson Cycle, ocean basins open and close and compressional mountain belts develop on or close to the site of extensional rifted margins. Isostatic studies of the foreland basins that flank mountain belts suggest that they may inherit the T_e structure of the underlying rifted margin (Lin and Watts, 2002). The foreland basin may be either narrow or wide, depending on whether it formed on a young or old margin. The very high ($>$70 km) T_e values that are associated with some foreland basins (e.g., central Andes) may be explained by the fact that the fold and thrust belts, the main driving load for foreland basin subsidence, will sometimes override the rifted margin altogether and "telescope" onto the more rigid cratonic interior, thereby inheriting its value.

As in the oceans, inverse modelling approaches have provided new insights into continental T_e, especially its spatial and temporal variation. The first studies (e.g., Dorman and Lewis, 1970; Banks et al., 1977; McNutt and Parker, 1978) were based on a Bouguer admittance, Fourier transform periodogram method, which yielded a number of low values. Forsyth (1985), however, pointed out that the low values might be a result of the low coherence that existed in continental regions between gravity and topography because of the presence of subsurface (i.e., buried) loads that were uncorrelated with surface topographic loads. Subsurface loads are difficult to define and so he suggested using the Bouguer coherence, rather than the Bouguer admittance, because it was less sensitive to the ratio of surface to subsurface loading. Forsyth's method was widely applied (e.g., Zuber et al., 1989) and as Bechtel et al. (1990) showed for North America, it yields low as well as high values, especially in cratonic regions. Subsequent studies have incorporated new techniques, including maximum entropy estimators (Lowry and Smith, 1995) and multitapers (McKenzie

and Fairhead, 1997). McKenzie and Fairhead (1997) recommended using the free-air admittance rather than Bouguer coherence because the surface topography, unlike buried loads, is a known load, the gravity effect of which should not really be removed from the free-air gravity anomaly. These workers argued that results based on Forsyth's Bouguer coherence technique maybe biased by the effects of erosion and his method will yield overestimates of T_e rather than true values. Pérez-Gussinyé and Watts (2005), however, used both Bouguer coherence and free-air admittance and found the highest values in Europe (>70 km) over the Archaen and Early Proterozoic (<1.5 Ga) East European craton (part of Baltica) and the lowest values (10–45 km) over the flanking Caledonian, Variscan, and Alpine orogenic belts (Figure 6). Similar results were found for North and South America (Kirby and Swain, 2009; Pérez-Gussinyé et al., 2007), Australia (Simons et al., 2000), and Africa (Pérez-Gussinyé et al., 2009), and a consensus seems to be emerging that the continental lithosphere is capable of showing both great weakness and great strength. Interestingly though, cratons are not always associated with a uniformly high T_e, and there are regions within them that have low values.

In another development, wavelets have been used instead of spectral methods. Wavelets have an advantage over spectral methods in that they are local in space and scale so that the relationship between gravity anomaly and topography can, in principal, be examined over a range of wavelengths without the need for annular averaging over discrete windows. They yield similar results as spectral methods, although the recovered T_e tends to be smoother (Audet and Mareschal, 2007; Sacek and Ussami, 2009; Stark et al., 2003; Tassara et al., 2006).

Irrespective of the methods used, caution needs to be applied when interpreting continental T_e data. This is because it is not clear whether the T_e deduced from inverse modelling refers to the same loading and unloading schemes as are assumed in forward modelling. In forward modelling, specific loads (e.g., fold and thrusts) and flexures are considered, and the T_e deduced usually refers to a particular thermo-tectonic event in the geological past (e.g., a rift or orogenic event). Inverse methods, by way of contrast, "see" *all* the loads that are acting on the lithosphere, and these include not only past loads, but sedimentary loads and erosional unloads, some of which continue to shape the Earth's surface up to the present day.

What is clear from all these studies is that Earth's lithosphere has a rich T_e structure. In the oceans, T_e varies by up to ±15 km over horizontal distances of 500–1,000 km (Watts et al., 2006). Spatial variations are even larger in the continents. The compilations of Pérez-Gussinyé and coworkers, for example, suggest ±25 km over similar distances. In many places (e.g., western Canada and USA), weak regions with T_e as low as 10 km abut strong regions with $T_e > 70$ km (Fluck et al., 2003). The consequences of such strength variations are profound, especially as they impact on the patterns of glacial isostatic rebound (Whitehouse et al., 2006), solid earth tides (Mantovani et al., 2005), and the terrane structure of continental lithosphere (Pérez-Gussinyé et al., 2007).

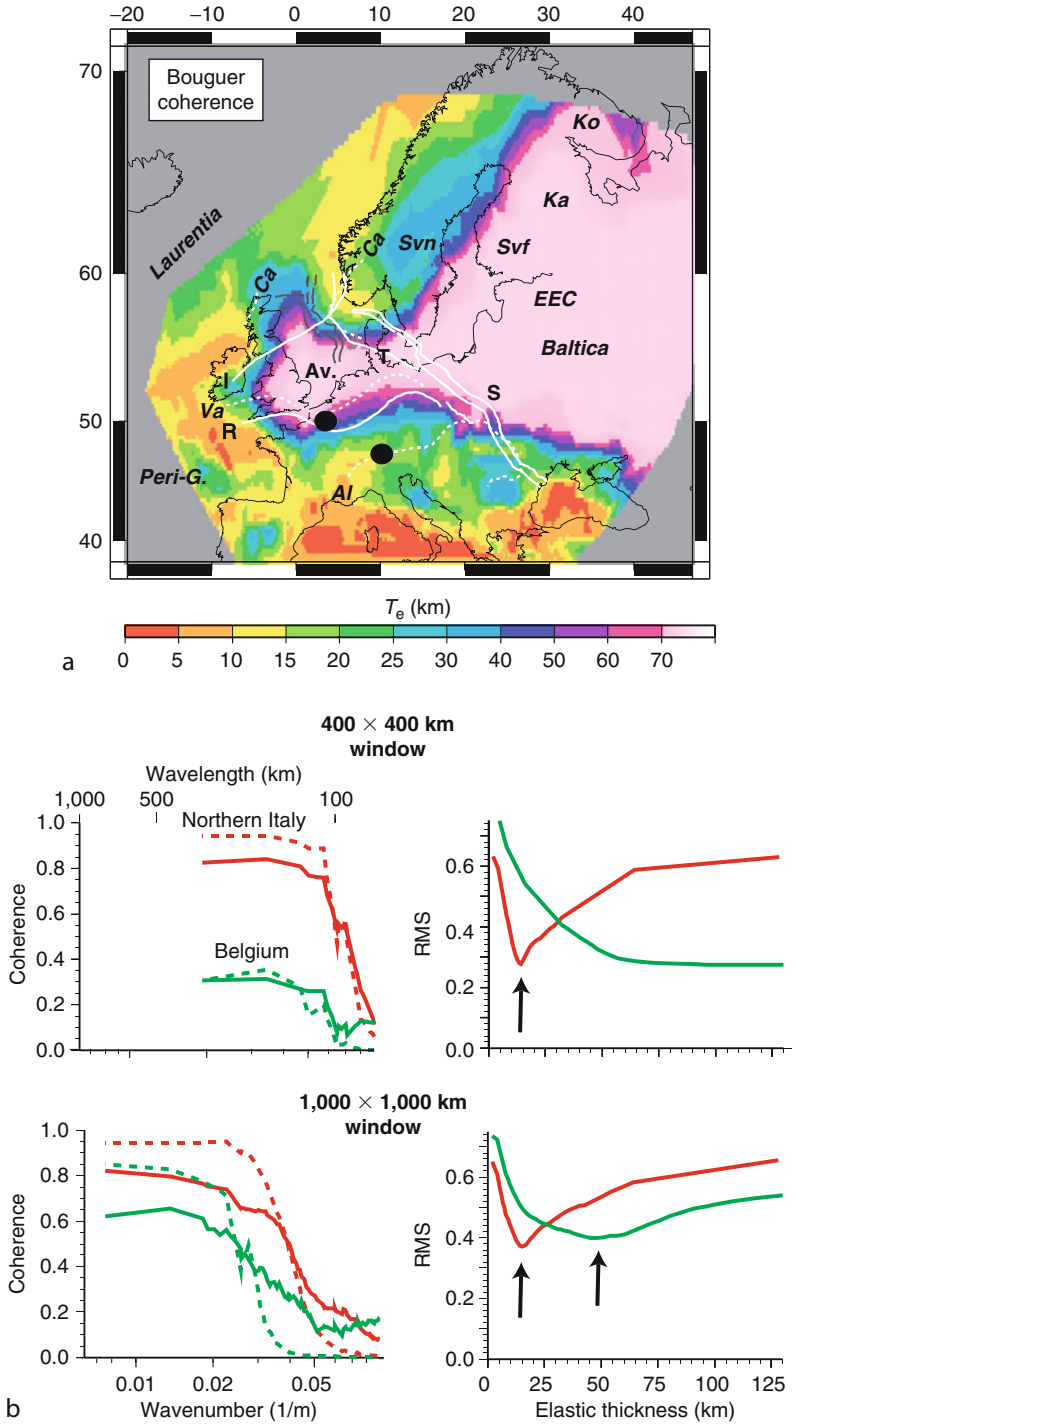
Current controversies and gaps in knowledge

Isostatic studies have never been very far from controversy as demonstrated by the vigorous debates on local vs. regional models that took place at the turn of the twentieth century. Central to these debates was the applicability of isostatic models to particular geological features, and certain "schools of thought" emerged among geologists, geophysicists, and geodesists. There were even debates either side of the Atlantic when an Airy model was preferred by Europeans and a Pratt model by North Americans. Today, there is general agreement on the relative role of local and regional models of isostasy. Debate is focused instead on the flexure model, particularly T_e, what it means and what it tells us about the long-term strength of the lithosphere, the timescales of isostatic adjustment, and the geological processes that shape the top and base of the lithosphere.

The long-term strength of the lithosphere

In the oceans, there is widespread agreement on oceanic T_e and what it indicates about the long-term strength of the lithosphere. While there is scatter in plots of oceanic T_e vs. plate age, most of it can be explained by viscoelastic stress relaxation (Watts and Zhong, 2000), curvature and yielding (McNutt and Menard, 1982), and spatial variations in the controlling isotherms that determine T_e (Kalnins and Watts, 2009).

There has not, however, been the same agreement concerning continental T_e estimates and their relationship to age. The controversy has recently come to a head in the so-called crème brûlée vs. jelly sandwich debate (Burov and Watts, 2006). Proponents of the crème brûlée model follow McKenzie and Fairhead (1997) and Jackson (2002) who believe that because T_e is small and similar in thickness to the seismogenic layer, the strength of the lithosphere resides mainly in the uppermost part of the crust. In their view, the lower crust and uppermost mantle are weak, which explains why deep earthquakes are rare. Proponents of the jelly sandwich model, however, follow Meissner (1986) who argues that the lithosphere is "jelly like" with a strong upper crust, a weak lower crust, and a strong uppermost mantle. This model is compatible with the results of seismic reflection profiling, which show a layered lower continental crust, and with the results of flexure studies, which show a wide range of T_e values. Low T_e is indicative of thin competent layers while high T_e values reflect thick competent layers. Very high T_e values (>70 km) are also permissible and occur when the upper and lower crust or the lower crust and mantle are coupled. Deep earthquakes are rare, not because the mantle is too weak but because it is too strong, and the tectonic stresses required to initiate faulting are not large enough.



Isostasy, Figure 6 The T_e structure of Europe as derived from the coherence between the observed Bouguer gravity anomaly and topography as a function of wavelength. (Modified from Pérez-Gussinyé and Watts [2005].) (**a**) T_e and its relationship to the terrane structure. Thin white lines show major sutures. *I* = Iapetus. *R* = Rheic. *A* = Alpine. *T* = Thor. *S* = Sorgenfrei-Tornquist. The tectonic provinces are Ko, Kola; Ka, Karelia; and Svf, Svecofennian. *Thin dashed lines* show the Caledonian (Ca), Variscan (Va), and Alpine (Al) deformation fronts. Peri-G. = Peri-Gondwanaland. Av = Avalonia. EEC = East European Craton. *Black filled circles* show the location of the coherence and RMS plots in (**b**). (**b**) Examples of the observed and predicted Bouguer coherence and RMS between the observed (*solid line*) and calculated (*dashed line*) coherence for a 400 and 1,000 km analysis window centered on Belgium and northern Italy. Note that northern Italy appears as a region of low T_e in both windows, but the high T_e region of Belgium only has a clear RMS minima in the larger window.

The debate has led to a reexamination of the methodologies used to estimate continental T_e and its physical meaning. Pérez-Gussinyé et al. (2004) showed that it is necessary when comparing observed and calculated free-air admittances to first window them using the same multitaper estimator, while Crosby (2007) showed that in order to recover T_e in cratonic shield regions large window sizes (up to 1,500 km) are needed; otherwise, T_e may be underestimated. Watts and Burov (2003) pointed out that while T_e may well be low and similar to the seismogenic layer thickness in some tectonic settings (e.g., Basin and Range, western USA), the two parameters are not the same. T_e reflects the integrated strength of the lithosphere while the seismogenic layer is the thickness of the uppermost part of the crust that responds to stresses by faulting and earthquakes. Finally, Handy and Brun (2004) argued that a strong uppermost mantle is required in order to explain the integrity of sinking slabs in subduction zones and the deep structure of rifted margins and orogens.

The continental T_e debate has proved a useful discussion point in isostatic studies. It highlights the importance of T_e while at the same time illustrates gaps in our knowledge about the Earth's lithosphere, especially regarding its long-term rheology. Other gaps are as follows.

Timescales of isostatic adjustment

Isostasy varies temporally, as well as spatially. Exactly how slow or fast isostasy operates is of fundamental importance to our understanding of the Earth's vertical motion history as well as to topics such as sea-level change. For example, Bloom (1967) pointed out that the height of a wave-cut notch above present day sea level depends not only on the amplitude of sea-level change, but how quickly isostatic equilibrium is achieved. If isostasy is fast then a sea-level rise will have time to load the crust and upper mantle and so the height of the notch will be low due to regional subsidence. If, on the other hand, isostasy is slow then there will be time and a notch will be cut at a higher elevation.

Several attempts have been made to estimate the time scales of isostatic adjustment associated with load shifts on the top or base of the Earth's crust. Watts (1978), for example, compared the T_e derived from oceanic flexure studies to the thermal and seismic thickness of the lithosphere and concluded that on loading there must be a rapid reduction in the thickness of the mechanical layer that supports a load as the lithosphere relaxes from its short-term seismic to its long-term elastic thickness. Beaumont (1979) used an elastic–plastic model based on the creep laws of olivine to argue that while oceanic lithosphere was essentially elastic on long-time scales, continental lithosphere continued to relax on timescales of up to several tens of million years. Willett et al. (1985) used a viscoelastic plate that overlies an inviscid substrate to model continental T_e data and showed that on loading there would be a weakening of the lithosphere that reduced the thickness of the mechanical layer by as much as a factor of 3–8, depending on the initial thermal structure of the lithosphere that was assumed. And finally, Watts and Zhong (2000) used the actual temperature structure of the oceanic lithosphere constrained from seafloor depth and heat-flow data to calculate a viscosity profile and then examined how the equivalent T_e would vary following volcano loading. They showed that because viscosity increases from low values in the lower lithosphere to high values in the upper lithosphere, the lithosphere relaxes from the bottom-up such that the reduction in the mechanical layer thickness that supports a load is initially fast and then slows with load age.

Figure 7 compares the T_e for a number of seamounts and ocean islands in the world's ocean basins to predicted curves based on a multilayered viscoelastic model. The model assumes an asthenosphere viscosity of 10^{21} Pa s and a lithosphere viscosity that increases from 10^{21} to10^{35} Pa s, depending on thermal age. The figure shows a rapid decrease in the thickness of the lithosphere that supports a load and hence a decrease in its strength. This weakening results in an increase in subsidence and a narrowing of the zone of subsidence with increase in load age. Eventually, the strength reduction slows and the thickness that supports a load approaches a steady state value.

The continents have a wider range of load and unload ages than the oceans and there are elastic thickness estimates for short-term earthquake loading (2–100 s) through intermediate (~10 ka) glacial isostatic rebound to long-term (>1 Ma) flexure. There are regions (e.g., western and eastern USA) where elastic layer thickness has been estimated for two or more timescales. These data suggest that the relaxation observed in oceanic lithosphere may also characterize the continental lithosphere, albeit over a much wider range of relaxation timescales. For example, the Hebgen Lake (Nishimura and Thatcher, 2003), Lake Bonneville (Nakibogluand Lambeck, 1983), and western Cordillera (Lowry et al., 2000) loads that reflect ages of 0–120 s, 10 ka, and ~60 Ma are associated with elastic layer thicknesses of 38, 30, and 5 km, respectively. There is therefore a decrease in T_e with increase in load age. The decrease is similar in form to the ocean loading cases modelled by Watts and Zhong (2000), but the viscosity of the asthenosphere that is required is less and $\sim 3 \times 10^{18}$ Pa s. This viscosity results in a rapid initial and a slow final weakening of the lithosphere and a transition between the two regimes at load ages of ~30 a. Interestingly, the transition appears to vary regionally such that loads on the tectonic western North America relax quicker than those emplaced on the more stable parts of eastern North America.

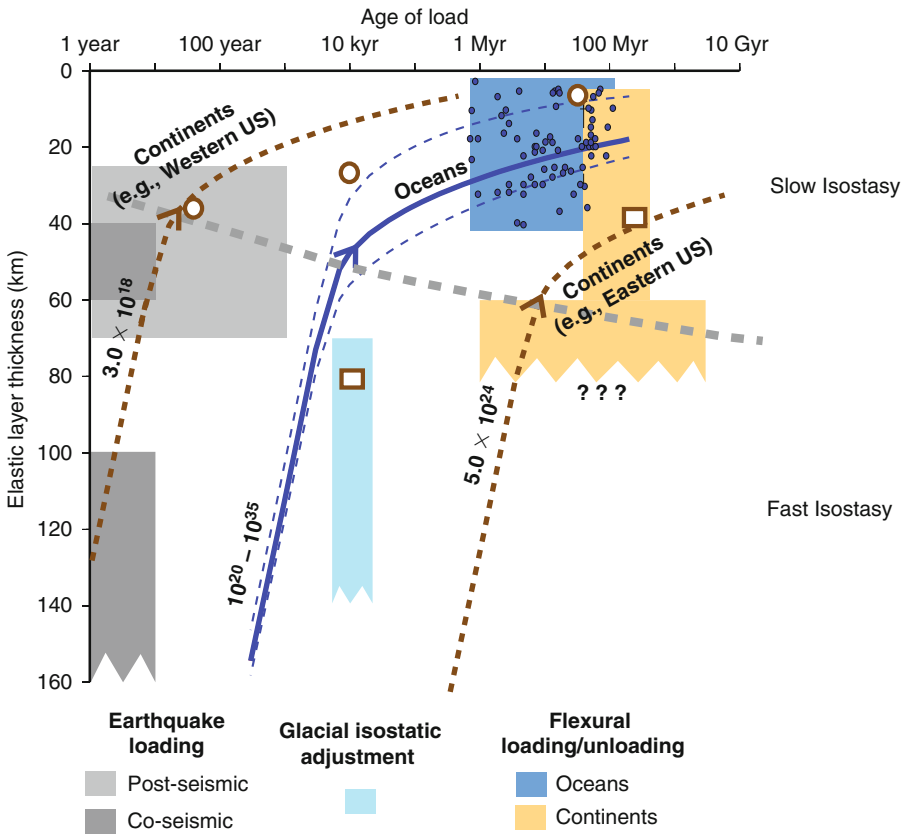
Isostasy, landscape evolution, and mantle dynamics

The behavior of the lithosphere and how it interacts with the cryosphere, hydrosphere, and atmosphere above and the asthenosphere below is a fundamental question that needs to be addressed if we are to fully understand

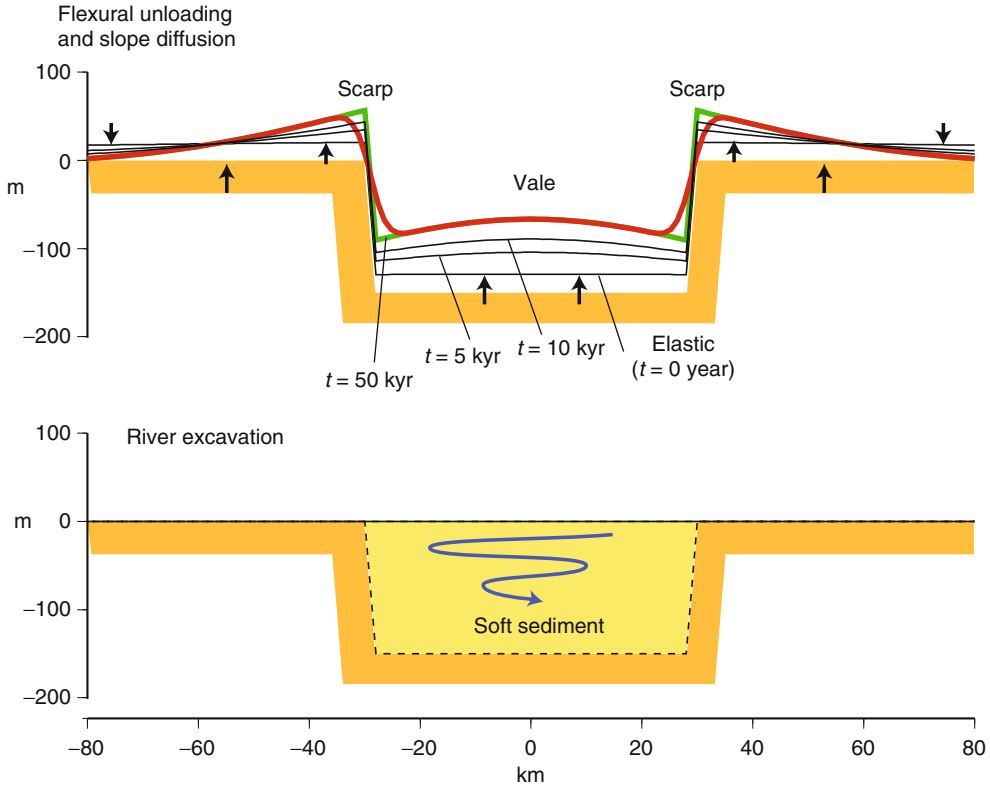
geological processes and construct realistic models. We know, for example, from flexure studies that the lithosphere behaves as a low-pass filter in the way that it responds to loads and unloads, suppressing the short-wavelength deformation and passing the long-wavelengths. The physical properties of the lithosphere therefore smooth out the effects of surface and subsurface processes such as those involved in landscape evolution and mantle convection, making it difficult to see the full effect of these processes.

Isostasy has played a major role in the development of the landscape, both in the constructive forces such as tectonics that build it and the destructive forces such as erosion that destroy it. Examples include the flexures that follow mechanical unloading on normal faults (ten Brink and Stern, 1992), fault scarp retreat (Gilchrist and Summerfield, 1990), and glacial erosion (Pelletier, 2004; Stern et al., 2005). Because flexure involves rock uplift and subsidence it is capable of modifying pre-existing drainage patterns, especially river knick points and base levels. This is particularly well seen in the rim uplifts that flank rifted and transform margins (Tucker and Slingerland, 1994) where flexure is a major factor in controlling the drainage divide that separates scarp and dip streams. Other examples have been described from the Cotswold Hills, southern England (Lane et al., 2007), where rim uplifts flank regions of fluvial incision and excavation.

Figure 8 illustrates the isostatic adjustment that would occur following fluvial incision and excavation of a 150 m deep and 60 km wide region of relatively low-density sediments. The calculations assume that the



Isostasy, Figure 7 Plot of elastic layer thickness vs. the age of load for oceanic and continental lithosphere. (Modified from Watts [2007].) The *thick solid blue line* and *thin dashed blue lines* show the predicted change in elastic layer thickness for young, intermediate, and old oceanic lithosphere according to Watts and Zhong (2000). *Filled blue circles* show the data from individual seamount and ocean island loads, which range in age from ~1 to 100 Myr. The data indicate that by ~10 kyr oceanic loads have undergone most of their relaxation. The *thick dashed brown lines* show the predicted change in elastic thickness for continental lithosphere. *Filled gray rectangles* are based on earthquake loading (post-seismic and co-seismic), *filled blue rectangles* are based glacial isostatic adjustment, and *filled beige and yellow rectangles* are based on continental flexure studies (see Watts, 2007 for references). *Open symbols* show elastic layer thickness estimates from the same tectonic region (*circles* = western USA, *squares* = eastern USA) based on the data in Nakibogluand Lambeck (1983), DiDonato et al. (2000), Lowry et al. (2000), Nishimura and Thatcher (2003), and Pazzaglia and Gardner (1994). The data suggest two modes of relaxation that correspond to "fast" and "slow" isostasy. Interestingly, the relaxation time that separates these two modes varies between oceans and continents with western USA relaxing much quicker (~10 year) than the oceans and eastern USA relaxing much slower (~70 Myr).



Isostasy, Figure 8 Simple model for flexure of the lithosphere due to river incision and excavation. The model assumes that the lithosphere responds to loads (and unloads) initially as a thick elastic plate (T_e = 80 km), then as a viscous material, and finally as a thin, essentially elastic, plate (T_e =10 km). The response shows an initial long-wavelength low amplitude uplift, a transient short-wavelength high amplitude uplift and subsidence, and a final short-wavelength high amplitude uplift and subsidence that together reflects the thinning of the lithosphere from its initial short-term thickness to its long-term elastic thickness. The *thick solid red line* shows the final topography after it has been modified by slope diffusion (assumed erosion time = 50 ka, diffusion constant = 50 $m^2\ a^{-1}$).

lithosphere behaves as a viscoelastic plate, similar to the model illustrated in Figure 7 and used by Watts and Zhong to calculate the time-dependant flexure that follows seamount loading. The main model features are an initial thick-plate elastic response, a viscous time-dependant response, and a final thin-plate, essentially elastic, response. The figure shows that lithospheric weakening due, for example, to load-induced stress relaxation has the capacity to create topography that locally either enhances or subdues the more regional deformation associated with the initial short-term response. Karner (1984) showed that topography is also created during lithospheric strengthening when, for example, the oceanic lithosphere is thermally rejuvenated (and weakened) at mid-plate hotspot swells and subsequently cools. The topography in this case subdued the original swell.

Incision and excavation, together with refilling, are common features of the fluvial response to glacial and interglacial cycles. Isostasy will therefore have a major role to play in the deformations that result. For example, incision due to meltwater-charged rivers is a feature of glacial periods when the sea level was low while valley-filling and delta construction are features of interglacials when the sea level was high. Repeated episodes of incision and valley fill will therefore resurface a landscape, creating in the process isostatic rim uplift and subsidence, as seems to have occurred in the region of the Mississippi River where it debauches in to the Gulf of Mexico (Blum et al., 2008). One consequence of this resurfacing is that the apparent sea level may vary along-strike the rifted margin of the northern Gulf of Mexico such that the Mississippi River valley in Texas subsides relative to the adjacent Alabama coast.

The Earth's lithosphere is deformed not only by surface geological loads and unloads, but also by subsurface loads, some of which originate within the crust while others have their source in the subcrustal mantle. Like surface loads, subsurface loads are associated with mass excesses and deficiencies and create flexures of the Moho and other crustal layers that are manifest in topography and gravity anomaly data. For example, subsurface loads due to intracrustal thrusting, obducted crustal blocks, and ophiolite emplacement cause flexures that contribute to both topography and gravity anomalies (e.g., Royden and Karner, 1984).

Irrespective, the tendency for isostatic loads and unloads to be compensated means that their gravity anomaly will be reduced and may approach zero at the longest wavelengths. This is most clearly seen in the free-air admittance that shows that Airy, Pratt, and flexure models have a distinct "roll-over" that approaches zero at the longest wavelengths because of isostasy (Watts, 2001). The existence in oceanic regions of admittances in the range 5–20 mGal/km at wavelengths 1,000–4,000 km (Crosby, 2007; Watts, 2007; Wieczorek, 2007) is therefore of much geodynamic interest. Watts (2007) has shown that the long-wavelength admittance remains approximately constant at ~18 mGal/km in the central Pacific Ocean as the analysis window size is increased from 1,000 to 4,000 km. He argued that the long-wavelength admittance cannot be attributed to isostasy and so must reflect dynamic processes in the subcrustal mantle.

It has been known for some time that the Earth is associated with both long-wavelength topography and gravity anomalies. The long-wavelength topography that cannot be attributed to isostatic processes was dubbed "dynamic topography" by Hager et al. (1985). It has been shown that dynamic topography is a significant contributor to the long-wavelength gravity and geoid anomaly field as well to the subsidence and uplift history of sedimentary basins, especially foreland-type (Liu and Nummedal, 2004), rift-type (Muller et al., 2000), and some intra-cratonic basins (Coakley and Gurnis, 1995) where slab-induced motions in the deep mantle may have perturbed the overlying plates. However, we are still far from fully understanding the spatial extent, magnitude, and origin of dynamic topography. More isostatic studies are therefore needed because they have the potential to separate the effects of lithospheric plate flexure from topography and gravity and geoid anomaly data and isolate the planform of motions in the Earth's mantle. The development of improved gravity anomaly and topography field data, new spectral analysis techniques, and better geodynamical models offer the most promise of addressing this problem in the future.

Conclusions

Isostasy is a principle that is central to the Earth Sciences. It was first formulated in the 1880s to describe the tendency of the crust to float, in hydrostatic equilibrium, on its denser substrate such that light areas stand at a greater elevation than dense areas. Today, we consider isostasy as a highly idealized state that the crust and upper mantle approaches, but rarely achieves. Nevertheless, the comparison of observed gravity anomalies to the predictions of local and regional isostatic models has led to a new understanding about the thermal and mechanical properties of the lithosphere. We now know, for example, that the lithosphere responds to long-term (i.e., $>10^5$ years) loading and unloading in a similar manner as would a strong elastic plate that overlies a weak fluid substrate. In the oceans, the thickness of the elastic layer that supports a volcano load increases with the age of the lithosphere at the time of loading. In the continents, the relation between elastic thickness and age is not as clear. However, there is evidence that older Archaen and Early Proterozoic cratons have high values of the elastic thickness (i.e., >70 km) while younger Middle/late Proterozoic and Phanerozoic orogenic belts and rifts have lower values. Data from experimental rock mechanics suggest that the elastic thickness derived from isostatic studies is a proxy for the long-term strength of the lithosphere. The elastic thickness differs from the seismogenic layer thickness, which is the thickness of the uppermost part of the lithosphere that responds to stresses by faulting and earthquakes and the seismic "lid" thickness, which is the mechanical thickness that supports short-term loads and unloads. Isostatic studies suggest that the timescales of isostatic adjustment varies regionally such that tectonically active areas respond to loads and unloads much quicker than cratonic areas. The behavior of the lithosphere on seismic to geologic timescales is important to take into account when modelling geological processes, especially those associated with the climate-induced glacial loading and unloading cycles.

Definition

Isostasy: (Greek: isos "equal," stasis "standstill") term used in geology to refer to the condition of gravitational equilibrium such that the rigid outer part of the earth's crust and uppermost mantle "float" at an elevation which depends on its density. This concept explains how different topographic heights can exist at the earth's surface.
Compositional isostasy: the part of isostasy traceable to density variations arising from compositional (rock type and mineralogy) differences.
Thermal isostasy: the part of isostasy traceable to density variations arising from temperature differences and thermal expansion within the rock column.
Isostatic equilibrium: the condition whereby a certain area of crust and upper mantle reaches the state of isostasy such that a hydrostatic equilibrium exists at depth below a level of compensation. The region is said to be in *isostatic equilibrium*.

Introduction

The condition in the earth whereby variations in crustal thickness and density determine the elevation of the earth's solid surface is known as isostasy and has been appreciated for a century and a half (Pratt, 1855; Airy, 1855; Watts, 2001, for general review). Local isostasy requires a hydrostatic equilibrium condition at a depth below a compensation level, implying that the integral of density over a rock column is constant. When density differences arise from differences in rock composition (rock type, mineralogy), the isostatic condition is referred to as compositional isostasy. It is compositional isostasy, and in particular the density contrast across the crust–mantle boundary, that dominates isostasy discussions in textbooks. If, on the other hand, density differences arise from different thermal states of the lithosphere and thermal expansion of rock, the condition is properly called thermal isostasy. This article is devoted to thermal isostasy, computation of thermal isostasy effects, and examples of thermal isostasy in oceanic regions and on the continents.

Thermal isostasy

Rock density is influenced by temperature through thermal expansion. If rock composition is identical in two vertical columns through the lithosphere, the warmer column has a lower density than the cooler lithosphere. Applying the isostatic condition of hydrostatic equilibrium at some depth of compensation leads to a prediction of elevation changes for the two regions.

Consider two regions of different lithospheric thermal states. Temperature differences between the two regions represented by a regional geotherm $T(z)$ and a reference geotherm $T_{\mathrm{ref}}(z)$, respectively, multiplied by a thermal expansion coefficient α_{V} and integrated over depth predict an elevation change, $\Delta\varepsilon_{\mathrm{T}}$, given by

$$\Delta\varepsilon_{\mathrm{T}} = \alpha_{\mathrm{V}} \int_0^{z_{\max}} [T(z) - T_{\mathrm{ref}}(z)]dz. \quad (1)$$

The maximum depth of integration, $z_{\max}$, is the depth at which the colder geotherm converges to a mantle adiabat assumed to be identical for both lithospheric regions.

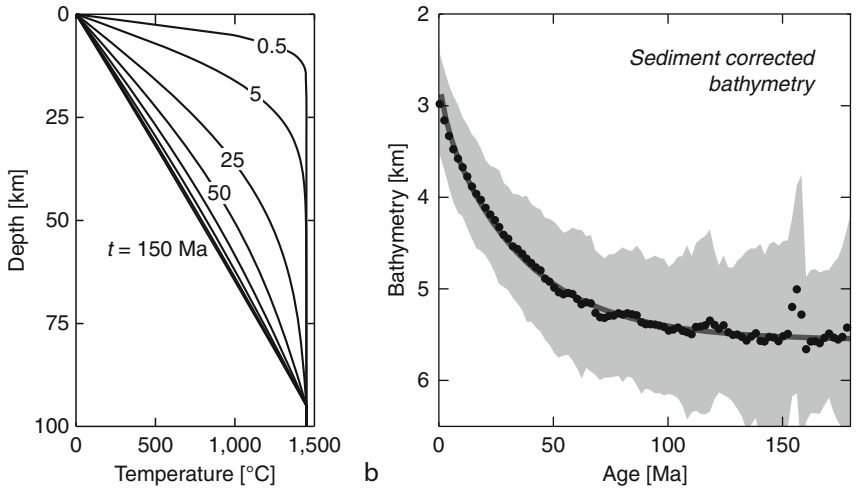
Most studies use a coefficient of thermal expansion of $3.0 \times 10^{-5}\,\mathrm{K}^{-1}$ within the crust, consistent with the values for major crustal forming rocks including granite and gabbro. Within the mantle, a value of thermal expansion of $3.2 \times 10^{-5}\,\mathrm{K}^{-1}$is used.

Oceanic thermal isostasy

The clearest example of thermal isostasy occurs in oceanic regions as hot, near-molten lithosphere at a spreading ridge cools over tens of millions of years leading to thermal contraction, increasing rock density, and subsidence of the seafloor by about 3,000 m. It is important to note that lateral compositional variations are small in oceanic regions. Oceanic crust about 7 km thick is formed at a spreading center and its thickness and composition are modified only in minor ways over its maximum 165 My existence. The thermal state of oceanic lithosphere, on the other hand, varies from a near molten state at the ridge to extremely cold lithosphere after up to 165 My of cooling. These contrasting thermal states have consequences for the rigidity of the lithosphere but in particular for its density and therefore elevation.

Almost since the discovery of plate tectonics and seafloor spreading, thermal isostasy has been invoked to explain the bathymetry of the oceans as a function of age. Figure 1a illustrates the time evolution of an oceanic geotherm for a cooling plate model. The initial condition is 1,450°C (Stein and Stein, 1993); other cooler values lead to similar subsidence curves if thermal expansion values are adjusted accordingly. The ocean lithosphere initially cools rapidly as shown by the large difference between the 0.5 My geotherm and the 5 and 25 My geotherms (Figure 1a). At longer times, the cooling slows and the geotherms reach near steady state shown by the 150 My geotherm. The average temperature change in the lithosphere between zero age at the ridge and about 150 My seafloor is 725 K.

Bathymetry is proportional to the integrated cooling of the oceanic lithosphere (Equation 1) incorporating as well the changing load of water as the seafloor subsides. This



Isostasy, Thermal, Figure 1 Thermal evolution of oceanic lithosphere after formation at a spreading oceanic ridge system. (**a**) Temperature-depth profiles as a function of lithosphere age in millions of years. (**b**) Subsidence of the seafloor as a function of seafloor age. Solid dots are data in 2 My age bins. Gray shading represents ±1 standard deviation about the mean bathymetry.

subsidence (Figure 1b) is explained very well by a simple one-dimensional (1-D) model of lithospheric cooling. A midocean ridge, or zero age lithosphere, has on average a depth of 2.7 km, a consequence of both its thermal state, crustal thickness and composition. But as the lithosphere ages and cools, temperature changes but crustal thickness and composition do not. Cooling over the first 9 My causes a subsidence of 1 km to a depth of 3.7 km. At a lithospheric age of 36 My, the solid surface has subsided a further kilometer to a water depth of 4.7 km. As the lithosphere reaches its thermal equilibrium, the bathymetry also approaches its equilibrium value of 5.5 km.

Continental thermal isostasy

On continents, thermal isostasy has been used successfully to examine the evolution of regions that mimic oceanic spreading, such as continental rifts and elements of provinces with extensive volcanism or back-arc regions (McKenzie, 1978; Jarvis and McKenzie, 1980; Brott et al., 1981; Lachenbruch and Morgan, 1990; Hyndman et al., 2005). However, direct thermal effects on continental elevation are difficult to discern because of the potential masking effect of compositional variations in lithospheric density and thickness.

The elevation effect due to compositional variation can be estimated by a simple isostatic calculation using continental extremes. A mountainous region with a crustal thickness of 50 km and a density of 2,800 kg m^{-3} (granodiorite) would have an elevation 5 km higher than a rift province with a crustal thickness of 25 km and a density of 2,900 kg m^{-3} (gabbro). Both columns assume a similar mantle density of 3,340 kg m^{-3}. The potentially large compositional effect can easily mask the effect of thermal isostasy. Therefore, in order to isolate the effect of thermal isostasy in the continents, it is necessary first to remove compositional isostatic effects.

Normalizing compositional elevation

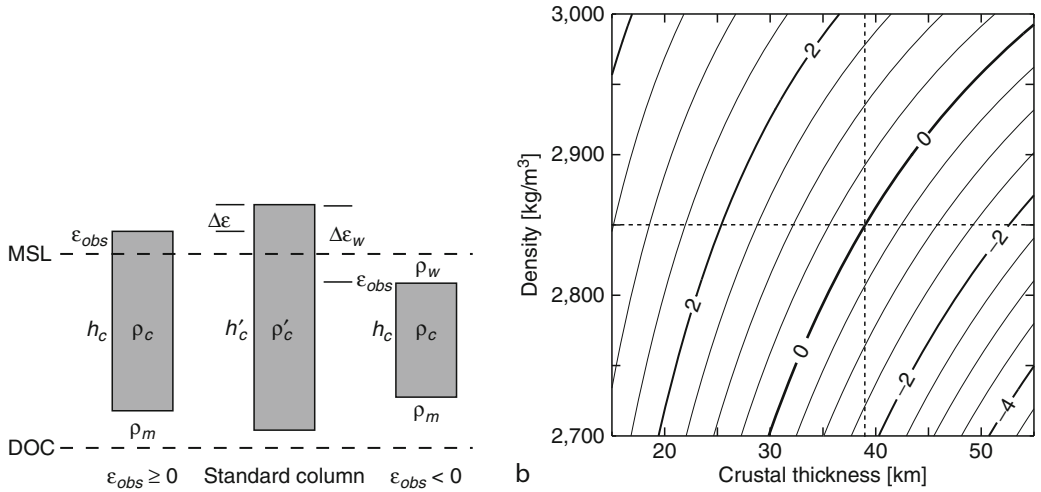
Compositional variations involving both crustal thickness and density are removed with a simple isostatic correction to the observed elevation (Han and Chapman, 1995). The adjustment normalizes any crustal column to an arbitrary crustal standard. In refining this method, Hasterok and Chapman (2007a) used a standard crustal thickness h'_c of 39 km and a standard crustal density ρ'_c of 2,850 kg m^{-3}. These values represent the average crustal thickness and density of North American provinces. A lithospheric mantle density of 3,340 kg m^{-3} is used based on the xenolith derived estimate by Griffin et al. (1999) for Proterozoic lithosphere.

Consider a crustal column with a crustal thickness, h_c, and crustal density, ρ_c, at an elevation of ε_{obs} (Figure 2a). If the density and thickness of the observed crustal column are adjusted to match the standard density and thickness, the elevation would change by an amount $\Delta\varepsilon_c$ (Han and Chapman, 1995) given by

$$\Delta\varepsilon_C = h'_c\left(1 - \frac{\rho'_c}{\rho_m}\right) - h_c\left(1 - \frac{\rho_c}{\rho_m}\right) \quad (2)$$

where ρ_m is the density of the mantle. If the province surface is below sea level (e.g., continental shelf), an additional term involving the water depth (where ε_{obs} is the bathymetry) and seawater density, ρ_w, is required and the elevation adjustment becomes

$$\Delta\varepsilon_C = h'_c\left(1 - \frac{\rho'_c}{\rho_m}\right) - h_c\left(1 - \frac{\rho_c}{\rho_m}\right) - \frac{\varepsilon_{obs}\rho_w}{\rho_m}. \quad (3)$$



Isostasy, Thermal, Figure 2 Compositional isostasy adjustments to continental elevation. (**a**) Cartoon illustrating parameters used in compositional correction for elevation. MSL is mean sea level and DOC is the depth of compensation. The observed crustal columns (*left* for regions above sea level and *right* for continental margins below sea level) are adjusted to an arbitrary standard crust (*center*) of thickness 39 km and density 2,850 kg m^{-3}. (**b**) Nomogram contouring the compositional elevation adjustment for observed crustal thickness and average crustal density. Contour interval is 0.5 km. Dashed lines for crustal thickness of 39 km and density of 2,850 kg m^{-3} represent the standard crustal column. Zero line is locus of values for which the elevation adjustment is zero.

By adding the elevation adjustment to the observed elevation one arrives at the final adjusted elevation, ε_{adj}, given by

$$\varepsilon_{adj} = \varepsilon_{obs} + \Delta\varepsilon_C. \quad (4)$$

Three important physical parameters must be estimated in order to make the compositional adjustment: ε_{obs}, h_c, and ρ_c. The observed elevation is obtained from GTOPO30 for elevations above sea level, and from bathymetric maps for elevations below sea level. Crustal thickness is obtained from 1-D whole crustal V_P models. Crustal density is estimated by using empirical velocity–density (V_P-ρ) relationships. The lateral dimension of each province analyzed varies from ~70 km in some provinces in the Western US to >500 km in shield provinces. See Hasterok and Chapman (2007a,b) for details.

The magnitudes of compositional elevation adjustments made using Equations 2 and 3 are shown in Figure 2b. The zero contour is the locus of crustal thickness and density combinations for which no crustal adjustment is made and therefore passes through the standard crust of thickness 39 km and density 2,850 kg m^{-3}. Over the extreme range of crustal thicknesses (20–60 km) and densities (2,700–3,000 kg m^{-3}), compositional elevation adjustments can be as much as 4 km. Regions that are thinner and/or more dense than the standard crust receive positive elevation adjustments, whereas regions that are thicker and/or less dense than the standard crust receive negative elevation adjustments. Most adjustments in Figure 2b fall in the range +/−1 km. From this nomogram we can also determine the uncertainty in elevation adjustment introduced by variations in crustal thickness and density. For example, to achieve an uncertainty of ± 250 m requires an uncertainty in crustal thickness less than 3 km and in density less than 43 kg m^{-3}.

Continental thermal state

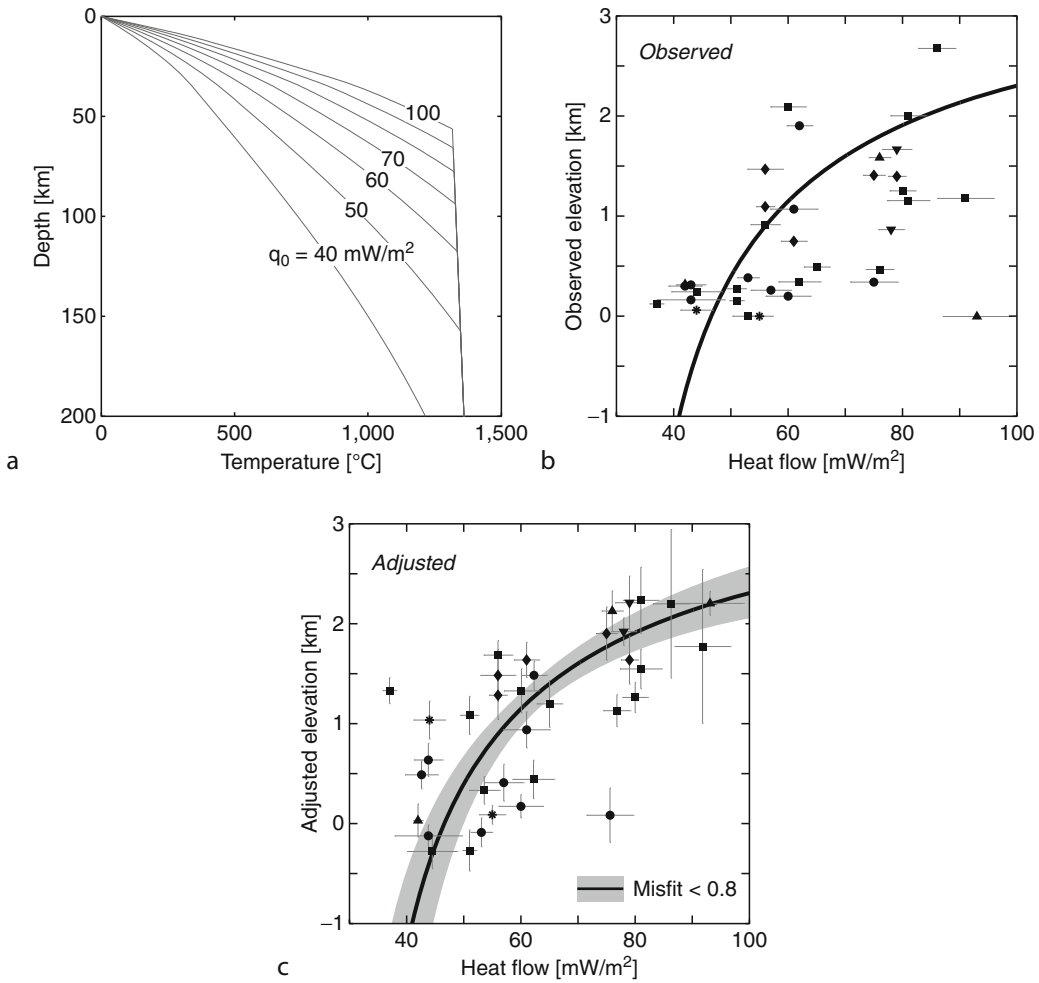
The thermal state of continental lithosphere is described by a set of geotherms. Whereas oceanic geotherms may be identified in terms of age, continental geotherms do not correlate well with rock age. Instead, the most important controlling parameter for continental geotherms is surface heat flow (Pollack and Chapman, 1977b; Chapman and Pollack, 1977; Blackwell, 1971; Lachenbruch and Sass, 1977; Rao et al., 1982).

There exist a number of geotherm models of the continental crust (Blackwell, 1971; Lachenbruch and Sass, 1977; Chapman, 1986; Chapman and Furlong, 1992). Many other models are based on locally derived estimates of thermal conductivity and/or heat production. Although locally and xenolith-derived models may be best in the region for which they are developed, they may be poor estimates when extended to other regions. Therefore, we feel it is best to use a consistent geothermal model based on the fewest parameters necessary to demonstrate the usefulness of this method. We chose the method of Chapman (1986) and Chapman and Furlong (1992) to compute our geotherms because they yield a set of geotherms that are well documented, commonly used, and yield temperatures which fall between other warm and cool models.

The properties of the geotherm model include a lithospheric structure divided into an upper and lower crust and mantle lithosphere. Thermal conductivity within the crust is determined using a pressure-/temperature-dependent relationship of Chapman (1986). Thermal

conductivities within the upper and lower crust are initially set as 3.0 and 2.65 W m^{-1} K^{-1}, respectively, corresponding generally to felsic and mafic crystalline rocks at STP conditions. Mantle lithospheric thermal conductivities include a radiation term at temperatures above 500 K. Surface heat production is determined assuming a 40% radiogenic contribution to surface heat flow with a characteristic depth of 8 km (Pollack and Chapman, 1977a). This characteristic depth is also used as the decay length of an exponentially decreasing function used to compute heat generation within the upper crust. Heat production of the lower crust is set as 0.4 μW m^{-3} consistent with many studies of exposed granulite terranes. Mantle heat production is assumed to be 0.02 μW m^{-3}, a lower value justified by Chapman (1986) and Chapman and Furlong (1992). Temperatures within the asthenosphere are computed using an adiabat with a potential temperature of 1,300 C and increase with depth of 0.3 C km^{-1}. Steady state, 1-D, conductive continental geotherms computed for surface heat flow values between 40 and 100 mW m^{-2} are shown in Figure 3a. Details of the geotherm calculation and boundary conditions used are given by Chapman (1986) and further discussed in Hasterok and Chapman, 2007a).

The thermal structure in some regions differs from the geotherm models used in this study as a result of nonsteady state processes and differences in thermophysical properties. However, we have chosen to



Isostasy, Thermal, Figure 3 Thermal isostasy on continents. (**a**) Generalized family of continental geotherms parametric in surface heat flow values from 40 to100 mW m^{-2}. Geotherms are truncated by the 1,300°C mantle adiabat. (**b**) Observed elevation versus heat flow for individual tectonic provinces of North America. Symbols denote dominant style of tectonic province: circle (shield), star (basin), square (collision), diamond (volcanic), triangle (extension). Error bars are one standard deviation of the mean for heat flow. The geotherms in (**a**) together with Equation 1 are used to calculate a theoretical thermal isostasy relationship shown as a bold line. (**c**) Elevation adjusted for compositional effects versus heat flow for the same tectonic provinces in (**b**). Elevation error bars are predicted from a Monte Carlo analysis of uncertainties in the seismic velocity to density conversion. Data trend confirms expected 3,000 m of thermal isostasy effect.

keep our thermal models as simple as possible, interpreting the more difficult and uncertain parameters, that is, heat production and thermal conductivity, as residuals from a reference thermal isostatic model.

Revealing thermal isostasy on continents

Because the thermal state of continents is not clearly related to the age of the lithosphere as it is in the oceans, one cannot confirm continental thermal isostasy by simply plotting elevation of continental regions against age of the province. Other approaches must be explored. One such approach examined elevation as a function of heat flow for several tectonic provinces around the globe (Han and Chapman, 1995; Nagihara et al., 1996). Hasterok and Chapman (2007a; 2007b) followed the same approach in much greater detail and made an assessment of the uncertainties related to removing compositional isostatic effects.

A thermal isostatic curve for the continents, derived from the geotherm family in Figure 3a and Equation 1 is shown in Figure 3b. We use a reference geotherm corresponding to a surface heat flow of 47 mW m^{-2} and assign a lithosphere having this thermal state an elevation of 0 km. Although the zero elevation reference heat flow at 47 mW m^{-2} is assumed here, the actual zero elevation could easily be set at another value. This initial assumption for the zero-elevation reference heat flow is refined further by Hasterok and Chapman (2007b). Within the range of surface heat flow for continental tectonic provinces (40–90 mW m^{-2}), the predicted elevation range resulting from thermal isostasy is approximately 3 km. This prediction is similar to the oceanic bathymetry difference between hot ridges and cold abyssal plains.

Figure 3b also demonstrates how much continental thermal isostasy is obscured by compositional effects. There is little correlation between observed elevation of 36 North American tectonic provinces and the continental thermal isostatic curve. Much of this scatter is the result of variations in crustal density and thickness between the different tectonic provinces.

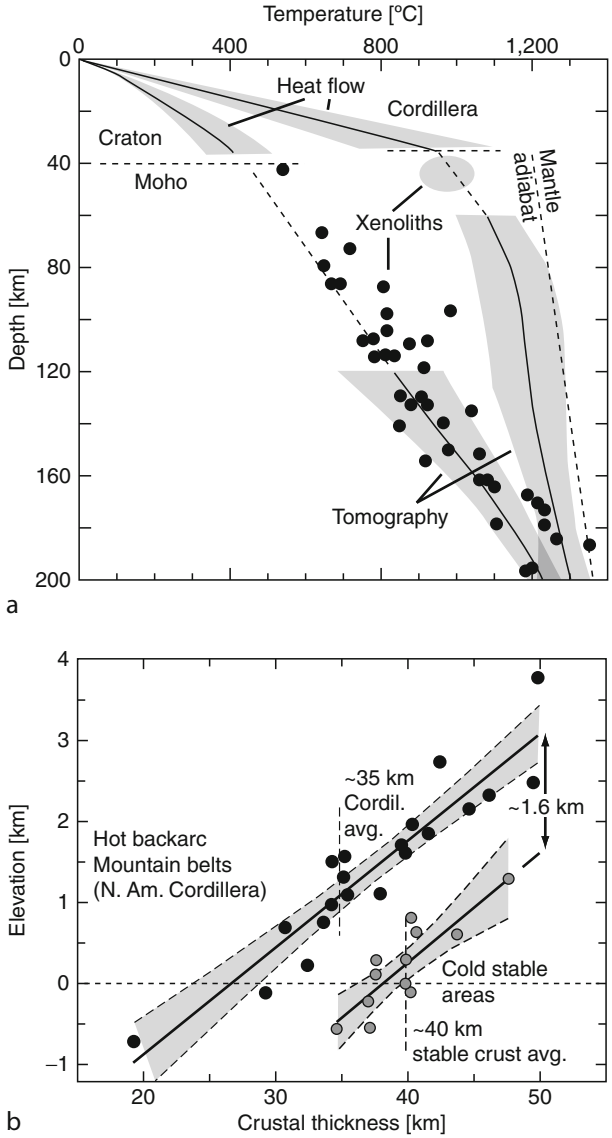
Compositional elevation adjustments for the 36 tectonic provinces of North America range from 763 ± 221 m in the Middle Rocky Mountains to 2,207 ± 119 m in the Gulf of California (Hasterok and Chapman, 2007b). Nearly all of the provinces have compositional elevation adjustments between −1 and +1 km. The results suggest that the compositional contribution to the elevation of North America accounts for ~3 km of observed elevation variation. Patterns are evident in variations of elevation adjustment as a function of crustal thickness and density (Figure 3c). The magnitude and range of elevation adjustments correlate with the type of tectonic regime that characterizes each North American province. Precambrian cratons have compositional adjustments between −0.5 and +0.5 km. Cenozoic rifts have elevation adjustments >0.5 km, and adjustments for volcanic provinces range from just under 0–1.0 km. Collisional orogens have a very large range of elevation adjustments relative to the other tectonic environments, ranging from 0.75 to 1.0 km.

The elevation adjustment is added to the observed elevation to determine the compositionally adjusted elevation (Figure 3c). Although the data shown in Figure 3c exhibit much scatter, two trends are clear. First, the adjusted elevation difference between hot and cold provinces is ~3 km, a magnitude roughly equal to the elevation range observed in the oceans between hot spreading centers and cold abyssal plains. Second, whereas observed elevations do not define a clear trend with heat flow, the adjusted province elevations are less scattered and define a pattern that more closely resembles our predicted thermal isostatic curve (black line). The considerable scatter in Figure 3c may be caused by imperfect compositional adjustment (seismic velocity characterization, velocity to density transform), by regions not being in isostatic equilibrium, or by surface heat flow not being perfectly representative of the thermal state of the lithosphere as described by the geotherm model used.

The North American Cordillera

The elevation of the North American Cordillera provides an excellent case study for thermal isostasy. Conventional wisdom suggests that many continental mountain belts, the result of continent–continent collision, are elevated because the collision process has thickened the continental crust. Airy isostasy considerations predict terrain elevations of 1,000–2,000 m as a result of thickened crust. But Hyndman (2010) point out that modern seismic data reveal that many of these collision provinces, in particular the North American Cordillera, do not have crustal roots. The Canadian Cordillera, for example, has a crustal thickness of only 35 km in comparison to the Canadian Shield crustal thickness of 40 km. But the elevation of the thinner crust Cordillera is more than 1,000 m higher than the Canadian Shield, exactly opposite to the Airy compositional isostasy prediction.

The solution to this apparent conundrum is found in thermal isostasy (Hyndman, 2010). Hyndman et al. (2005) and Currie and Hyndman (2006) have shown that high upper mantle temperatures characterize most subduction back-arc regions (see also Lewis et al., 1992; Lewis et al., 2003). And that many mountain belts also occur in current or recent back-arc locations. The temperature-depth field for the Cordillera, therefore, is much hotter than for a cratonic region (Figure 4a). The Cordillera geotherm approaches a mantle adiabat at a depth of about 60 km, defining the lithospheric thickness for the Cordillera, while the Craton geotherm does not approach the mantle adiabat until a depth of more than 200 km. If Equation 1 is applied to these two regions, the estimated difference in elevation, once compositional effects have been removed should be about 1,600 m. Figure 4b (from Hyndman, 2010) shows exactly that effect. Elevations for both back-arc mountain belts and cold stable areas



Isostasy, Thermal, Figure 4 Thermal isostasy case study for North America Cordillera (after Hyndman, 2010). (**a**) Temperature-depth plot for the northern Cordillera in comparison to the adjacent craton. Shaded regions in the mantle are general results from tomography; solid dots are temperature-depth loci from xenolith studies (see Hyndman, 2010 for details). (**b**) Elevation adjusted for composition (density) versus crustal thickness (Table 3 of Hasterok and Chapman, 2007b) for the hot Cordillera and cold stable areas of North America. The ~1.6 km elevation difference can be explained by thermal isostasy using Equation 1.

corrected for compositional density effects are plotted against local crustal thickness. Each group of data exhibit the expected trend of increasing elevation with increasing crustal thickness, but the Cordillera elevations are consistently 1,600 m higher than stable area elevations for the same crustal thickness.

Summary

Thermal isostasy, that part of isostasy traceable to density differences being caused by temperature differences and thermal expansion of rock, is an important but underappreciated condition in crustal geophysics. The condition/process of thermal isostasy received much attention in oceanic regions with the discovery of plate tectonics and seafloor spreading. It was quickly recognized that systematic cooling of the lithosphere formed at a spreading ridge could explain the 3,000 m of seafloor subsidence away from a ridge. On continents, thermal isostasy effects are obscured by compositional isostasy, principally crustal thickness, which produces over 3,000 m of elevation effects. Recent analyses, however, have developed methods to adjust elevations for compositional effects. When those adjustments are made, there is a clear trend of increasing elevation of a continental province with surface heat flow – a confirmation of thermal isostasy. The magnitude of elevation differences between hot and cold continental regions is also about 3,000 m, comparable to thermal isostasy effects in marine areas. An excellent example of thermal isostasy effects is drawn from the North American Cordillera where Airy isostasy is unable to explain the elevation of the Cordillera terrains relative to stable shield areas. Instead, the hot upper mantle associated with current or recent back-arc activity, conveniently explains the 1,600 m of elevation difference that is observed.

Definition

The legal continental shelf comprises the submerged prolongation of the land mass of a coastal State beyond 200 nautical miles from the territorial sea baselines, and consists of the seabed and subsoil of the shelf, the slope, and the rise. Formulae to determine the outer limits of the legal continental shelf are in article 76 of the United Nations Convention on the Law of the Sea. These formulae are based on seafloor morphology and sediment thickness. The outer limits of the legal continental shelf cannot exceed 350 nautical miles from the territorial sea baselines or 100 nautical miles beyond the 2,500 m isobath.

Introduction

The United Nations Convention on the Law of the Sea (UNCLOS) was adopted in 1982 after 9 years of discussion, bargaining, and compromise (Division for Ocean Affairs and the Law of the Sea DOALOS, 2007). Significant features of UNCLOS relevant to the management of natural resources include establishment of the 200 nautical mile (M) Exclusive Economic Zone (EEZ) and of the legal continental shelf.

Within the 200 M EEZ a State has rights to resources in the water column, such as deep-sea fisheries, and resources on and beneath the seafloor, such as oil, gas, and other minerals. Within the legal continental shelf, a State has rights to resources on and beneath the seafloor, but not to resources in the water column.

Areas of legal continental shelf in submissions to the United Nations cover large parts of the oceans and include seafloor with a wide variety of morphologic and geologic characteristics. The attribute these areas have in common is an interpreted link to the land mass of a coastal State. Techniques to establish the outer limits of the legal continental shelf are described in article 76 of UNCLOS and Annex II of the Final Act of the Third United Nations Conference on the Law of the Sea (the Statement of Understanding).

Establishing the outer limits of the legal continental shelf

Delimitation of the 200 M EEZ is a geodetic calculation using basepoints and/or baselines established along the coastline of the State, subject to negotiations with other States where EEZs overlap. Article 76 of UNCLOS states that the continental shelf comprises the submarine prolongation of the State's land mass and consists of the shelf, slope, and rise but it does not include the deep ocean floor (Figure 1). The article sets out a process whereby States can define the outer limits of a legal continental shelf beyond 200 M. The Statement of Understanding extends the principles of article 76 to coastal States in the southern part of the Bay of Bengal that have an extraordinarily extensive rise.

Application of the concept of prolongation to the complex seafloor and geological relationships of continental margins can be challenging. Establishing whether prolongation occurs and the nature of that prolongation are of primary importance because they determine (a) whether a legal continental shelf exists and (b) how far it extends beyond 200 M. Article 76 refers to a variety of submarine features, including plateaux, rises, caps, banks, spurs,

submarine ridges, and oceanic ridges. Submarine ridges, for example, are subject to the 350 M constraint (Symonds and Brekke, 2004), whereas other features are subject to the 2,500 m + 100 M constraint. On margins with expansive, relatively shallow slopes the 2,500 m + 100 M constraint could lie far seaward of the 350 M line.

Prolongation of land mass

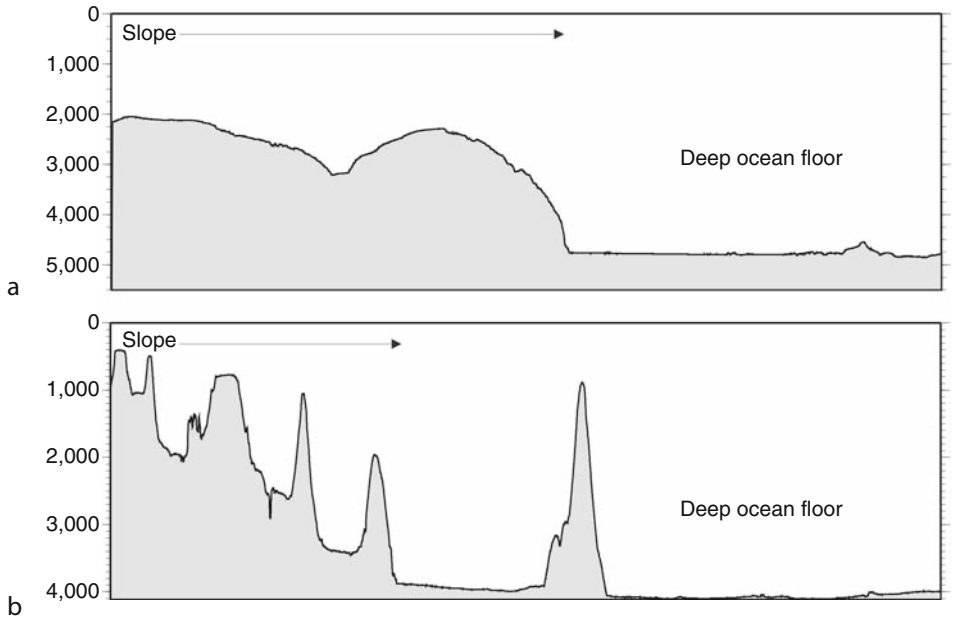
There are three aspects of prolongation of a land mass:

- Morphologic – the seafloor shape is a continuation of the land mass morphology
- Geologic – the rocks beneath the seafloor are the same as, or related to, those of the land mass
- Tectonic – the rocks beneath the seafloor share their history with those of the land mass

The morphological transition from land mass to deep ocean floor is the result of the composition and density of the rocks beneath the seafloor, the geologic processes that form and shape them, and the tectonic forces that act on them. This transition is relatively simple on many margins, with a shelf dipping gently to a depth of several hundred meters, a steeper slope deepening to a depth of several thousand meters, and on some margins a gently dipping rise lying between the slope and the almost flat deep ocean floor (Figure 2a). Other margins have a complex morphology with ridges, seamounts, and canyons and the transition with the deep ocean floor can be harder to recognize (Figure 2b).

Prolongation of a land mass cannot be established solely on the basis of rock type. Land masses are usually the result of igneous, metamorphic, sedimentary, and tectonic processes that form geologically complex crust that is generally distinctly different from the crust of the deep ocean floor. The deep ocean floor is the result of sea floor spreading and is characterized by basaltic rocks. Rocks such as granite, marble, and sandstone only form as part of continent building processes and can be used to infer that an area is continental in origin, but land masses are not always composed of continental-type rocks. Iceland and other volcanic islands are examples of land masses that are composed of basaltic rocks, and oceanic rocks can be thrust onto or accreted to a land mass or continent by tectonic movements.

Lines of volcanoes are common above active and fossil subduction zones, particularly around the Pacific. Volcanic arcs often extend into large continental blocks and the rocks associated with them form the core of many continents. The Three Kings Ridge, Colville Ridge, and Kermadec Ridge are three volcanic arcs that extend thousands of kilometers north of the North Island of New Zealand (Figure 3). These ridges are part of the



Legal Continental Shelf, Figure 2 Bathymetry profiles across a continental margin showing a relatively simple (**a**) and a more complex morphology of the continental slope (**b**).

morphological, geological, and tectonic prolongations of the land mass of New Zealand (e.g., Mortimer et al., 2007).

Tectonic prolongation implies that the rocks beneath the seafloor have a shared history with the rocks of the land mass. Shared history refers to the processes of continent building: sediment deposition, igneous activity, and suturing or accretion of rocks along plate margins. Disruption of this history results from fragmentation of the land mass by the tectonic processes of rifting and seafloor spreading. Continents and land masses are part of the plate tectonic conveyor system, and their extent and composition changes with time as the result of interactions along the plate margins.

The geologic, morphologic, and tectonic boundaries are seldom, if ever, abrupt, and implicit in the determination of prolongation is an assessment of the degree of the continuity or uniformity of the geology, morphology, and tectonic history.

The Hikurangi Plateau is an example of a basaltic tectonic block that is a part of the prolongation of the New Zealand land mass (Figure 3). The plateau was accreted to the New Zealand continent when it collided with a subduction zone along the Gondwana margin more than

100 million years ago (Davy, 1993). The plateau stands more than 1,000 m above the deep ocean floor and is morphologically, geologically, and tectonically connected to the New Zealand land mass.

Application of UNCLOS article 76

The process for defining the outer limits of a legal continental shelf beyond 200 M has four steps (Figure 4); (1) the area of prolongation of the land mass is determined using two formulae, (2) constraint lines are determined using two methods, (3) the appropriate constraints are applied to the area of prolongation, and (4) the resulting line composed of formulae and/or constraint lines is smoothed with 60 M bridging lines.

Both formulae use the location of the foot of the continental slope as a reference point. The Commission on the Limits of the Continental Shelf (CLSC) (1999) declares a preference for identifying the foot of the continental slope as the point of maximum change in seafloor gradient as the general rule, and use of "evidence to the contrary" as exceptions to the rule. The guidelines state that these exceptions can be applied when the foot of the continental slope is not located reliably by the point of maximum change in sea floor gradient, and that they provide an opportunity for States to use geological and geophysical evidence to locate the foot of the continental slope.

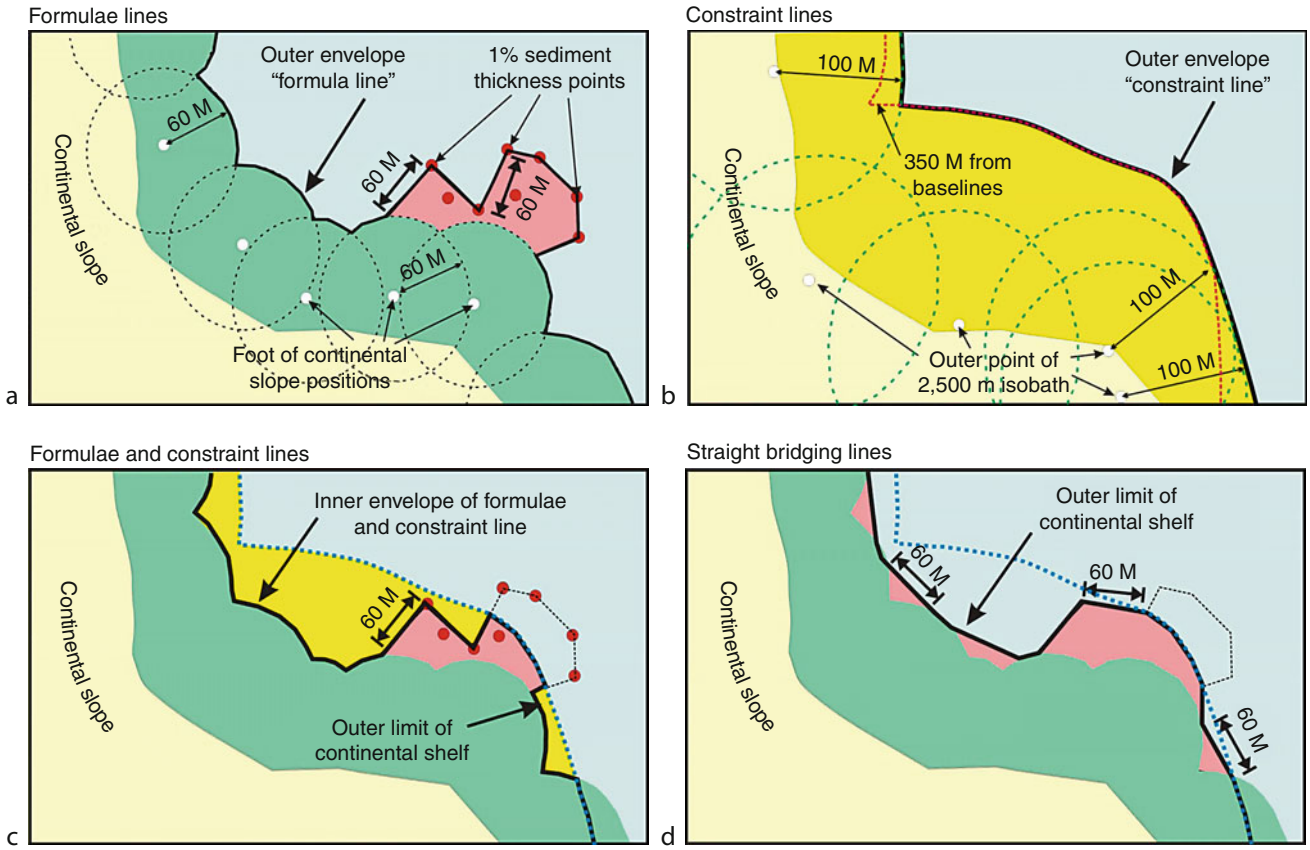
Locating the foot of the continental slope

There are two steps to find the foot of the continental slope:

1. Identify the region of the base of the continental slope.
2. Determine the location of the foot of the continental slope within that region.

Identification of the region of the base of the continental slope may be on the basis of morphological evidence and/or geological and geophysical evidence.

In areas where the morphology of the continental margin can be clearly subdivided into shelf, slope, rise, and deep ocean floor (Figure 1), the region of the base of the continental slope is where the lower continental slope meets the rise, or where it meets the deep ocean floor in



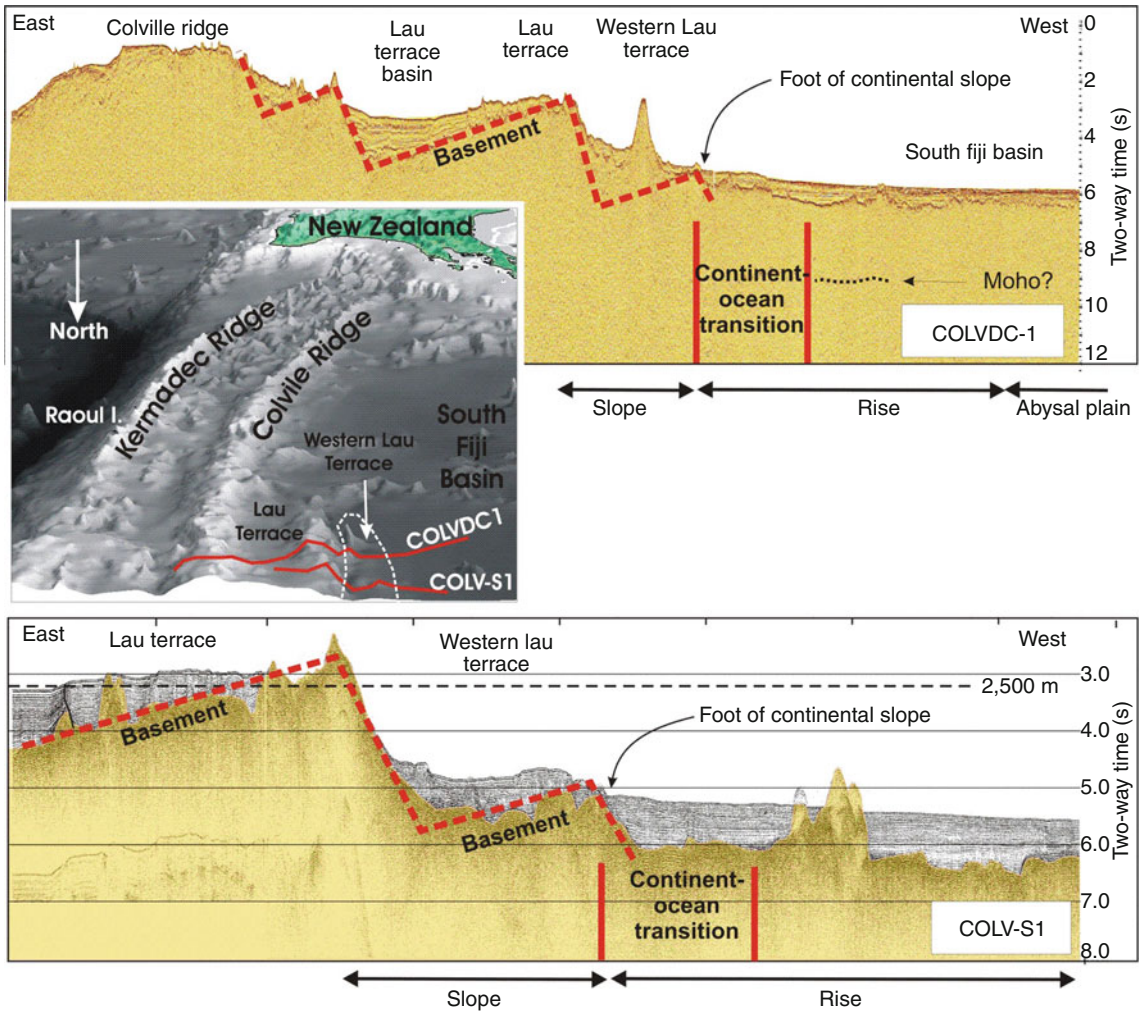
Legal Continental Shelf, Figure 4 The four steps for establishing the outer limits of the legal continental shelf: (**a**) Determine foot of slope positions and apply formulae in paragraph 4 of article 76; (**b**) Establish constraint line by application of paragraphs 5 and 6 of article 76; (**c**) Intersect formula and constraint lines to establish fixed points along outer limits of the continental shelf; (**d**) Delineate the outer limits of the continental shelf with straight bridging lines no more than 60 m long between fixed points, as specified in paragraph 7 of article 76.

cases where a rise is absent. Regional gradients can be used to narrow the search for the region of the base of the continental slope. Regional gradients less than 1° are generally considered representative of the rise and deep ocean floor, and regional gradients greater than 2° are generally considered representative of the slope. There are many exceptions to these values, however, and other evidence, such as the erosion effects of deep-sea currents, underwater slides, margin collapse, local volcanic activity, and deep-sea canyons must be considered before finally establishing the region of the base of the continental slope. The width of the region of the base of the continental slope is typically 4–10 km, but can vary according to the complexity of the margin.

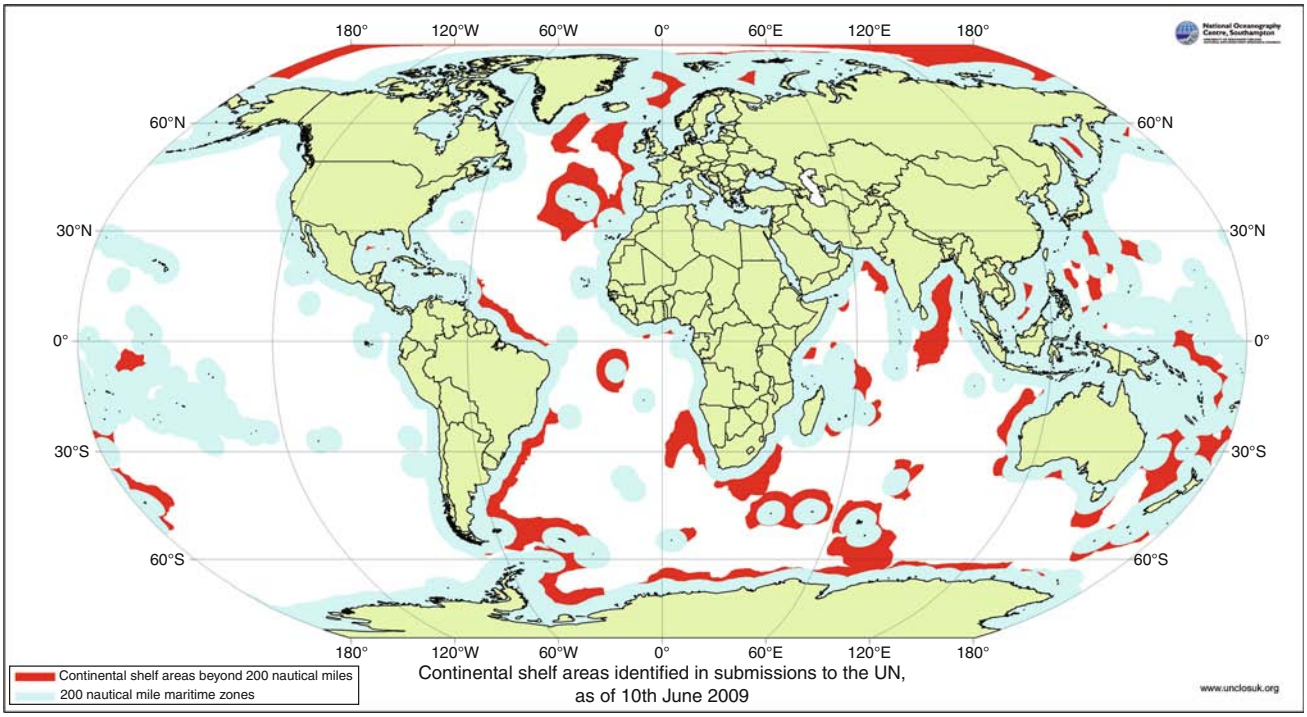
The point of maximum change in gradient is determined by computing the second derivative of the bathymetry within this region. The foot of the continental slope is the point with the maximum value of the second derivative of the bathymetry.

Situations in which the maximum change in seafloor gradient rule might not reliably locate the foot of the continental slope include continental margins that have a very smooth transition from slope to rise and no single point represents a significant maximum change in gradient, and continental margins with irregular seafloor morphology and a point of maximum change in gradient that is not consistent with other data that indicate the location of the foot of the continental slope.

The region of the Western Lau Terrace, north of New Zealand (Figure 5) provides an example of the use of geological and geophysical evidence to identify the region of the base of the continental slope. This part of the New Zealand continental margin is characterized by terraces and sediment-filled basins formed by tilted basement blocks that step down to the deep ocean floor of the South Fiji Basin. The continent ocean transition lies at the western edge of the Western Lau Terrace and the foot of the continental slope is identified as the point with



Legal Continental Shelf, Figure 5 Seismic sections and a location map (looking south) of the Lau Terrace and Western Lau Terrace. Basement fault blocks are shown by *red dashed lines*.



Legal Continental Shelf, Figure 6 Red areas indicate areas of legal continental shelf submitted to the United Nations. Please also refer to www.unclosuk.org.

the maximum change in seafloor gradient within the transition zone.

Once the foot of the continental shelf points are established, then the outer limits of the continental margin are constructed either 60 M from these points, or at fixed points where the sediment thickness is at least 1% of the distance to these points, whichever is greater (Figure 4b).

Establishing constraint lines

The constraint line is constructed from the line 350 M from the basepoints from which the breadth of the territorial sea is measured and the line 100 M from the 2,500 m water depth contour, whichever is greater. Construction of the constraint line requires consideration of whether the features are submarine ridges or are natural components of the continental margin. The continental shelf cannot extend beyond the constraint line, so the intersection of the constraint line with the area inside the formula lines defines fixed points along the outer edge of the continental shelf (Figure 4c).

Straight bridging lines

The final step in the construction of the outer limits of the continental shelf is to join the fixed points with straight bridging lines no more than 60 M long (Figure 4d). The outer limits of the continental shelf therefore can be comprised of points that lie on arcs 60 M from foot of the slope positions, points where the sediment thickness is at least 1% of the distance to foot of the slope positions, points 350 M from the territorial sea basepoints, points 100 M from the 2,500 m isobath, and points on bridging lines between fixed points.

Summary

Ratification of UNCLOS by coastal States has led to a renewed interest in the morphology and geology of continental margins. These States have applied the terms of article 76 and the Statement of Understanding to their continental margins and identified large areas of legal continental shelf (Figure 6). At the time of writing most of these areas are awaiting recommendations by the United Nations Commission on the Limits of the Continental Shelf.

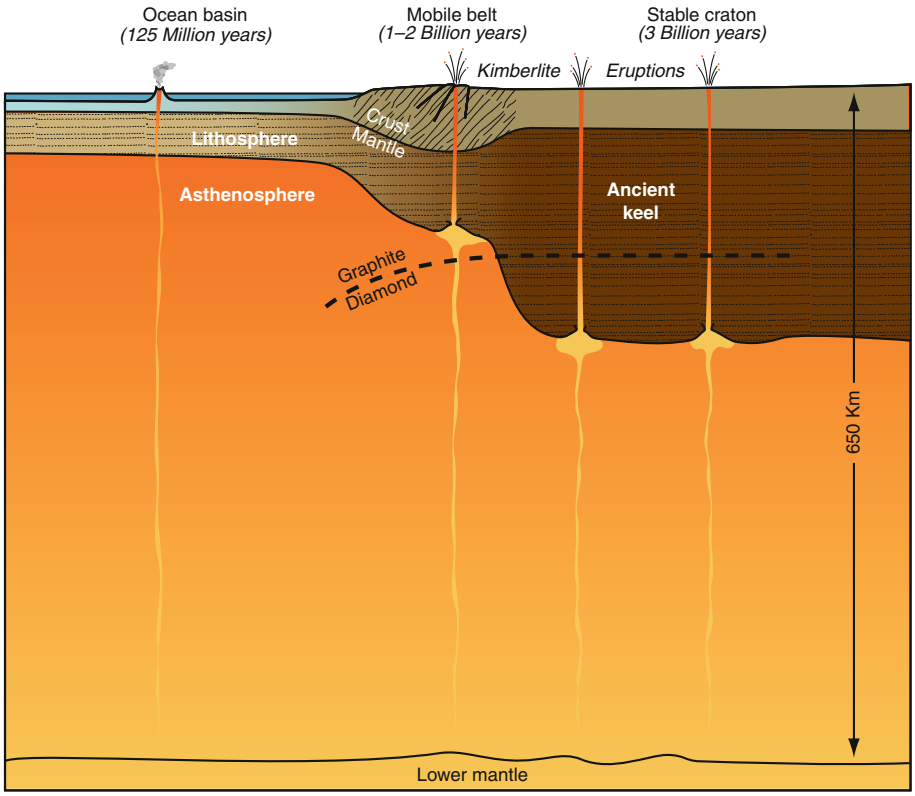
LITHOSPHERE, CONTINENTAL

David E. James
Department of Terrestrial Magnetism, Carnegie Institution of Washington, Washington, DC, USA

Definition and introduction

The continental lithosphere consists of the continental crust and, typically, some nonconvecting part of the underlying upper mantle (Figure 1). In plate tectonics terms, the continental lithosphere is part of the rigid outer rind of the Earth, which is segmented into several major plates. The cold lithosphere lies atop a hotter, more mobile (low strength) asthenosphere. In this context, oceanic lithosphere for the most part obeys comparatively simple thermal models, with the boundary between lithosphere and asthenosphere represented by an isotherm marking the transition in mantle peridotite between elastic and ductile behavior (but see *Lithosphere, Oceanic* for the growing list of complications). By contrast, the continental lithosphere is heterogeneous and its structure highly variable. That contrast reflects the fact that oceanic lithosphere is formed in much the same way worldwide and that it is continually recycled into the interior of the Earth via the plate tectonic "conveyer belt." Continental lithosphere, on the other hand, is generally too buoyant to be subducted, although an increasing number of instances have been reported in which parts of continental lithospheric mantle show evidence of gravitational instability, forming "drips" where lithosphere delaminates and sinks into the deeper mantle (Zandt et al., 2004). The detachment of continental mantle from the crust in such circumstances may be an important factor in intraplate



Lithosphere, Continental, Figure 1 Schematic cross section showing transition from oceanic lithosphere to younger continental lithosphere and into the thick, cratonic lithosphere (tectosphere) beneath the ancient continental nucleii. Melts rising from depth ascent through relatively thin oceanic and young continental lithosphere to produce volcanoes at the surface, whereas thick tectosphere acts as a barrier to melts percolating from depth, requiring evolved, volatile-rich kimberlitic magmas to bore a conduit through the mantle to the surface.

deformation and volcanism (Carlson et al., 2005). Thus, while no known oceanic lithosphere is older than about 200 my, the continental lithosphere has evolved over billions of years, one consequence of which is that it is seen today as the resulting collage of many superimposed tectonic events, including rifting, subduction, continental collision, accretion, and hot spot magmatism, that recur repeatedly over geologic time.

The study of continental lithosphere has been revolutionized over the past two decades with the advent of portable broadband seismology. Passive array experiments (see *Seismological Networks*) have made it possible to obtain high-resolution images of deep lithospheric structures beneath every continent (James, 2007). The greatest concentration of high-density broadband deployments has been in western North America, Europe, and Asia, with large-scale experiments also in Africa, Central and South America, and Australia. Within the USA, the Transportable Array of the national EarthScope project has already resulted (at the time of this writing) in uniformly high-resolution seismic imaging of the mantle beneath the western half of the nation. The lithosphere so revealed consists of a collage of overlapping structures produced by ongoing subduction, trench migration, ridge override, regional extension, mantle upwellings and volcanism, and lithospheric delamination. In some tectonically active regions, a thin crust is the only lithosphere remaining intact (Carlson et al., 2005). This complex and disrupted lithosphere is in marked contrast to that of stable cratonic regions, including the continental nuclei of north-central North America, western Australia, and southern Africa. The cratons of southern Africa are perhaps the best studied of the Archean cratons of the world, where results from large-scale passive array experiments show that lithospheric roots as deep as 250 km or more underlie the undisturbed parts of the cratons (James and Fouch, 2002; Ritsema and van Heijst, 2000).

Despite remarkable progress in imaging the continental lithosphere over the past 2 decades, a precise definition of continental lithosphere remains elusive. No single definition of continental lithosphere can be made to fit all circumstances. Particularly controversial is the definition of what constitutes the base of the lithosphere. Many definitions of continental lithosphere appear in the literature – seismological, mechanical, rheological, thermal, and compositional. Depending on one's view, the continental lithosphere may be a *mechanical boundary layer,* a *thermal boundary layer*, or a *chemical boundary layer.* In the remainder of this entry, we shall explore these various concepts in some detail. Our goal here is to describe the continental lithosphere in terms of global Earth structure, plate tectonics, and the long-term evolution of the continents. By this view, the continental lithosphere is envisaged to be a long-lived plate tectonic unit, consisting both of continental crust and, typically, a very significant mantle "keel" that is attached to and translates with the continent. In this sense, it is seen as a stable component of the continent and does not participate in the convective processes of the deeper dynamic mantle.

Mechanical models

A simple expression of the lithosphere is *elastic thickness*. While rarely used to describe continental lithospheric in a geologic or structural sense, elastic thickness is a useful concept in that it models the mechanical response of the lithosphere as an elastic plate overlying a weak (asthenospheric) substrate. As discussed in detail elsewhere in this volume (see *Lithosphere, Mechanical Properties*), the elastic thickness of the lithosphere may be determined through topographic response to surface loads (such as volcanoes), the relationship between topography and Bouguer gravity anomalies, or the shape of depositional surfaces in basins. The thickness of elastic lithosphere so determined is rarely as much as 100 km and in areas of extension or hotspot activity may be less even than crustal thickness. The elastic thickness of the continents is chiefly controlled by the thermal state of the lithosphere (see *Lithosphere, Mechanical Properties*). As Forsyth (Forsyth, 1989) points out, however, the apparent elastic thickness is also affected by the state of stress and the rheological stratification in the crust and mantle, so mechanical thickness may not bear a simple relationship to a particular isotherm.

One important aspect of the mechanical structure of the continental lithosphere as it relates to lithospheric evolution is the large decrease in strength of crustal rocks in the deep crust. The steep geothermal gradient in the crust produces increasing ductility of crustal rocks with depth. The brittle zone in tectonic areas typically extends only to about 15 km, below which the rocks deform plastically. The topmost part of the underlying mantle, however, is relatively much stronger as temperatures there are still far from the melting point of mantle rocks. Thus, it is widely posited that there is a zone of weak lower crust sandwiched between strong upper crust and strong upper mantle, creating a possible zone of crust–mantle decoupling (see *Lithosphere, Mechanical Properties*).

While the flexural lithosphere is a useful *mechanical* concept, it fails as a plate tectonic description of lithosphere. In many tectonic regions, the flexural lithosphere is not even as thick as the continental crust. As low-density sialic crust is not easily subducted into the mantle, it must persist as the primary long-lived component of continental lithosphere. From the perspective of plate tectonics, it may be argued that the full definition of the lithosphere should account both for the long-term structural coherence of continental plates and the impact of asthenospheric processes that affect either the formation or the removal of lithospheric mantle beneath the crust.

Thermal models

A convenient definition for *thermal lithosphere*, or the thermal boundary layer, is the outer layer of the Earth in

which heat transfer is dominated by conduction (see *Heat Flow, Continental*; *Lithosphere, Continental: Thermal Structure*). Thus, the stronger lithosphere acts as a barrier to thermally induced buoyancy forces that drive convective heat transfer in the underlying asthenosphere (Morgan, 1984). In the case of the oceanic lithosphere, this conductively cooled layer of the Earth is thought to have finite thickness (i.e., the lithosphere ceases to undergo thermal contraction as it ages beyond about 80 Ma, implying that heat is supplied to the lithosphere from the underlying asthenosphere) (see *Lithosphere, Oceanic*; *Lithosphere, Oceanic: Thermal Structure*). For the continents, the situation is far more complex. The continental lithosphere does not undergo simple monotonic cooling, but may be subjected to repeated episodes of thermal or tectonic disturbances. Thus, superimposed upon the geological age of the lithosphere is the thermal or tectonic age of the lithosphere, factors that have led to significant compositional heterogeneity in both crust and lithospheric mantle.

We consider first the thickness of the thermal boundary layer beneath the stable cratonic cores of the continents. Here, the lithosphere is both at its thickest and its strongest. If the effective viscosity of the asthenosphere beneath the cratonic lithosphere is taken to be about 10^{21} Pa s, based upon glacial unloading and gravity/topography correlations (see *Mantle Viscosity*), it implies a temperature of transition from conductive to convective heat transfer of about 1300–1400°C for typical mantle compositions (Morgan, 1984). If crustal heat production is taken into account, the thickness of the thermal lithosphere of the stable continental cratons as calculated from surface heat flow may range from about 90 to 220 km (Rudnick et al., 1998).

The lithospheric thickness obtained by thermal modeling depends upon other factors, the most important of which is the composition, including volatile content, of the subcrustal mantle. If the continental lithospheric mantle consists of low-density peridotite depleted of its low-melting basaltic fraction and devolatilized over time due to metamorphic and magmatic events (see discussion below), the continental mantle will be less dense and substantially more refractory than the rest of the mantle. The chemical boundary layer represented by this depleted subcontinental mantle peridotite may stabilize the continental mantle root against thermal disruption to depths below the thermal boundary layer (Jordan, 1978, 1981).

Tectono-thermal events, such as those that are widespread across the western USA, will have the effect of thinning the existing lithosphere. Regions where prior thermal disturbances have occurred, therefore, may be more prone to reactivation, whereas stable cratons, particularly those buffered by bordering Proterozoic mobile belts as in southern Africa, should be comparatively less vulnerable to thermal perturbations from the underlying asthenosphere (Pollack, 1986). Tectonic reactivation seems to be particularly true of continental rifting, where repeated episodes apparently recur along the same long-lived zones of weakness. The greatly expanded scope of tomographic studies in recent years has revealed a number of localities in which various forms of lithospheric delaminations, or "drips" appear to be occurring, including a number in the western USA (e.g., [West et al., 2009; Zandt et al., 2004]). Such processes suggest that lithospheric mantle beneath tectonically active areas of the continent may be thinned or removed and later regenerated. Indeed, a wide range of epeirogenic (vertical) movements within continental interiors have been interpreted to be due to thermal disturbances that produce lithosphere heating and thinning, followed by conductive relaxation and asymptotic thickening of the lithospheric thermal boundary layer.

Seismological/compositional models – tectosphere

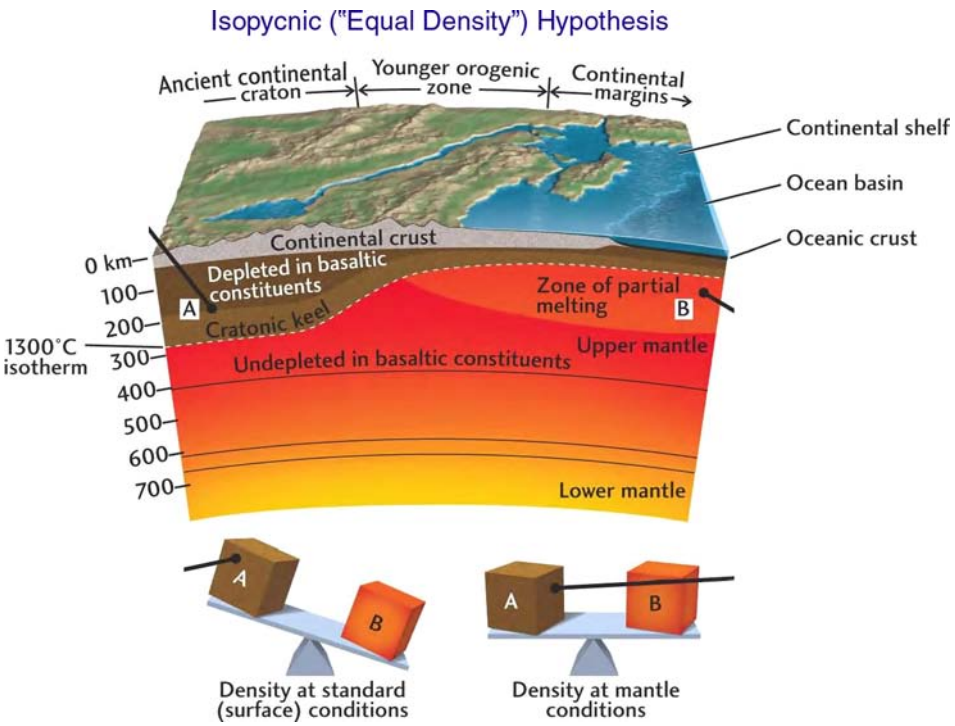
It is well known that average seismic velocities, especially shear velocity, are much higher under cratons than under oceanic or tectonically active areas. This was first shown by surface wave dispersion measurements and later by measurements of vertically travelling ScS phases. Sipkin and Jordan (Sipkin and Jordan, 1980) showed that ScS one-way travel-time anomalies associated with the upper mantle beneath stable continental interiors could be as large as 3.5 s (fast) relative to the upper mantle beneath the western Pacific. Moreover, the high-velocity continental paths are also associated with high Q_s, suggesting that the anomalies are due to thermal and/or compositional variations in the upper mantle (Jordan, 1981). Since the early studies of Sipkin and Jordan, numerous other studies based on three-dimensional inversion of travel-time anomalies for velocity structure have been carried out regionally across the globe (see summaries in [Carlson et al., 2005; James, 2007]). The results nearly all show that regional velocity contrasts, even between provinces entirely within the continents, extend to at least 200–250 km (James, 2007).

The notion of a long-lived thermochemical boundary layer in the upper mantle beneath vast regions of Precambrian crust raised many difficult questions as to how they formed and how they survived over geologic time and to a significant extent these questions remain only partially answered. There is general agreement, however, that the longevity and stability of ancient cratonic roots must be due, at least in part, to a combination of factors, primarily compositional buoyancy and strength and secondarily buffering of cratons by marginal Proterozoic mobile belts. The concept of a stabilizing chemical boundary layer is at the heart of the *temperature-depletion compensation* hypothesis laid out by Jordan in an important series of papers on the continental *tectosphere* (see [Jordan, 1981] for references) and discussed in some detail below. The term tectosphere was introduced by Jordan in an attempt to circumvent some of the difficulties associated with the conflicting definitions of lithosphere alluded to above. It is a particularly convenient concept for understanding those seismological and petrological/geochemical aspects

of deep continental structure that appear to indicate continent-ocean heterogeneity to depths of at least 200 km, and perhaps considerably more.

There is a large body of knowledge about the composition of deep cratonic mantle from the study of xenoliths that have been carried to the surface in explosive volcanic pipes. The development of accurate mineralogical geothermometers and geobarometers, which allow the equilibrium depth and temperature of xenolith source regions to be determined, made it possible to "map" xenolith compositions as functions of position in the mantle. A comprehensive summary of results from the geochemical study of mantle xenoliths can be found in (Carlson et al., 2005). Most of the ultramafic nodules associated with older cratonic areas are highly depleted in their basaltic melt fraction to a depth of at least 200 km and are approximately the same age as the overlying crust (Carlson et al., 2005; James et al., 2004). Depleted mantle xenoliths, which are by far the most common, are characterized by significantly lower density and higher seismic velocities than the more typical fertile suboceanic mantle (Boyd and McCallister, 1976). This fact led Jordan (Jordan, 1981) to postulate a thick *chemical boundary layer* for the continental tectosphere.

The effect of removing a basaltic partial melt from a fertile mantle peridotite (such as the hypothetical pyrolite of suboceanic mantle) is to reduce the density of the residue and to increase seismic velocities. Jordan compared densities of depleted peridotite nodules with densities of a hypothetical pyrolite composition and shows that average depleted peridotite of subcontinental mantle has a normative density about 1.3% less than that of pyrolite. This reduction in density will approximately compensate for the density contrast in a homogeneous mantle that would result from the temperature contrast of about −400° between a typical shield geotherm and the average oceanic adiabat. The model then, is based on the supposition that the lower density of the subcontinental mantle due to basalt depletion is gravitationally balanced by the density decrease in the oceanic mantle caused by a much higher geotherm, hence the expression *temperature-depletion compensation* (Figure 2). The thickness of the chemical boundary layer is generally taken to be about 150–200 km.



Lithosphere, Continental, Figure 2 Schematic diagram (adapted from Jordan, e.g., [Jordan 1988] with reference to previous work) showing the principal components of the isopycnic ("equal density") hypothesis. The cold, strong lithosphere (A) extends to at least 250 km beneath the ancient cratons and migrates with the craton during plate motions. At comparable depths beneath the oceans (B), the mantle is hot, weak, and mobile. The depleted mantle peridotite that makes in the cratonic keel is depleted in heavier constituents (e.g., Fe) and is therefore intrinsically less dense than more fertile oceanic mantle at the same temperature and pressure. At the same time, the sub-cratonic mantle is colder than the suboceanic mantle so the densities are approximately equal (the "temperature-depletion compensation" model). The chemical buoyancy of the cratonic root, along with its anhydrous strength, helps stabilize it against convective disruption over geologic time.

The tectosphere model remains controversial. The mechanisms by which a chemical boundary layer can be built up to form a deep mantle keel beneath ancient continental crust are poorly understood, although there are many modes by which magma can be extracted from continental mantle over time (Carlson et al., 2005). The most difficult aspect of deep mantle roots to model, however, has been their remarkable dynamical stability over billions of years of a chemical boundary layer whose thickness varies laterally by 150 km or more (Shapiro et al., 1999). Convective instability should act to disperse and thin the zone of depleted mantle, and the fact that this does not occur appears to be due largely to the anhydrous, highly viscous, nature of the depleted mantle keel.

One aspect of lithospheric formation that may be important in some cases involves underplating of continental lithosphere by oceanic lithosphere. There is evidence, for example, that among the eclogites brought up in kimberlite pipes in Africa some may be relicts of basaltic oceanic crust emplaced beneath the continental lithosphere in Precambrian time (MacGregor and Manton, 1986). The data on which this conclusion is based come primarily from measurements of oxygen isotopic ratios combined with trace element and radiogenic isotopic ratios. The oxygen isotopic ratios (low ∂O^{18}), in particular, are difficult to explain as originating anywhere other than in oceanic crust. Similar evidence for underplating of cratonic mantle by oceanic lithosphere has also been found in sulfide inclusions in eclogitic diamonds from southern Africa, where episodic diamond formation has been linked to the accretion of oceanic lithosphere onto early cratonic nuclei, with subsequent stabilization of the tectospheric mantle (Shirey et al., 2001).

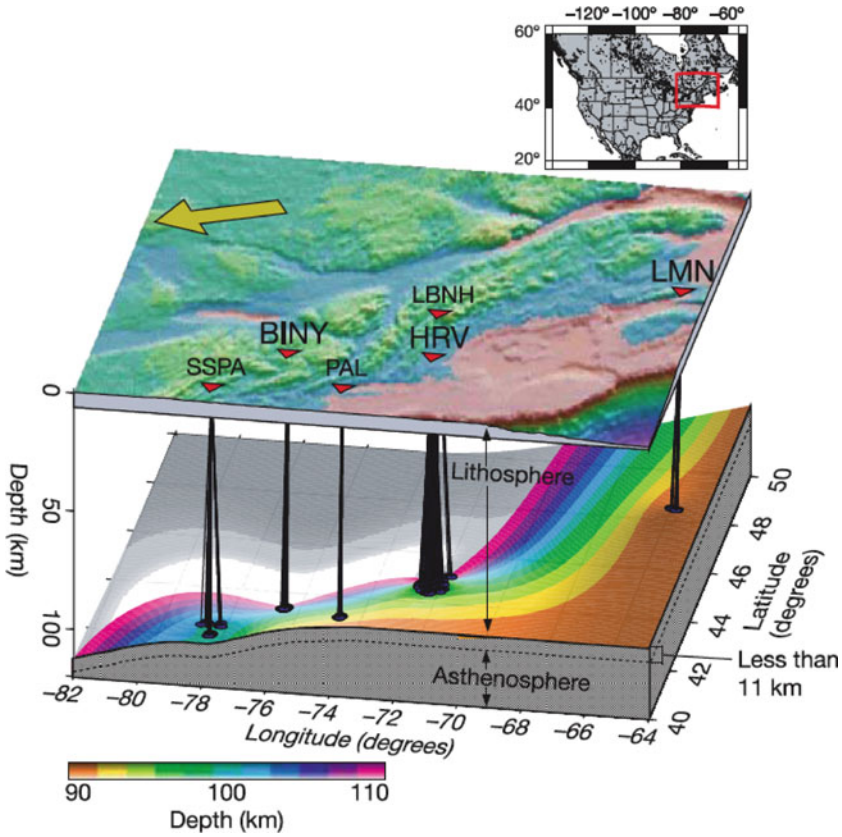
Lithosphere–asthenosphere boundary

A fundamental concept of plate tectonic theory is that the cold, rigid lithospheric plates of the Earth's outer rind are decoupled from the hot, ductile underlying mantle of the convecting Earth at the lithosphere–asthenosphere boundary (LAB). The detailed nature of this global boundary, despite many years of intense study, is still very poorly known. Yet understanding the seismic and rheological character of the decoupling zone between lithosphere and asthenosphere is a critical element in understanding the dynamical interaction between the lithospheric plates moving across the surface of the globe and the convecting asthenospheric mantle beneath. While seismic studies of the LAB beneath the ocean basins show that in many cases – although by no means all – the LAB can plausibly be related to an isotherm or rheological interface, the LAB beneath continents is far more problematic, particularly beneath the stable continental interior, where the LAB has been remarkably difficult even to detect, and its specific nature remains largely unknown.

Much of the information gleaned over the past 2 decades on the velocity structure and thickness of the continental lithosphere comes from seismic tomography, which images 3-D variations in velocity distribution in the upper mantle. Where continental lithospheric mantle is present, it is seen as a higher velocity layer overlying a lower velocity asthenosphere. On the other hand, tomographic imaging, while an invaluable tool for 3-D mapping of velocity structure, provides little or no information as to the sharpness of the lithosphere–asthenosphere boundary or the velocity contrast across it. This is a significant limitation, as knowledge of the fine structure of the LAB is crucial to sorting out the competing effects of varying geothermal gradients and the presence or absence of hydrous/carbonate fluids or partial melts for decoupling the continental lithosphere from the mobile mantle beneath.

Direct approaches to determining velocity structure at the base of the lithosphere generally involve investigating the small seismic signals produced either by the *conversion* or the *reflection* of teleseismic body waves incident on the underside of the lithosphere–asthenosphere discontinuity (e.g., [Rychert et al., 2005; Sacks and Snoke, 1977]). A converted phase is generated when some fraction of the energy of a compressional/shear wave that is obliquely incident on a velocity discontinuity in the Earth is converted to a shear/compressional wave. One widely used method, *receiver function analysis* (see *Seismic, Receiver Function Technique*), can effectively isolate the small signals on seismic records that represent conversions from the LAB. In principle, the waveform and amplitude of converted phases can provide detailed information about the structure (sharpness) and the velocity contrast – including the sign of the velocity contrast – across a discontinuity. Similarly, underside reflections from the LAB, which are seen on seismic records as small precursors to the large amplitude SS or PP surface reflections from distant earthquakes can be used to determine the sharpness and velocity contrast across the LAB. Unlike conversions, however, underside reflections sample substantial areas of the LAB (typically ~1,000 km in the case of SS phases) and, therefore, measure average regional, rather than local, structure.

Unlike most discontinuities in the Earth, the LAB represents a reversal in velocity with depth, the effect of which is to produce a converted or reflected signal with opposite polarity to that produced by a velocity increase. Results of receiver function studies of converted phases from the LAB have been decidedly mixed. An important study published in 2005 (Rychert et al., 2005) revealed a sharp LAB at a depth of about 100 km beneath northeastern USA (Figure 3). The authors suggested on the basis of the magnitude of the negative shear-wave velocity contrast across the LAB (~5–10%) and the sharpness of the velocity transition (~10 km or less) that the LAB cannot be produced by thermal or compositional contrast alone, but must represent a transition from solid (melt-free) lithosphere to a porous asthenosphere containing at least a few percent of partial melt or fluid phase. Thus, the LAB could correspond to the solidus, or point of incipient



Lithosphere, Continental, Figure 3 A schematic 3-D rendering of LAB conversion points beneath six permanent seismic stations (*red* triangles) in northeastern USA (From [Rychert et al., 2005]. With permission). Inset map at top shows location of 3-D rendering. Topography is shown as shaded relief on the upper 3-D panel. The lower surface represents the base of the lithosphere, which ranges in depth from 90 km (*orange*) to 110 km (*pink*). *Blue* circles on the LAB discontinuity surface indicate the conversion points of the Ps phases. Black lines connect piercing points to the station at which the conversion is observed (Rychert et al., 2005).

melting, in the mantle beneath the continent, or it could mark the depth at which an impermeable barrier (the lithosphere) blocks the upward migration of fluids or partial melts from deeper in the mantle. In either case, the LAB in the Rychert et al. study represents a remarkably sharp rheological boundary, implying an abrupt transition from rigid lithosphere to ductile asthenosphere. Subsequent studies employing similar methodologies to those of Rychert et al., however, have proven difficult to interpret (e.g., [Rychert and Shearer, 2009]), in that LAB depths so measured, particularly those beneath the stable continental interior, are incompatible either with tomographic images or with expected lithospheric thickness based on xenolith data or heat flow analysis (Pollack, 1986; Romanowicz, 2009). Thus, while the lithosphere–asthenosphere boundary beneath continents may be sharp and readily identified in some areas, notably tectonic regions or those of younger age, it would appear that beneath large parts of the stable continents the LAB may simply be too diffuse and/or heterogeneous to be identified as a single coherent discontinuity.

Summary and conclusions

Lithosphere, as it is understood in plate tectonic phraseology, is a term that was developed almost entirely in the context of oceanic plates. There, the discontinuity separating oceanic lithosphere from asthenosphere is widely recognized to be a rheological boundary between a strong melt-free plate and a weak, probably partially molten asthenosphere. In many important respects, we now know that this easily visualized oceanic model – universally displayed in textbooks both elementary and advanced – is a cartoonish oversimplification when applied to the continental lithosphere. Although there do appear to be regions where the continental lithosphere is almost as well defined as it is beneath ocean basins, the distinction between lithosphere and asthenosphere at depth beneath the continents, specifically the boundary between the two, is still shrouded in uncertainty. The failure of our ability seismologically to determine where lithosphere ends and asthenosphere begins has major implications for plate tectonic models in a dynamical earth. If we do not understand the coupling (or lack thereof) between lithosphere

and asthenosphere, and the depth at which that occurs, then the task of sorting out the geodynamical drivers for plate tectonics becomes an exceedingly difficult exercise. While seismology ultimately has the ability to ferret out the truth of how continental plates are coupled or decoupled from the mobile mantle beneath, we are not quite at that point in the science. Nonetheless, the study of the continental lithosphere, particularly the lithospheric mantle, is entering a period of unprecedented expansion. In the USA, the EarthScope program's Transportable Array of 400 broadband seismic systems has migrated to the country's midsection, with nearly 1,000 stations occupied at the time of this writing. Similar large-scale programs are well underway in Japan, China and Europe, giving hope that within the next several years the continental lithosphere and the lithosphere–asthenosphere boundary will have been mapped at high resolution over much of the globe's surface.

Definition

Thermal conduction is the dominant form of heat transport across the lithosphere. The thermal structure of the continental lithosphere and its thickness are determined by the distribution of heat-producing elements in crust and lithospheric mantle, and the boundary condition at its base. Vertical seismic velocity profiles, geothermobarometry on mantle xenoliths, and sedimentary records of subsidence provide additional constraints on lithospheric thickness and temperature. The base of the lithosphere can be defined as the intersection of the conductive temperature profile with the mantle isentrope.

Introduction

The lithosphere is the superficial shell, or *boundary layer*, that lies at the top of the convecting mantle and experiences little internal deformation. The concept of lithosphere has evolved over the years, leading to various definitions and estimates of its thickness. The base of the lithosphere was initially defined by a seismic low-velocity zone associated with partial melting. In the oceans, it was also determined by the variations of sea floor depth and surface heat flux as a function of age. It was clear from the beginning that all these definitions are related to the thermal structure. For instance, partial melting requires temperatures above the solidus of mantle rocks. These definitions were introduced, and tested, in the oceans with varying degrees of success but could not be readily extended to the continents. Over large continental areas, no seismic low-velocity zone can be detected and, for a long time, the meager scatter-shot heat flux data set allowed conflicting interpretations.

In the oceans, the lithosphere is made out of homogeneous starting material that is well characterized. It is affected by few thermal perturbations and tectonic events during its short residence time at Earth's surface. Its thermal structure and thickness are essentially functions of only one variable, age, and evolve in simple ways that can be studied with several independent geophysical techniques. In comparison, the continental lithosphere is heterogeneous and thick. Not only was it formed a long time ago by processes that are still debated today, but it has been affected by a succession of perturbations and tectonic events which have left their imprints. Its thermal structure is sensitive to the large amounts of heat-producing elements in the crust and cannot be characterized by age only.

Because the continental lithosphere is thick, its thermal relaxation time is very large, which offers opportunities to study mechanisms that are no longer active today. Because of its old age, it preserves structural and chemical records of ancient geological processes. From a purely thermal standpoint, it plays an important role in regulating the Earth's heat loss and in storing large quantities of radioactive elements that are no longer available to power mantle convection.

The thermal boundary layer of mantle convection

The lithosphere can be defined from a purely thermal standpoint. There are two basic mechanisms of heat transport within the Earth, conduction and convection. Convection refers to the transport of energy by matter that is set in motion by buoyancy forces. Without mass transport, energy can be transferred by conduction in association with a temperature gradient. These mechanisms are important in different parts of the Earth. At shallow depths beneath the surface, the cold upper layer does not deform easily on geological timescales, so that conduction is the dominant heat transport mechanism. The lithosphere may be defined from this perspective, but this definition does not account for heat that is supplied by convection from below. One must add a relatively thin convective boundary layer at the base of the lithosphere, which connects the rigid and purely conductive upper region to the well-mixed mantle below. In this basal boundary layer, heat transport by conduction is not negligible, as discussed below in more detail.

Thermal structure

In the continental lithosphere, heat is in part supplied from below by convection and in part generated by the decay of radioactive elements. In steady state and assuming that heat transport occurs in the vertical direction only, the heat balance equation is:

$$0 = -\frac{dq}{dz} + H \tag{1}$$

where z is depth, q is the vertical heat flux, and H the rate of heat production. In the upper part of the thermal boundary layer, there is no convection and the heat flux is given by the Fourier law of heat conduction:

$$q = -\lambda \frac{dT}{dz} \tag{2}$$

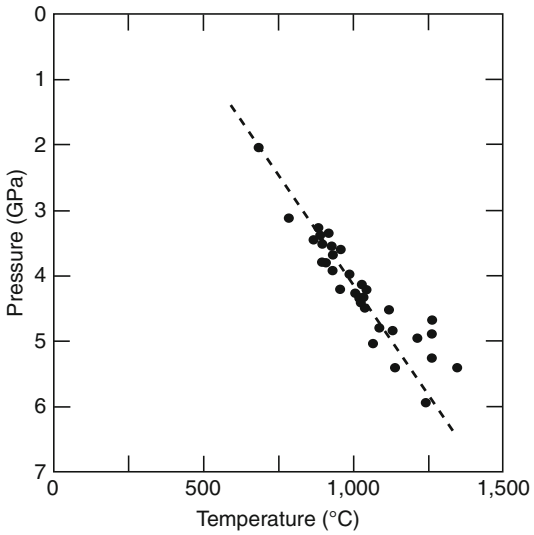
where T is temperature and λ thermal conductivity. The temperature gradient can be measured at Earth's surface in deep boreholes, and determined in the lithospheric root below the crust using the thermodynamic equilibrium conditions between mineral assemblages found in sample from the mantle, mantle xenoliths found in kimberlite pipes. Typical values in stable continents are 15 K km^{-1} and 5 K km^{-1}, respectively (Figure 1). The difference between these two values is due to radiogenic heat production in the continental crust. Below the lithosphere, the temperature gradient is dictated by the convective regime and is expected to be close to an isentrope. By definition, entropy is conserved when going up or down an isentrope, such that:

$$\frac{dT_S}{dz} = \frac{\alpha g T_S}{C_p} \tag{3}$$

where α is coefficient of thermal expansion, g is acceleration of gravity, T_S is temperature, and C_p is specific heat at constant pressure. For the Earth's mantle, the isentropic gradient is typically 0.5 K km^{-1}, which is much less than the conductive gradient in the lithospheric mantle. One identifies the isentrope by its *potential temperature*, that is, the value of its temperature at atmospheric pressure.

Three different depths may be defined in the thermal boundary layer (Figure 2). The shallowest boundary, h_1, corresponds to the base of the rigid upper part and of what we shall call the thermal lithosphere. The deepest boundary, at depth h_3, corresponds to the top of the well-mixed mantle and lies along the mantle isentrope. With no knowledge of boundary layer characteristics and heat transport mechanisms, one cannot determine h_1.

An intermediate depth, h_2, is obtained by downward extrapolation of the conductive geotherm to the mantle isentrope. h_3 is obtained from seismic velocity anomalies, as it is such that temperatures do not deviate significantly from those beneath oceans or from the average mantle velocity profile. These thickness determinations say nothing about h_1. Yet, it is h_1 that defines the mechanically coherent unit (the "plate"), which moves at Earth surface and sets the thermal relaxation time that follows tectonic and magmatic perturbations. Uncertainty on this thickness has severe consequences because the diffusive relaxation time is $\propto h^2/\kappa$, where κ is thermal diffusivity.



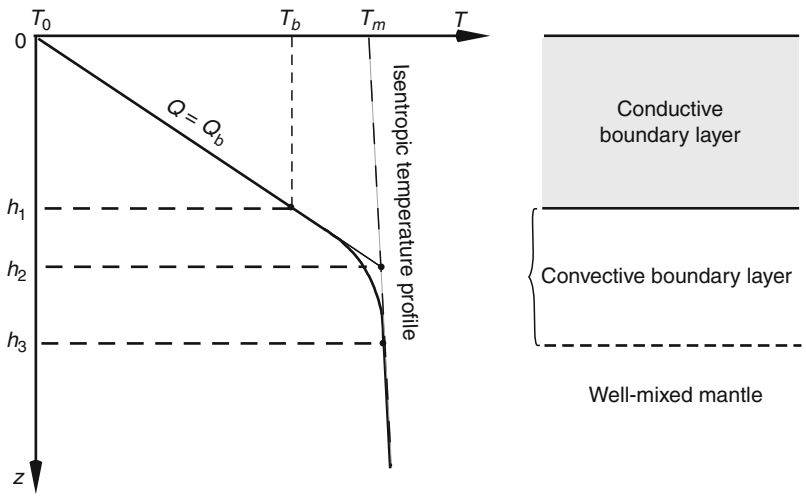
Lithosphere, Continental: Thermal Structure, Figure 1 Pressure and temperature estimates from studies of mineral assemblages in xenoliths from the lithospheric mantle beneath the Kirkland Lake kimberlite pipe, Abitibi sub-province, Canadian Shield. Data are taken from Vicker (1997). The best fit (*dashed line*) indicates a temperature gradient of 5 K km^{-1}. Note that it intersects Earth's surface at a temperature of about 400°C, showing that the temperature gradient is larger than 5 K km^{-1} in the crust.

Three contributions to the surface heat flux

In steady state, Q_0, the heat flux at Earth's surface, is obtained by integrating the heat balance Equation 1 and can be broken down into three components:

$$Q_0 = Q_{\text{crust}} + Q_{\text{lith}} + Q_b \tag{4}$$

where Q_{crust} and Q_{lith} stand for the contributions of heat sources in the crust and in the lithospheric mantle and Q_b is the heat flux at the base of the lithosphere. To describe heat transport mechanisms and the lithosphere structure, one must introduce three temperatures, T_0 at the upper boundary, which, for all practical purposes, may be taken as fixed and equal to 0°C, T_b at the base of the lithosphere, and T_m along an isentrope in the well-mixed convective interior (Figure 2). One can reasonably assume that the mantle potential temperature is the same beneath continents and oceans, and hence that it can be deduced from the composition of mid-ocean ridge basalts (Kinzler and Grove, 1992). Today, this temperature is about 1,325°C. T_b, the temperature at the base of the thermal lithosphere (the rigid lid), cannot be determined from geophysical measurements.



Lithosphere, Continental: Thermal Structure, Figure 2 *Left*: Schematic vertical temperature profile through the continental lithosphere, illustrating three different thicknesses and temperatures. Thickness h_1 corresponds to the rigid upper part of the thermal boundary layer. h_2 is determined by downward continuation of the temperature profile in the rigid upper part to the isentrope that approximates the temperature profile in the well-mixed convective mantle. h_3 denotes the base of the thermal boundary layer, such that temperature is along the well-mixed isentrope. *Right*: three different regions with different heat transport characteristics. Heat is transported by conduction only above depth h_1 and by convection only below depth h_3. Between these two depths, a convective boundary layer is such that both heat transport mechanisms are important.

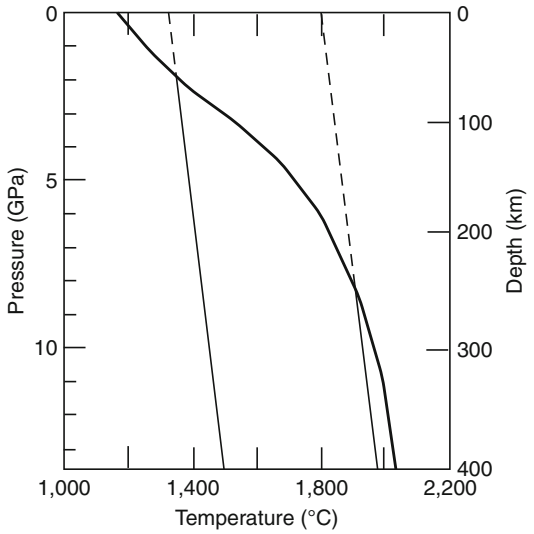
In the oceans, one may ignore Q_{crust} and Q_{lith} and, for sea floor older than 100 My, the surface heat flux is equal to the basal heat flux. In this case:

$$Q_0 = Q_b = \lambda \frac{T_b - T_0}{h_1} = \lambda \frac{T_m - T_0}{h_2} \quad (5)$$

Well-established convection theory leads to a closure equation relating Q_b to the temperature difference across the convective boundary layer, $(T_m - T_b)$ (Davaille and Jaupart, 1993; Solomatov, 1995). In this case, therefore, measurement of the surface heat flux Q_0 allows determination of the basal heat flux and of the temperature difference $(T_m - T_b)$. In turn, this leads to the values of thicknesses h_1 and h_2 as well as of basal temperature T_b. In the oceans, therefore, the values of all the variables can be deduced from surface measurements. In the continents, the problem is more complicated because the surface heat flux includes the crustal contribution Q_{crust}, which may vary by large amounts. This crustal component is typically about 30 mW m^{-2} out of a total of 42 mW m^{-2} in Archean (i.e., older than 2.5 Gy) cratons. In such conditions, surface heat flux measurements do not provide a direct measure of the heat flux at the base of the lithosphere, which must be inferred from other data with methods that will be discussed below. Q_{crust} depends on the composition of the continental crust, which itself reflects the past history of magma emplacement and tectonic deformation/accretion. Observations show that it varies by large amounts even in a single geological province. It cannot be calculated from first physical principles and must be determined on a case-by-case basis using a host of different measurements.

Controls on lithosphere thickness

The lithosphere owes its physical properties to partial melting and melt extraction processes which leave a solid residue that is both less dense and mechanically stronger than the starting mantle material. Mechanical strength is due to both the lower temperature in the lithosphere than in the convective mantle, and to dehydration that occurred during partial melting (Pollack, 1986). Melting may be achieved by two different mechanisms operating in different settings. One mechanism is decompression in an upwelling and has been documented in considerable detail in mid-ocean ridges (McKenzie and Bickle, 1988). Decompression melting begins at a depth, which depends on mantle temperature and water content (e.g., 60–80 km for the oceans today). Continents are not linear features, and were probably not generated by linear mantle upwellings such as present-day mid-ocean ridges. Their formation has been linked to large mantle plumes or subduction zones (Carlson et al., 2005). For mantle plumes, the mechanism is basically the same as that beneath mid-ocean ridges and the depth where melting starts dictates the thickness of the buoyant solid residue. In a dry mantle, high potential temperatures are required for the generation of thick lithospheric roots (Herzberg, 1983) (Figure 3). For a thickness



Lithosphere, Continental: Thermal Structure, Figure 3 Solidus temperature of dry mantle peridotite as a function of pressure and depth, from Herzberg (1983). Also shown are two isentropes that intersect the solidus at depths of 60 and 250 km.

of 250 km, for example, the mantle potential temperature must be about 1,800°C. On the other hand, if the Archean mantle was wet, melting occurred at shallower depths and at lower temperatures (Grove and Parman, 2004). In this case, a second event is required to account for the large thickness of continental lithosphere, involving large-scale compression and/or thrusting. For both types of models, the lithosphere thickness provides a strong constraint on the mechanism of continent formation.

Heat flux at the base of the continental crust and at the base of the lithosphere

Constraints on the thermal structure of the continental lithosphere may be obtained with several geophysical methods. To obtain continuous temperature profiles, however, one can only use surface heat flux data and downward continue shallow temperature measurements. To this aim, one needs to specify the heat flux at the base of the lithosphere. A first step is to determine the amount of heat produced in the continental crust or, alternatively, the heat flux at the Moho discontinuity.

Crustal heat production

Uranium and thorium are the main heat-producing elements in rocks. They are located mostly in accessory minerals and grain boundaries, which depend weakly on the bulk chemical composition. Thus, their concentrations are not related to physical properties such as density and seismic velocity and cannot be retrieved from large-scale geophysical studies. In addition, they vary by large amounts at all scales, from that of a petrological thin section to that of a whole massif. Within an apparently

homogeneous pluton, they can change in both vertical and horizontal directions due to fluid migration and late-stage alteration. In the Bohus granite, Sweden, for example, thorium concentrations vary by a factor of 5 over horizontal distances as small as a few tens of meters (Landstrom et al., 1980).

In a geological province, radioelement concentrations cannot be estimated using data from other provinces and must be measured in all the major rock types present. They depend on lithology and are high in granites and metasediments, so that a geological map gives a rough idea of the spatial distribution of heat production. With the very wide ranges that exist for each rock type, however, the standard deviation of the heat production distribution is large, and often larger than the mean. As a consequence, a single thermal model for a province would gloss over the important lateral temperature variations that occur due to the heterogeneous crustal structure. For a reliable thermal calculation in a specific area, one cannot use the local heat production values of a few rock types found on the outcrop because temperatures are sensitive to heat that is generated over rather large volumes. Average heat production values must be determined on a scale that is intermediate between the dimensions of individual plutons and the size of the province.

Vertical variations of heat production can be determined in deep boreholes or from exposed crustal sections. On a vertical scale of ≈10 km, data from the deep boreholes at Kola, in the Russian part of the Baltic Shield, (Kremenentsky et al., 1989) and the KTB, Germany, (Clauser et al., 1987), show no systematic change with depth. At KTB, heat production between 8 and 9 km depth is the same as between 1 and 2 km, and higher than above 1 km. At Kola, heat generation in the Archean rocks between 8 and 12 km is higher (1.47 μW m^{-3}) than in the shallower Proterozoic section (0.4 μW m^{-3}).

Over a crustal thickness scale, heat production is lower in mid-crustal assemblages than in the upper crust. This vertical variation is not monotonous and cannot be described by a simple function valid everywhere, as shown by exposed crustal sections such as the Vredefort in South Africa (Nicolaysen et al., 1981), the Cordilleran core complexes of Arizona (Ketcham, 1996), or the Pikwitonei-Sachigo and Kapuskasing-Wawa areas of Canada (Fountain et al., 1987; Ashwal et al., 1987). One robust feature is the depletion of lower crustal assemblages in comparison to upper and middle crustal ones (Table 1).

Table 1 lists estimates derived from global geochemical models of the crust and a very large number of measurements. The crust is split into three different crustal horizons corresponding to average regional seismic models. The model crust is 40 km thick with middle crust in the 12–23 km depth range, and is such that Q_{crust} = 36 mW m^{-2}. Another method relies on heat flux data and will be explained below (Table 2). With this method, one may also evaluate heat production variations between Provinces. The two independent methods lead to comparable results and show that crustal heat generation typically accounts for more than half of the surface heat flux.

Lithosphere, Continental: Thermal Structure,
Table 1 Element concentration and heat production in the continental crust, from Rudnick and Gao (2003). Element concentrations are given in ppm

	U	Th	K	μW m^{-3}
Upper crust	2.7	10.5	23,300	1.65
Middle crust	1.3	6.5	19,200	1.00
Lower crust	0.2	1.2	5,080	0.19
Total crust	1.3	5.6	15,080	0.89

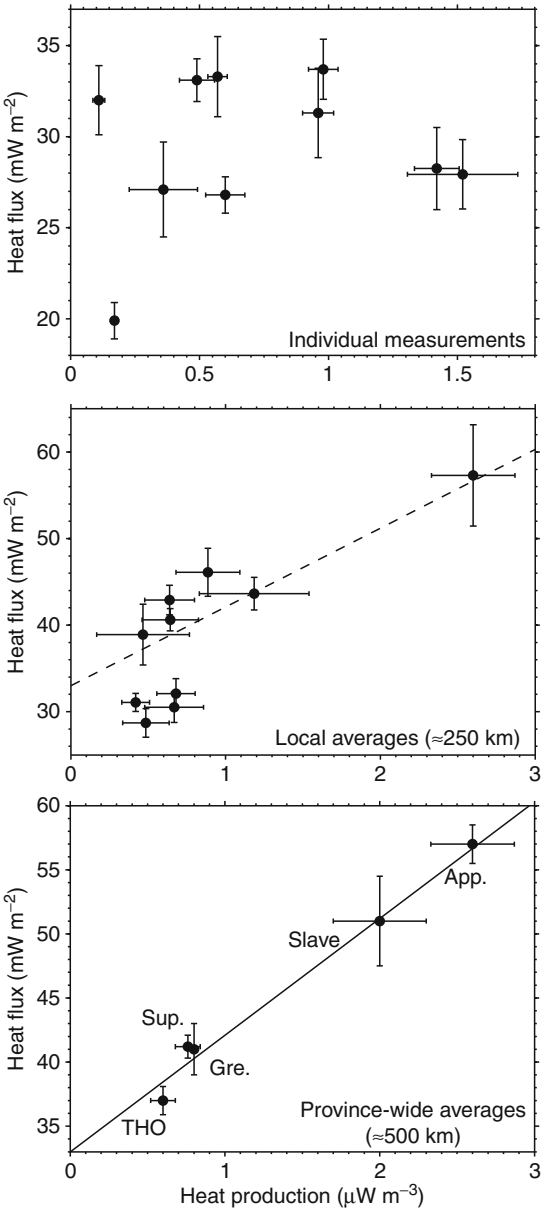
Heat flux and heat production

With the large variations in the concentrations of heat-producing elements that have been documented in crustal rocks, it is not surprising that, in continents, the surface heat flux changes by large amounts over small horizontal distances of a few tens of kilometers. The largest anomalies occur in association with enriched granitic plutons. These plutons are usually of small size, and the local value of the heat flux is not representative of the average crust that lies below the measurement site. In such conditions, studies of the thermal structure of continents require large data sets. The challenge is to obtain average values of heat flux and heat production that are representative of the whole crust in an area. We discuss the scales over which this can be done in a reliable manner.

There is only a weak relationship between local values of heat flux and heat production in a geological province (Figure 4). For a representative thermal model, one must determine an average heat flux value over an area that is sufficiently large for the smoothing of small-scale variations due to isolated anomalous massifs. Figure 4 also shows data for 10 ≈ 250 km × 250 km windows distributed in North America. These are located in the same area as the individual heat flux values discussed previously, and show that a relationship between heat flux and heat production begins to emerge at this scale. Even at this scale, the relationship is not defined tightly due to insufficient sampling of heat production. A single heat flux value



Lithosphere, Continental: Thermal Structure,
Figure 4 Relationship between heat flux and radiogenic heat production in North America at different scales, from Levy et al. (2010). *Top panel*: for individual measurements, there is clearly no relationship between the two. Middle panel: at an intermediate scale of about 200 km, a relationship between the average values of heat flux and heat production begins to emerge. The *dashed line* corresponds to the best-fit linear relationship defined by province-wide averages. *Bottom panel*: shows a strong correlation between the average values of heat flux and heat production for the five major geological provinces of North America. The best-fit linear relationship has a slope of 9 km and an intercept of 33 mW m^{-2}. Symbols are as follows: App, Appalachian province (400 My); Gre, Grenville province (1,100 My); THO, Trans-Hudson Orogen (1,800 My); Sup, Superior province (>2,500 My); Slave, Slave province (>2,500 My).

is sensitive to crustal heat production over large horizontal distances and records the contribution of many different geological units. In contrast, the heat production values correspond to a small number of rocks found at shallow depth in boreholes used for heat flux determinations. The limited sampling achieved at a scale of 250 km does not account for the full range of rock types and heat production rates in the crust. For representative heat production averages, one needs to work at a larger scale. Figure 4 shows data for five major geological provinces in North America with typical dimensions of ≈500 km × 500 km. These provinces cover the geological history of the stable continent and represent different types of continental crust. Furthermore, they have been extensively deformed and eroded, so that rocks from a large range of depths can be found at the surface. The metasedimentary-plutonic belts of the western Superior Province, Canadian Shield, for example, include rocks from all metamorphic grades up to granulite facies. The province-wide averages exhibit a remarkable linear relationship, with a heat flux intercept of ~33 mW m^{-2} corresponding to crust with zero surface heat production. The data for the 10 ≈ 250 km × 250 km windows lie close to this global linear relationship (Figure 4).

The Moho heat flux is equal to:

$$Q_M = Q_0 - Q_{\text{crust}} = Q_{\text{lith}} + Q_b \qquad (6)$$

which depends on heat production in the lithospheric mantle and on the heat flux at the base of the lithosphere. Both components come from depths larger than the crustal thickness, so that lateral variations, if they exist, get smoothed out by horizontal diffusion. For an average lithospheric thickness of 250 km, variations of the basal heat flux Q_b over wavelengths smaller than 500 km are not detectable in the surface heat flux (Mareschal and Jaupart, 2004). A similar statement can be made for the contribution of heat sources in the lithospheric mantle, Q_{lith}. Thus, on scales that are smaller than 500 km, one must consider that the Moho heat flux is uniform and that variations of the surface heat flux come solely from changes of crustal heat production.

The strong correlation that is observed between the province-wide average surface heat flux and heat production indicates that variations of the Moho heat flux are small throughout the whole North American continent (Figure 4). If there were large variations of the Moho heat flux, they would need to be compensated by opposite variations of the average lower crustal heat production. No physical mechanism can explain how such independent variables can be linked to one another. Variations of the Moho heat flux are therefore less than the intrinsic uncertainty on the heat flux measurements and the magnitude of departures from the heat flux–heat production relationship, which is about 2–3 mW m^{-2} (Mareschal and Jaupart, 2004). The absolute value of the Moho heat flux is not specified by this analysis, however, and this issue is discussed in the next section.

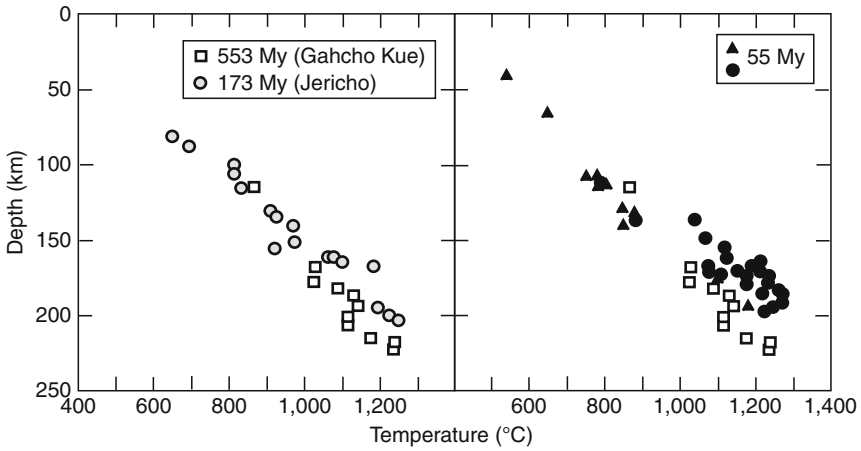
The Moho heat flux

Direct determination of the heat flux through the lithospheric mantle can be made using xenolith samples brought from lithospheric depths by powerful *kimberlitic* eruptions. Coexisting mineral assemblages and mineral compositions allow estimates of pressure and temperature and of the geothermal gradient. Together with a thermal conductivity estimate, they lead to values of the heat flux beneath the crust. For the Kirkland Lake pipe, within the Superior Province, Canada, (Figure 1), Rudnick and Nyblade (1999) obtained a best-fit Moho heat flux estimate of ≈18 mW m^{-2} within a total range of 17–25 mW m^{-2}. Russell and Kopylova (1999) derived a best-fitting value of 15 mW m^{-2}, within a range between 12–24 mW m^{-2}, for the Jericho kimberlite area of the Archean Slave Province, also in Canada. Figure 5 shows data from several kimberlite pipes in the Slave Craton (D. Canil, 2007, personal communication). There are significant temperature differences between the different data sets. Surprisingly, the youngest eruptions, which provide recent samples of the lithospheric mantle, yield the highest temperatures. A similar result is obtained in the Kaapvaal craton, South Africa (Michaut et al., 2007). If these temperature variations are indeed due to age and reflect the time evolution of lithospheric temperatures, they are not consistent with secular cooling of the Earth's mantle. The pipes do not overlap so that the data may in fact record lateral variations of temperature in the lithospheric mantle, which can only be explained by changes of heat production. Nevertheless, these data lead to similar values of the temperature gradient and heat flux.

Bounds on the Moho heat flux can be obtained by taking advantage of the variations of heat flux and crustal structure in a geological province. Combined with heat production data for the various rock types involved, one can isolate the variable crustal component and the uniform Moho heat flux. In Canada, Moho heat flux values of 10–15 mW m^{-2} have thus been derived for the Grenville Province, the Trans-Hudson Orogen (THO), for the Abitibi belt of the Superior Province (Jaupart and Mareschal, 2007). Crustal thickness and composition can also be constrained by combining seismic refraction, gravity, and heat flux. Such methods lead to values of Q_M between 7 and 15 mW m^{-2}.

Another method relies on P_n velocities from seismic refraction surveys (Perry et al., 2006). For given values of the surface heat flux, the Moho temperature depends on the amount of crustal heat production and hence on the Moho heat flux. One can therefore obtain a relationship between Moho temperature and seismic velocity with the Moho heat flux as control parameter. One can also derive independently a relationship between temperature and seismic velocity using laboratory measurements of elastic properties and seismic velocities, with the bulk mantle composition as control parameter. The two relationships are only consistent with one another over a restricted range of composition and Moho heat flux. For depleted mantle compositions appropriate to the Superior Province, a good fit between predicted and observed P_n velocity values is obtained if the Moho heat flux is within a range of 12–25 mW m^{-2} (Perry et al., 2006).

The three different and independent methods that we have described have all been applied to the Abitibi belt in the Canadian Shield and can be combined to tighten the final range to 12–15 mW m^{-2} for that sub-province. Lower and upper bounds on the Moho heat flux have been derived using other arguments. Upper bounds on the mantle heat flux are obviously provided by the lowest heat flux



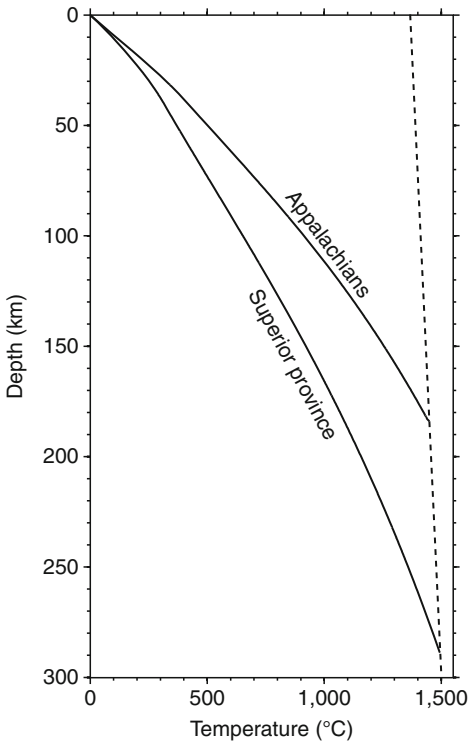
Lithosphere, Continental: Thermal Structure, Figure 5 Relationship between temperature and depth in the lithospheric mantle of the Slave Province, Canada (from D. Canil, 2007, personal communication). The Slave Province is small and has been pierced repeatedly by kimberlite pipes in the same area. *Left panel*: data from the two oldest pipes. *Right panel*: data for two young pipes compared to those for the oldest pipe in the area. On average, temperature estimates from the two young pipes are larger than those of the older pipes by about 150 K. Such differences may indicate lateral temperature variations in the lithospheric mantle.

measured. Values of 20–23 mW m^{-2} have been reported within the Canadian Shield (Mareschal et al., 2000). Regional values as low as 18 mW m^{-2} have also been reported for the Baltic or Siberian Shield. One can refine this estimate to 18 mW m^{-2} using lower bounds on crustal heat production.

The methods that we have described here rely on different data and hence are associated with different sources of uncertainty. That such completely independent methods converge to similar results allows some confidence in the final range obtained. Values lower than 12 mW m^{-2} are not consistent with the xenolith data whereas values higher than 18 mW m^{-2} can be excluded because of the heat flux data. This upper bound appears to be valid for all the shields (Jaupart and Mareschal, 2007).

Lithospheric geotherms

Using information on heat flux values at the surface and at the Moho, one may determine geotherms through the lithosphere. The calculation requires values for thermal conductivity that are discussed in the Appendix. Figure 6 shows two such geotherms for two provinces in North America, which are consistent with both seismic and heat flux data (Levy et al., 2010). These two geotherms intersect the well-mixed mantle isentrope at different depths, indicating large lateral thickness variations for the continental lithosphere. The maximum thickness is reached beneath the Archean Superior province and is estimated to be 280 ± 30 km.



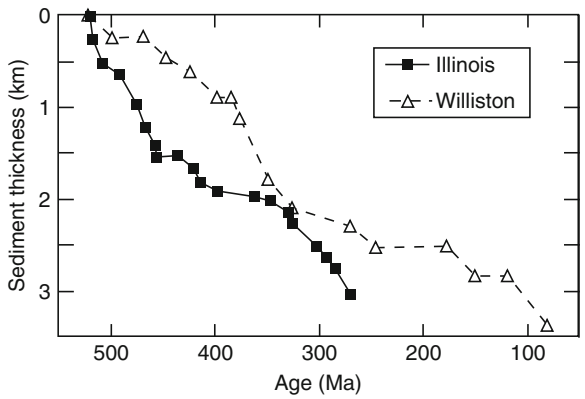
Lithosphere, Continental: Thermal Structure, Figure 6 Two steady-state lithospheric geotherms beneath the Appalachian and Superior provinces of North America, from Levy et al. (2010). These two geotherms were deduced from measurements of the surface heat flux and heat production, and were constrained by requiring consistency with seismic data. The *dashed line* is the isentrope for a potential temperature of 1,350°C.

Thermal transients

Because the continental lithosphere is thick, it is characterized by a long thermal relaxation time. For a thickness of 250 km and a thermal diffusivity κ equal to 10^{-6} m^2 s^{-1}, the characteristic diffusion time $\tau = h^2/\kappa$ is ≈2 Gy. This is much longer than that of the oceanic lithosphere, which is only about 200 My (for a thickness of 80 km). We shall now discuss two types of thermal transients in thick lithosphere.

Thermal relaxation following a thermal/tectonic perturbation

Thermal relaxation of the lithosphere following a deep thermal perturbation can lead to subsidence, which has been recorded in intracratonic sedimentary basins located away from active plate boundaries. Subsidence histories for two such basins of North America, the Michigan and Williston basins, are shown in Figure 7 and emphasize their long durations exceeding 200 My. On the basis of models for heat transport and cooling in the vertical direction only, the thickness of the North American lithosphere is found to about 115 km beneath the Michigan basin and 270 km beneath the Williston (Haxby et al., 1976; Ahern and Mrkvicka, 1984). There is no obvious explanation for such a large thickness difference in the middle of the North American continent, which suggests that the subsidence models may be oversimplified. These models rely on 1-D calculations and hence are only valid if the thermal anomaly stretches over a horizontal distance that is much larger than the lithosphere thickness. The Michigan and Williston basins have been attributed in large part to plate flexure driven by a deep load (Nunn and Sleep, 1984;



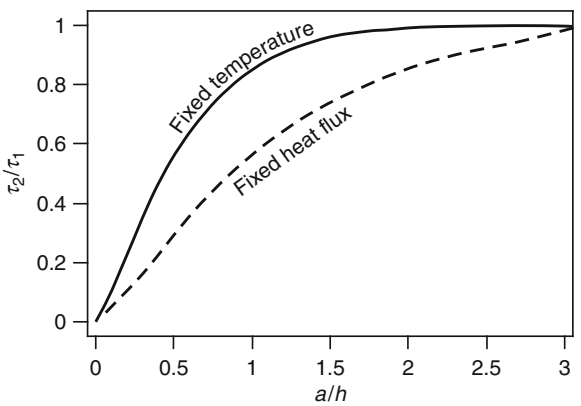
Lithosphere, Continental: Thermal Structure, Figure 7 Subsidence histories for the Michigan and Williston basins, North America.

Ahern and Mrkvicka, 1984). This load is related to the initial thermal anomaly and has a radius of about 120 km beneath the Michigan basin (Haxby et al., 1976), which is smaller than the thickness of the lithosphere beneath the North American craton. In these conditions, the assumption of purely vertical heat transfer is not tenable. Kaminski and Jaupart (2000) have reevaluated thermal models for the continents by taking into account lateral heat transport within thick lithosphere. They considered a lithosphere of thickness h with a cylindrical thermal anomaly of radius a between depths h and b. At the surface ($z = 0$), temperature is fixed at T_0. At steady state, the base of the lithosphere is at $T = T_0 + \Delta T$. Assuming, for example, that the thermally perturbed region is initially at a uniform temperature $T_0 + \Delta T$, temperature can be written as the sum of the equilibrium temperature and a dimensionless perturbation θ:

$$T(r, z, t) = T_0 + \Delta T \left[\frac{z}{h} + \theta(r, z, t)\right], \qquad (7)$$

where r is the radial distance. The temperature perturbation may be expressed in terms of a vertical component θ_Z, which corresponds to the 1-D solution, and a radial component, which can be calculated using Bessel functions. For thermal anomalies with planforms that are not circular, lateral heat transfer is dominated by the smallest horizontal dimension.

The acceleration of cooling due to lateral heat loss can be measured simply by the time to achieve 90% of the final subsidence, noted τ_2, scaled to that for an infinitely wide initial perturbation, τ_1 (corresponding to the 1-D calculation) (Figure 8). Results are sensitive to the boundary condition at the base of the lithosphere and show that the impact of lateral heat transport is significant for $a/h < 1$,



Lithosphere, Continental: Thermal Structure, Figure 8 Time to achieve 90% subsidence in thick lithosphere as a function of the radius of the deep lithospheric thermal anomaly, a (scaled to the lithosphere thickness h). The subsidence time has been scaled to the value obtained with a 1-D thermal model for purely vertical heat transport. Results have been obtained for two different boundary conditions at the base of the lithosphere. (Adapted from Kaminski and Jaupart (2000)).

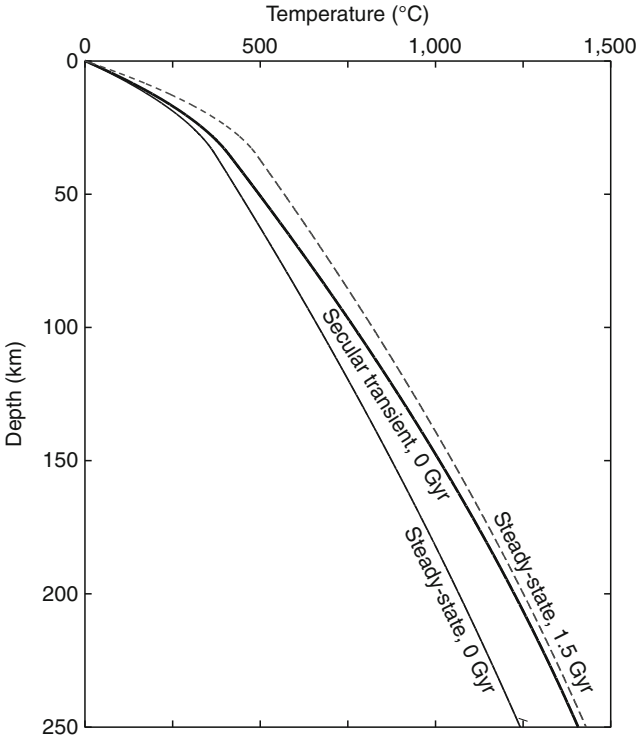
corresponding to $a <\approx 250$ km in the North American craton. This is the case of all the major intracratonic basins. In comparison to the oceans, thermal relaxation in the continents is lengthened by the larger lithosphere thickness and shortened by lateral heat transport. Different subsidence histories and durations are generated by the same basic process operating over different lateral distances.

Secular transients

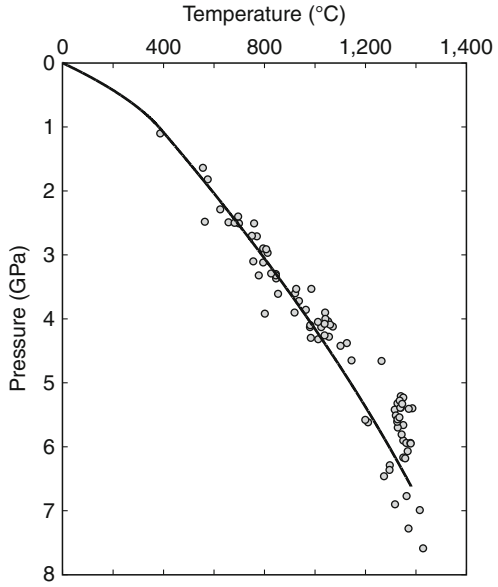
We have shown above that continental temperatures depend strongly on radiogenic heat production. Thus, continents cool down continuously due to the rundown of radioactivity with time. One should also add that conditions at the base of the lithosphere also evolve with time due to secular cooling of the whole Earth. This is ill constrained and we focus our attention to the effects of decaying heat sources. For the Appalachian geotherm of Figure 6, for example, crustal heat production contributes about 300°C. For average Th/U and K/U ratios, radiogenic heat production decreases by a factor of 2 in about 2.7 Gy. We thus deduce that continental temperatures decrease at a rate of about 50 K Gy^{-1}, which is comparable to the bulk mantle cooling rate (Abbott et al., 1994). This simple argument relies on a quasi steady-state approximation, such that ancient geotherms are calculated using the steady-state heat equation together with past values of heat production. For thick lithosphere, this approximation is not valid and may lead to significant errors.

In thick continental lithosphere, the timescale for diffusive heat transport is comparable to the half-lives of Uranium, Thorium, and Potassium. As noted above, the characteristic time for heat diffusion, equal to h^2/κ is 2 Gy for 250 km thick lithosphere, which is close to the decay time of radiogenic heat production (≈2.7 Gy). Thus, heat diffusion is not efficient enough to keep up with the decaying heat sources and lithospheric temperatures are not in equilibrium with the instantaneous rate of heat production. In these conditions, the vertical temperature profile exhibits significant curvature and may be hotter than a steady-state profile by as much as 150 K depending on the absolute value of the heat generation rate (Figure 9). Another consequence is that forcing a steady-state temperature profile through xenolith (P,T) data leads to an overestimate of the mantle heat flux.

For illustration purposes, Figure 9 shows the instantaneous vertical temperature profile with decaying sources and a steady-state geotherm derived for the same present-day values of crust and mantle heat production. The difference between the two geotherms increases with depth because of increasingly inefficient transport of heat to the Earth's surface. For comparison, we have also calculated a steady-state geotherm corresponding to heat production values 1.5 Gy ago. The transient geotherm falls between the steady-state geotherms calculated for heat production rates at 0 and 1.5 Gy, showing that it is sensitive to heat generation in the past. At the base of the



Lithosphere, Continental: Thermal Structure,
Figure 9 Present-day vertical temperature profile for transient thermal model with decaying heat sources (*thick line*) compared with two steady-state geotherms (*solid line* for present-day heat production; *dashed line*, for heat production rate values 1.5 Gy ago) for the same set of parameters (h = 250 km, crustal heat production A_c = 1.0 μW m^{-3}, lithospheric mantle heat production A_m = 0.02 μW m^{-3}, basal heat flux Q_b = 10 mW m^{-2}). Surface heat flow is of 49 mW m^{-2} for the transient solution, 46 mW m^{-2} for the present-day steady-state profile, and 62 mW m^{-2} for the 1.5 Gy steady-state profile.



Lithosphere, Continental: Thermal Structure,
Figure 10 Xenolith P-T data from the Kimberley, Jagersfontein, Premier and Frank Smith kimberlite pipes, Kaapvaal craton, South Africa (Rudnick, 2003, personal communication). *Thick line*: vertical temperature profile for a transient thermal model with decaying heat sources and for a lithosphere thickness of 225 km. Parameter values are crustal heat production A_c = 0.8 μW m^{-3}, mantle heat production A_m = 0 025 μW m^{-3}, and basal heat flux Q_b = 12 mW m^{-2}. Note that the geotherm terminates above several deep data points, due to the starting assumption on lithosphere thickness.

lithosphere, all geotherms are parallel because of the constant heat flux bottom boundary condition. Secular transient behavior is not important at shallow depths, due to the efficiency of diffusive heat transport over small distances. In the crust, differences between the transient and present-day steady-state profiles are very small and can be neglected for all practical purposes. Between 50 and 150 km depth, heat flux is about 13 mW m^{-2} for the present-day steady-state model and 16 mW m^{-2} for the transient one. Maximum departure from thermal equilibrium is achieved at the base of the lithosphere. The magnitude of transient effects essentially depends on mantle heat production as well as on lithosphere thickness. Large values of heat production in the lithosphere do not introduce large transients at shallow depths. In contrast, even small values of heat production lead to significant effects in a thick lithosphere.

The secular transient geotherm is compared to xenolith (P-T) data from Kaapvaal craton, South Africa, for h = 225 km in Figure 10. For this solution, the surface heat flux is 47 mW m^{-2}, which is close to measurements in this region, and heat production in the lithospheric mantle is 0.025 μW m^{-3}, which lies in the lower range of values proposed by Rudnick and Nyblade (1999). The basal heat flux is 12 mW m^{-2}. The Kaapvaal xenolith (P,T) data suggest a change of slope in the geotherm at a pressure of about 5 GPa (Bell et al., 2003). According to some authors, this marks the transition between lithosphere and asthenosphere, with the deepest data points belonging to the convecting mantle below the lithosphere. Rudnick and Nyblade (1999) and Bell et al. (2003) have argued that all data points belong to unperturbed lithosphere. Significant curvature of the secular transient geotherm allows a good fit to all the data and does not suggest a break in the geotherm.

Due to the intrinsic decay of radioactive heat sources, the lithospheric mantle therefore undergoes secular cooling even when thermal conditions at the base of the lithosphere remain steady. Predicted cooling rates are in the range of 50–150 K Gy^{-1}. Such transient behavior also has implications for heat flow studies. Assuming that the decay of radiogenic heat production can be represented by a single exponential, such that $A_m(t) = A_o \exp(-\alpha t)$,

the contribution of lithospheric heat production to the surface heat flux is:

$$\Delta Q_{\text{lith}}(t) = A_o h \frac{tan\sqrt{\alpha\tau}}{\sqrt{\alpha\tau}} exp(-\alpha t) \quad (8)$$

This is compared to the instantaneous amount of heat produced in the lithosphere:

$$\Delta Q_{\text{lith},i}(t) = A_o h exp(-\alpha t) \quad (9)$$

Ratio $Q_{\text{lith}}/Q_{\text{lith},i}$ increases as a function of lithosphere thickness and is 1.5 for h = 300 km, for example. This shows that surface heat flux measurements record some time-average of the deep lithospheric heat production.

Summary

The continental lithosphere is much thicker than its oceanic counterpart and its thermal structure depends strongly on radiogenic heat production in both the crust and in the mantle. Because of these two characteristics, its behavior depends on its geological history and is not a simple function of age. Beneath Archean Shields, it can be as thick as 300 km.

Appendix: thermal conductivity

For an isotropic medium, Fourier's law is:

$$\mathbf{q} = -\lambda \nabla T \quad (10)$$

where λ is the thermal conductivity measured in W m^{-1} K^{-1}. More generally, if the medium is not isotropic, the thermal conductivity must be defined as a second order tensor. Thermal conductivity can be broken into lattice and radiative components, which have different behaviors as temperature and pressure change.

At low temperatures, heat transport is in large part effected by lattice vibrations. Lattice conductivity decreases with increasing temperature.

At larger temperatures, electromagnetic waves transport energy in continuous media. Radiation is rapidly attenuated but the medium reemits energy if the temperature is sufficiently high. In a temperature gradient, the net energy flux will be $\propto T^3 \nabla T$, which has the same form as the flux for lattice conduction. One can therefore define a radiative component of conductivity, λ_R, such that the radiative heat flux is:

$$\mathbf{q_R} = -\lambda_R \nabla T \quad (11)$$

The gray body law states that:

$$\lambda_R = \frac{16}{3} \frac{n^2}{\varepsilon} \sigma T^3 \quad (12)$$

where n is the refractive index, $\in$ is the opacity, and σ is the Stefan constant of black-body radiation (σ = 5.67 × 10^{-8} W m^{-2} K^{-4}).

Lattice conductivity

For individual crystals, theoretical arguments suggest that, below the Debye temperature, the temperature dependence of lattice conductivity takes the following form:

$$\lambda(T) = \lambda_{298} \sqrt{\frac{298}{T}} \quad (13)$$

For polycrystalline assemblages, this equation is no longer valid and one relies on empirical fits to the data. Reasonable agreement can be obtained with a relationship of the type:

$$\lambda(T) = A + \frac{B}{350 + T} \quad (14)$$

where T is in °C and where constants A and B depend on the rock type (Table 3).

The effect of pressure on conductivity can be treated independently of temperature, so that one can write:

$$\lambda(T, P) = \lambda_o(T)(1 + \beta P) \quad (15)$$

where β is a constant coefficient (Table 4). The effect of pressure increases conductivity by about 20% between the surface and 200 km.

Radiative conductivity

For olivine, several independent laboratory measurements suggest that:

$$\lambda_R = 0.368 \times 10^{-9} T^3 \quad (16)$$

This equation leads to $0.13 < \lambda_R < 1.8$ W m^{-1} K^{-1} for $700 < T < 1{,}700$ K. It is only valid in a single crystal if the mean free path of photons is independent of temperature.

Lithosphere, Continental: Thermal Structure,
Table 3 Constants for calculating the thermal conductivity of different rock types, from Clauser and Huenges (1995)

Rock type	T range (°C)	A	B
Metamorphic rocks	0–1,200	0.75	705
Felsic rocks	0–1,400	0.64	807

[a]Coefficient in Equation 15 for thermal conductivity

For mantle rocks, one must account for scattering and for the effect of interfaces in a mineral assemblage. Such complications led Marton et al. (2005) to use a constant radiative conductivity component λ_R = 1 W m^{-1} K^{-1} for temperatures higher than 700 K.

Geosphere

Definition

Lithosphere (*mechanical*). This is the rigid ("litho" = stone) outer layer of the Earth that remains mechanically strong over geological time spans. *Mechanical lithosphere* includes rigid layers of crust and outermost mantle capable to maintain high differential tectonic stresses, from 10 MPa to 1 GPa. *Mechanical lithosphere* is 1.5–2 times thinner than "seismic," "thermal," or "chemical" lithosphere.

Mechanical properties of the lithosphere. This term refers to the *integrated strength* of lithospheric plates, their *rheological structure* and parameters, and mechanical behavior in response to various tectonic loads.

Introduction

Mechanical properties of the lithosphere are of primary importance for local and global geodynamics. In particular, compared to the convective mantle, high long-term mechanical strength makes the lithosphere a unique stress/strain guiding and accumulating envelope with lasting mechanical memory. High strength prohibits internal *heat advection*, so *thermal conduction* is main heat transfer mechanism in the lithosphere, in contrast to the convective mantle. High strength also stabilizes vertical lithological structure of lithosphere making it a *stagnant layer*. In contrast to viscous mantle, long-term *rheology* of the lithosphere is strongly influenced not only by its *ductile* but equally *elastic* and *brittle* properties. It is probably the nonviscous properties of the lithosphere that shape it in the characteristic *plate tectonics* patterns.

The term *lithosphere* has been introduced in the second half of the nineteenth century, while the notion of *mechanical lithosphere* appeared in early twentieth century, in conjunction with that of *seismic lithosphere* (see *Earth's Structure, Global*), after formulation of the *continental drift theory* by Wegener and first interpretations of *regional isostasy* by J. Barrel and Vening-Meinesz (Watts, 2001; see entry *Isostasy*). The fact that the lithosphere has finite measurable strength has been demonstrated from observations and models of *regional isostatic compensation* of large topographic loads. Before that, the lithosphere was considered either as a very strong solid layer (*Pratt's model*) or, in turn, a weak fractured layer (*Airy's model*). *Postglacial rebound studies* of early twentieth century have contributed to the definition of the *mechanical lithosphere* as the uppermost layer of the solid earth characterized by slow *viscoelastic relaxation*, in contrast to the underlying, relatively low-viscosity asthenosphere. The long-term mechanical base of the lithosphere, h_m, is limited by the depth to isotherm 500–600°C in oceans and 700–800°C in continents, compared to almost twice as deep 1,330°C isotherm delimiting the thermal lithosphere (see entries *Lithosphere, Oceanic: Thermal Structure*; *Lithosphere, Continental: Thermal Structure*). As suggested on the basis of recent mantle–lithosphere interaction models (e.g., Schmeling et al., 2008), it is the elastic and plastic properties of the lithosphere that essentially determine the geometry of lithospheric plates and the mechanisms of formation of constructive, destructive, and transform plate boundaries at global scale. At smaller scale, *mechanical properties* of the lithosphere control formation and evolution of major geological structures such as rifts, passive margins, foreland basins, mountain ranges, plateau or strike-slip faults. They also control short-term processes such as seismicity (Watts and Burov, 2003).

Mechanical properties at different timescales

Mechanical properties of the lithosphere are timescale dependent (e.g., Watts, 2001). At seismic timescales (<0.5 h), the lithosphere behaves as an elastic or brittle-elastic layer of a thickness largely exceeding h_m. At *post-seismic timescales* (from days to years), the uppermost crust relaxes a part of seismically induced stress evoking some rather poorly understood short-timescale viscoelastic properties. At *postglacial rebound* timescales (~several 1,000 year), lithosphere remains largely elastic, with thickness of the elastic domain almost as important as its *seismic thickness*. At geodynamic timescales

(>1 Myr), the thickness of the *elastic core* is reduced to values smaller than h_m, and the stresses are slowly relaxed at timescales on the order of several Myr. The long-term properties of the lithosphere were first assessed from geodynamic-scale observations, first of all, *regional isostasy*. According to these data, the lithosphere exhibits a large spectrum of long-term behavior from quasi-elastic to brittle and viscous. Observation of crustal and lithosphere scale faults and *distributed seismicity* shows that some domains within the lithosphere deform in brittle-plastic regime over long time spans, while relaxation of deformation below, for example, oceanic volcanic islands, points to long-term viscoelastic strength. However, the long-term properties of the lithosphere are more generally studied indirectly using extrapolations from *rock mechanics data*.

Sources of information on the mechanical properties of the lithosphere

Flexural studies and *experimental rock mechanics data* are major sources of quantitative information on long-term behavior and strength of the lithosphere. In structured *viscous-elastic-plastic* media, all rheological properties are interrelated, and various time- and scale-dependent factors may cause variations in the effective elastic, brittle, and ductile deformation. Consequently, observations of long-term deformation are of primary importance for assessment of the effective mechanical properties of the lithosphere. These and other sources of information are summarized below:

1. Observations of long-term ($t > 1{,}000$ year) lithosphere response to tectonic loading, in the order of importance:
   - Observations of *regional isostatic compensation*: *gravity-flexural studies* providing estimates for the *equivalent elastic thickness* of the lithosphere, T_e
   - Vertical motions due to *postglacial rebound*, *lake, and volcanic island* loading
   - Observations of *lithosphere folding* (*folding wavelength* is a function of plate strength)
   - Field observations of ductile and brittle deformation in the outcrops
   - Interpretations of *deformational microstructures* and *paleo-stresses*
   - *Seismic tomography* (e.g., evidence for more or less strong slabs at depth)
   - *Borehole* stress measurements
2. Intermediate timescale observations ($t > 3$–10 year):
   - *Slow-rate rock mechanics experiments* (strain rates 10^{-9} to 10^{-4} s^{-1}, for ductile properties)
   - Geodetic (GPS-INSAR) data over >5 year time spans (strains, viscoelastic properties)
   - *Inter-seismic deformation*; *slow earthquake* data
3. Observations of deformation in response to short-term loading ($t < 1$ year):
   - Short-term *rock mechanics experiments* (elastic and brittle properties)
   - Distribution of intraplate seismicity (brittle properties)
   - Tidal deformation (viscoelastic properties)
   - Post-seismic relaxation (viscoelastic properties)
   - Geodetic (GPS-INSAR) data (strains, viscoelastic properties)
   - Attenuation of S waves (proxy to low-viscosity zones)
   - Magnetotelluric sounding (reduced electrical resistivity is proxy to low-viscosity zones)
4. Physical considerations and self-consistent thermo-mechanical models:
   - Estimates of the minimal *integrated strength* of the lithosphere required for lifetime stability of geological structures, *subduction* or transmission of tectonic stresses, and forces over large spatial scales, including horizontal pressure gradients caused by lateral variations in lithospheric density structure and topography (*gravity potential energy* theory). For example, lithosphere must be strong enough to transmit *ridge push* and *slab pull* forces on the order of 10^{11}–10^{13} N per unit length.
   - Lithosphere scale *numerical thermo-mechanical models* of tectonic processes integrating multidisciplinary data, which allows for testing the validity of data and hypotheses on lithosphere rheology.

Observations of long-term deformation provide key parameters such as the *integrated strength* of the lithosphere. These parameters are needed to constrain *rock mechanics data* obtained at laboratory conditions, because they are too far from geological conditions: short timescales ($t < 5$ years), small spatial scales ($l \sim 0.1$ m), high strain rates ($\dot{\varepsilon} > 10^{-9}\ s^{-1}$), small strains ($\varepsilon < 10$), high temperatures, simple deformation, largely mono-phase samples. *Rock mechanics data* allow only for assessment of general form of rheology laws, their sensitivities, and relative strengths of different kinds of rocks. Their extrapolation to geodynamic scales ($t > 10^6$ years, $l \sim 1{,}000$ km, $\dot{\varepsilon} < 10^{-14}\ s^{-1}$, $\varepsilon > 100$, cold temperatures, aggregate rocks) needs re-parameterization and validation using real-scale observations and models.

Interpretation of short-term data (seismic, satellite geodesy, INSAR) is not straightforward. In particular, interpretation of *intraplate seismicity* (see entry *Seismicity, Intraplate*) and *post-seismic relaxation* data is questioned due to the lack of evidence that mechanisms of this short-term deformation can be physically linked to those of long-term deformation.

Observations of flexural behavior and effective long-term strength of the lithosphere

Observations of *regional isostatic compensation* (e.g., Watts, 2001; see entry *Isostasy*) have shown that the lithosphere has substantial long-term *elastic rigidity* that allows for transferring and maintaining intraplate stress levels (10 MPa–1 GPa) over geodynamic time spans (>several Myrs). Studies of gravity anomalies observed

over mountain ranges and subduction zones have demonstrated that lithospheric plates bend like *thin elastic plates* of finite stiffness in response to tectonic, topography, and sedimentary loads. With improvement of geophysical measurement techniques during the second half of twentieth century, multiple studies (specifically, forward *flexural models*) have produced robust estimates of *flexural rigidity*, D, and *equivalent elastic thickness*, T_e, of lithospheric plates. These data arguably present a major source of information on the long-term *mechanical properties* of lithosphere. *Flexural studies* reveal strong variations of lithosphere strength, from near zero at ocean ridges to 100–150 km thick quasi-elastic cores detected within old and cold cratons (Burov and Diament, 1995; Kirby and Swain, 2009). In *flexural models* of *regional isostatic compensation* (Watts, 2001), D is varied until the model-predicted basement or *Moho topography* provides optimal fit to observations. *Gravity data* (see entry *Gravity Anomalies, Interpretation*) are used when basement topography is hidden (e.g., by sediments) or not representative of flexure (e.g., modified by erosion). The most robust *gravity models* are *forward models*. *Inverse models* are widespread due to the ability to cover large zones, but their results are more sensible to errors and should be cross-checked with *forward models*. For example, if not properly formulated, *gravity admittance* techniques may generate spurious results in continents (e.g., Kirby and Swain, 2009).

D provides a direct measure for the *integrated long-term strength* of the lithosphere and is linked to the *equivalent elastic thickness* of the lithosphere, $T_e : D = E\,T_e^3\left(12(1-\nu^2)\right)^{-1}$, where E and ν are Young's modulus and Poisson's ratio, respectively. *Plate bending or flexure* is characterized by its vertical deflection, $w(x)$ and local radius of curvature, $R_x(x)$ or curvature, $K(x) = -R_x^{-1} = \partial^2 w / \partial x^2$ (Figure 1). The flexural equation, when expressed using *bending moment* $M_x(x)$ is rheology independent and is valid for all, elastic and inelastic plates:

$$\frac{\partial^2}{\partial x^2}\overbrace{\left(\underbrace{\frac{E\,T_e^3}{12(1-\nu^2)}}_{D(x)}\underbrace{\frac{\partial^2 w(x)}{\partial x^2}}_{K(x)}\right)}^{M_x(x)} + \frac{\partial}{\partial x}\left(F_x\frac{\partial w(x)}{\partial x}\right) + \Delta\rho g w(x) = \rho_c g h(x) + p(x) \tag{1}$$

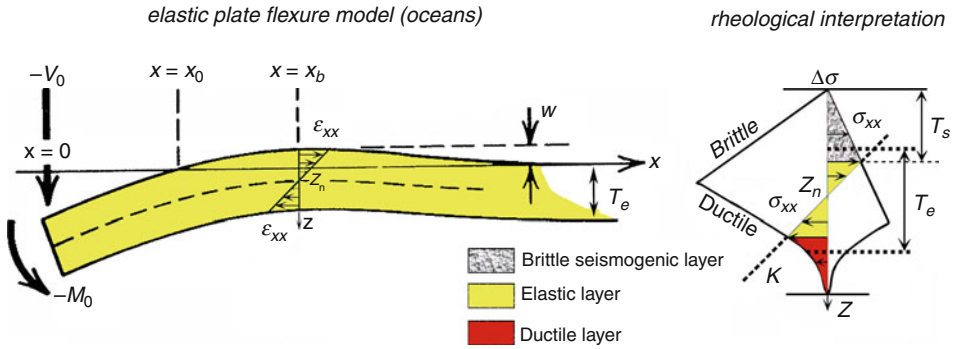
where F_x is horizontal *fiber force*, $\Delta\rho$ is the density contrast between surface and subsurface material (i.e., between mantle density ρ_m and topography/sediment/water density ρ_c), $h(x)$ is topography elevation, and $p(x)$ is additional surface or subsurface load. The elasticity is used just as simplest rheological interpretation of bending strength: elastic bending stress is linear function of curvature and depth: $\sigma_{xx}(x,z) \approx (0.5T_e - z)EK(1-\nu^2)^{-1}$. T_e is thus effective parameter and should not be automatically related to any real layer within the lithosphere. For inelastic plates, T_e and D have a sense of "condensed" plate strength and are direct proxies for the long-term *integrated strength*, B, of the lithosphere (Watts, 2001). For example, for a single-layer oceanic plate ($T_e = T_{e\_ocean}$, Figure 1):

$$B = \int_0^{h_m} \sigma^f(x,z,t,\dot{\varepsilon})dz$$

$$\text{while } T_{e\_ocean} = \left(12\left(\frac{\partial \sigma_{xx}^f}{\partial y}\right)^{-1}\overbrace{\left(\int_0^{h_m}\sigma_{xx}^f(z-Z_n)dz\right)}^{M_x(x)}\right)^{\frac{1}{3}};$$

$$T_{e\_ocean} < h_m \tag{2}$$

where $\sigma_{xx}^{\ f}$ is brittle-elastic-ductile bending stress (Burov and Diament, 1995); T_e is usually much smaller than



Lithosphere, Mechanical Properties, Figure 1 Classical flexural model of oceanic lithosphere (*left*). *Right*: brittle-elastic-ductile *yield stress envelope* (YSE) and interpretation of the *equivalent elastic thickness* T_e of the lithosphere. $\varepsilon_{xx}(z)$ is *flexural* strain, $\sigma_{xx}(z)$ is *flexural stress*, $K(x)$ is local plate curvature, $\Delta\sigma$ is *differential stress*, $Z_n(x)$ is *neutral plain*, and T_s is brittle seismogenic layer. $w(x)$ is vertical plate deflection. V_0 and M_0 are boundary cutting force and *flexural moment*, respectively.

h_m. M_x and, hence, D can be obtained from depth integration of σ_{xx}^f. D and T_e may spatially vary due to their dependence on local bending that leads to localized plate weakening (called *plastic or ductile hinging*) in the areas of utmost flexure, for example, near *subduction zones* or below mountains and islands.

Rheological properties of lithosphere according to rock mechanics data

The long-term mechanical behavior of rocks is represented by *extended Maxwell solid*, in which total strain increment equals a sum of elastic, viscous (ductile), and plastic (brittle) increments while the elastic, viscous, and plastic stresses are mutually equal. The weakest rheological term thus defines the effective behavior of this solid. Goetze and Evans (1979) used *Maxwell solid* and rock mechanics data to introduce the *yield stress envelope* (YSE) of the lithosphere (Figures 1 and 2). This approach consists in predicting, for a representative *background strain* rate and depth–pressure–temperature profile, the maximal *yield strength* $\Delta\sigma_{\max}(z)$ as function of depth, z. If elastic *differential stress* estimate $\Delta\sigma^e(z) < \Delta\sigma_{\max}(z)$, the deformation is elastic and *differential stress* $\Delta\sigma(z) = \Delta\sigma^e(z)$. If $\Delta\sigma^e(z) \geq \Delta\sigma_{\max}(z)$, then $\Delta\sigma(z) = \Delta\sigma_{\max}(z)$ and the deformation is brittle or ductile depending on z.

Elastic properties

The *elastic behavior* is described by linear Hooke's law:

$$\sigma_{ij} = \lambda\varepsilon_{ii}\delta_{ij} + 2G\varepsilon_{ij} \tag{3}$$

where λ and G are Lame's constants. Repeating indexes mean summation, δ is Kronecker's operator. For most rocks $\lambda \approx G = 30$ GPa (Turcotte and Schubert, 2002).

Brittle-plastic properties

Brittle resistance, τ, is a linear function of normal stress, σ_n and, that is, of pressure (Byerlee, 1978):

$$\tau = 0.85\sigma_n, \quad \sigma_n \leq 200 \text{ MPa} \tag{4}$$

$$\tau = 50 \text{ MPa} + 0.6\sigma_n, \quad 1,700 \text{ MPa} > \sigma_n > 200 \text{ MPa}$$

Byerlee's law is equivalent of *Mohr-Coulomb* (*Coulomb-Navier*) *plastic failure criterion* (e.g., Burov, 2007):

$$\tau = C_0 + \tan(\phi)\sigma_n \tag{5}$$

where C_0 is *cohesive strength* (<20 MPa) and ϕ is the *internal friction angle* (30–33°).

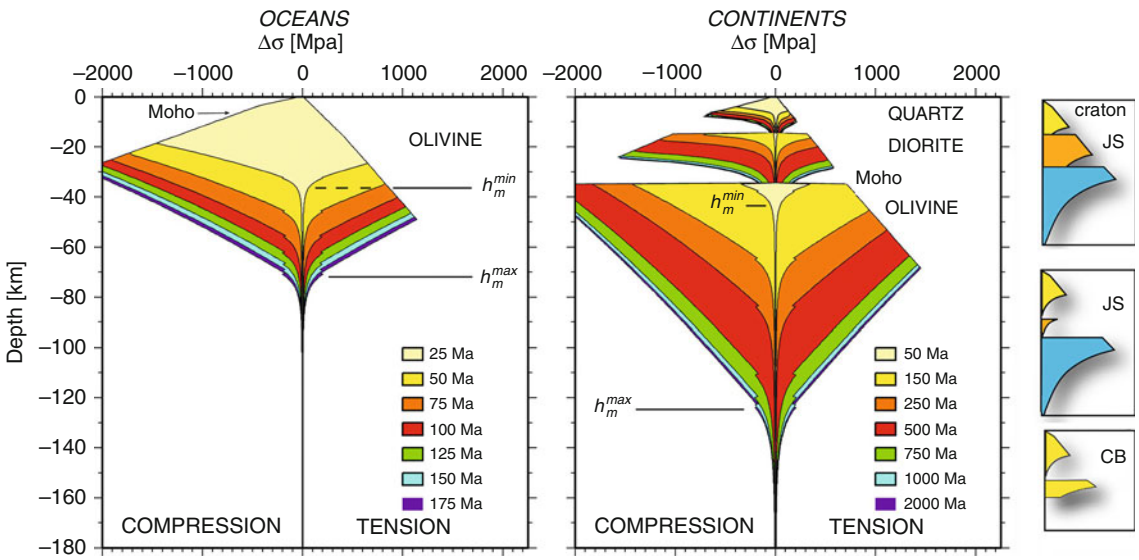
The Griffith criterion extends (5) to pure tensile domain:

$$\tau^2 = 4T_0^2 + 4T_0\sigma_n \tag{6}$$

where $T_0 = C_0/2$ is tension cut-off.

Viscous-ductile properties

Effective viscosity of the lithosphere varies from 10^{19} Pa s at the lithosphere–asthenosphere boundary to $>10^{26}$ Pa s in cold mantle near Moho depth. Several ductile mechanisms such as *diffusion creep*, *grain boundary sliding* (*GBS*), *pressure solution*, and *cataclastic flow* may play



Lithosphere, Mechanical Properties, Figure 2 Commonly inferred (brittle(Byerlee)-elastic-ductile) rheological *yield stress envelopes* (YSEs) as function of *thermotectonic age* for oceans and continents. In mantle, maximal strength can be limited by *Peierls* or *GBS* law instead of *Byerlee's law*. For continents, variations in crustal composition and fluid content result in various Jelly Sandwich, *Jelly Sandwich*, and more rare *Crème Brûlée*. After Burov (2007).

important role at appropriate conditions, but the leading part belongs to the *dislocation creep* (Kohlstedt et al., 1995):

$$\dot{\varepsilon}^d = Af_w\Delta\sigma^n \exp\left(-H(RT)^{-1}\right) \quad \text{for } \Delta\sigma < 200 \text{ MPa (Power law)}$$
$$\dot{\varepsilon}^d = Af_w \exp\left(-H\left(1-\Delta\sigma/\sigma_p\right)^2/RT\right) \quad \text{for } \Delta\sigma > 200 \text{ MPa (Harper}-\text{Dorn law)} \tag{7}$$

where $\dot{\varepsilon}^d$ is shear strain rate, A is material constant, n is power law constant, f_w is water fugacity factor, $\Delta\sigma$ is differential stress, R is universal gas constant, $H = Q + PV$ is creep activation enthalpy, Q is activation energy (100–600 kJ/mol), P is pressure, V is activation volume, T is temperature in K. σ_p is Peierls-like stress ($\sigma_p \sim$ several GPa). For tectonically relevant $\Delta\sigma/\sigma_p$ ratios (<0.1), Harper-Dorn's flow refers to *Peierls plasticity* that limits rock strength in high stress regime. *Dislocation creep* is strongly nonlinear non-Newtonian viscous flow ($n \sim 2$–4).

The second most important deformation mechanism, low-stress *diffusion creep* (Nabarro-Herring, Coble), results from directional diffusivity of rocks under applied stress (Kohlstedt et al., 1995):

$$\dot{\varepsilon}^d = Aa^{-m}f_w\Delta\sigma^n \exp\left(-H(RT)^{-1}\right) \tag{8}$$

where a is grain size and m is diffusion constant. For olivine, $m \sim 3$ and $n \sim 1$ and the constitutive law is linear Newtonian.

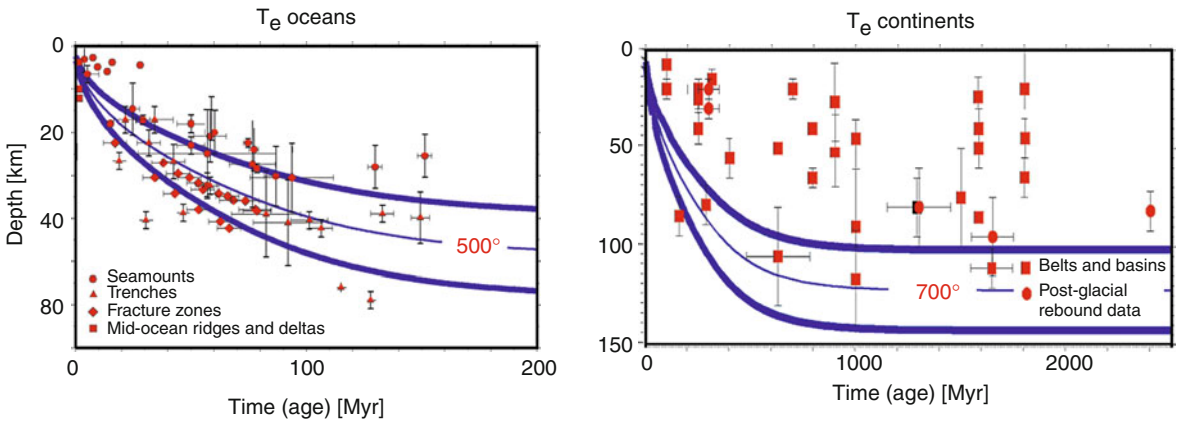
The *Peierls* super-plasticity is likely to replace *Byerlee's law* in the mantle below 30–40 km depth (Kameyama et al., 1999), that is, at high confining pressures (>1 GPa). Since *Peierls* plasticity includes strong water-weakening ($H = Q + p(V - \beta\Delta V_w)$), where ΔV_w is molar volume change due to incorporation of hydroxyl ions in the main rock and β is experimental parameter, it may play an important role in localization of deformation in subduction zones. This role may be shared with *GBS* creep, which might be responsible for aseismic localization of deformation in the lithosphere mantle.

Mechanical properties of oceanic lithosphere versus continental lithosphere

Due to its temperature dependence, ductile strength limits the depth to the base of mechanical lithosphere, h_m, to that of the isotherm 500–600°C in oceans and 700–800°C in continents (in continents, higher pressure for given temperature increases yield strength via the H term in Equation 7).

Oceanic YSEs ($0 < T_e <$ 50–70 km) derived from (3) to (8) predict brittle seismogenic behavior in the upper parts of lithosphere, where depth of *brittle-ductile transition*, BDT, varies from few km near ridges to 40 km near subduction zones (Figures 2 and 3). The competent domains below the *elastic core* are dominated by aseismic ductile creep, where important ductile strength is preserved down to the depths of 80–100 km near subduction zones.

Continental YSEs ($0–5 < T_e <$ 150 km) reflect strong *rheological stratification* between the upper, intermediate, lower crust and mantle lithosphere (Figures 2 and 3). There might be several BDT depths, typically at 15–25 and 30–45 km (Watts and Burov, 2003; Burov, 2007, 2010). The depth to the mechanical bottom of strong ductile lithosphere may vary from 30 to 200 km.



Lithosphere, Mechanical Properties, Figure 3 Observed T_e distribution in oceans and continents as function of *thermotectonic age* of the lithosphere, compared to depth of geotherms of 500 and 700°C defining, respectively, the mechanical base of oceanic and continental lithosphere (Burov and Diament, 1995; Watts, 2001; see also *Isostasy*). Assumed thermal thickness of continental lithosphere is 250 km. Depending on assumed thermal thickness and boundary conditions, predicted depth to 500–700°C may shift up or down by up to 25%. In continents, crust-mantle decoupling leads to ~50% T_e reduction compared to the depth to its mechanical base at 700°C. This explains occasional correlation of T_e with 400°C depth.

T_e estimates (Figure 3) reveal important difference between the mechanical properties of oceanic and continental lithosphere. In oceans, T_e (<70 km) follows the geotherm of 500 ± 100°C and correlates with age. It fits into the mechanically competent core (Figure 1).

In continents, maximal T_e values in cratons are 110–150 km, while T_e distribution reveals complex "bimodal" behavior (clustering around 25–30 and 70 km), which does not allow for geometrical interpretation of T_e. This complexity is explained by *rheological stratification* of continental plates, specifically of their 35–70 km thick crust (see entry *Lithosphere, Continental*). Continental plates consist of several layers of contrasting strength (upper, lower, intermediate crust, mantle) that can be mechanically coupled or uncoupled. For plates younger than 200–400 Ma, T_e grows with age yet exhibiting large scatter of values between 0 and 70 km. Older plates (>500–700 Ma) are in stationary thermal regime; the age dependence of T_e is expectedly small, but T_e scatter is still strong revealing influence of factors other than thermal age. Using rock mechanics data (Figure 4), it can be shown that continental T_e should be strongly controlled by the crustal thickness and mechanical state of crust-mantle interface (Burov and Diament, 1995). When the lower crust is mechanically strong, crust and mantle are mechanically coupled yielding a single strong layer with high T_e:

$$T_e \approx h_1 + h_2 \ldots = \sum_n h_i \tag{9}$$

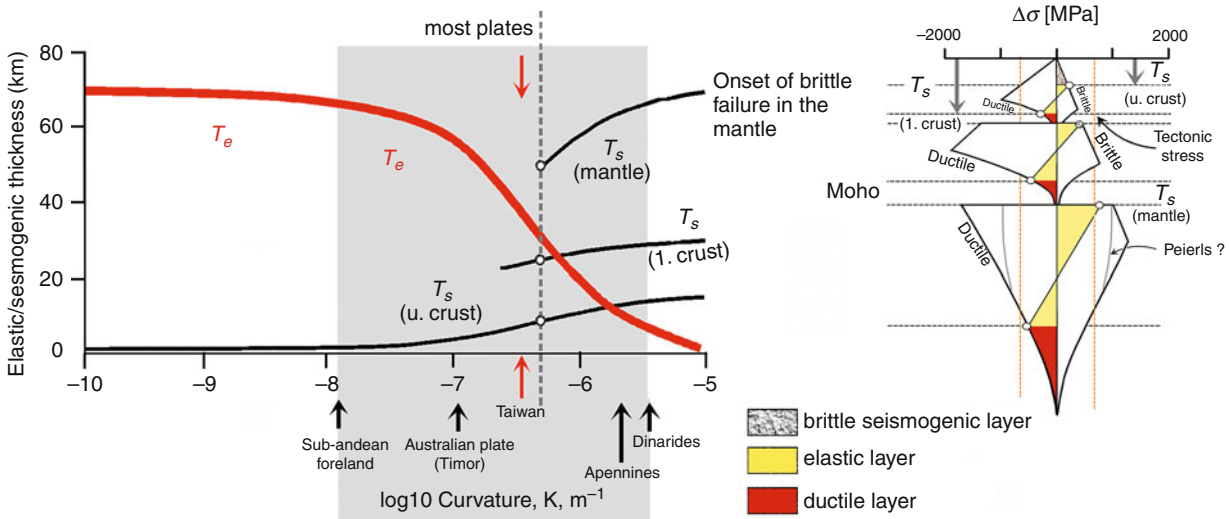
where h_i are thicknesses of crustal and mantle competent layers. Mechanical decoupling between crust and mantle leads to *structural weakening*, that is, dramatically smaller T_e (Burov and Diament, 1995):

$$T_e \approx \left(h_1^3 + h_2^3 \ldots\right)^{1/3} = \sqrt[3]{\sum_n h_i^3} \approx \max(h_i) < \sum_n h_i \tag{10}$$

"Decoupled" T_e roughly equals to the *mechanical thickness* of strongest layer in the lithosphere. In particular, $T_e \geq h_c$ (h_c is crustal thickness) identifies mantle as the strongest layer. Based on T_e data it has been shown that continental crust is systematically mechanically decoupled from mantle, except for cratons, and that mantle lithosphere is generally stronger or at least as strong as the crust (Burov and Diament, 1995). *Numerical thermomechanical models* have later confirmed these assertions (e.g., Burov, 2007, 2010).

Mechanical properties of the lithosphere and four modes of horizontal deformation

In addition to flexure under normal loads, four modes of lithosphere deformation and their combinations can develop under extensional or compressional conditions: (1) *pure shear* (extension: *McKenzie rifting model*; compression: plate *collision*), (2) *simple shear* (extension: *Wernicke rifting model*; compression: *subduction*), (3) *tensional/compressional instability* (extension: *boudinage*; compression: *folding-buckling*), and (4) *gravitationally instable pure shear* (slow *passive margins*, *Rayleigh-Taylor instabilities* due to thickening of a colder and thus denser lithosphere mantle overlying hotter and thus lighter asthenosphere). Ductile properties largely control these



Lithosphere, Mechanical Properties, Figure 4 Mechanical and rheological interpretation of continental T_e and *seismogenic layer thickness* T_s (*right*) computed for a representative YSE as function of local plate curvature K (*left*). After Burov (2010). Homogeneous horizontal stresses will shift T_e and T_s up or down in opposite directions, but will not change the character of their dependence on plate curvature.

deformation modes, including brittle fault spacing observed at surface (e.g., slow oceanic spreading centers vs. fast spreading centers). Brittle properties play an important role as well, specifically in localization of small and large-scale deformation, dyking, stabilization of cratons, transmission of tectonic stresses, and seismicity. Some of brittle mechanisms such as *low-angle faulting*, localization of large-scale *strike-slip* or *transform faults* and large-scale *dyke propagation* remain enigmatic.

Rheological stratification of continents is likely to influence the response of the lithosphere in all deformation modes. *Crust-mantle coupling* results in formation of narrow deep rifts while decoupling at different crustal levels may produce a variety of basins, from shallow large basins to narrow rifts. Under compression, *crust-mantle decoupling* plays a major role for continental subduction, UHP rock exhumation, slab detachment, formation of plateaus, or *lithosphere folding*. Lateral lower crustal flow is believed to be one of the key mechanisms affecting orogenic building and rift/passive margin formation or assuring feedback between surface and subsurface processes. For *mantle-continental lithosphere interactions*, such as *plume impingement*, the presence of ductile lower crust results in damping of the long-wavelength *dynamic topography* at surface, which is replaced by short-wavelength tectonic-scale deformation.

Uncertainties of data on the mechanical properties of the lithosphere

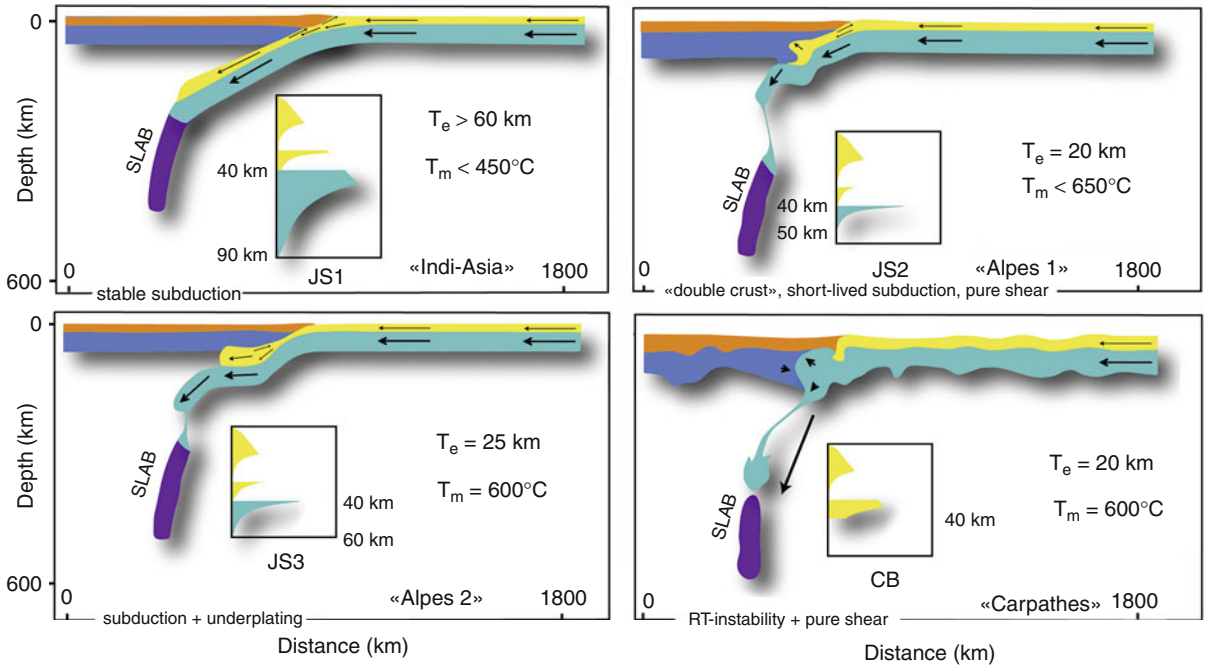
T_e studies play a key role in interpretation of *rock mechanics data*, allowing for parameterization of laboratory-based *flow laws* to geological time and spatial scales. Indeed, due to the large differences between time (10 orders) and spatial scales (6 orders) of the laboratory experiments and nature, *rock mechanics data* cannot be solely used to quantify the long-term *mechanical properties* of the lithosphere. Yet, since the *integrated strength B* of the lithosphere is directly related to T_e, one can use inelastic *flexural models* in combination with *rock mechanics data* (Equations 1–10) to constrain, parameterize, and validate rheology parameters for geological timescales. In particular, one can derive YSEs that are compatible with the host of different observations such as T_e, heat flow, seismic imagery, gravity, and so on. There is generally a good correlation between the observed T_e and T_e predicted from experimental YSE (Watts, 2001, Figure 4). In oceans, T_e values scale well with *rock mechanics data* and *thermal models of the lithosphere* (e.g., McNutt and Menard, 1982, Figure 3). In continents, T_e rheology parameterization is delicate but can be done if one respects the physics of underlying processes (Burov and Diament, 1995; Burov, 2010). Three types of *rheological envelopes* can be proposed for continental lithosphere: *Cratonic Jelly Sandwich*, *Jelly Sandwich*, *Crème brûlée* (with its variant hydrated *Banana Split* rheology) (Watts and Burov, 2003; Burov, 2010, Figure 2). The first two types evoke strong mantle lithosphere that can be either mechanically coupled with the crust (*Cratonic type*) or decoupled from it by weak lower or intermediate crustal layer (pure *Jelly Sandwich*). These first two rheologies dominate and correspond to 80–90% of all cases, as confirmed by matching T_e predicted from YSEs with the observed T_e and mechanical models. The *Crème brûlée* rheology infers weak lithosphere mantle, and applies to few cases of hot lithospheres (e.g., *Basins and Range Province*).

Mechanical properties of the lithosphere and styles of tectonic deformation

Important constraints on lithosphere rheology and properties come from physical considerations including *thermo-mechanical numerical models* of geodynamic processes. One can verify the validity of rheological assumptions by comparing predictions of thermo-mechanical models based on these assumptions with the observed tectonic evolution in various contexts such as collision and mountain belts (Figure 5), rifts and passive margins, and subduction zones and lithosphere folding. The analytical and *numerical thermo-mechanical models* of geological processes show that predicted evolution is highly sensitive to rheology choices (Figure 5). It has been demonstrated that in most cases mantle lithosphere has to be rheologically strong to insure stability of geological structures and the observed styles of deformation. In particular, stability of mountain ranges, continental *subduction* (e.g., Figure 5, Burov, 2010) and most observed *rifting modes* (Buck, 1991; Bassi, 1995) need initially strong mantle lithosphere with *mechanical thickness of the mantle part* more than 30–50 km. Collision models (Figure 5) quantify relationships between the collision styles and deep lithosphere structure and rheology. They show that tectonic evolution depends not only on the integrated strength (T_e) but as much on strength distribution with depth, that is, on which particular lithological layer (upper crust, lower crust, or mantle lithosphere) provides main contribution to T_e. Rift models show that *narrow rifts* are associated with initially strong mantle lithosphere, while metamorphic core complexes "need" warm lithospheres with negligible mantle strength. Wavelengths of *boudinage* and deca-kilometric upper crustal fault spacing observed in rift zones also appear to be a direct function of the ductile properties of the underlying lower crust. In compressional settings, observed *folding wavelengths* provide constraints on plate rheology since these wavelengths (50–1,000 km) are proportional to 5–10 times thickness of competent layers in the lithosphere and correlate with T_e values (e.g., Burov, 2007).

Links between different timescales: Burger's rheology model

The abundance of short-timescale observations such as *earthquake distributions* or *post-seismic relaxation* explains attempts to interpret these data in terms of long-term rheology. Yet, these attempts are typically based on



Lithosphere, Mechanical Properties, Figure 5 Numerical thermo-mechanical models of long-term geological processes (here, continental collision) allow for validation of inferred rheology profiles (*Jelly Sandwich*, JS1–JS3, and *Crème Brûlée*, CB) by testing the compatibility of model-predicted and observed tectonic evolution. Models JS2, JS3, and CB have similar T_e (20–25 km) but different mantle strength, leading to strong differences in resulting collision styles. The models show that strong mantle lithosphere is needed to drive continental subduction while strong crust cannot play same role (its low density prohibits subduction if there is no mantle drag). T_m – temperature at Moho. Colors: *orange*, *yellow* – crust; *blue*, *azure* – mantle; *purple* – oceanic slab. Modified from Burov (2010).

misinterpretation of Goetze's YSEs that are valid only for geodynamic strain rates. Earthquakes and relaxation occur at locally and temporarily high strain rates that are not representative of long-term rates. Hence, the fact that continental lithosphere below Moho depth is mainly aseismic cannot be interpreted as a sign of weak ductile behavior (Figure 4). It rather indicates that either mantle stress levels are insufficient to induce brittle sliding, or that seismogenic *Byerlee's law* does not operate at high pressure (>36–70 km depth), or that the frictional behavior is strain-rate dependent. At seismic strain rates (10^{16} times higher than geodynamic strain rates), the entire lithosphere acts as a brittle-elastic body and no ductile flow can occur. Strictly speaking, T_e and *maximal seismogenic depth* T_s should rather anti-correlate (Watts and Burov, 2003, Figure 4). However, T_s cannot be used to constrain T_e without knowing intraplate stress level. The fact that T_s distributions in oceans and continents are similar, while their rheological and mineralogical structures are different, adds to the argument that seismicity is primarily related to stress levels.

Post-seismic relaxation data provide controversial results yielding effective viscosities of deforming domains about 1–2 orders of magnitude smaller than *postglacial rebound data* that provide minimal viscosity (10^{19} to 5×10^{19} Pa s) of the Earth's weakest layer – asthenosphere. Since these estimates are based on inversion of *surface deformation*, they strongly depend on initial assumptions on lithosphere structure and properties, while it is impossible to determine which layer in the lithosphere relaxes post-seismic deformation. Nevertheless, whatever is this layer, the estimated viscosities appear too low for long-term properties. To explain this controversy, one can consider *Burger's model* of solids. According to this model, lithospheric behavior is described by two independent serially connected terms, one of which is *Kelvin solid* responsible for the primary creep (seismic, post-seismic) and the second one is *Maxwell solid* responsible for secondary long-term creep (geodynamic timescale). The viscosity of the first term is independent of that of the second term. In other words, the physics of deformation mechanisms activated at seismic-scale strain rates is different from that of the mechanisms acting at geodynamic strain rates.

Summary

Lithosphere has important long-term ductile, elastic, and brittle-plastic strength and is capable of maintaining (not relaxing) differential stresses at geological timescales. These properties can be accessed mainly from estimates of the *equivalent elastic thickness*, T_e, combined with *rock mechanics data*, validated by analytical and *numerical*

thermo-mechanical models of geological and geodynamic processes. In oceans, T_e fits in the mechanical core of the lithosphere, but in continents, it generally does not represent any particular layer due to strong *rheological stratification*. The brittle-plastic properties of the lithosphere are governed by *Byerlee's law* to 30–40 km depth and likely by *Peierls* plasticity and/or *GBS* creep below. The ductile properties are dominated by *dislocation power-law creep*, which is strongly nonlinear and rock-type dependent. Highest *integrated strength* ($T_e \sim$ 100–150 km) is detected in cratons (*Cratonic Jelly Sandwich rheology*) where strong crust is mechanically coupled with strong mantle. In warmer continental lithospheres, mechanical decoupling between crust and mantle leads to *structural weakening* resulting in ~50% reduction of T_e (*Jelly Sandwich rheology*). In most cases, mantle lithosphere provides main contribution to the integrated plate strength. The cases where mantle is weaker than crust (*Crème-Brûlée rheology*) refer to hot lithospheres such as metamorphic core complexes. There is probably no exploitable link between short-term deformation such as earthquake data or post-seismic relaxation and long-term properties of the lithosphere.

Definition and introduction

The term "lithosphere" is used or defined in a variety of formal and informal ways. All are fundamentally linked to a comparison of near-surface (lithosphere) mechanical and/or thermal properties with those properties deeper in the Earth (the asthenosphere). And all are linked to the concept of a thermal boundary layer between the bulk of the Earth and its atmosphere/ocean above. In this entry, we deal with the oceanic lithosphere, and we will define it as that part of the oceanic crust and the uppermost mantle that is usually created at mid-ocean spreading centers and that generally is consumed in subduction zones. For space purposes, we will specifically exclude oceanic sediments, island or continental arcs, and continental margins.

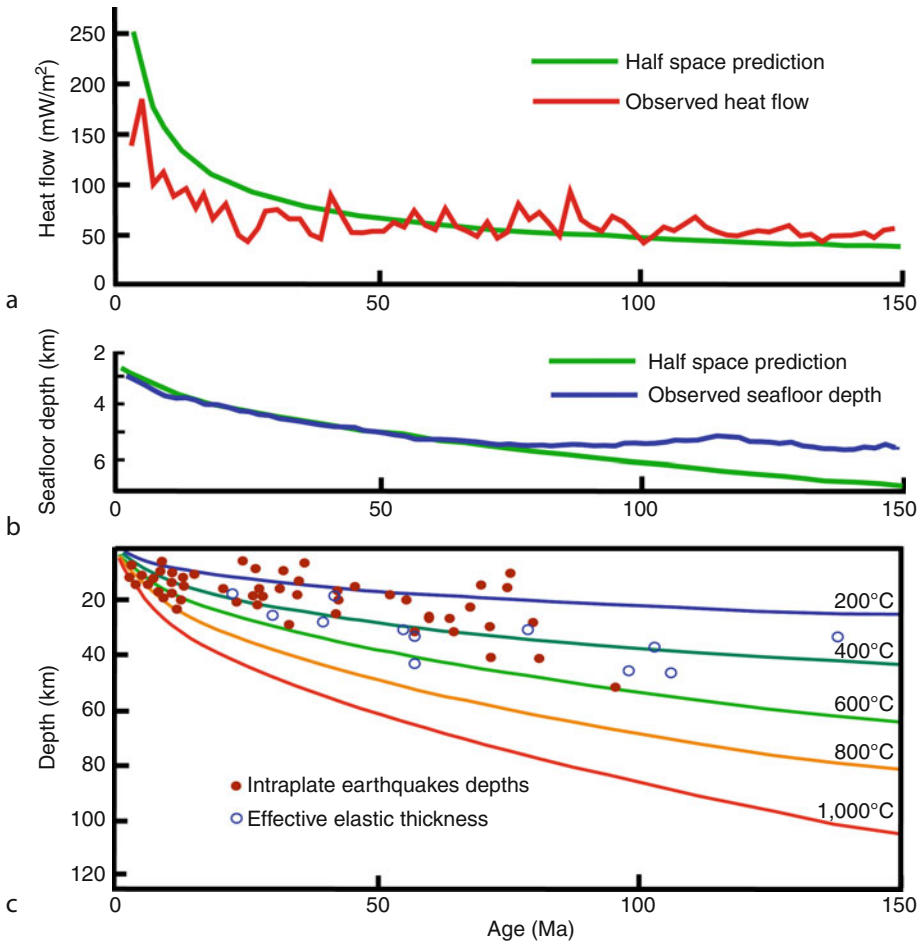
The ocean lithosphere is generally considered the outer carapace of the Earth that is cool, with an elastic rheology, and exhibiting brittle failure (e.g., failure by earthquake). This contrasts with the asthenosphere, which exhibits viscous rheology and higher temperatures. The concept of lithosphere was first developed in 1914 by Barrell (1914), who realized that the outer part of the Earth must be able to support tectonic loads over geological timescales. Since that time, workers additionally have defined the lithosphere in terms of plates that move coherently in plate tectonics. Alternatively, the oceanic lithosphere may be defined as the relatively high velocity or low attenuation "seismic lid," or as that part of the earth that can sustain earthquakes. These various definitions are not

necessarily mutually exclusive, but it is important to consider how the term lithosphere is used (Figure 1).

The uppermost mantle lithosphere

The mantle component of the lithosphere is composed of peridotite, and the thermomechanical transition from lithosphere to asthenosphere is defined on the basis of the data used to detect that transition. Many have used the seismic low-velocity zone often inferred for the upper mantle as the essential (e.g., Forsyth, 1977; Nishimura and Forsyth, 1989). Typically exploiting surface wave observations, these studies have been very useful in defining variations in lithospheric thickness.

Another approach to estimating lithospheric thickness is derived from observations of the response of the lithosphere to tectonic loading (e.g., Calmant et al., 1990). Specifically, the addition of a large seamount or island should cause the lithosphere (including the seafloor) to deflect downward as the load is accommodated by the asthenosphere. The amount of deflection or flexure, and the regional distribution of the deflection, can be considered a function of the thickness of the strong lithospheric plate. The topography of the seafloor around a seamount can be used to calculate this "effective thickness." A compilation of thicknesses is shown in Figure 1c, and reveals the thickness of the lithosphere coincides with isotherms between 400°C and 600°C in the mantle. Similar values for lithospheric thickness are obtained if one uses the depths of intraplate earthquakes, which presumably are indicators of brittle failure confined to the lithosphere (Wiens and Stein, 1983) see (Figure 1c).



Lithosphere, Oceanic, Figure 1 Different observables are used to constrain models for the oceanic lithosphere, primarily its mantle component. (**a**) Observed heat flow data (in *red*) averaged in 2-million-year bins (Stein and Stein, 1992) compared to predictions for a conductively cooled half space (in *green*). Heat flow is too low and scattered for ages less about 40 Ma, indicating nonconductive (hydrothermal circulation) cooling must be taking place. (**b**) Observed seafloor depth (in *blue*) compared to predictions for a conductively cooled half space (in *green*). Depths are too shallow beyond 80 Ma, indicating temperatures have stabilized and heat is being supplied from below. (**c**) Plot of earthquakes depths and effective elastic thickness on top of expected isotherms for a half-space model.

Regardless of the thermomechanical observable used, the lithosphere is observed to thicken with age as it spreads away from the mid-ocean ridges, a result of cooling of the mantle. Independent evidence for this cooling is the progressive deepening of the oceans with age, and the coincident decrease in heat flow. Simple, conductively cooled, half-space models (e.g., Davis and Lister, 1974) yield a prediction that depth must increase linearly with the square root of age ($t^{1/2}$), and heat flow must decrease proportionally with the one over the square root of age ($t^{-1/2}$) (see Figure 1a and b, modified from Stein and Stein, 1992).

Even the earliest studies pointed out that heat flow and depth data did not perfectly fit the half-space model. Parsons and Sclater (1977) and Stein and Stein (1992) made detailed analysis of the global compilations of depth and heat flow measurements. They document that, at great ages (e.g., >80 Ma), the seafloor is too shallow, and heat flow values are too high compared to predictions (Figure 1a and b). They point out that a plate model, where heating from below restricts continued cooling of the plate would explain the discrepancy. The source of this heating could be small-scale convection in the asthenosphere below the plate, radioactive decay in the mantle, or mantle plumes. Parsons and Slater derived a plate (i.e., lithosphere) thickness of 125 km at great ages. Using a larger data set and more refined analysis, Stein and Stein (1992) achieved a better fit for a lithosphere that thickens to 95 km. We note these thicknesses are substantially greater than those that would be derived from the earthquake depths and flexural loading; this illustrates the fact that the characteristics determined for the lithosphere are obervation-dependent.

The second discrepancy of global data with the half-space model was the fact that heat flow values were highly scattered and substantially lower for seafloor less than 50 million years old. Using their conductively cooled plate model, and the misfit between the predicted and measured heat flow, Stein and Stein (1994) calculate that some 34% of the oceans heat loss is accommodated by hydrothermal circulation. They further conclude that about 70% of the advective heat loss occurs in crust from 1 to 65 million years, and not through vigorous hydrothermal activity occurring at the mid-ocean ridges.

The crustal component of the oceanic lithosphere

The top few kilometers of lithosphere comprise the ocean crust. To a first approximation, the crust is viewed as the mafic member of the lithosphere, and most is generated by magmatic, tectonic, and hydrothermal processes at the mid-ocean ridges, and modified by the ongoing hydrothermal circulation noted above. Our knowledge of the crust is dominated by three lines of evidence, all of which provide key constraints on the nature of oceanic lithosphere. These include direct sampling of seafloor rocks where they are exposed or from boreholes, seismic experiments that reveal the seismic velocity structure of the crust, and the study of crustal analogues exposed above sea level. These studies led to a convergence on the so-called Penrose or "ophiolite" model (defined below). While this model is highly successful in its predictions about the crust and upper mantle, the research in the last 10 years has led to recognition, at least for some crust generated at ridges with slow to ultraslow spreading rates, that the ophiolite models must be revised to include newly discovered features.

Samples of crustal rocks

Ocean crustal rocks are generally recovered from near the mid-ocean ridges before sediments have a chance to accumulate on the aging seafloor. Samples are collected using dredges and other techniques from surface ships, as well as exploiting manned submersibles and remotely operated vehicles (ROVs).

The vast majority of rocks recovered from the seafloor are mafic basalts, although other types, such as gabbros and serpentinites, are sometimes exposed at transform faults or on rifted mid-ocean ridges. However, it is the striking uniformity of seafloor basalts that reveal the similarity processes that form the mantle and crustal components of the lithosphere.

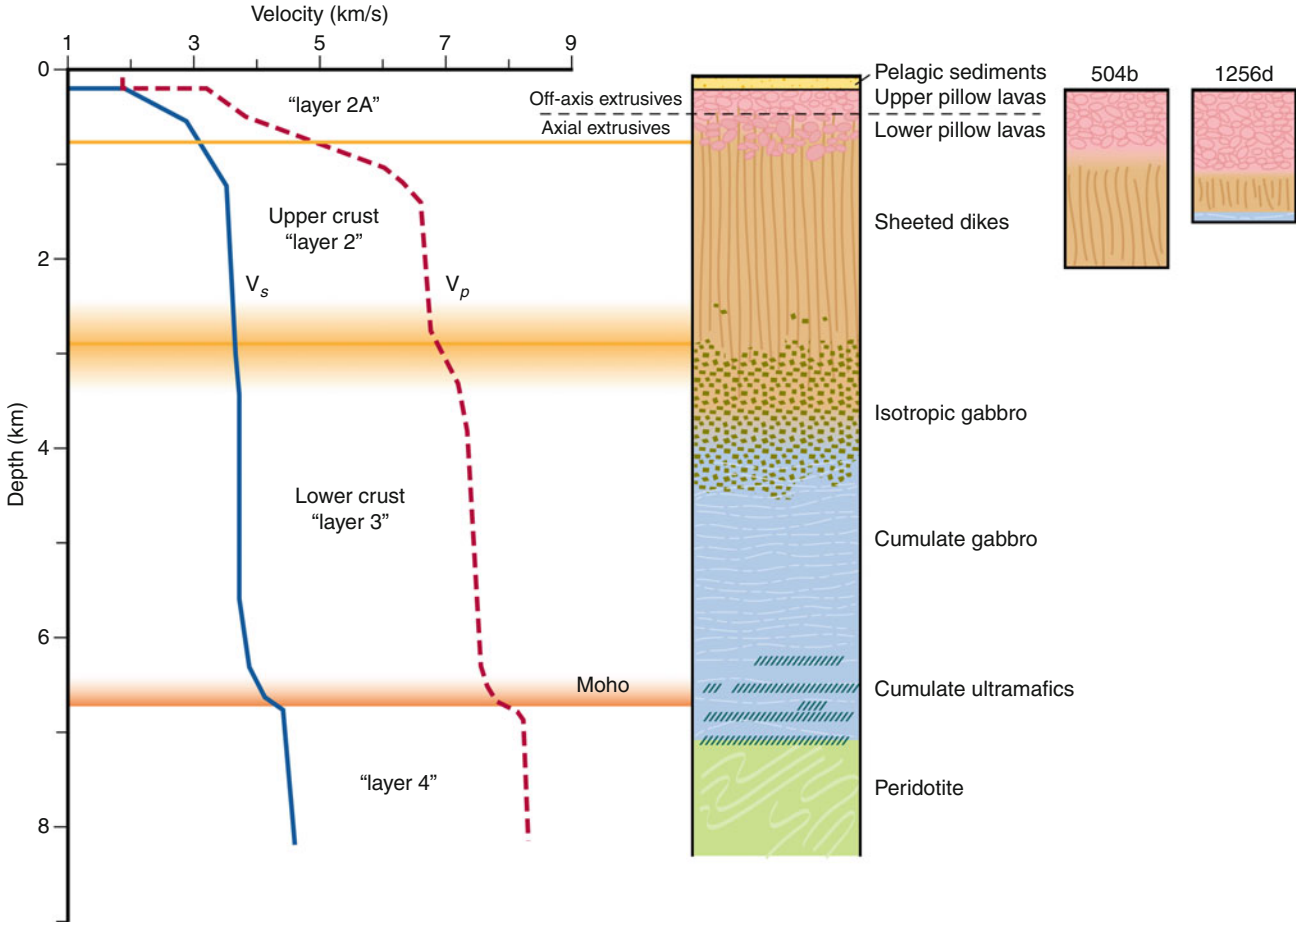
Most of the mafic rocks recovered on the mid-ocean ridges are so-called MORBs or mid-ocean ridge basalts. The composition of MORBs indicates that the mid-ocean ridge basalts originate from partial melting of a depleted upper mantle beneath the ridges. MORBs have been further parsed into N-MORB (normal-MORB) and E-MORB (enriched-MORB), and intermediate compositions (transitional or T-MORB) have been observed. These observations generally are interpreted to indicate they originated in a heterogeneous, but still depleted mantle source. It is this depleted mantle that will, upon cooling with age, form the mantle lithosphere.

An additional inference made from analysis of seafloor basalts was that the detailed composition required partial fractionation at shallow (i.e., lower crustal) pressures; that is, a magma chamber exists beneath most ridge axes.

Ophiolites, ocean drilling, and the ocean crust

Ophiolite sequences have been studied for over 100 years, and have been the source of substantial controversy. Complete ophiolites see (Figure 2) include a coherent stratigraphy extending from submarine lava flows into sheeted dikes, the latter representing the feeders for the lava flows. Beneath the sheeted dikes are gabbros, often divided between isotropic gabbros (no preferred fabric) at the top, and layered (cumulate) gabbros at the base. Gabbros represent the frozen magma chamber, originally inferred from the composition of MORB. Beneath the gabbros are ultramafic peridotites (inferred to be the mantle), varying between harzburgites, lherzolites, and dunites. In general, the peridotites are serpentinized to a greater or lesser extent, but is unclear whether the serpentinization occurs during emplacement and uplift onto land, or on the seafloor.

Early on, ophiolites were thought to originate as ocean crust and uppermost mantle, and to have been thrust up on land by convergent processes (see Moores, 1982). Substantial debate centered on whether particular ophiolites



Lithosphere, Oceanic, Figure 2 Comparison of seismic velocities with an idealized ophiolite, and with drilling results for two Pacific ODP (504b) and IODP (1256d) drill holes that successfully penetrated to mid-crustal levels (Modified from McClain, 2003). The seismic structure is for a specific profile on 16-Ma crust generated on the fast-spreading southern East Pacific Rise. The mid-crustal inflection is used here as the boundary between Layer 2 and Layer 3 for this particular crust. The inflection could be caused by the lithological boundary between sheeted dikes and gabbros as shown here, or by changes in porosity, or by changes in metamorphic grade. From velocity alone, we cannot tell. However, all three causes could occur at the same depth.

originated in arc or backarc settings, or whether some may have originated on mid-ocean ridges. Regardless of the origin of any particular ophiolite, it is clear that ophiolites provide an important analog for ocean crust generated on mid-ocean ridges. The presence of sheeted dikes to deliver magma from a crustal magma chamber, and the presence of gabbros originating from the freezing of the chamber, leads to a model that is consistent with petrologic models that originate from seafloor sampling.

The Ocean Drilling Project, and its predecessor Deep Sea Drilling Project and successor the Integrated Ocean Drilling Project, also provide support for the "ophiolite" model. In particular, drilling results in the Costa Rican rift (Hole 504b) and off southern Mexico (Hole 1257) have penetrated through the seafloor lavas and into the sheeted dikes. For the latter site, gabbros, intercalated with sheeted dikes have been reached at the base of the sheeted dike column (see Figure 2).

Seismic studies of the ocean crust

Except for studies of subareal ophiolites, rare exposures on the seafloor, and a few deep drilling efforts, seismic studies provide the only information about the ocean crust below the seafloor. The information they reveal about the structure and seismic velocities in the subsurface leads to inferences about the petrology of the upper mantle and crust.

After World War II, marine institutions began to exploit the seismic refraction technique to explore the Earth beneath the sea. These experiments usually yielded compressional or P-wave seismic velocities, although converted shear waves were sometimes observed. In these early studies, theoretical and computational tools necessarily restricted models to laterally homogeneous structures, and a consistent four-layer model for the sediments, crust, and mantle was developed (e.g., Shor et al., 1969). The first layer was that of sediments, with

velocities averaging about 2 km/s. Beneath that was "Layer 2," and because the seafloor was known to reveal lavas in unsedimented areas, it was expected that Layer 2 was the "volcanic layer." The thickest part of the oceanic crust is "Layer 3," with velocities of about 6.8–7.2 km/s and thicknesses on the order of 2–4 km. The lithology of Layer 3, also known as the "oceanic layer," has been controversial, with some workers preferring a gabbroic composition, and others a serpentinite composition. The former model has gained general acceptance, partly because of the presence of gabbros in ophiolites (e.g., Christensen and Salisbury, 1975). Underlying Layer 3 is Layer 4, with compressional wave velocities of about 8 km/s, and corresponds with the upper mantle. The lithology of the mantle is generally taken to be peridotite, consistent with the above-mentioned models for partial melting. Thus, the "crust" comprises Layers 2 and 3, and the boundary between the crust and mantle, Layers 3 and 4, is known as the Moho or Mohorovicic discontinuity.

With better experiments, the original four-layered model was subdivided into more finely divided structures. The earliest refinement was the observation of "Layer 2A." This was the shallowest and lowest velocity portion of the upper crust, and the low seismic velocities were attributed to the high porosities of basalt flows. This interpretation is further supported by the observation that the velocities of Layer 2A tend to increase to normal Layer 2 values and/or that Layer 2A thins over a few million years. This was interpreted as infilling of pores by metasomatic precipitation of minerals as the crust ages (e.g., Houtz and Ewing, 1976). Such an explanation requires fluid circulation in the crust must continue over millions of years after the crust forms, consistent with recent models for the cooling of the lithosphere mentioned above (Stein and Stein, 1994).

In the 1970s, the development of new theoretical and computation tools allowed workers to move beyond the simple layered models, to those that with continuously varying, but usually vertically stratified models. As models grew more sophisticated, it became possible to correlate them with ophiolite structures, using both velocities and thicknesses (e.g., Christensen and Salisbury, 1975; Spudich and Orcutt, 1980; McClain, 2003). As a result, the so-called Penrose model or "ophiolite model" for the oceanic lithosphere has become the accepted model (Figure 2). For the crust, this led to models where Layer 2 was divided into an upper zone in with relatively low velocities (Layer 2A), underlain by a high velocity gradient extending to Layer 3. The high-gradient zone, sometimes labeled Layer 2B, was attributed to a decrease in crustal porosity, and is correlated with the transition to sheeted dikes of the ophiolite model.

The same experiments revealed a slight inflection in seismic velocities at mid crustal levels, and often seismic velocities at mid crustal levels only reach "Layer 3" values beneath that inflection see (Figure 2). This inflection is not always observed, because it is obscured in the data, or because of the analysis techniques used, or because the change in velocity is too gradual. In the latter case, Layer 3 is often interpreted to be at the base of the high-gradient zone. The origin of this slight transition was (and is) attributed either to a metamorphic boundary between lower and higher grade metamorphic changes in lithology, a reduction in residual porosity, or to a transition from diabase dikes to the gabbros in the lower crust. For the drilling results for hole 504B (Figure 2), the velocity boundary was imaged seismically, and then successfully drilled within the sheeted dikes. In that case, it appears the boundary corresponds to a change in metamorphic grade and/or a change in porosity. These explanations are not necessarily mutually exclusive; the penetration of metasomatic fluids requires some porosity, and gabbros in ophiolites typically reveal little or no alteration or relict porosity in comparison to the overlying sheeted dikes.

Finally, the Moho is more gradational in these refined models, and the mantle velocities are well correlated with those expected for peridotites. While the velocity difference between a gabbro and peridotite is large, the apparent, more gradual observed change is most likely because the transition is gradual, with laterally heterogeneous and interleaved gabbros and peridodtites at the Moho.

The mid-ocean ridges

The ocean crust is generated by a complex interaction of magmatic, tectonic, and hydrothermal processes that take place at the mid-ocean ridges where seafloor spreading occurs. As a result, the majority of seismic experiments over the last 2–3 decades have focused on the tectonic plate boundaries, with particular attention on the ridges. Interpretation of the data from these experiments required models that allowed for two- or three-dimensional structure, rather than the laterally homogenous models from earlier. Early ray-tracing techniques have given way to more robust tomographic inversion. In addition, the development of longer seismic hydrophone streamers and new processing algorithms now permits detection of subbasement (crustal and upper mantle) reflections using multichannel reflection experiments.

One of the critical controversies about the structures beneath oceanic spreading centers was the presence of a seismically resolvable axial magma chambers (AMC). As stated above, petrologic data seemed to require some sort of magma chamber in the lower crust, and the ophiolite model includes a thick gabbro layer. However, models resulting from seismic surveys were equivocal, with some revealing crustal AMC (e.g., Orcutt et al., 1975) and some not (e.g., Bratt and Solomon, 1984). McClain et al. (1985) were able to provide convincing evidence for a narrow magma chamber on the East Pacific Rise at 13° north. The seismic velocity required for the chamber was 4.5 km/s, suggesting a partial melt rather than a pure magma. Further evidence for the resolved AMC was found in an extensive tomographic experiment on the East Pacific Rise at 9°30′N (Toomey et al., 1990).

For fast-spreading ridges, the question of magma chamber presence was largely resolved when a large

multichannel experiment was conducted along the northern East Pacific Rise (e.g., Detrick et al., 1987). Using the long hydrophone streamers, researchers were able to resolve reflections from the base of Layer 2A, as well as the Moho. However, most striking was the presence of a reflection at mid-crustal levels along most of the length of the ridge. Analysis of the reflection amplitude and the change in the sign of the reflection requires that the reflection result from a sudden decrease in seismic velocity. The explanation for this velocity inversion was the presence of an axial magma chamber. Furthermore, the large amplitudes of the reflections require a rather low velocity compared to models obtained from refraction experiments. This suggests that reflections result from pure or nearly pure melt sills. The discrepancy results because refraction experiments do not resolve the sills, and instead image an average structure made up of the sills and partial melt zones. Early models have suggested these sills form at the top of the magma chamber, and may be responsible for the isotropic gabbros observed in some ophiolites. The larger partial melt zones would form the cumulate gabbros that make up the bulk of the lower crust.

Subsequent to the initial experiment of Detrick and others (1987), similar magma reflections have been imaged on other segments of the fast or ultrafast spreading East Pacific Rise (e.g., Detrick et al., 1993; Singh et al., 2006) as well as ridges with intermediate spreading rates (e.g., Canales et al., 2009). Most studies suggest that the crustal AMC is generally narrow, the result of vigorous hydrothermal cooling. However, recent studies also have revealed that melt sills are sometimes distributed in depth and laterally.

Hydrothermal activity

One of the most spectacular discoveries in the annals of earth science was the observation of vigorous hydrothermal circulation at the spreading centers (e.g., Corliss et al., 1979). While the presence of hydrothermal circulation was not surprising, the exceptionally high temperatures, the deposition of hydrothermal minerals, and a vigorous chemosynthetic biological community were a major breakthrough in the study of mid-ocean ridges. It is clear that the chemical, biological, and geological contribution of these vents is present throughout the world's oceans. Thus far, over 200 hydrothermal vent fields have been discovered, and as many as 1,000 may lie on the world's mid-ocean ridges (Baker and German, 2004).

Early studies suggested that a substantial portion of the Earth's heat was lost along the high-temperature hydrothermal circulation on mid-ocean ridges. More recent analyses indicate that more heat is lost through lower temperature circulation in older crust. However, it is clear that near-axis circulation is a major component of the crust-forming process, and their discovery has led to a new appreciation for the interdisciplinary nature of mid-ocean ridge science.

High-temperature venting is observed on all ridges, and at all spreading rates. Such systems require a heat source and a permeability structure that permits a focused flow of fluids to the surface. For fast-spreading ridges, heat sources are plentiful, with the presence of axial magma chambers, and frequent eruptive events. Indeed, the narrowness of the axial magma chamber requires that circulation penetrate at least to the top of the chamber and/or into the gabbros at its flanks (e.g., Lister, 1983; Morton and Sleep, 1985). The geometry of the down-going limb of the seawater into the crust remains uncertain. It may be that it penetrates along axis, perhaps along faults or fissures, or it may penetrate from the sides along normal faults.

For slower spreading ridges, the heat source is unclear. Certainly volcanic eruptions do occur, so a heat source is present at least some of the time. However, it may be that water also can penetrate to the deeper hot, but not molten, rocks. The large normal faults often present on slow-spreading ridges may accommodate this deeper circulation.

Along-axis variations in ridge processes and slow-spreading ridges

It has long been known that mid-ocean ridges display a systematic variation in cross-sectional topography, varying from rifted ridges, with rift valleys of 1–2-km deep, and to non-rifted ridges that display topographic highs. In general, rifting is associated with slower spreading ridges, while non-rifted ridges usually exhibit intermediate to rapid seafloor spreading. There are a number of exceptions to the rule. For the Reykjanes Ridge adjacent to the Iceland Hot Spot, the slow-spreading ridge is unrifted. On the Galapagos Ridge, the ridge segments closest to the hot spot there is also unrifted. For ridges spreading at intermediate rates, both rifted and unrifted ridge segments are observed (e.g., the Gorda and southern Juan de Fuca Ridges), and are often separated by only a transform fault.

These observations suggest that the presence or absence of a rift valley is more likely controlled by magma supply rather than spreading rate itself. On slow-spreading ridges, the isotherms are narrowly spaced, and plunge more steeply as the lithosphere ages. Thus, less melt may reach the surface unless excess temperatures and magma are supplied by a nearby mantle plume. For intermediate spreading ridges, local variations in magma supply, and perhaps along-axis flow may influence the formation of a rift valley.

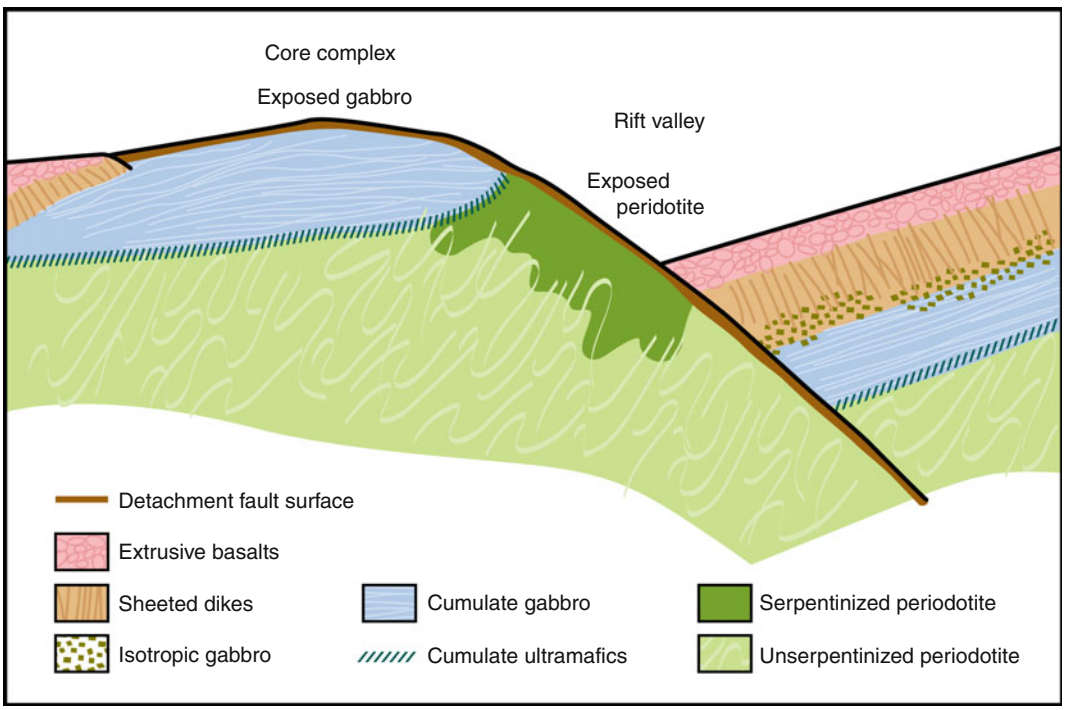
With the advent of multi-beam systems, it was found that ridges are segmented on a variety of scales, with offsets between segments also varying in character and length. In a series of papers, a correlation between segment depths and cross-sectional geometry was pointed out (e.g., Macdonald and Fox, 1988), and it was suggested that these variations were linked to focused magma supply at segment centers and subsequent magma flow along axis to the

segment ends. It is logical to assume that the magma supply would be tied to the resulting crustal structure and thickness, with thicker crust at the segment centers. The seismic reflection results of Detrick et al. (1987) seemed to support that linkage. However, the inferred correlation of ridge topography with crustal thickness has been called into question for fast-spreading ridges by a series of seismic experiments (e.g., Barth and Mutter, 1996; Kent et al., 2000).

Chen (1992) made a global study of crustal thicknesses, and found very little correlation or variation in thickness for spreading rates greater than 30 mm/year, and it appears that segmentation does not have a major influence on crustal thickness at these spreading rates. However, for ridges that spread slowly, or very slowly, crustal thicknesses are far more variable.

With the improvement of techniques, mid-ocean ridge researchers have been able to overcome the complexities caused by topography on rifted ridges. For such ridges, crustal thickness is closely tied to location along a segment, and it is likely that magma and mafic crust production is enhanced at segment centers (e.g., Hooft et al., 2000). Surveys on slow-spreading ridges revealed that gravity anomalies tended toward low values at segment centers where the ridge axis was shallow. At the ridge-transform intersections, the seafloor is deep, and gravity anomalies tend to be high. These gravity "bulls eyes" were shown by Tolstoy et al. (1993) to be correlated with a crust that was thick at the segment centers compared to that adjacent to the transforms.

It appears that thin crust exists at the intersections of rifted ridges and transforms, where we expect the lowest mantle temperatures, and a suppressed magma supply (e.g., Cannat, 1996). The discovery of oceanic core complexes, defined here as exposures of gabbro and/or peridotite on the seafloor, provides observational support models for "new" crustal processes at ridges with slow- to ultraslow-spreading rates (Cann et al., 1997) see (Figure 3). It has been recognized that the ophiolite model may not suffice for such locations. Instead, the model must incorporate substantial rifting that dissects the crust, and exposes the lower crust and upper mantle (Figure 3). Thus, magma intrusions are not continuous beneath oceanic core complexes, and gabbros may not form a continuous layer as it does for the ophiolite model (e.g., Canales et al., 2008). During non-magmatic rifting phases, we would argue that the mafic crustal thickness could be zero; that is, the mantle comes to the seafloor. However, depending on the depth of serpentization in the peridotites, with the consequent decrease of velocities, the seismic crust (velocities less than or equal to 7 km/s) may have a non-zero apparent thickness (Figure 3). The discovery of spectacular, serpentine-hosted hydrothermal circulation at



Lithosphere, Oceanic, Figure 3 Cartoon of rift-dominated processes on a slow- or ultraslow-spreading ridges. Substantial normal faulting along a detachment fault exposes the deeper gabbros and peridotites, as volcanic/magmatic processes cannot "keep up" with the extension. Rock units are the same as those in Figure 2. Serpentinization of exposed peridotites will lower the seismic velocity, perhaps to crustal values. Thus, even where there are no crustal rocks, a thin seismic crust may occur.

least one core complex confirms the importance of rifting and serpentization on the slow- and ultraslow-spreading ridges (Kelley et al., 2001).

Summary

The definition of lithosphere depends on the observations one makes, which in turn depend on the thermomechanical properties on which those observations depend. However, the resulting characteristics are consistent. The basic features of the oceanic lithosphere include an upper mantle component, and it thickens with age. That thickening depends critically on the loss of heat into the ocean, and observations require that cooling in young lithosphere is accommodated by hydrothermal circulation as, well as thermal conduction. Cooling is restricted because of the addition of heat at depths of about 95 km, and that forms the limit for thickening beyond about 80 million years. For ridges spreading at intermediate to fast rates, models for the crustal component of the lithosphere have converged on the Penrose, or ophiolite, model, and this crust is most notable for its striking uniformity. This implies a uniformity of magmatic, hydrothermal, and tectonic processes that act to form that crust. However, recent work on slow and ultraslow ridges shows a great deal more complexity in crustal structure and the processes that form it. It is clear we do not yet understand how models must be changed to accommodate these magma-depleted processes.

Definition

Lithosphere. The outermost shell of the Earth that is sufficiently strong to support long-term geologic loads and transmit stress. These properties are attributed to low temperature and possibly composition.

Asthenosphere. The mobile layer underlying the lithosphere where heat transfer is dominated by convection. Its properties are attributed to high temperature and trace quantities of water.

Plate tectonics. Lateral motion of large intact pieces of lithosphere (plates) carrying both continents and oceans. Mountain building, volcanoes, and earthquakes are the consequences of the relative motion of plates at their convergent, divergent, and transform boundaries.

Boundary-layer cooling. Conductive cooling of an initially hot semi-infinite medium, applied to the vertical cooling of aging oceanic lithosphere created at a seafloor spreading center.

Plate cooling. The description of the cooling of an initially hot layer of uniform thickness having a lower boundary maintained at a uniform temperature.

Rayleigh number. A dimensionless number reflecting the ratio of the forces driving and resisting convection.

Nusselt number. A dimensionless number reflecting the vigor of convection, equal to the ratio of the total heat transport relative to the transport that would take place by conduction alone across the same temperature differential.

Introduction

The thermal structure of the oceanic lithosphere is of profound importance. One of the dominant mechanisms of heat loss from the Earth is the creation at seafloor spreading centers and subsequent cooling of oceanic lithosphere. Ocean lithosphere constitutes roughly 60% of the Earth's surface, and the total heat flow through its surface comprises more than 80% of the global mantle heat flow (i.e., excluding the contribution from radiogenic heat production in continental crust; Jaupart et al., 2007). The thermal structure of the lithosphere plays key roles in constraining the rigidity and ultimate strength (seismic rupture potential) of the outermost layer of the Earth, and influencing many geodynamic processes including the Earth's most fundamental and defining one, plate tectonics. Driving forces for the motion of tectonic plates, and numerous consequent geological processes, are derived from the integrity and density of the oceanic lithosphere as controlled to a large degree by its thermal structure. And the volume of ocean basins, and hence the continental freeboard relative to sea level, are influenced directly by the thermal structure of oceanic lithosphere.

"Lithosphere" has multiple meanings. It was first defined as the outer layer of the Earth, including the crust and upper mantle, having sufficient strength to support loads such as those imposed by mountains, volcanoes, and major river deltas (Barrell, 1914). It was later identified as the high seismic velocity lid that overlies a deeper low-velocity zone in the mantle; its base was inferred to correspond to the closest approach of the geotherm to the mantle melting temperature (Gutenberg, 1959). More recently and most fundamentally, it has become a geodynamic term, which refers to the part of

the mantle that forms relatively rigid plates, and within which heat is transported by conduction. Flexural strength, long-term immobility, seismic properties, and possibly composition are properties that are used to define the lithosphere and its thickness, and all are tied to temperature. Beneath the lithosphere is the relatively mobile asthenosphere, where heat transport is dominated by vigorous (high Rayleigh number, high Nusselt number) convection of near-solidus mantle. The oceanic lithosphere forms a thermomechanical upper boundary layer to a "conveyor-belt" convection system, in which the Earth's interior heat is liberated through the seafloor as the layer moves laterally away from the locus of formation at a seafloor spreading center, and is absorbed by the cooled layer when it sinks back into the asthenosphere at a subduction zone. Convection in the asthenosphere is to a large extent decoupled from the lithosphere. It is characterized by Rayleigh and Nusselt numbers of the order of 10^7 and 200, respectively, and is driven both by cooling at the top by heat lost through the lithosphere, and by heating from the bottom and internally by deep and distributed sources derived from secular cooling and radiogenic heat production.

Oceanic lithosphere includes a 7-km-thick basaltic oceanic crust, produced by partial melting of the upper mantle at a seafloor spreading center, and underlying upper mantle that has been cooled by an amount that gives the material its short- and long-term mechanical and elastic properties that contrast with the underlying mobile asthenosphere. Contrasting composition, a consequence of the refractory process of producing the oceanic crust, may also play a part in defining the properties of the oceanic lithosphere. These various aspects are summarized in Figure 1. Previous reviews can be found in Davis (1989) and Jaupart and Mareschal (2007).

Key observations

Because the creation and cooling of ocean lithosphere is a transient process, observations used to constrain its thermal structure are most commonly placed in the context of lithospheric age, and considered in the context of a model for transient cooling. Various observations are discussed in this section, and theoretical models are discussed in the next.

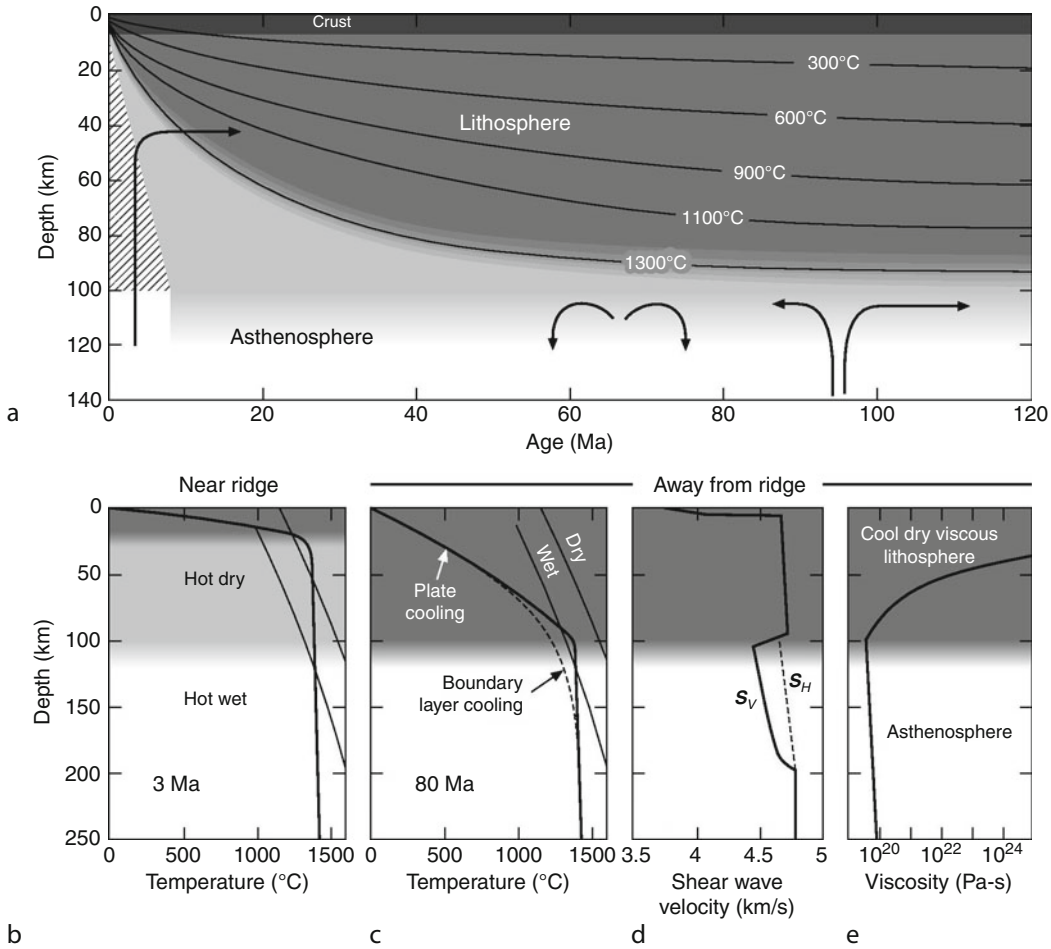
Heat flux

Heat flux through the seafloor provides the most direct constraint on the thermal structure of the underlying lithosphere, although observational uncertainties are often large (Figure 2a). Detailed studies of the thermal regime just below the seafloor commonly reveal a hydrologic regime that in young areas is dominated by high Rayleigh- and Nusselt-number pore-water convection (see discussions in Harris and Chapman, 2004, and *Heat Flow, Seafloor: Methods and Observations* entry, this volume), with high permeabilities in the uppermost few hundred meters of young igneous crust resulting from the volcanic and tectonic processes involved in crustal creation. Hydrothermal alteration of the crust slowly reduces the permeability, but the effects of convective heat transport are observed to persist for tens of millions of years (Von Herzen, 2004). Heat passing advectively through the seafloor is virtually impossible to assess quantitatively, and often goes unrecognized. Hence, wholesale compilations of seafloor heat flux observations are strongly biased, particularly in young, sparsely sedimented areas where igneous crustal outcrops, serving as permeable ventilation points, are frequent. Where thick and extensively continuous accumulations of low-permeability sediment are present, advective ventilation ceases, and the heat flux becomes fully conductive and thus measurable. If circulation within the igneous crust persists, however, heat-flux variations can still be present, and large numbers of measurements must be made over a large area to obtain a meaningful average of the conductive seafloor heat flux at any given age.

To avoid the biasing effects of advective heat loss, two approaches have been used. Values from older data sets have been selected to be far from areas of basement outcrop (relying on statistics for a reliable mean to emerge; e.g., Sclater et al., 1976). Newer surveys have been carried out with large numbers of observation points positioned carefully in context of local and regional sediment/igneous hydrologic structure to rule out effects of ventilation and properly account for the effects of sub-sedimentary fluid flow that produces scatter (e.g., Lister et al., 1990; Davis et al., 1999; Fisher et al., 2003). From such studies, a reliable relationship between lithospheric heat flux and age has emerged, with heat flux decreasing proportionately with $\text{age}^{-1/2}$ out to an age of roughly 100 Ma (Figure 2b), and becoming fairly constant at greater ages at roughly 48 mW m^{-2}.

Seafloor depth

The most reliably measured consequence of lithospheric cooling is seafloor subsidence (Figure 3a). Regardless of the potentially unquantifiable means by which heat passes through the seafloor, the depth-integrated heat loss and accompanying thermal contraction are reflected by seafloor subsidence, and hence bathymetry provides a valuable constraint for understanding lithospheric thermal structure. As in the case of seafloor heat flux, seafloor depths must be considered with some care, with attention given to several potential perturbations. These include checks on isostatic compensation, sediment loading, crustal thickness variations, and sub-lithospheric density anomalies. Early data compilations were made with only modest regard to these factors (e.g., Parsons and Sclater, 1977; Davis and Lister, 1974); later studies, such as those of Schroeder (1984), Johnson and Carlson (1992), Marty and Cazenave (1989), Hillier and Watts (2005), and Crosby et al. (2006), have put more effort into "filtering" data to define depth/age transects that are relatively free of the effects of known or suspected major mantle

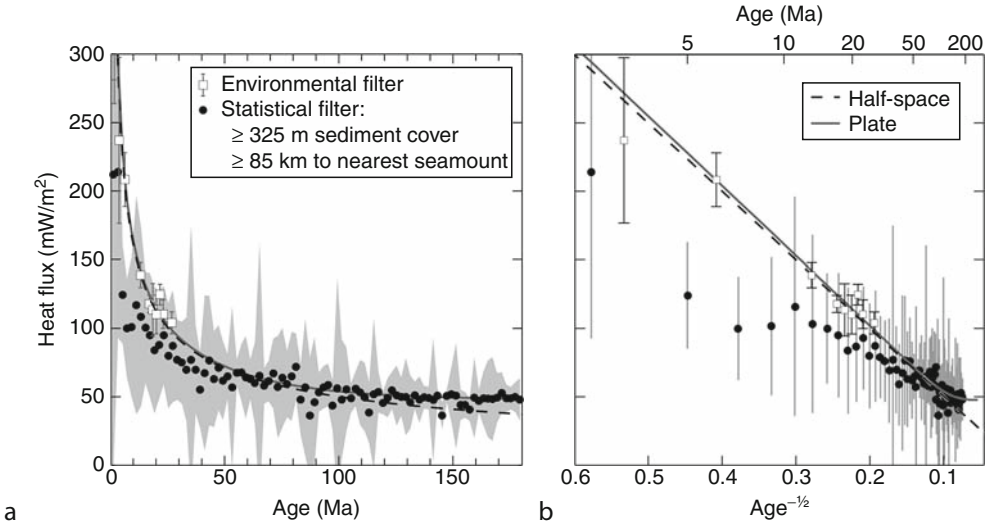


Lithosphere, Oceanic: Thermal Structure, Figure 1 Schematic illustration of the creation and subsequent thermal evolution of oceanic lithosphere (**a**). Dominant control of the mechanical properties of the lithosphere may be thermal (medium gray) or compositional (light gray). Arrows show three modes of convection in the asthenosphere, including upwelling beneath the ridge axis, small-scale convection driven by cooling and associated instability below the base of the lithosphere, and plumes driven by deep-seated heating. In the near-ridge environment, the geotherm (solid line in **b**) intersects a hydrous solidus at a depth of about 100 km; extraction of the partial melt from the rising asthenosphere (hachured zone in (**a**)) produces a basaltic crust about 7 km thick (dark gray), and leaves behind a dried, refractory, and probably stronger residue. Continued conductive cooling at great age (boundary-layer cooling geotherm in (**c**)) may be limited to the compositionally established lithosphere or arrested by regulated convection in the asthenosphere (as shown by the plate cooling geotherm). Properties such as shear-wave seismic velocity (**d**) and effective viscosity (**e**) are controlled by a combination of temperature and water content.

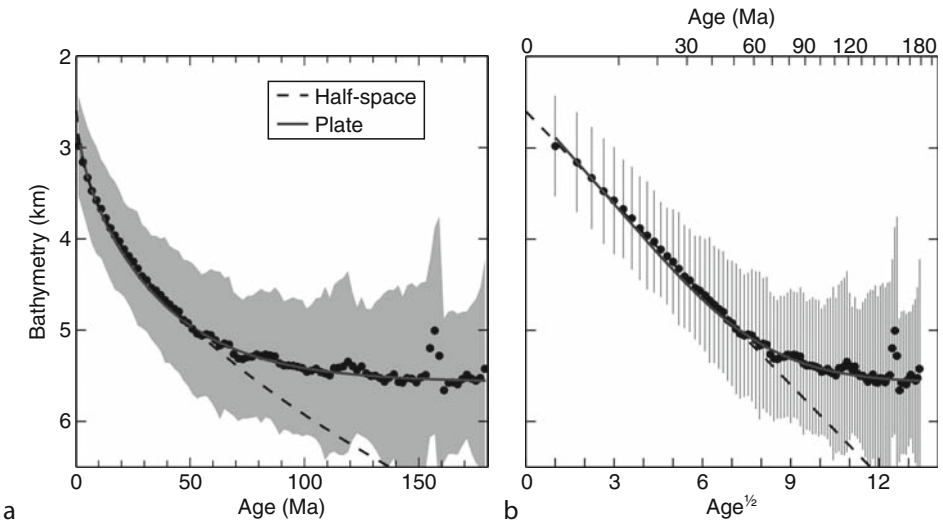
convective upwellings and downwellings, crustal thickness anomalies, and thick sediment accumulations. Despite the various potential sources of "noise" (which, as in the case of heat flux data, add bias, in this case typically causing observed depths to be anomalously shallow), all compilations have shown a similar result, with seafloor depths increasing proportionately with age$^{1/2}$ until 70–80 Ma (Figure 3b). Depths at greater ages fall off of this trend and generally stabilize at about 5.6 km. Some systematic behavior has been gleaned from the compilations, most notably that the rates of subsidence vary both locally and regionally, and that the rate of subsidence is related to the depth of the local ridge axis (Davis and Lister, 1974; Marty and Cazenave, 1989; Hillier and Watts, 2005; Crosby et al., 2006). This is believed to reflect variations in the temperature of the asthenosphere supplying material at spreading centers (Klein and Langmuir, 1987).

Other constraints

Additional constraints on lithospheric thermal structure are provided by observations of shear-wave velocity, flexural rigidity, gravity, and geoid. Gravity data provide little information about the very long wavelength signature of lithospheric cooling except to confirm that the topography is isostatic, but at the shorter wavelengths of abyssal hills, seamounts, and swells, gravity is sensitive to the vertical mass distribution. Hence, it can be used to discriminate



Lithosphere, Oceanic: Thermal Structure, Figure 2 Oceanic heat flux. Data are plotted versus lithospheric age in (**a**) and versus $(\text{age})^{-1/2}$ in (**b**). Because raw heat-flux data in young, sparsely sedimented areas is systematically biased by hydrothermal circulation, the data in these plots have been filtered to exclude sites where sediment thickness is less than 325 m and which are within 85 km of a known seamount. Data are drawn from all oceans. Solid dots show median heat flux for 2 My age bins; gray shading is ± 1 standard deviation for the measurements in a bin. Open symbols represent high-quality data sets drawn from experiments where the environment of the heat flux sites is known from seismic imaging of the sea floor and other geophysical observations. The dashed and solid lines represent heat flux for half-space and plate cooling models, respectively.



Lithosphere, Oceanic: Thermal Structure, Figure 3 Oceanic bathymetry. Data are plotted versus lithospheric age in (**a**) and versus $(\text{age})^{1/2}$ in (**b**). Bathymetry plotted is the position of the top of the igneous crust, 1-D isostatically adjusted for the effect of local sediment loading. Solid dots are median values for 2 My bins of sea floor age; gray shading is ± 1 standard deviation for the measurements in a bin. Dashed and solid lines represent bathymetry for half-space and plate cooling models, respectively.

whether topography is supported or unsupported by lithospheric strength and to constrain the depth of compensation of isostatic topography (e.g., Watts, 2007; Crosby and McKenzie, 2009). The geoid is sensitive to long-wavelength density structure, and provides a useful constraint on the thermally influenced density of oceanic lithosphere. A linear relationship between geoid and age is seen over young seafloor, with a proportionality ranging between 0.1 and 0.14 m Myr^{-1}, whereas the response is flat at ages greater than 80 Ma (e.g., Haxby and Turcotte, 1978; Sandwell and Schubert, 1980; De Laughter et al., 1999).

Laboratory observations and field calibrations show that shear-wave velocity in mantle rocks is a strong function of temperature, with values decreasing rapidly (up to 0.1% K^{-1}) with approach to the melting temperature (Gibb and Cooper, 1998; Priestley and McKenzie, 2006). Hence, shear-wave velocities determined from dispersive surface waves provide a valuable constraint on temperature at depth. Observations show a clear age-dependent structure. A low-velocity zone (Figure 1d), present everywhere in the oceans and centered at roughly 150 km, thickens and rises to the surface at mid-ocean ridges, and extends beneath a high velocity lid (the "seismic lithosphere") that thickens with age out to roughly 70 Ma (Ritzwoller et al., 2004). In addition to temperature, the presence of partial melt and water may be important factors controlling this structure.

Flexural rigidity (usually expressed as effective elastic thickness) and ultimate strength are also strongly controlled by temperature. The first of these related properties is reflected by the long-term load-bearing capacity, and is determined using the wavelength of flexure and the relationship between gravity and topography in the vicinity of seamounts, trenches, fracture zones, and other crustal or tectonic loads. As in the case of the thickness of the high shear-wave-velocity lid, a clear age dependence has been revealed that shows that the effective elastic thickness is limited by temperature. The scatter in thicknesses and inferred maximum temperatures is large, with values falling between 200°C and 600°C. This reflects in part the dependence of this property on the duration of loading.

A limiting constraint on ultimate strength is provided by the occurrence of earthquakes, and when placed in a context of age, a relationship is also seen. The maximum depth of hypocenters increases with increasing age, and the limiting temperatures for seismogenic failure falls at roughly 600°C (McKenzie et al., 2005). Again, the rate of loading that leads to seismogenic failure is an important factor (in addition to temperature) controlling this property.

Ways of understanding lithospheric thermal structure

Boundary-layer cooling

The simplest physical description of the thermal structure of oceanic lithosphere is provided by boundary-layer cooling theory (Parker and Oldenberg, 1973; Davis and Lister, 1974). Except very near the ridge axis, cooling is vertical and the equivalent to cooling of an initially uniform-temperature half space. The lithosphere is defined simply as cooled asthenosphere with the boundary defined by an isotherm that deepens with age and thus distance from the ridge. Heat flux through the seafloor, Q, decreases with age, t, as $Q = \lambda\, T_a\, (\pi\, \kappa\, t)^{-1/2}$, and seafloor depth, h, increases as $h = 2\, \alpha_{eff} T_a\, (\kappa\, t/\pi)\, t^{1/2}$, where T_a = the initial temperature of the asthenospheric material from which the lithospheric forms (relative to seawater at $T \approx 0$°C), κ = thermal diffusivity, $\alpha_{eff} = \alpha\ \rho_0/(\rho_a - \rho_w)$ is the effective volumetric thermal expansivity adjusted for seawater loading, and ρ_a and ρ_w are the densities of the asthenosphere and seawater, respectively. The thermal properties are known to be sensitive to temperature (e.g., Hofmeister, 1999); this must be considered when estimating temperatures at depth (e.g., McKenzie et al., 2005), but it does not change the simple predicted dependence of subsidence and heat flux on age (Davis and Lister, 1974; Lister, 1977). The simplest application of boundary-layer cooling theory produces a heat flux singularity at the ridge axis; this is dealt with by applying a heat-balance boundary condition at the ridge axis. Two important predictions of the theory are that the heat flux, integrated from $t = 0$ to $t = a$ is 2 $Q(a)$, and that the heat flux is related to seafloor depth as $Q = (\rho\ c_P/\alpha_{eff})\ \mathrm{d}h/\mathrm{d}t$, where c_P is the specific heat at constant pressure and α_{eff} is appropriate for 0.7 of T_a (Lister, 1977). Wherever cooling follows boundary-layer behavior, this relationship can be used to obtain a robust estimate of the heat loss from the oceanic lithosphere without a need for relying on sparse, scattered, and potentially biased seafloor heat-flux data.

When plotted as functions of $t^{-1/2}$ and $t^{1/2}$ as they are in Figures 2b and 3b, and considered in light of the heat-flux/subsidence relationship given above, the heat-flux and depth observations clearly demonstrate the efficacy of boundary-layer cooling theory for characterizing lithosphere younger than 70–80 Ma. The same is true for the geoid, which is predicted by boundary-layer cooling theory to decline at a rate of 0.16 m Myr^{-1} (Haxby and Turcotte, 1978). The cessation of simple subsidence and flattening of the geoid beyond 70–80 Ma and the relatively constant heat flux beyond an age of roughly 100 Ma, require something more than the heat supplied via transient cooling, however.

Plate cooling models

That ocean depths at great ages are relatively uniform and consistently shallower than those predicted by boundary-layer cooling provided the fundamental rationale for plate cooling models, which describe the lithosphere as a layer of constant thickness having a fixed lower boundary temperature. This description (McKenzie, 1967) was initially used out of mathematical convenience. There was little physical justification for the lithosphere to have an intrinsic thickness, or for constant heat flux to be supplied by asthenospheric convection beneath old lithosphere, until physical arguments were made for the latter by Parsons and McKenzie (1978) by way of an age-dependent onset of convection in the growing thermal boundary layer below the cooled, mechanically immobile lithosphere. Physical modeling of convection using material having a strongly temperature-dependent viscosity has shown how this phenomenon can serve to stop and possibly even reverse subsidence, and later stop the decline in heat flux with age (Davaille and Jaupart, 1994; Crosby et al., 2006). The key factor in this model is the growth of the

thermal boundary layer beneath the conductively cooled plate. Once this layer reaches a sufficient thickness to become convectively unstable, convection begins to bring heat from the large reservoir of the asthenosphere beneath. A balance is ultimately reached between the heat conducted through the lithosphere and that carried by convection in the asthenosphere.

Alternate means suggested for maintaining an effectively steady-state lithosphere at great age include convection driven from below (plumes, distributed radiogenic heat, and secular cooling), and creation of a compositionally distinct lithosphere at the ridge axis. The first by itself is precluded as a general case by both topographic and heat-flux observations, which show no statistically significant influence of augmented heat flux at intermediate ages. The second may provide a viable alternative to age-initiated top-down convection. The means for creating a compositional constraint on lithospheric thickness can be understood by considering Figure 1a and b. Asthenosphere rising beneath a ridge axis to balance the mass lost to lateral plate motion will begin to melt when it reaches a depth where the adiabat meets the local solidus. The depth at which this occurs depends on the water content of the asthenosphere. Estimates for water content range from 50 to 150 ppm by weight, and the depth at which melting begins is estimated at roughly 115 km, twice the depth for dry conditions (Hirth and Kohlstedt, 1996; Azimow and Langmuir, 2003). The partial melt fraction segregates and rises to produce the oceanic crust, leaving a residue that may differ in composition, and hence in mechanical properties, from normal asthenosphere (Oxburgh and Parmentier, 1977; Morgan, 1997). More importantly, water, being much more soluble in the melt than in the solid fraction, is very efficiently removed from the residue, and this drying will have a strong influence on the viscosity of the residual asthenosphere. Hirth and Kohlstedt (1996) estimate an increase in viscosity by a factor of 500 may result from complete drying. Hence, the mechanical property of the lithosphere that controls convection may indeed be established very near the ridge axis. Lithospheric cooling will initially follow conductive boundary-layer behavior, and temperature-sensitive properties such as shear-wave velocity, flexural strength, and seismic rupture potential, will follow isotherms. Once the depth of the compositional change established near the ridge is reached by cooling, the effects of convection in the normal, relatively wet, and hence invicid asthenosphere away from the ridge axis will be manifest in arrested subsidence, then uniform heat flux. If this is the case, then the thermal state of old lithosphere will simply reflect the combination of its intrinsic thickness and the relatively uniform temperature of the vigorously convecting asthenosphere beneath.

Influence of plumes

Convective plumes in the asthenosphere have been argued to thin, or "reset" the thermal age of oceanic lithosphere (see review in Detrick et al., 1989), with the eventual collective contribution from plumes resulting in the departure from boundary-layer cooling behavior (Heestand and Crough, 1981) and possibly in the supply of much of the heat flux to the base of plates (Malamud and Turcotte, 1999), although these possibilities remain controversial. The influence of plumes can certainly be large; while surface volcanism from plumes is typically highly focused, the associated topographic swells are large and extensive, often exceeding 1 km in amplitude and having a wavelength approaching 1,000 km. A similarly broad thermal anomaly is implied as a source for swells. Given the large thermal time constant of the lithosphere, seafloor heat flux provides an inherently poor constraint on the depth of the thermal source; attempts have been made to detect anomalies with understandably mixed results (e.g., Von Herzen et al., 1989). A study of the geoid signature over the Hawaiian Swell by Moore and Schubert (1997) suggests that the lower part of the lithosphere is involved, but a study of the topography and gravity over swells by Crosby and McKenzie (2009) reveals an admittance (30 mGal km^{-1}) that is consistent with the thermal density anomaly being below the base of the plate. This study also shows no evidence for age dependence of the admittance, which suggests that the conductive lithosphere is established at a very young age. If true, this would support the hypothesis that oceanic lithosphere acquires one of its key properties by virtue of its composition established at the ridge axis.

Summary

A broad suite of observations gathered in context of powerful physical models have brought plate tectonics from a largely geometrical description of the history of the surface of the Earth to a robust theory. Among other things, this theory addresses the mechanisms by which plates form and are driven, the thermal structure of oceanic lithosphere that influences its mechanical and geodynamic behavior, and the dominant modes of heat loss from the Earth. Uncertainties remain, however, and further work is required to resolve several lingering questions about lithospheric creation, cooling, and eventual stabilization. Among these are (1) to what degree is the mechanical behavior of oceanic lithosphere (particularly its resistance to thinning by convection of any form in the asthenosphere) established compositionally by partial-melt extraction at ridge axes, (2) to what degree does asthenospheric convection stimulated by top-down cooling regulate heat loss through and limit the growth of the lithosphere at great age, and (3) to what degree do plumes, the consequence of convective instabilities generated deep in the asthenosphere, contribute to heat flux at the base of plates, and do they convectively thin or merely conductively warm the plates beneath which they ascend? Addressing the first will improve constraints on plate drive generated by gravitational sliding forces, which are maximum for the case of a mechanical lithosphere being

defined purely as a cooling boundary layer. Addressing the second and third will help resolve just what the primary regulating factor is that constrains the rate of heat loss from the Earth, such as the vigor of asthenospheric convection, the quotient of asthenospheric temperature and lithospheric thickness, or the rate of production and destruction of lithosphere at ridges and subduction zones.

MAGNETIC ANISOTROPY

Leonardo Sagnotti
Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy

Definition

The magnetic properties of rocks and minerals are generally anisotropic, that is, they are directionally dependent. Magnetic anisotropy of minerals arises from either fundamental anisotropy in the crystal structure or from the shape of nonspherical ferromagnetic grains. The most common cause of magnetic anisotropy in rocks is the preferential distribution-orientation of the constituting minerals, in other words the rock fabric.

Introduction

Pioneering works on the magnetic anisotropy of rocks were carried out during the 1940s and 1950s (Ising, 1942; Graham, 1954). These authors first realized that magnetic methods may be used to characterize the preferred orientation of minerals within the rock samples. Ising studied varved clays in Sweden and noticed that the magnetic susceptibility was higher on the bedding plane than orthogonally to it. Graham recognized that the anisotropy of magnetic susceptibility (AMS) may be regarded as a petrofabric element; he later extended the analysis to various sedimentary rocks of the Appalachian Mountains and pointed out the existence of distinct and systematic relationships of the magnetic properties with structural setting (Graham, 1966). The studies progressively developed in the following decades and a first comprehensive review on magnetic anisotropy and its application in geology and geophysics was published by Hrouda (1982). Over the past 20–30 years, researches on magnetic anisotropy gained widespread use and were extended to examine the fabric in a variety of sedimentary, igneous, and metamorphic rocks (e.g., see reviews by Jackson, 1991; Jackson and Tauxe, 1991; Rochette et al., 1992; Tarling and Hrouda, 1993; Borradaile and Henry, 1997; Borradaile, 2001; Borradaile and Jackson, 2004; Tauxe, 2005; Lanza and Meloni, 2006; Hrouda, 2007). Presently, the study of the magnetic anisotropy of rocks is still one of the most promising research issues in the field of rock magnetism.

Theoretical principles

Two principal mechanisms control the magnetic anisotropy of rocks: (1) lattice alignment of crystals with magnetocrystalline anisotropy, (2) shape alignment of ferromagnetic grains.

Magnetocrystalline anisotropy

This is an intrinsic property of all minerals since it arises from the ordered structure of elementary particles in the crystal lattice; it is defined as the energy per atom needed to move the crystal magnetization from one crystallographic direction to another. Magnetocrystalline anisotropy thus reflects the dependence of the free energy of a magnetic system on the direction of magnetization. In the atomic structure of a crystal, the spin–orbit coupling between the magnetic spins and the lattice establish "easy" and "hard" directions of magnetization and determine the orientation of the spin moments with respect to the crystal structure. Within ferromagnetic crystals (the term ferromagnetic will be used in the following in its broader sense, that is to indicate all minerals with ordered magnetic spin structures, including ferrimagnetic and antiferromagnetic ordering), the exchange energy in the 3d electronic orbitals of transition elements (e.g., Fe, Co, Ni) is, unlike the *s* orbitals, anisotropic. Hence, within these crystals

Harsh K. Gupta (ed.), *Encyclopedia of Solid Earth Geophysics*, DOI 10.1007/978-90-481-8702-7,

electron spins will be easier to coordinate in some directions than in others. Along these directions, the elemental electron spins align more readily and the magnetization acquired in an applied field is greatest. In magnetite the direction of the lowest magnetocrystalline anisotropy energy (i.e., the easy axis of magnetization) is along the body diagonal, that is the [111] crystallographic direction. In hematite, magnetocrystalline anisotropy is very weak in the basal plane, but it is very high along the crystallographic *c*-axis, perpendicular to this plane. As a consequence, hematite crystals may be easily magnetized by magnetic fields applied along the basal plane and are almost unaffected by fields applied perpendicular to it.

Shape anisotropy

Shape anisotropy mostly occurs in ferromagnetic minerals with high intrinsic susceptibility and low degree of magnetocrystalline anisotropy (e.g., magnetite, maghemite), where just a slight deviation from the isometric shape produces notable magnetic anisotropies, in order to minimize the magnetostatic energy due to the formation of surface magnetic poles at the extremities of the mineral grains. In ferromagnetic minerals, the alignment of electron spins produced by exchange energy or by the application of an external magnetic field generates an external magnetic field that is proportional to the spontaneous or induced magnetic moment and may be represented as a field produced by an apparent distribution of north and south magnetic poles on the surface of the crystal. In turn, the surface magnetic poles generate an internal field whose field lines start on the north magnetic poles on the surface and end on the south poles (Figure 1). This internal field is, therefore, antiparallel to the alignment of the magnetic moments within the crystal and it is known as the demagnetizing field $\mathbf{H}_d$. Such a demagnetizing field is proportional to the magnetization $\mathbf{M}$ of the crystal and is sensitive to its shape:

$$\mathbf{H}_d = -N\mathbf{M}$$

where N is a demagnetizing factor which is determined by the shape of each crystal.

Shape anisotropy arises from the dependence of the demagnetization factor N on the direction of magnetization with respect to the particle shape; different directions resulting in different arrays of surface poles. By analogy with electrostatics, magnetostatic forces decrease with distance and the internal demagnetizing field is reduced when the surface poles are furthest apart. For a spherical grain $N = 1/3$. In an ellipsoid grain with principal axes $a \geq b \geq c$, $N_a + N_b + N_c = 1$. In the case of an ellipsoid magnetized parallel to the elongation axis a the demagnetizing field, which depends on $1/r^2$, is weaker than in the case of a sphere (i.e., $N_a < 1/3$). Similarly, if the ellipsoid is magnetized along the shortest axis c, the demagnetizing field is stronger (i.e., $N_c > 1/3$). In general, the demagnetizing factor N is minimum for very elongated ("pencil-shaped") grains and maximum for platy grains ("disk-shaped"). In an ellipsoid of revolution, N_a approaches 0 for an infinite needle ($N_b = N_c = ½$), and N_c approaches 1 for a disk of infinite thinness ($N_a = N_b = 0$).

The demagnetizing factor N determines the intensity of the magnetic field which effectively acts ($\mathbf{H}_{eff}$) within a grain subjected to an external applied field $\mathbf{H}_{ex}$:

$$\mathbf{H}_{eff} = \mathbf{H}_{ex} - N\mathbf{M}$$

The magnetization M_j of a grain along an arbitrary direction j is given by

$$M_j = k_0\mathbf{H}_{ex} = k_i\mathbf{H}_{eff} = k_i\left(\mathbf{H}_{ex} - N_jM_j\right)$$

where k_0 is the observed magnetic susceptibility along the direction j, k_i is the intrinsic magnetic susceptibility of the grain and $\mathbf{H}_{ex}$ is the intensity of the external magnetic field.

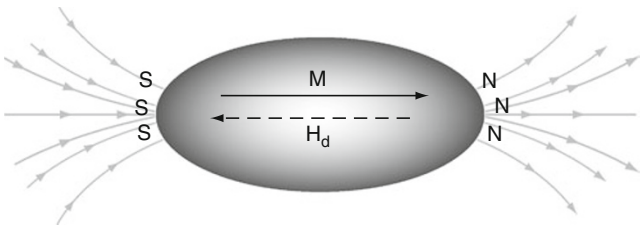
The observed magnetic susceptibility along a given direction of a grain is related to the intrinsic magnetic susceptibility of the mineral by

$$k_0 = k_i/(1 + Nk_i)$$

The degree of magnetic susceptibility shape anisotropy in a grain is defined as

$$P = (1 + k_iN_c)/(1 + k_iN_a);$$

where the intrinsic susceptibility k_i is isotropic and dependent only on the chemical composition of the mineral. Therefore, the net effect of the shape anisotropy is to favor the orientation of the induced magnetization along the long axis of a magnetic grain, where the internal demagnetizing field is minimized.



Magnetic Anisotropy, Figure 1 Surface magnetic poles and internal demagnetizing field H_d (dashed arrow) for an ellipsoidal grain with uniform axial magnetization M.

Magnetostriction – stress anisotropy

The application of an external stress to a rock may cause reversible as well as irreversible changes to its magnetic anisotropy. In fact, straining a ferromagnetic crystal can rotate its spontaneous magnetization away from the easy axis given by magnetocrystalline anisotropy. Also, the application of a magnetic field that rotates the spontaneous magnetization of a ferromagnetic crystal away from its intrinsic preferred direction can strain the lattice and modify the crystal shape, producing changes in its demagnetization factors and shape anisotropy. Both processes are

expression of the phenomenon known as magnetostriction and are due to changes in the exchange energy when modifications in the magnetization or in the crystal shape alter the spin–orbit coupling in neighboring atoms (e.g., O'Reilly, 1984).

Magnetostriction is defined as the spontaneous change in crystal dimensions that accompanies the process of magnetization or as the change in the magnetization of a crystal as the result of the application of stress. The linear saturation magnetostriction constant λ is defined as the fractional change in the length $\Delta L/L$ of a demagnetized ferromagnetic crystal as its magnetization increases from zero to saturation (e.g., Moskowitz, 1993). Magnetostriction is positive when the crystal expands in the direction of magnetization. In magnetite at room temperature, the magnetostriction depends crucially on the direction, being positive for a magnetization along a <111> easy axis but negative for magnetization along a <100> hard axis.

In a cubic crystal, the anisotropy of λ is given by:

$$\lambda = 3/2\lambda_{100}(\alpha_1{}^2\gamma_1{}^2 + \alpha_2{}^2\gamma_2{}^2 + \alpha_3{}^2\gamma_3{}^2 - 2/3) + 3\lambda_{111}(\alpha_1\alpha_2\gamma_1\gamma_2 + \alpha_2\alpha_3\gamma_2\gamma_3 + \alpha_3\alpha_1\gamma_3\gamma_1),$$

where α_i, ($i = 1, 2, 3$) are the direction cosines of saturation magnetization (**Ms**) with respect to the <100>, <010>, and <001> crystallographic axes, respectively, and γ_i are the equivalent direction cosines of the direction along which the magnetostriction is being measured (Dunlop and Özdemir, 1997). λ_{100} and λ_{111} are the crystal's magnetostriction constants along the <100> and <111> crystallographic axes for **M** aligned in the same direction.

In the case of isotropic magnetostriction (i.e., $\lambda_s = \lambda_{100} = \lambda_{111}$), the magnetoelastic energy caused by the application of a stress σ to a magnetic crystal is given by:

$$E = 3/2\lambda_s\sigma\sin^2\theta$$

where θ is the angle between **Ms** and σ.

In this simple case, the energy is minimum when **Ms** is parallel to σ and $\lambda_s\,\sigma > 0$ or when **Ms** is perpendicular to σ and $\lambda_s\,\sigma < 0$. Thus, the application of a uniaxial stress will cause **Ms** to rotate toward the stress axis if $\lambda_s\,\sigma > 0$ (i.e., under the combination of a compression and a negative λ_s or of a tension and positive λ_s).

In the general case, the relationship between the change in the magnetic anisotropy and the increase of strain induced by a stress field is not simple, reflecting the complex behavior due to the superposition of the strain effects upon an already magnetically anisotropic specimen.

Exchange anisotropy

Exchange anisotropy results from superexchange interaction across the interface of two different magnetically ordered phases (Meiklejohn, 1962; Berkowitz and Takano, 1999). In the simplest model, the origin of exchange anisotropy is considered to be the coupling of a ferromagnetic spin system to an antiferromagnetic spin system, separated by a planar interface. To obtain a preferred direction of the coupling it is necessary that Curie temperature T_C of the ferromagnet be greater than the Néel temperature T_N of the antiferromagnet. When a magnetic field is applied at a temperature $T_N < T < T_C$, the spins of the ferromagnet will orient parallel to the applied field. Then, as the material is cooled through T_N, the spins of the antiferromagnetic lattice closest to the ferromagnet will align in the same direction as the ferromagnet and subsequent spin planes in the antiferromagnetic lattice will orient antiparallel to each other. When the antiferromagnet is fully ordered, with high magnetocrystalline anisotropy, it holds the magnetization of the ferromagnetic material in the direction of the applied field, giving rise to a unidirectional magnetic anisotropy.

Exchange anisotropy can be detected from a shifted hysteresis loop when the material is cooled in a magnetic field and from the presence of a $\sin\theta$ term in torque curves measured in high fields due to a rotational hysteresis loss.

Exchange anisotropy in natural minerals has been found in titanomagnetite or in the intergrowth of maghemite with hematite and has been invoked to explain self-reversals in the direction of magnetization of natural rocks (e.g., Nagata and Uyeda, 1959). In the last decades there has been an increase of interest about this magnetic phenomenon because of the importance of its technological applications in spin-valve devices, such as hard-disk read heads, and in magnetic thin layers.

Anisotropy of magnetic susceptibility (AMS)

The magnetic anisotropy of rocks is often determined by means of the analysis of the anisotropy of the magnetic susceptibility (AMS), which is the property that has found the most applications in geophysical studies so far. The AMS of rocks is controlled by preferentially oriented magnetic mineral grains and, therefore, it contains information about both the grain susceptibilities and their orientation-distribution. Knowing the composition of the rock-forming minerals and their magnetic anisotropy characteristics, it is possible to determine the spatial distribution of the grains and infer the geological processes that originated it. A preferential orientation-distribution of mineral grains is in fact typical of almost all rock types and it develops during various geological processes, such as water flow in sediments, magma flow in igneous rocks, ductile deformation in metamorphic rocks, and even incipient strain in the paramagnetic clay matrix of apparently undeformed fine-grained sediments.

The magnetic susceptibility is the capability of a material to be magnetized under the effect of an external magnetic field; all the materials are "susceptible" to become magnetized in the presence of an applied magnetic field, and the magnetic susceptibility describes this transient magnetism within a material sample. If the magnetic field is relatively weak, the magnetization of a rock is a linear function of the intensity of this field. The low-field magnetic susceptibility is defined as the ratio of the induced magnetization (**M**, dipole moment per unit volume or **J**, dipole moment per unit mass) to the applied low-intensity

magnetic field (**H**). Only for isotropic substances the induced magnetization is strictly parallel to the applied field, and the magnetic susceptibility is a scalar. In the general case of anisotropic media, like minerals and rocks, the induced magnetization is not parallel to the applied field, and the magnetization induced along the direction i is related to the magnetic field acting along the direction j by:

$J_i = \chi_{ij} H_j$ (mass specific), where χ is given in SI units of m^3/kg

or

$M_i = k_{ij} H_j$ (volume specific), where k is dimensionless in SI units

On the basis of the magnetic susceptibility all substances may be classified as diamagnetic, paramagnetic, and ferromagnetic.

In diamagnetic minerals the induced magnetization increases linearly with the increasing field, but in the opposite direction; the magnetic susceptibility is therefore negative and typically very low ($k \sim -10^{-5}$ SI). In paramagnetic minerals the magnetization increases linearly with increasing field, along the same direction, and the susceptibility is positive ($k \sim 10^{-4}$ to 10^{-5} SI). In ferromagnetic minerals, the induced magnetization increases nonlinearly with increasing field and the magnetic susceptibility is typically positive and much higher (k ranges from 10^{-3} to 10 SI) than in diamagnetic and paramagnetic minerals.

If the applied field is so low to approximate as linear the magnetic response of the body, the magnetic susceptibility can be represented by a set of coefficients (k_{ij}) that form a second-order symmetric tensor; each coefficient quantifies how much a body can be magnetized along a certain Cartesian direction according to a Cartesian component of the applied field. The relationship between the components of the magnetization M_i (i = 1, 2, 3) and the components of the magnetic field H_j (j = 1, 2, 3) is expressed by the equations

$$M_1 = k_{11}H_1 + k_{12}H_2 + k_{13}H_3$$

$$M_2 = k_{21}H_1 + k_{22}H_2 + k_{23}H_3$$

$$M_3 = k_{31}H_1 + k_{32}H_2 + k_{33}H_3$$

which can be rewritten in subscript notation as:

$$M_i = k_{ij}H_j$$

where the coefficients k_{ij} define a matrix that has six independent elements, since the second-order tensor must be symmetric to guarantee real eigenvalues, and k_{ij} is imposed equal to k_{ji}. Among all possible Cartesian reference systems, there exists one in which the non-diagonal terms of the tensor are zero so that the above equations simplify to:

$$M_1 = k_{11}H_1$$

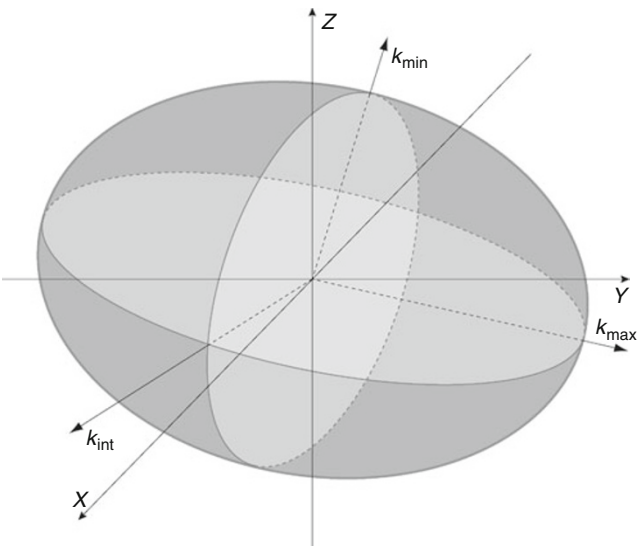
$$M_2 = k_{22}H_2$$

$$M_3 = k_{33}H_3$$

where in this case the three coefficients k_{11}, k_{22}, and k_{33} are the eigenvalues of the magnetic susceptibility tensor: they are called the principal susceptibilities and are generally indicated as $k_{max} \geq k_{int} \geq k_{min}$ (or $k_1 \geq k_2 \geq k_3$), the maximum, intermediate, and minimum susceptibilities

The corresponding eigenvectors are the maximum, intermediate, and minimum principal susceptibility directions that are the directions along which the induced magnetization is strictly parallel to the direction of the applied field. The magnetic susceptibility tensor may be represented geometrically by a triaxial ellipsoid, which is termed the magnitude ellipsoid, whose axes are parallel to the AMS tensor eigenvectors and whose semiaxes lengths are proportional to the AMS tensor eigenvalues (Figure 2). We will refer to this ellipsoid in the following as the AMS ellipsoid. Since for diamagnetic minerals the negative AMS eigenvalues make the magnitude ellipsoid difficult to visualize, the magnetic susceptibility ellipsoid may also be expressed by the representation quadric, in which the length of the radius vector in any direction from the origin is equal to the inverse square root of the susceptibility in that direction. It has however a less direct relationship to the eigenvalues.

In practical measurements, each AMS eigenvector is determined with two uncertainty angles, which define the regions where each principal susceptibility direction lies with a probability of 95% (Figure 3). The definition of a magnetic susceptibility ellipsoid identifies two important elements: a "magnetic foliation" (the plane orthogonal



Magnetic Anisotropy, Figure 2 The magnetic susceptibility ellipsoid. The anisotropy of magnetic susceptibility (AMS) tensor may be geometrically represented by a triaxial ellipsoid, in which the three orthogonal axes correspond to the AMS eigenvectors, k_{max}, k_{int}, and k_{min}, respectively. The orientation of the AMS eigenvectors is then defined in a reference system of Cartesian coordinates (X, Y, and Z).

to the direction of minimum magnetic susceptibility) and a "magnetic lineation" (the direction of maximum magnetic susceptibility).

AMS ellipsoid shapes are classified according to the relationships between the magnetic susceptibility eigenvalues:

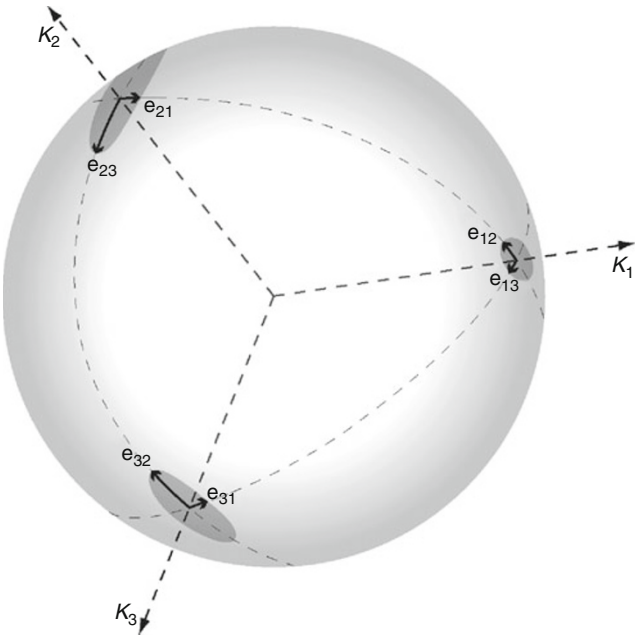
$k_1 \approx k_2 \approx k_3$; isotropic susceptibility, the AMS ellipsoid is a sphere (Figure 4a)

$k_3 \ll k_2 \approx k_1$; the AMS ellipsoid has an oblate shape (i.e., the magnetic fabric is planar, Figure 4b)

$k_3 \gg k_2 \approx k_1$; the AMS ellipsoid has a prolate shape (i.e., the magnetic fabric is linear, Figure 4c)

$k_1 > k_2 > k_3$; the AMS ellipsoid is triaxial (Figure 4d)

The orientations of principal susceptibilities for a set of samples are conventionally visualized in Schmidt equal-area projection, lower hemisphere (Figure 5).



Magnetic Anisotropy, Figure 3 Relationship of the 95% confidence ellipses (e_{12}, e_{23}, e_{13}) to the anisotropy of magnetic susceptibility (AMS) eigenvectors. Around each principal susceptibility axis, the major and minor semiaxes of 95% confidence ellipse lay within the planes defined by the eigenvectors.

The bulk low-field magnetic susceptibility of a rock is a summation of the contribution from all mineral species composing the rock, weighted according to their relative abundance and susceptibilities. Obviously, the contribution of ferromagnetic minerals to the overall magnetic susceptibility of a rock specimen is overwhelming upon those of the paramagnetic and diamagnetic matrix. The contribution of the matrix will be negligible when the percentage of ferromagnetic minerals exceeds 0.1% ($k >$ 3,000–4,000 μSI). Conversely, for rocks in which $k <$ 200–300 μSI, the magnetic susceptibility is almost completely controlled by the contribution of the paramagnetic matrix. For very small or even negative k values (i.e., $k < 50$ μSI), the contribution of the diamagnetic matrix to the bulk susceptibility of a rock specimens is not negligible.

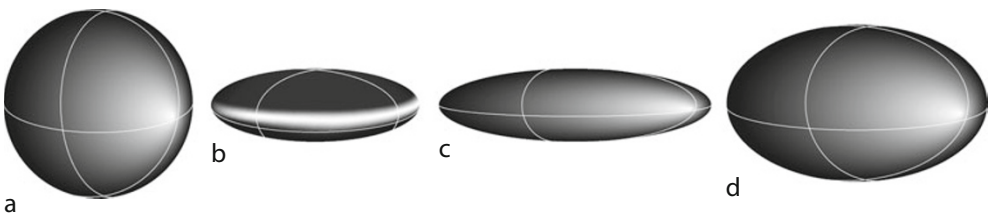
All the rock's constituent mineral fractions contribute to the development of an AMS fabric depending on their intrinsic susceptibility and degree of preferential orientation-distribution.

Among ferromagnetic minerals, hematite and pyrrhotite are the most anisotropic, both with anisotropy degree $P > 100$; whereas for magnetite P shows a typical range of variation between 1.1 for nearly isometric grains and 3 for highly anisometric grains (Table 1). Paramagnetic minerals are characterized by a much smaller AMS degree. In biotite and most phyllosilicates, the k_{max} and k_{min} directions are respectively parallel and orthogonal to the basal plane and their AMS ellipsoid is typically oblate. Finally, the main diamagnetic minerals typically show low magnetic susceptibilities and low anisotropy (Table 1).

In comparison to other methods of petrofabric analysis, the study of AMS has the advantage to be quick, cost-effective, highly sensitive, and above all it can be performed systematically on all rock types. AMS data are usually employed to obtain some information about the geological processes that gave a fabric to a rock unit, both during lithogenesis and during any subsequent deformational event.

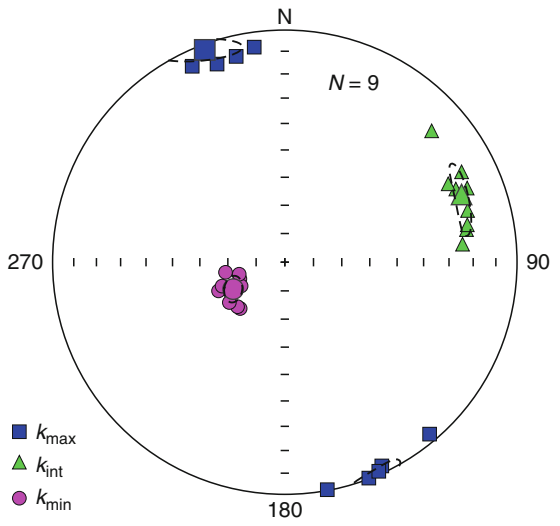
AMS: applications in geology and geophysics

Magnetic anisotropy is an essential petrostructural phenomenon which can be used to study rock fabric, deformation, and various other processes that took place during the geologic history of a rock. The AMS of rocks can be



Magnetic Anisotropy, Figure 4 Shape of anisotropy of magnetic susceptibility (AMS) ellipsoids. (**a**) spherical, (**b**) oblate, (**c**) prolate, (**d**) triaxial.

determined with high accuracy and the method is so sensitive that in rocks with a very weak preferred orientation-distribution of minerals it is the only approach that gives reasonable results. The study of AMS has been therefore used as a tool of structural analysis for almost all rock types and AMS analyses were applied to investigate a wide variety of geological processes capable to produce a preferential orientation-distribution of minerals in rocks. Moreover, AMS studies are an important complement to paleomagnetic researches, as a way to assess the reliability of paleomagnetic data and to determine possible deflections in the natural remanent magnetization components induced by deformation and compaction. For these reasons, the analysis of the AMS has experienced broad use in many branches of the Earth Sciences.



Magnetic Anisotropy, Figure 5 Equal area projection of the principal anisotropy of magnetic susceptibility (AMS) directions and the 95% confidence ellipses for a single sampling site. Squares: k_{max}; triangles: k_{int}; circles: k_{min}. Small symbols indicate individual specimens and large symbols indicate the mean tensor.

A brief overview of the wide spectrum of potential applications of the AMS research is provided below.

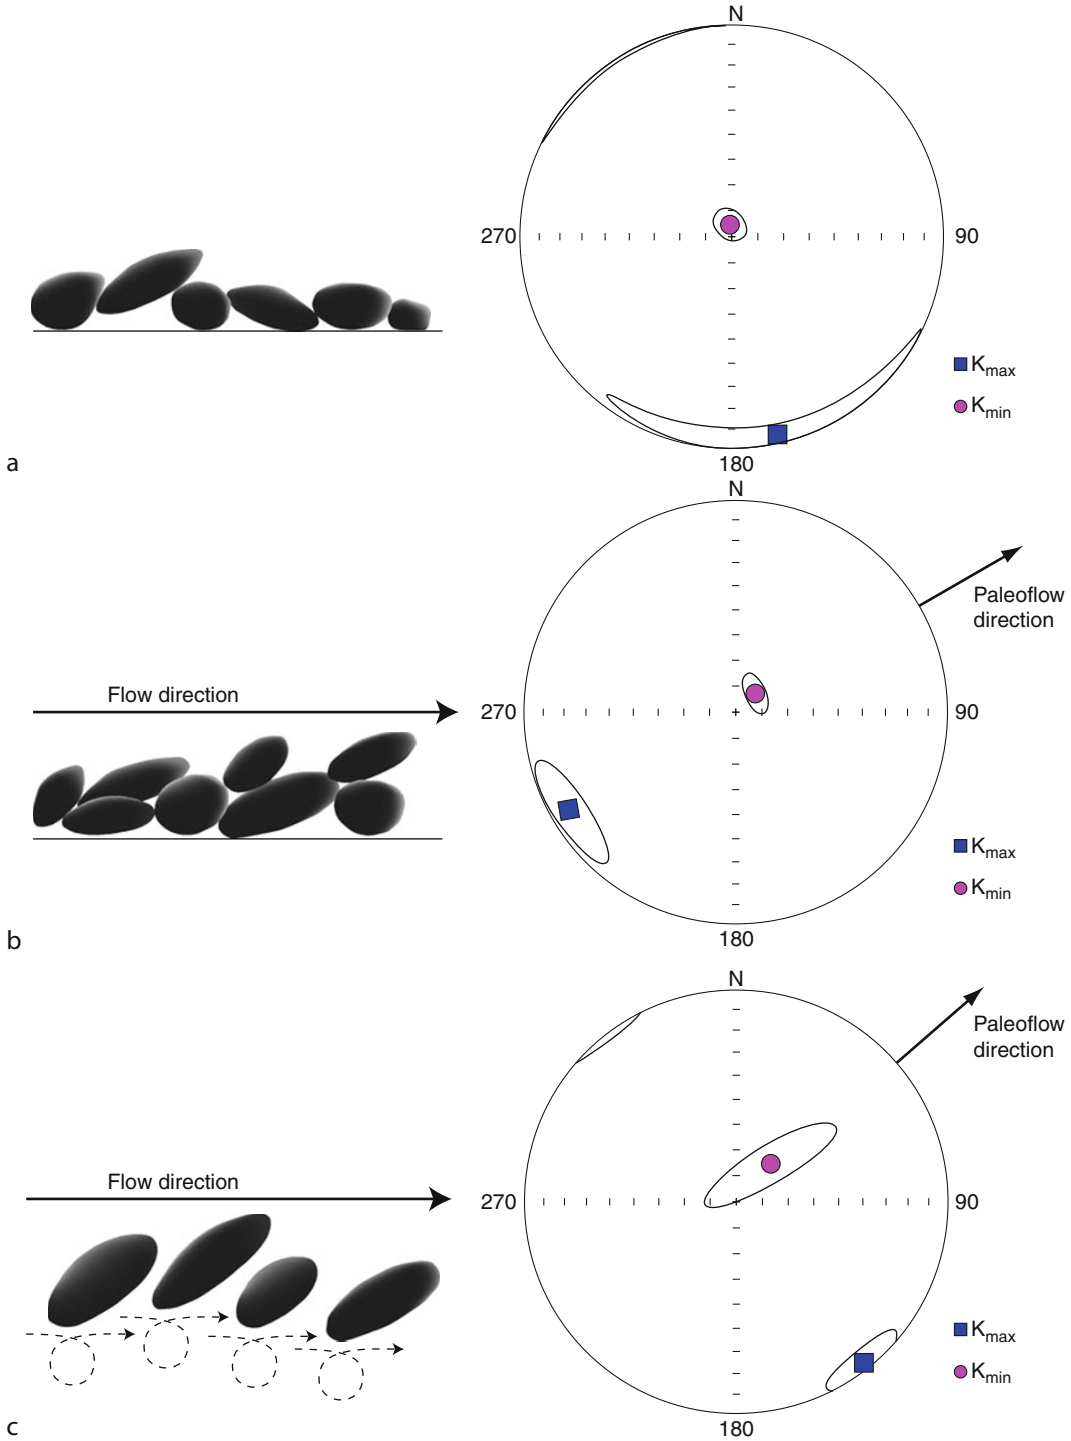
In undeformed *sediments*, the magnetic anisotropy may indicate the orientation of the sedimentation paleo-horizontal and eventual paleo-flow directions. The primary magnetic fabric of sediments is strongly affected by the processes that govern deposition and compaction. In quiet water deposition, such as in a lagoon or lake environment, gravity-driven sedimentation brings platy grains to lay with their longer dimensions statistically parallel to the bedding-compaction plane. Then, with further sediment burial, the effect of diagenetic compaction on platy minerals by pressure and water expulsion reinforces the parallelism between the magnetic foliation and the bedding plane.

Thus, if the magnetic fabric is purely depositional, or related only to compaction loading, the AMS ellipsoid shows an oblate shape, with the k_{min} axis perpendicular to the bedding plane (which can be determined through AMS analyses with high accuracy) and the k_{int} and k_{max} axes scattered in the bedding plane itself (Figure 6a). The action of flow currents may cause the maximum susceptibility axis to be aligned either parallel or perpendicular

Magnetic Anisotropy, Table 1 Grain anisotropy of magnetic susceptibility (AMS) determinations reported for various common minerals (Adapted from Hrouda, 1993, 2007; Tarling and Hrouda, 1993; Borradaile and Jackson, 2004)

Mineral	k (SI)	P	T	AMS type
Ferromagnetic (s.l.)				
Magnetite	2.0–5.7	1.1 – 3.0	Variable	Shape
Hematite	$1 \times 10^{-3} \div 5 \times 10^{-2}$	>100	~1	Magnetocrystalline
Pyrrhotite	$5 \times 10^{-2} \div 3 \times 10^{-1}$	100 – 10,000	~1	Magnetocrystalline
Paramagnetic				
Biotite	$1.0 \div 2.8 (\times 10^{-3})$	1.2 ÷ 1.6	0.9 ÷ 1	Magnetocrystalline
Muscovite	$0.12 \div 0.17 (\times 10^{-3})$	1.3 ÷ 1.4	0.4 ÷ 0.7	Magnetocrystalline
Phlogopite	$0.3 \div 1.2 (\times 10^{-3})$	1.3 ÷ 1.5	0.78 ÷ 0.95	Magnetocrystalline
Chlorite	$0.07 \div 1.55 (\times 10^{-3})$	1.2 ÷ 1.7	0.3 ÷ 0.7	Magnetocrystalline
Hornblende	$8.92 (\times 10^{-3})$	1.67	−0.51	Magnetocrystalline
Tourmaline	$1.69 (\times 10^{-3})$	1.005	~1	Magnetocrystalline
Siderite	$3.98 (\times 10^{-3})$	1.56	−0.9	Magnetocrystalline
Diamagnetic				
Quartz	$-13.4 \div -15.4 (\times 10^{-6})$	1.01	–	Magnetocrystalline
Calcite	$-13.8 (\times 10^{-6})$	1.11	1	Magnetocrystalline
Aragonite	$-19 (\times 10^{-6})$	1.15	0.8	Magnetocrystalline

k = mean magnetic susceptibility
$P = k_1/k_3$ – degree of anisotropy
$T = (2\eta_2 - \eta_1 - \eta_3)/(\eta_1 - \eta_3)$ – shape parameter for the AMS ellipsoid (Jelínek, 1981) where $\eta_1 = \ln k_1$, $\eta_2 = \ln k_2$, $\eta_3 = \ln k_3$, $\eta = (\eta_1 + \eta_2 + \eta_3)/3$



Magnetic Anisotropy, Figure 6 Schematic representations of the anisotropy of magnetic susceptibility (AMS) development for undeformed sediments deposited in quiet conditions (**a**), under the action of a weak or moderate water currents (**b**), and under the action of strong currents, sufficient to entrain particles and to induce the rolling of elongated grains with their long axis perpendicular to the water flow (**c**). (Modified from Tauxe, 2005.)

to the paleocurrent direction (e.g., Rees, 1961, 1966, 1983; Hamilton and Rees, 1970; Rees and Woodall, 1975; Ellwood and Ledbetter, 1979; Liu et al., 2001; Pàres et al., 2007). In moderate currents, platy particles tend to imbricate and elongated particles tend to align with their greatest axis parallel to the flow. On the AMS results obtained from a group of specimens, the imbrication induces a slightly vertical offset of the mean k_{min} and the clustering of the k_{max} axes in a direction antiparallel to the paleo-flow (Figure 6b); the overall AMS fabric is still characterized by an oblate ellipsoid. In such a case, imbrication yields a better estimate of the flow direction than magnetic lineation, which may wander within the foliation plane and even be orthogonal to the flow direction. In fact, when deposition occurs under high current flow (traction transport mode of sedimentation) the distribution of k_{min} axes from various samples is streaked, the k_{max} axes cluster in a direction perpendicular to the flow (Figure 6c), and the fabric is characterized by prolate or triaxial AMS ellipsoids.

In general, sedimentary depositional fabrics are comparatively low in both susceptibility ($<10^{-4}$ SI) and in anisotropy ($P < 1.05$).

In *igneous rocks*, AMS analyses are mostly used to determine the orientation of the plane and flux direction of the magma flows. In these rocks, the viscosity of the magma plays a fundamental role for the genesis of a rock fabric. The movement/rotation of magnetic minerals is hindered when viscosity reaches a level that impedes any further ductile flow.

It is useful to distinguish the case of extrusive and shallow intrusive rocks (lava flows, ignimbrites, and dykes) from plutonic rocks. In volcanic rocks, the processes that induce a preferential orientation of the magnetic minerals (mostly titanomagnetites) are connected to the plane and direction of magma flow, both for lavas from effusive eruptions, for pyroclastic flows from explosive volcanism, and for dykes and other shallow tabular intrusive rocks (e.g., Khan, 1962; Incoronato et al., 1983; Knight et al., 1986; MacDonald and Palmer, 1990; Tauxe et al., 1998; Cañon-Tapia, 2004; Gurioli et al., 2005). Titanomagnetite grains are oriented in the flow plane with their greatest dimension parallel to the magma flow, so that for lava flows the magnetic foliation matches the (paleo)topographic surface, whereas for dikes or sills it develops parallel to the walls of the hosting rocks. The magnetic lineation is mostly parallel to the magma flow directions, even though perpendicular or oblique relationships can also be rarely found. The efficiency of the volcanic flow to impart a preferential orientation on magnetic grains is usually relatively low, causing rather low anisotropy degrees, comparable to those typical of undeformed sediments.

A random fabric may be an indication of turbulent motion, which for dikes and sills occurs in the case of injection along wide enough fractures and for ignimbrites and surges occurs at a short distance from the vent where the eruption energy causes a chaotic motion of the transported solid particles. A coherent fabric may develop however at farther distance from the eruption centers where the kinetic energy decreases and the particles deposit on the morphological paleo-surfaces.

As for undeformed sediments, an eventual imbrication of the magnetic grains may be used to reconstruct the sense of the flow. In fact, the normal fabric of pyroclastic flows is considered the one with the foliation plunging upflow, so that the flow direction is given by the azimuth of the foliation pole and the lineation is close to it. AMS analyses in volcanic rocks have been used to constrain the location of the eruption centers.

In plutonic rocks, the analysis of the AMS may provide information on the processes of magma injection, differentiation, and crystallization (e.g., Heller, 1973; Hrouda et al., 1971; Jover et al., 1989; Hrouda and Lanza, 1989; Bouchez, 1997). The AMS fabric may therefore be affected by the flow of the magma, the changes in its viscosity and composition, and the finite deformation it undergoes under regional stress before complete crystallization. Generally, the AMS of plutonic rocks whose magnetic fabric was produced through magma flow are characterized by a low anisotropy degree which overlaps with that of volcanic rocks and undeformed sediments, and the shape of their AMS ellipsoid ranges from oblate to prolate according to the local character of the magma flow; the magnetic foliation is parallel to the flow plane and the magnetic lineation is parallel to the flow direction.

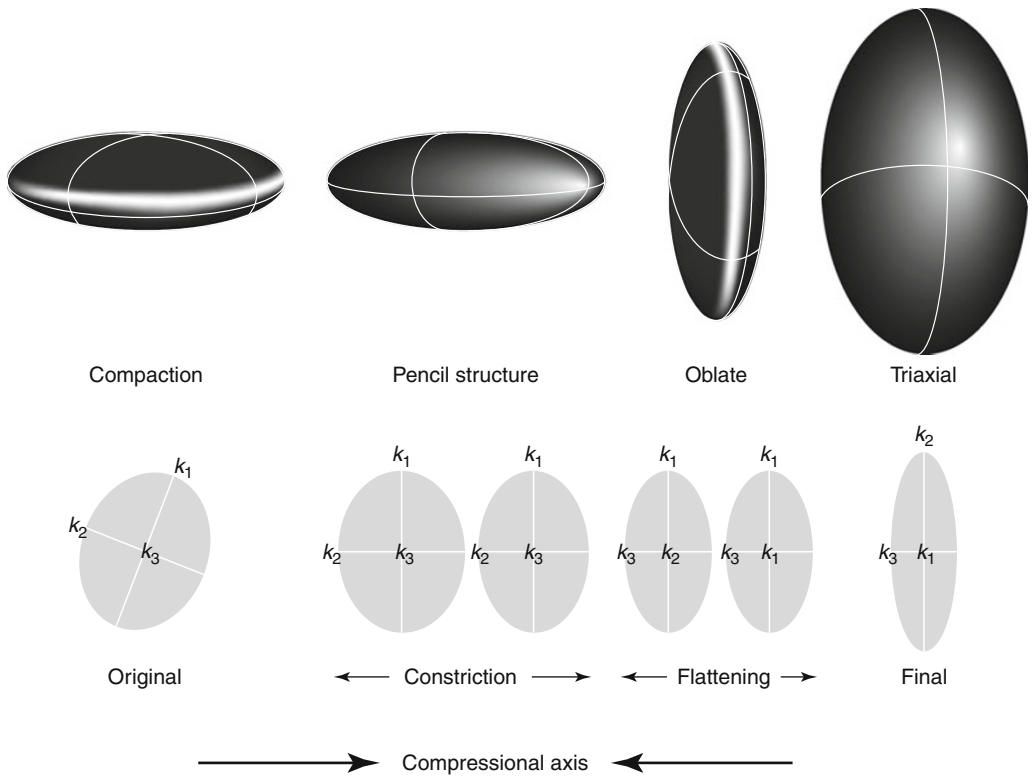
Conversely, the AMS of plutonic rocks which cooled under high temperature and pressures in the lower levels of the crust and are associated with metamorphic rocks may have a high anisotropy degree mostly determined by ductile deformation, which is a relatively efficient mechanism for the reorientation of magnetic minerals. The magnetic fabric in these rocks usually indicates a preferred orientation of magnetite minerals that nucleated at a late stage of the geological history of the pluton, and are therefore younger than the surrounding silicates. These magnetite grains grew in highly anisometric intergranular spaces and show therefore a high degree of shape anisotropy. This magnetic fabric is usually termed as mimetic magnetic fabric.

In *deformed rocks*, AMS analyses are used to evaluate the orientation of the strain ellipsoid (e.g., Borradaile, 1991; Hrouda, 1993; Borradaile and Henry, 1997; Borradaile and Jackson, 2004). In fact, AMS analysis is a very sensitive tool for the detection of rock strain, even in weakly deformed sediments and where other strain markers are scarcely developed or even totally absent.

AMS studies in nearly undeformed sediments have also been used as a tool for recognizing intervals affected by significant coring-induced deformation and assess the reliability of paleomagnetic data derived from such sediments (e.g., Rosenbaum et al., 2000).

AMS is extremely sensitive to incipient strain and it develops well before other macro- and mesoscopic strain features, such as cleavage, can be observed. As a matter of fact, the preferred orientation of phyllosilicate grains

in mudstones may reflect the strain produced by compaction and tectonic processes. If there is a stress field acting on a sediment, causing progressive strain, the primary magnetic fabric is modified according to the nature and the extent of the deformation (e.g., Graham, 1966; Lee et al., 1990; Sagnotti and Speranza, 1993; Sagnotti et al., 1998; Parés et al., 1999; Parés, 2004) (Figure 7). The first effect of strain upon such undeformed-compactional AMS fabric is to induce the clustering of the k_{max} axes in the direction of maximum stretching, which is roughly perpendicular to the maximum compressive stress. The rotation of platy grains around the intermediate strain axis makes the planar bedding fabric less pronounced. Anyway, at such very first stage of deformation the k_{min} axes are still normal to the bedding. AMS studies carried in clayey and weakly deformed sediments pointed out a significant relationship between the magnetic fabric of apparently undeformed clays and the tectonic history of the sedimentary basins in which they were deposited, including compressional as well as extensional tectonic settings (e.g., Sagnotti et al., 1994; Mattei et al., 1997). In such sediments the magnetic foliation generally indicates the sedimentation-compaction plane, whereas the magnetic lineation is perpendicular to the shortening direction in the compressional settings and parallel to the stretching direction in the extensional settings. The magnetic lineation found in macroscopically undeformed fine-grained sediments from extensional settings develops from the spatial distribution of the basal planes of the paramagnetic phyllosilicates of the clay matrix and is parallel to the common axis of differently oriented basal planes (Cifelli et al., 2004, 2005). A further increase of strain under compression causes the dispersion (scattering) of the k_{min} axes in such a way that they tend to describe a girdle normal to the k_{max} cluster: the AMS ellipsoid becomes prolate and the primary depositional fabric is progressively obliterated and overprinted by a tectonic fabric (Figure 7). Mineral rotations are sufficient at this stage to produce a fabric strong enough to impart the well-known "pencil structure." Further increasing strain occurs entering in the field of metamorphism and leads to the progressive return of the AMS ellipsoid into the flattening field. Mineral rotation leads to the production of an imperfectly formed cleavage crossing bedding, called embryonic cleavage. A cleavage stage is achieved when the tectonic strain imprint is sufficiently strong to form a dominant planar cleavage fabric, where platy and acicular minerals are oriented in this cleavage plane. The magnetic foliation plane that develops at this stage is parallel to the plane of cleavage or schistosity visible in the rock. With increasing strain, the planar cleavage and lineation are intensified, this last one very close to or parallel to the strain maximum stretching direction (Figure 7).



Magnetic Anisotropy, Figure 7 Schematic representations of the sequence of anisotropy of magnetic susceptibility (AMS) development in progressively deformed sediments in a compressional setting. (Redrawn after Graham, 1966.)

The AMS of *metamorphic rocks* is generally considerably higher than the AMS in undeformed sedimentary and volcanic rocks. As a matter of fact, the mechanisms of ductile deformation and recrystallization operating during metamorphism (e.g., diffusion, crystal plasticity, particulate flow, neomineralization) may be very effective to determine a preferential orientation-distribution of magnetic grains. In rocks with strong tectonic fabrics the principal directions of susceptibility and of finite strain coincide and a quantitative genetic relationship between strain and AMS has been pointed out in some cases (see reviews by Borradaile, 1988 and Borradaile and Jackson, 2004). Nevertheless such relationships are not universal and strain-AMS relationship or correlations found under certain circumstances and lithologies cannot be extrapolated to different situations.

A magnetic fabric is defined normal when the principal magnetic axes correspond one by one to the petrofabric axes. An inverse or intermediate magnetic fabric occurs when the magnetic susceptibility principal axes exchange their position. Inverse AMS fabrics are associated with the prevalence of certain magnetic minerals (see Rochette et al., 1992, 1999). Specifically, some minerals posses an inverse AMS fabric related to their shape (e.g., goethite and tourmaline) or to intracrystalline gliding during ductile deformation (e.g., siderite and other iron-bearing carbonates). Moreover, SD ferrimagnetic particles with prolate shape anisotropy may originate an inverse magnetic fabric as well. As a matter of fact, pseudo single domain (PSD) and multidomain (MD) particles of a ferrimagnetic mineral such as magnetite have a maximum susceptibility parallel to their long (easy) morphological axis, while a stable single domain (SD) magnetite particle, whose magnetization is always saturated along its long axis, has a maximum susceptibility value perpendicular to it (Stephenson et al., 1986; Potter and Stephenson, 1988). Even if inverse and anomalous AMS fabric are relatively rare in nature, in all cases when AMS directions cannot be correlated with obvious structural markers, the mineralogical source of the AMS should be closely investigated and the AMS compared with other types of magnetic anisotropy (i.e., the anisotropy of artificially induced magnetic remanences).

Anisotropy of the magnetic remanence (AMR)

AMS represents the sum of the susceptibility anisotropies of all the mineral components in a rock, including the diamagnetic and paramagnetic fractions. The studies on the AMR are directly relevant to paleomagnetic studies (as early recognized by Fuller, 1960, 1963), since they only measure the anisotropy of the remanence carrying particles. AMR studies also have a large spectrum of application in geological sciences (e.g., see reviews by Jackson, 1991; Potter, 2004; Hirt, 2007).

In fact, AMS may be inappropriate for the purposes of correcting paleomagnetic data, since it depends critically on the size of the remanence carrying particles. One of the advantages of AMR is that it precludes the effect of inverse AMS fabric due to single domain magnetites (Stephenson et al., 1986), since the grain long axis is the axis of maximum remanence irrespective of particle size. The most common AMRs are anisotropy of anhysteretic remanence (AARM), anisotropy of isothermal remanence magnetization (AIRM), and high-field magnetic anisotropy (HFAMS).

AARM: anisotropy of anhysteretic remanence

The anisotropy of anhysteretic remanence (AARM) is the most commonly studied anisotropy of remanence. An anhysteretic remanent magnetization (ARM) is acquired by a sample when it is simultaneously exposed to an alternating magnetic field with decreasing amplitude (usually with a maximum peak in the range 10–100 mT) and a steady DC magnetic field (typically values close to the intensity of the geomagnetic field, e.g., about 50–100 μT). Prior to acquisition of the ARM, the specimen should be demagnetized in an AF peak higher than that used for the ARM acquisition, and its residual remanence measured as a baseline. Then the ARM is imparted and computed as the difference between the measured remanence and the baseline.

There are two principal advantages of using ARM for the characterization of the anisotropy of the remanence: (1) the acquisition curve of ARM vs DC field is expected to be linear in the range of low DC magnetic field commonly employed, (2) a window of AC field can be used to impart ARM. In fact, by measuring different windows of coercivity (partial AARM), one can expect to characterize different subpopulations (size and shape) of ferromagnetic grains.

The ferromagnetic particles that define the AARM tensor may have a broad range of grain sizes.

Since there is a strong empirical correlation between partial anhysteretic remanence (pARM) and magnetite grain size (e.g., Dunlop and Özdemir, 1997), it is possible to isolate the AARM tensor associated with distinct populations of grains by using partial rather than total anhysteretic remanence anisotropy. This can be done by imparting a magnetization to a specific particle fraction during anisotropy determinations. In this regard, Jackson et al. (1988) first documented multiple AARM magnetic fabrics for the same sample by using different windows of coercive field. They called this partial anisotropy of anhysteretic remanent magnetization (pAARM).

Observed AARM indicates possible anisotropy in acquiring NRM. This provides a warning that the rock might not be an accurate paleomagnetic recorder. Measuring the AARM thus provides a fast and reliable method to correct paleomagnetic deviation in rocks. In sedimentary rocks, AARM has been proposed to provide a quantitative correction for inclination error (e.g., Jackson et al., 1991; Kodama and Sun, 1992; Deamer and Kodama, 1990; Collombat et al., 1993; Hodych et al., 1999; Tan and Kodama, 2002; Tan et al., 2003; Vaughn et al., 2005),

and to correctly evaluate the amplitude of paleosecular variation recorded in volcanic rocks (e.g., Gattacceca and Rochette, 2002).

AIRM: anisotropy of isothermal remanent magnetization

Another type of magnetic anisotropy is the anisotropy of isothermal remanent magnetization (AIRM) (Jelínek, 1966). In order to study the IRM anisotropy, a sample is successively subjected to a pulse magnetic field (with intensity generally of the order of 5–60 mT) in several appropriate directions and the acquired IRM is measured. As for the study of the anisotropy of ARM, before the measuring process and after each magnetization step the sample is AF demagnetized. The determination of the IRM anisotropy makes it possible to study the ferromagnetic fraction of a rock separately from the contribution of the paramagnetic and diamagnetic matrix.

Although usually successful, AIRM risks nonlinear susceptibility effects where strong magnetic field is required.

HFAMS: high-field magnetic anisotropy

High-field methods are used to separate the AMS due to ferromagnetic minerals from the AMS due to diamagnetic and paramagnetic minerals (e.g., Hrouda and Jelínek, 1990; Martn-Hernandez and Hirt, 2001). These methods are based on the field dependence of the magnetic susceptibility and rely on the different response of ferromagnetic and paramagnetic minerals to large applied fields, that is, large enough to saturate the ferromagnetic mineral fraction. For rocks that have both ferromagnetic and paramagnetic minerals, changes in magnetization at fields greater than ferromagnetic saturation are due primarily to the paramagnetic susceptibility.

The high-field magnetic anisotropy measurements have been made using torque magnetometers (e.g., Banerjee and Stacey, 1967; Bergmüller et al., 1994) or a high-field, rotating sample, cryogenic magnetometer (Rochette and Fillion, 1988). Although these techniques have great potential to separate paramagnetic and ferromagnetic fabrics, torque magnetometers and high-field cryogenic magnetometers are not available in most magnetic laboratories and HFAMS is not routinely applied.

Summary

Magnetic anisotropy is an essential property of rocks and minerals.

The AMS of rock specimens can be determined with a high degree of precision and the method is sensitive, rapid, and nondestructive. The study of AMS is a fundamental tool of petrofabric analysis, which has the potential to recognize even subtle preferred orientations of mineral lattices or shapes and to infer the causative processes, ranging from the effects of paleocurrents in undeformed sediments to pervasive strain in deformed rocks. As such, it has a wide range of applicability in the Earth Sciences.

The AMR instead refers to the preferential orientation-distribution of the ferromagnetic grains only. The techniques to determine AMR are time consuming because artificial remanences must be applied and then removed along each measurement axis. The study of AMR is more directly relevant to paleomagnetic researches since it may provide a tool to correct paleomagnetic deviations in all cases when the direction of the magnetic remanence is deflected from the direction of the magnetic field in which it was acquired.

Definition

Magnetic anomaly. On Earth, magnetic anomalies are defined as the vector or scalar difference between the measured magnetic field and an estimate of the main field. Magnetic anomalies are commonly assumed to reflect the magnetic properties of rocks lying in the Earth's crust.

Introduction

The Earth's magnetic field is the vector sum of fields of internal and external origins that operate on a wide range of spatial and temporal scales (Hulot et al., 2007). On Earth, the three major sources are the main or core field, which is generated by electrical currents in the liquid outer core, the lithospheric also referred to as crustal field, which results from magnetized materials in the outer layer of the Earth, and the external fields produced by currents in the ionosphere and the magnetosphere. An anomaly field approximates well the magnetic field of the Earth's lithosphere only if the main and external fields have been corrected to an accuracy comparable to the data noise.

When the magnetic field is known on the surface of a sphere, the magnetic potential field may be expressed in current free regions as the vector $B = -\nabla V(r,\theta,\phi,t)$ with the scalar potential V expanded in terms of Spherical Harmonics (SH)

$$V(r,\theta,\phi,t) = a\sum_{n=1}^{\infty}\sum_{m=0}^{n}\left(\frac{a}{r}\right)^{n+1}\left(g_n^m(t)\cos(m\phi) + h_n^m(t)\sin(m\phi)\right)P_n^m(\cos\theta) + a\sum_{n=1}^{\infty}\sum_{m=0}^{n}\left(\frac{r}{a}\right)^{n}\left(q_n^m(t)\cos(m\phi) + s_n^m(t)\sin(m\phi)\right)P_n^m(\cos\theta). \quad (1)$$

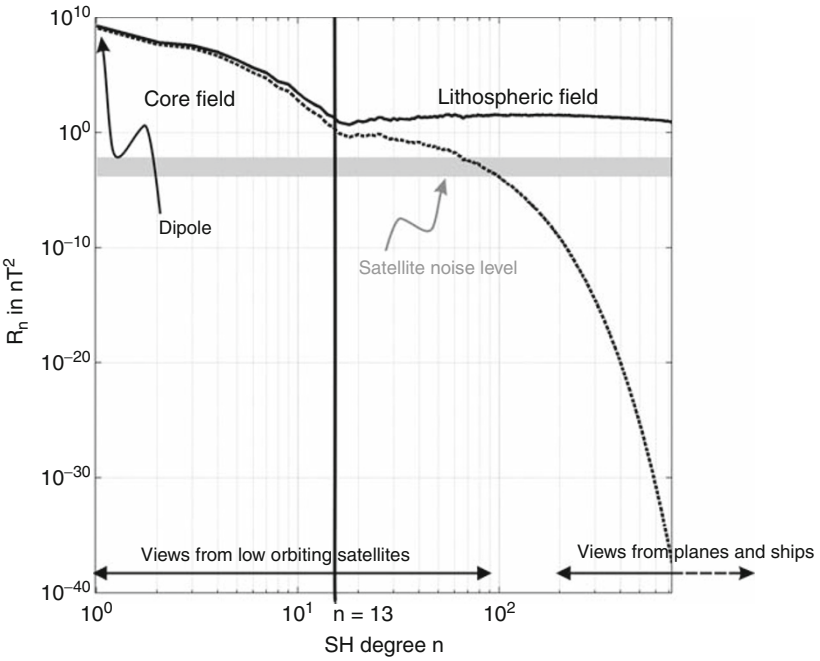
The parameters a, r, θ, and ϕ are the Earth's reference radius (6,371.2 km), the radius, the co-latitude, and the longitude, respectively. The internal (g_n^m, h_n^m) and external (q_n^m, s_n^m) coefficients may be time varying and are expressed in [nT] with respect to the shell of radius $r = a$. In geomagnetism, $P_n^m(\cos\theta)$ is the Schmidt semi-normalized associated Legendre function of integer degree n and order m. The spatial power spectrum of the internal field is defined by (Lowes, 1974)

$$R_n = (n+1)\left(\frac{a}{r}\right)^{2n+4}\sum_{m=0}^{n}\left[\left(g_n^m\right)^2 + \left(h_n^m\right)^2\right], \quad (2)$$

with R_n expressed in nT^2. The power spectrum provides an estimate of the contribution of each SH degree n to the square amplitude of the observed magnetic field of internal origin at the radius r. The horizontal spatial wavelength λ in kilometers [km] at the Earth's mean radius a associated with each degree n, is defined by (Backus et al., 1996, p. 101)

$$\lambda = \frac{2\pi a}{n}$$

Figure 1 displays the power spectrum of an internal model expanded to SH degree $n = 720$ (Maus, 2010). It is derived from satellite, airborne and ship measurements (*Geomagnetic Field, Measurement Techniques*). The break in slope of the power spectrum indicates that long-term dynamo processes (the core field and its secular variation; see *Geomagnetic Field, Secular Variation*) dominate the Earth's lithospheric field at least up to SH degree 13–15. The magnetic field of the Earth's core is thus not accurately represented by its dipole term only. Prior to epoch 2000.0, International Geomagnetic Reference Field (IGRF) models were derived to SH degree 10, and 13 thereafter (*Geomagnetic Field, IGRF*). When processing datasets collected at different epochs, disagreements between, or inaccuracies of, core field models lead to different anomaly field pictures. The geometrical attenuation of SH harmonics with increasing altitudes is important and represents the main impediment to the detection of the lithospheric field at all scales. The fast coalescence of small-scale anomalies with altitude demonstrates that different platforms of magnetic measurements at different altitudes do not detect the same



Magnetic Anomalies, Interpretation, Figure 1 Geomagnetic field power spectrum to SH degree 720 at 400 km altitude (*dashed line*) and (*solid line*) at 0 km above the Earth's mean radius (After Maus, 2010).

properties of the anomaly fields. Techniques for preparing an anomaly map of model at space or near-surface altitudes include removing the best estimates of fields not originating in the Earth's lithosphere, including their slow and rapid time variations, selecting suitable subsets of quiet-time data and averaging a large number of data to better highlight the finest permanent crustal field structures. A magnetic anomaly thus depends on altitude and on the care taken to remove all field contributions not originating from the lithosphere, which is strongly related to the advances made toward analyzing and understanding the Earth's magnetic field as a whole.

The sources of crustal and lithospheric fields

When the errors incurred in correcting the data for core and external fields are mitigated, the anomaly field is assumed to have sources in the crust (*Continental crustal structure*) or sometimes even deeper in the lithosphere (*Continental Lithosphere: Thermal Structure*).

The subject of rock magnetism is complex (Dunlop and Özdemir, 2007) but the general mechanisms are well known. The amount of magnetization carried by a rock depends on many parameters such as size, shape, mineralogy, domains, and temperature (*Magnetic Domains*). Most magnetic minerals on Earth are titanomagnetite and titanohematite, for which the Curie temperatures are between 580°C and 670°C (*Curie temperature*). Curie temperatures are met at depths of about 30 and 7 km, in stable continental and oceanic regions, respectively. Deeper rocks are considered nonmagnetic even though the Curie depth may penetrate the lithosphere. The minerals found in the Earth carry both permanent, $\mathbf{M}_r$ (see *Remanent Magnetism*) and induced magnetizations, $\mathbf{M}_i$. The magnetization $\mathbf{M}_r$, arises when a main field is locked into the material when, for example, the temperature of an igneous rock decreased below the Curie temperature of its magnetic phase. The magnetic field generated by remanent magnetization is a small fraction of the ancient magnetic field, whose direction may be very different from the contemporary field, both because of rock reorientation to their present positions and because of changes of the main field directions over geological times (see *Geomagnetic Field, Polarity Reversals*). The ease with which the magnetization of a material can be induced depends on the magnetic susceptibility k such that $\mu_0\mathbf{M}_i = k\mathbf{B}$, where $\mathbf{M}_i$ is the vector of induced magnetization, $\mathbf{B}$ the inducing ambient field, and μ_0 the magnetic permeability of free space. Susceptibility values vary with rock types. They are smaller for sedimentary than for metamorphic rocks, themselves lower than igneous rocks. In all cases, the induced magnetization produces a field much less intense than the inducing field. Since the Earth's core magnetic field does not vary significantly on a decadal timescale (*Geomagnetic Field, Secular Variation*), the induced lithospheric field is quasi-static over historical times. The total magnetization $\mathbf{M} = \mathbf{M}_i + \mathbf{M}_r$ thus points in a different direction from both the present and ancient fields. The Königsberger ratio M_r/M_i measures the relative importance of remanent to induced magnetization. Since we measure the magnetic fields resulting from magnetization rather than magnetization itself, it is difficult to resolve it into its induced and remanent components without collecting rock specimens and measuring their magnetic properties. The Königsberger ratio is generally large for oceanic rocks. Thanks to the rather homogeneous nature and structure of the oceanic crust (see *Lithosphere, Oceanic*), inferring the remanent magnetization over an entire oceanic chrons by interpolating the magnetic properties of a few distant samples is achievable (see *Paleomagnetism, Principles*). In contrast, it is almost impossible to predict the remament magnetization over continents. The Königsberger ratio is there anyway small because rock materials contain coarse magnetite grains. Common practice is thus to disregard remanent magnetization on continental areas and to consider induced magnetization negligible on oceans.

Important theorems show that not all magnetization distributions, in particular the uniform distribution (Runcorn, 1975) or contrasts oriented North–south near the Equator, produce magnetic fields above the Earth's surface. The spatial variation of the crustal magnetic field reflects lateral contrasts of magnetization rather than magnetization itself. Two adjacent geological units having both strong but comparable susceptibilities may produce magnetic field variations comparable to a body with lower magnetization but surrounded by sediments, for instance. Therefore, obvious outcropping geological features do not necessarily have a detectable magnetic signature and interpretations of magnetic maps are nonunique.

Measuring magnetic anomalies from planes and ships

Inland measurements are available but cover very small areas only (a few tens of meter squares). Near-surface surveys are routinely undertaken for mineral and hydrocarbon exploration and sometimes for basic research. Airborne magnetic surveys are generally carried out to support mineral and petroleum exploration and aid in subsurface geological mapping (*Magnetic Methods: Airborne*). These surveys are generally executed in a regular pattern at some hundred meters altitude above mean terrain clearance, with a horizontal distance about twice as much as the aircraft altitude (Reeves, 2005). The flight lines are oriented perpendicular to the geological strike directions to detect better the magnetic contrasts. For reconnaissance mapping of large regions (e.g., states, countries) typical line spacing is 1-km kilometer at altitudes above the sea level ranging between 1 and 5-km. More widely spaced segments crossing the flight lines at right angles are then used to correct the scalar data for offsets caused, either by magnetic field time variations, or by measurement errors. Local and regional surveys do not detect the same magnetic anomalies (Figure 1). Low altitude surveys provide locally detailed profiles but little

information about the magnetic structures exceeding the survey dimension. Likewise, high altitude surveys provide a synoptic view of the magnetic anomalies but generally miss the features with length scales smaller than the altitude and larger than the survey area. Near-surface measurements are carried out during days. Marine and aeromagnetic surveys provide raw total field intensity data and more rarely vector measurements because the reference frame is not sufficiently stable.

The anomaly field is defined by correcting the raw data for a main field model, in general an International Geomagnetic Reference Field model (*Geomagnetic Field, IGRF*), or simply a regional trend, and then for external field variations that occurred during the survey. Current practice is to use the magnetic records of magnetic observatories or a nearby ground station purposefully set up for the survey to monitor the Earth's magnetic field, to identify the disturbances and eliminate spikes, and to correct ultimately for the diurnal magnetic field variation. The final product is a map of anomaly values, reaching up to a few thousands nanotesla in amplitude, built by interpolation between data points and leveled to a common altitude onto a regular grid. An anomaly map build upon the compilation of various surveys displays crustal features with typical spatial scales from kilometers to hundred kilometers (Figure 1). They mostly highlight the magnetic properties of the upper crust.

Satellite measurements

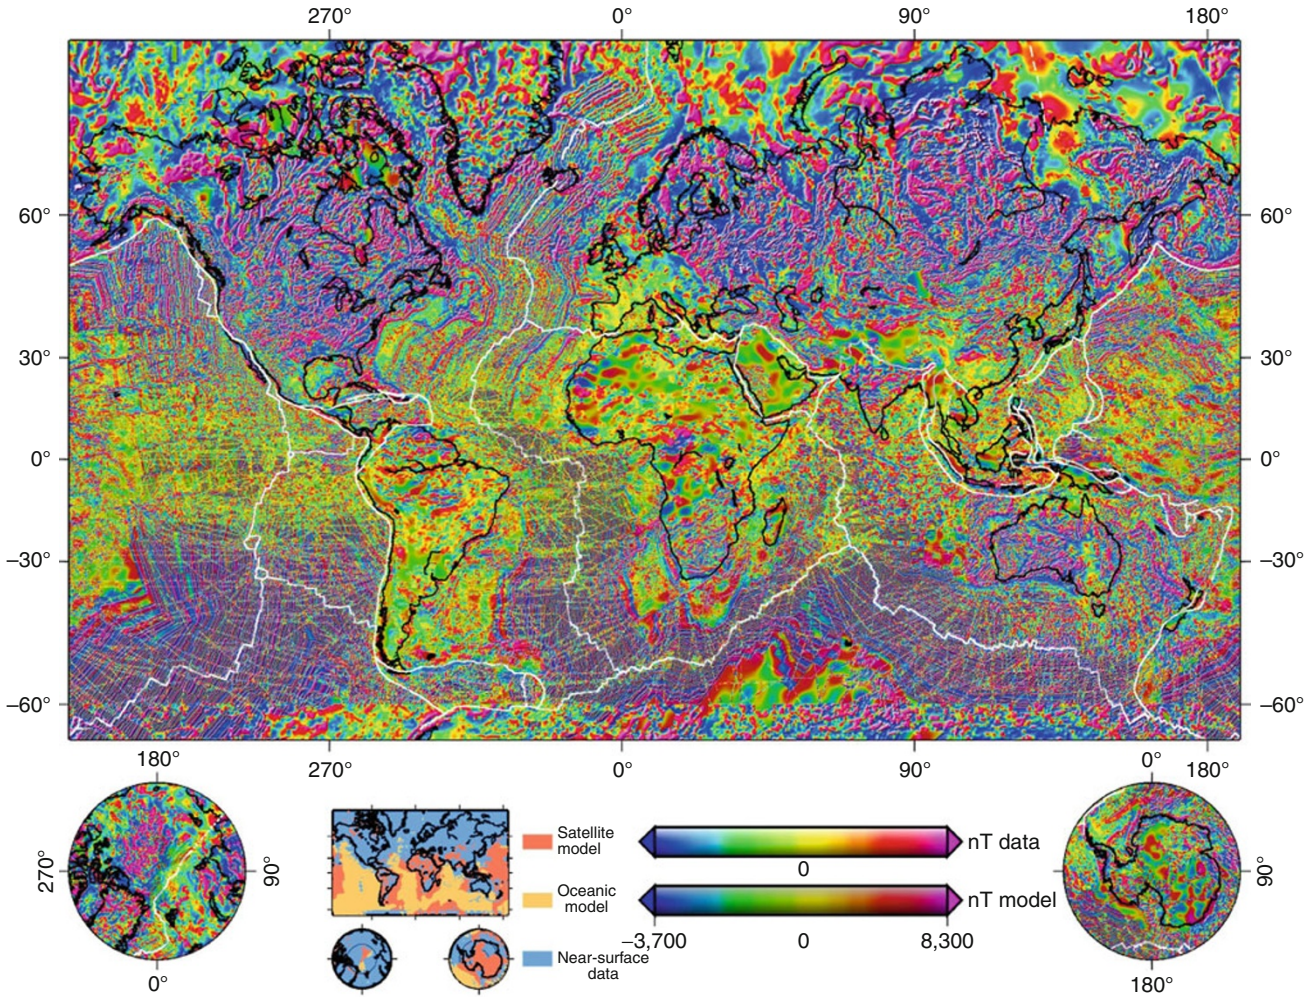
Large geologic structures with dimensions of a few hundred kilometers can be inferred from Low Earth Orbiting (LEO) satellites. Satellites provide scalar and vector homogeneous measurements at the Earth's scale (*Magnetic methods, satellite*). The lithospheric field is one of the weakest detectable source at the satellite altitudes. It represents less than 0.1% of the full signal, on average (Figure 1), and magnetic anomalies rarely exceed 20 nT at 400-km altitude (*Magnetic Methods, Satellite*). Satellites are also closer to (and sometimes fly through) the ionospheric sources and are more sensitive to the external field than the ground-based measurements. Measurements of satellites may be exploited to co-estimate the core and the lithospheric field in SH. This considerably reduces the error introduced by correcting the data with an independent core field model such as IGRF. Satellites also allow to select nighttime measurements, which permits to disregard the diurnal external magnetic field; the counterpart being that a stacking of systematic errors may be caused by local external fields unidentified on Earth on the nightside. The corrected data represent vector magnetic anomalies expressible in terms of SH. Such models are easily upward or downward continued to any spherical surface.

A satellite is constantly moving along its orbit and such displacements may be interpreted in terms of spatial or time-varying magnetic fields. Attitude uncertainties of the spacecraft, time errors, misalignment of magnetometers, and the absence of baseline control introduce a total error whose magnitude is enhanced by the spacecraft velocity. At about 7.5 km s^{-1} at 400 km altitude for the CHAMP satellite (Reigber et al., 2002), such uncertainties can convert into a few nT error. The absence of traverse lines also introduces East–west artificial offsets that may easily be confused with genuine anomalies (Thébault et al., 2010). For this reasons, only long periods of observations allow improving the signal-to-noise ratio. After a few years of measurements, it is generally accepted that lithospheric field models are robustly described to about SH degree 60 only because the signal drops into the noise somewhere between SH degree 60 to 90 (Figure 1). However, recent measurements acquired at 350-km altitude improved our view of the Earth's lithospheric field down to 350-km spatial wavelenghts (Maus et al., 2008) although these finer structures have not yet been ascertained by independant approaches. Magnetic anomaly maps obtained from space provide a statistical view of the entire crust down to the lithosphere (Langel and Hinze, 1998).

Aeromagnetic and satellite data offer a complementary view of the lithospheric field, yet incomplete. We remain partly blind for the wavelengths between 200 and 400 km. Such wavelengths could be in principle registered by stratospheric balloon at 20–30 km altitude but controlling the airship route is challenging. Thus, current efforts focus instead on ways to improve the resolution achievable from space by considering gradient measurements and constellation of satellites (Friis-Christensen et al., 2006).

World magnetic anomalies – WDMAM

For scientific purposes, it is essential to map the data over long distances, in order to evaluate the crustal structures, to understand the geological processes, to establish tectonic models of continental and oceanic crust, to enable paleo-reconstructions, and to contribute to geodynamic models. The merging of ground, near-surface, and satellite measurements is a way to access this multi-scale view of the Earth's lithospheric magnetic field. The World Digital Magnetic Anomaly Map (WDMAM) project is an international effort directed toward compiling magnetic anomaly data available in the public domain (Khorhonen et al., 2007). WDMAM 1.0 is based upon more than 50 years of aeromagnetic and marine surveys and provides a three arcmin spacing grid at 5 km altitude (Figure 2). It relies on published continental-scale compilations derived by independent groups (e.g., the North Atlantic Magnetic Anomaly Group NAMAG, or the Antarctic Digital Anomaly Map, ADMAP), as well as upon independent contributions from countries and individuals. Several mergers were tested and led to different candidate grids for the WDMAM 1.0. This difference illustrates the difficulty of blending such a variety of datasets. Continuous efforts are being made to improve the quality and the data coverage and will benefit WDMAM 2.0, which should be released in 2011.



Magnetic Anomalies, Interpretation, Figure 2 World magnetic anomaly compilation using aeromagnetic, marine, and satellite data. The magnetic signal in some oceanic part is computed via a magnetization model (After Khorhonen et al., 2007; courtesy of the Commission for the Geological Map of the World, CGMW).

Qualitative interpretations

Most susceptibility contrasts may give rise to a magnetic field detectable by a magnetometer (*Geomagnetic Field, Measurement Techniques*). An exhaustive review of qualitative magnetic anomaly map interpretation is impossible. Magnetic surveys are traditionally acquired for resource exploration in order to detect ore bodies, but also oil and natural gases, which are trapped in sedimentary basins. Magnetic maps are also useful to track anthropogenic buried materials, like unexploded bombs, hidden weapons, abandoned oil wells, but may also be used for guiding archaeological excavations, for instance.

At a regional scale, mapping the patterns of magnetic anomalies is a very effective way of reconnoitering large areas of geology virtually everywhere (Purucker and Whaler, 2007), in remote regions where rock outcrop is absent and bedrock covered by glacial, sand, vegetation, or water overburdens. In particular, the interpretation of magnetic anomalies over oceans was crucial to the development of the plate tectonics paradigm (Vine and Matthews, 1963). Over continents, tectonic processes are detailed in a magnetic anomaly map because they are responsible for the creation, destruction, and movement of magnetic materials within the lithosphere of the Earth that modify preexisting magnetic signatures. New magnetic contrasts are created by volcanism and related igneous processes such as dike emplacement, rifting, and faulting.

At a continental scale, magnetic anomalies are particularly prominent over the main old and cold continental masses in Africa, Antarctica, Asia, Australia, Europe, Greenland, India, and North and South Americas (Figure 2), and comparatively weaker over younger and hotter oceans. The largest magnetic anomaly features correlate well with cratons, Precambrian and Paleozoic provinces. Within each structure, magnetic anomalies of

smaller extension like mobile belts, collision zones, and volcanic areas can be characterized. Crustal thickness variations at continent ocean boundaries and large subduction zones are also sometimes outlined. Large magnetic anomalies often correlate with plate boundaries and seismotectonic activity around the world. Reconstructions of wide separated geological units or rotated blocks make extensive use of the seafloor stripes and transform faults.

Quantitative geological interpretations

Interpretation of magnetic maps is nonunique because potential theory shows that a single magnetic anomaly can be caused by an infinite variety of magnetized bodies. Quantitative analyses such as depth, shape, and position of a magnetized body require drastic assumptions or significant a priori information derived from other geological and geophysical results. Locally, on continents, a quantitative description of a magnetized body is performed (1) by planar geometry and by using processing techniques inherited from Fourier analyses; (2) by setting a distribution of equivalent magnetic poles in the subsurface and interpreting the observed anomaly in terms of inducing field; (3) by analyzing only simple regular anomalies (*Magnetic Anomalies of Simple Geophysical Models*). The picture of a magnetic anomaly is generally more understandable after a pole reduction that transforms an observed magnetic anomaly into the anomaly that would be measured at the north magnetic pole. The pole reduction method relocates the magnetic anomalies so that its maximum lies in the middle above the magnetized body, thus making magnetic interpretation easier. The flank of anomalies may also be clarified by upward and downward continuation and quick depth estimations are empirically obtained by computing the map of the magnetic anomaly derivatives. Baranov (1975) summarizes these techniques.

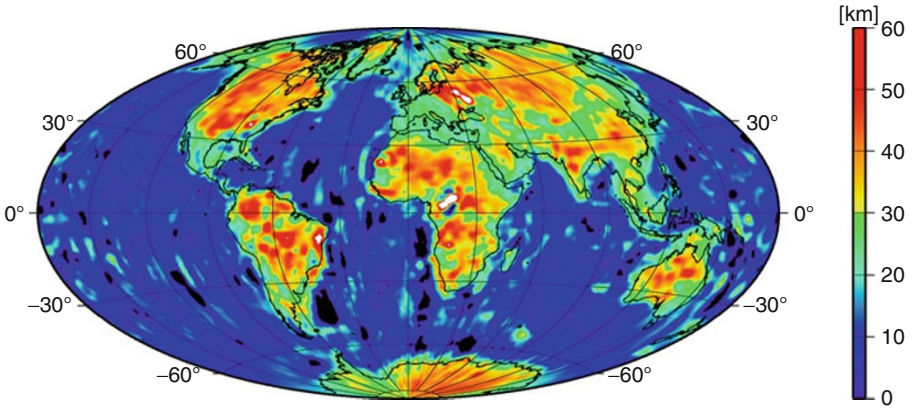
When the geometrical parameters are bounded, the magnetization of the body can be found by trials and errors and its rock type can be subsequently inferred from a table of rock magnetization (see *Magnetic Domains*). The magnetic field anomaly created by a simple geometric body at depth (*Magnetic Anomalies of Simple Geophysical Models*) is compared to the measured anomaly field until the residuals between both is comparable to measurement errors. In some areas, interpreting individually each magnetic anomaly is not feasible, particularly if the geophysical body has no simple geometry. In such cases, the ambiguities in interpreting the magnetic anomaly maps can be reduced only by requesting guidance from other disciplines like, gravity, seismic, geology, etc.

The systematic recourse to integrated geophysical information led to some successes in interpreting measurements from space at the global scale. Simplifying assumptions are easier to justify from space because of the measurements altitude and their horizontal spatial resolution. In particular, the magnetization can be assumed to vary laterally and be constant in a crustal layer of varying thickness because at 400 km altitude, the Earth's crust appears as a thin layer within which we cannot distinguish between the different sources depths and the problem can be solved in two dimensions only.

Maus and Haak (2003) verified that, statistically, the lithospheric magnetization was indeed mostly induced over continent and remanent over oceans at satellite altitudes. For this reason, it makes sense to assume over continents that the anomaly source is due to an array of equivalent dipole with moments aligned along the main core field. The bare thickness contrast between continental (~40 km) and oceanic (~7 km) crusts of uniform, but different, susceptibility values, generates magnetic anomaly field that are seen in magnetic field measurements (Counil et al., 1991). This shows that magnetic crustal thickness plays a significant role in the dichotomy between oceanic and continental magnetic signals observed at satellite altitudes (see *Magnetic Methods, Satellite*, Figure 1). Cohen and Achache (1994) went a step further and introduced a model of oceanic topography to estimate a more realistic crustal thickness in some oceanic areas; they could explain the magnetic anomalies observed over oceanic plateaus. On ocean bottoms, remanent magnetism predicted by Dyment and Arkani-Hamed (1998) explains well large magnetic signatures over superchrons in the North Atlantic and Indian oceans. Hemant and Maus (2005) synthesized these induced and remanent studies in a unique model in order to predict the lithospheric magnetic field anomalies at the altitude of the CHAMP satellite and could show that our understanding of the Earth's magnetic lithosphere was statistically reasonable.

Following the same scheme, the magnetic crustal thickness can be estimated by trials and errors by iterative comparisons between such predicted anomaly fields with real satellite magnetic anomalies. The solution shown in Figure 3 provides an estimate of the magnetic crustal thickness of the continents, thus a statistical estimate of the Curie depth (Purucker et al., 2002). The magnetic lithosphere is bounded at depth by temperatures and the magnetic crust can be related to thermal processes. Such picture shows, for instance, that despite a thick crust under the Tibetan plateau, the magnetic crust is there thinner because of enhanced heat flows. To some extent, the average heat flow (Fox Maule et al., 2005) may be estimated from the magnetic crustal thickness. However, it requires simplifying assumptions about the thermal state of the continental crust and a starting model to constrain the longest wavelengths of the lithospheric field, in excess of SH degree 15 (~2,900 km), which are difficult to assess because they are dominated by core field processes as is shown in Figure 1.

Quantitative interpretations of magnetic anomalies are thus possible although non-unique. Unfortunately, there is currently no alternative between analyzing aeromagnetic data assuming planar geometries and studying satellite data using spherical harmonics and equivalent dipole techniques. This lack of joint processing is explained by the poor compatibility between near-surface data and satellite data.



Magnetic Anomalies, Interpretation, Figure 3 Estimation of the world magnetic crustal thickness of continents from the magnetic anomaly map based on satellite data (After Purucker et al., 2002; Mollweide projection).

Summary

On Earth, a magnetic anomaly is defined with respect to the core and external fields. Magnetic anomaly maps give the essence of the crustal magnetic field that in turn provides useful geological information about the magnetization of rocks in the subsurface. Characterizing the anomaly field and depicting all spatial dimensions is not simple as data processing leading to anomaly maps differ with altitudes and epochs. Nowadays, the main sources of discrepancies are the rapid temporal changes of the external magnetic field that are poorly understood. The lack of data at intermediate altitudes is the main impediment to the reconciliation between near-surface and satellite-based anomaly maps. There is indeed little overlap between the wavelengths measured by satellite and airborne surveys and even between the communities involved in their analysis. Current efforts are being made to reprocess ancient aeromagnetic and marine data, and to acquire unprecedented high-resolution magnetic data. This should ultimately provide us with a complete view of the magnetic crust and thus prompt for novel joint analysis techniques.

Magnetic data processing

Definition

Magnetic data are measurements of the magnetic field (generally of its intensity). Corrections of magnetic data are processing operations designed to remove unwanted features in the data. Enhancements of magnetic field data are processing operations designed to preferentially accentuate the expression of a selected magnetization at the expense of others.

Introduction

Measurement of the earth's magnetic field is used in exploration geophysics as a remote-sensing method to investigate subsurface distributions of magnetization (see *Magnetic Methods, Surface*). The measurements require correction to eliminate artifacts and to remove the primary core field of the earth, thereby improving the expression of local field variations due to upper crustal magnetizations. These corrections are applied to produce clean and robust output suitable for interpretation (see *Magnetic Anomalies, Interpretation*). For specific interpretation objectives, enhancements are also applied to the data to increase the expression of selected sources at the expense of others.

The strong linkage between electricity and magnetic fields allows the development and calibration of magnetometers that supply absolute measurements of the magnetic field (see *Magnetometers*). Most processing corrections are designed to safeguard this integrity of data values and provide data suitable for input to modelling and inversion. Conversely, some enhancement operations distort the data, and care must be taken to ensure that enhanced data is not used inappropriately.

Most magnetic field measurements are of the strength of the field, termed "total magnetic intensity" or TMI. Although these measurements are commonly treated as a scalar, it is important to remember that they are the amplitude of a vector, that the direction of that vector is also significant, and that in regions of strong fields the direction may vary across the survey area. The second most common form of magnetic field measurements are gradients of TMI, acquired by simultaneous measurement with two or more TMI sensors at fixed offsets (see *Magnetic Gradiometry*). Other forms of magnetic field data include measurements of the Cartesian components of the field and of the gradient tensor. Details of corrections and enhancement change only slightly between these different types of magnetic field measurements. The mathematical derivation of many correction and enhancement operators is presented in "Potential Theory in Gravity and Magnetic Application" (Blakely, 1996) which provides an excellent basis to understand this topic. A brief review by Milligan and Gunn (1997) (http://www.ga.gov.au/image_cache/GA2486.pdf) is also useful reading.

Standard magnetic data processing corrections

Measurement of the earth's magnetic field provides a spot value at a specific time and location. Magnetic field data is recorded together with ancillary information such as horizontal position, elevation, and time, as required for processing and interpretation. Corrections of data that are specific to instrumentation are an integral part of data acquisition, and are not discussed in this topic. Common corrections in the processing of magnetic data include diurnal correction, leveling, IGRF correction, gridding, and reduction to pole.

Diurnal correction

The earth's magnetic field is continuously changing (see *Geomagnetic Field, Secular Variation*), and this clearly presents a challenge in mapping spatial variations. Temporal changes of the magnetic field during the progress of a survey are generally termed "diurnal" variation, although this name more correctly describes field variations specifically at the 24 h rotation cycle of the earth.

On normal "quiet" days the strength of the geomagnetic field varies across a range of approximately 50–100 nT. The amplitude and pattern of diurnal variation are functions of latitude, but vary sufficiently day to day that they must be measured at a fixed base station for subtraction from the field data. Surveys presenting the greatest challenges for diurnal correction are marine surveys away from suitable locations for a base station or that including substantial lateral variation in bathymetry or crustal conductivity (which influence diurnal variation through secondary induction fields). If a simple diurnal correction is insufficient, a spatial function can be generated from a distributed network of base stations incorporating time shifts according to the longitude of the base stations and the survey measurements.

There are also periods of rapid, high-amplitude variations in the magnetic field termed "magnetic storms" which follow periods of high sun spot activity. It is not feasible to accurately correct for field variations during magnetic storms, and surveys are generally suspended during these periods.

Network adjustment (leveling)

Most magnetic field measurements are made sequentially from platforms moving along a profile. In particular, airborne magnetic surveys are generally flown on parallel, equally spaced flight lines (see *Magnetic Methods, Airborne*). To reduce errors arising from imperfections in diurnal correction, and to compensate for any residual platform heading effects, a subset of lines, termed "tie lines," is flown perpendicular to the main flight line direction, at a spacing typically five or ten times larger than for the flight lines. The purpose of the tie lines is to provide a set of intersections with the flight lines that can be used for network adjustment or "leveling" of the data. Network adjustment progressively changes base levels, gradients, and curvatures of individual lines and line segments to minimize the misfit of flight line and tie line measurements across the network of intersection points. Leveling errors are primarily manifest as sharp field variations along the axes of the flight lines.

Micro-leveling

The standard network adjustment of data is an empirical, least-squares optimization which leaves residual errors. Micro-leveling or "de-correlation" is a grid-based filtering process designed to attenuate residual level shifts between adjacent lines. These features are recognized as being parallel to the flight line direction and having a spacing related to the flight line spacing. Any valid magnetic field variations with similar characteristics will also be attenuated by micro-leveling (although any features parallel to the flight line direction are always of uncertain validity and difficult to interpret). Micro-leveling commonly has the objective of attenuating noise which becomes evident in the sun-shading of images, or to smooth "herring-bone" patterns in contour lines. Micro-leveling is also used to precondition data for subsequent enhancements that would otherwise include strong expressions of these residual leveling errors. Micro-leveling improves the quality of images of the magnetic field, but it also produces poorly controlled attenuation of the amplitude of field variations, and should not be used for modelling and inversion studies.

Elevation correction

Absolute elevation values are much less significant in magnetic field data processing than in gravity data processing (see *Gravity, Data to Anomalies*). The IGRF definition (see *Geomagnetic Field, IGRF*) includes elevation terms, but these only become significant over ranges much more substantial than those encountered in almost any survey. More significant to the information content of magnetic field data is the elevation separation between the sensor and the shallowest magnetic sources. For this reason, airborne surveys are commonly flown on drape surfaces at a nominal terrain clearance. Rugged terrain clearly increases the problem of drape flying, and rugged areas are best flown on a compromise, smooth drape surface to reduce abrupt elevation steps from line to line. Rugged terrain also poses problems for leveling of data because of difficulties in achieving identical elevations on flight lines and tie lines at each intersection point. The most effective way to correct for these elevation differences is to re-project data from the sensor elevation onto a suitable smooth drape surface by using a set of equivalent sources (Dampney, 1969; Emilia, 1973) to invert the data, and then forward computing the field from those sources onto the reference surface.

Terrain correction, used extensively in processing gravity data, is rarely applied to magnetic field data. It is unusual for terrain to have a consistent magnetization such that the magnetic field of the terrain can be derived by any simple integration. Also, the ground surface is only an effective magnetization contrast over the top of strongly magnetized bodies, and in situations of deep weathering or transported cover, the top of any strong magnetizations may be substantially beneath the ground surface. In areas of rugged terrain the influence of terrain magnetization can sometimes be recognized, but these variations are generally less than those due to variations in separation between the sensor and the terrain. Typical elevation clearance variations include lower clearance over peaks and crests than over the flanking slopes, and increased clearance over deeply incised valleys. It is generally this variation in terrain clearance which carries the danger of incorrect geological interpretation. For instance, an increase in terrain clearance causes attenuation of magnetic field expressions of shallow sources which might be misinterpreted as due to zones of alteration and partial magnetite destruction.

Each magnetic field data channel should be linked to an elevation channel. For the primary field measurements this is generally the sensor elevation determined from

GPS altitude measurements. The smooth drape surface derived or implicit in leveling the magnetic field data is the effective elevation of that data for any modelling or inversion. With some airborne magnetic data no elevation channel is supplied, and in these cases, the best option is to derive a synthetic elevation channel by interpolating the ground elevation (e.g., from SRTM data) onto the lines, adding the nominal terrain clearance reported for the survey, and then low-pass filtering. Another situation sometimes faced by an interpreter is to have only radar altimeter data available. The radar altimeter can be added to the terrain channel to recover sensor elevation, but before doing this, the radar data should be carefully inspected, as it may contain short-wavelength noise which needs to be smoothed, and possibly spikes or abrupt steps which must be eliminated.

De-culturing of magnetic field data

The expressions of man-made features in magnetic field data used for geological studies are termed "cultural" anomalies, and the process of removing these anomalies is termed "de-culturing" the data. Anomalies may be recognized as being man-made by their sharpness, indicating that they are distinctly shallower than other field variations in the area, by distinctive characteristics, or by correlation with mapped man-made features. Automated search algorithms can be used to scan data for possible cultural anomalies, but generally removing cultural anomalies is an interpretive, labor-intensive effort. Removal of cultural features is best done from the primary data. More general removal of sharp variations in the data is known as "despiking."

Gridding of magnetic field data

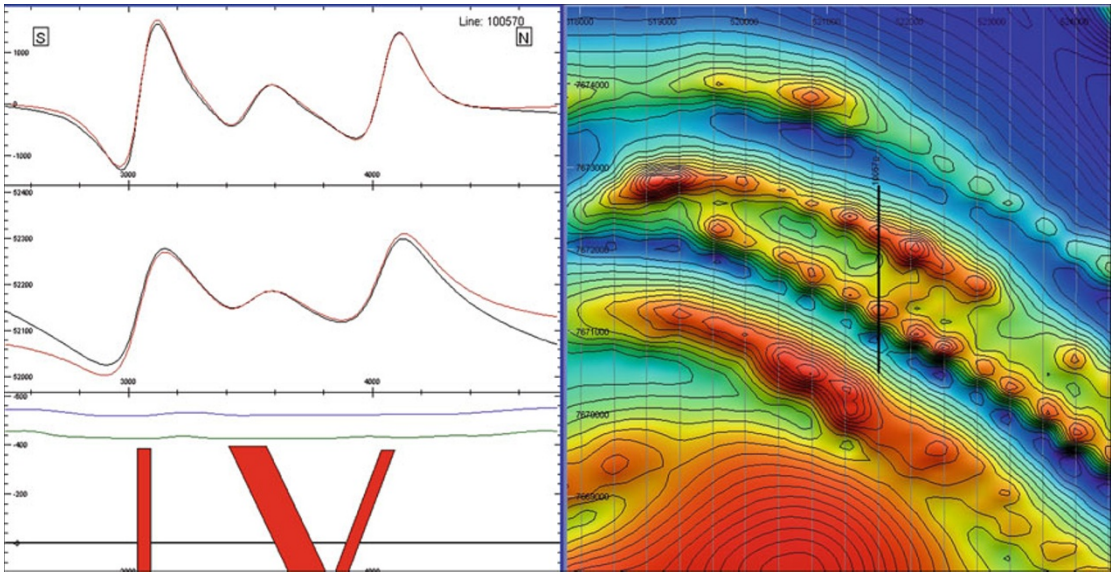
Operations through to leveling of the magnetic data are performed on the primary located data, and key channels are appended to the data so that changes can be tracked through the processing sequence. Once data has been levelled, the next process is generally to grid the data. Gridding is not a correction process, but is crucial to all subsequent processing, enhancement, display, and interpretation. Gridding interpolates the data from the measurement locations to nodes of a regular mesh, creating a new and fundamentally different construct of the data. Magnetic field data is generally gridded using minimum curvature operators to cell sizes of 1/4 or 1/5 of the line spacing. Minimum curvature operators (Briggs, 1974; O'Connell et al., 2005; O'Connell and Owers, 2008) are generally implemented as multi-pass functions with control parameters which can be modified to adjust to different data sets. Minimum curvature is an appropriate imposition on magnetic field data as the magnetic field is continuous with continuous derivatives. More sophisticated gridding algorithms, such as anisotropic diffusion (Smith and O'Connell, 2005), can also be justified as supplying superior interpolation of the field, but minimum curvature is the current industry standard and is adequate in most situations. Gridding breaks down most readily for sharp anomalies due to small, shallow sources. For surveys of regular flight line orientation and spacing, this can occur either where the magnetized unit is particularly shallow or where it trends oblique to the flight line direction. In these situations, the anomaly due to a continuous magnetic unit may break down to a "string of pearls" or "bicycle chain" pattern (Figure 1) because of the insufficiency of the gridding algorithm to interpolate that sharp field curvature from one flight line intersection to the next. These artifacts restrict the use of sun-shading to highlight subtle features in the data and must be removed prior to any attempt to highlight those details by subsequent enhancement processing. These gridding artifacts can be attenuated by re-gridding at a coarser cell-size, or by using a redesigned gridding operator to produce a smoother, lower curvature grid. Interpretation of the depth to the top of a magnetic source is based primarily on the sharpness of curvature of magnetic field variations, and limitations in preserving the sharpest gradients through the gridding process mean that depths estimated from inversion or modelling of grid data may be overestimated, particularly for shallow sources.

IGRF correction

Across survey areas of length several tens of kilometers or more, variations in the earth's primary field may contribute significantly to the measured field variations. In order to emphasize more local field variations due to crustal sources, the International Geomagnetic Reference Field (IGRF), a global model of the earth's magnetic field, is subtracted from the measured data. The IGRF is not a separation of field components from specific sources, but the long wavelength IGRF terms represent mostly core components and broad, lower crustal magnetizations. The IGRF is defined and published by the International Union of Geodesy and Geophysics (IUGG). The 11th generation model released in 2009 (http://www.ngdc.noaa.gov/IAGA/vmod/igrf.html) contains coefficients of degree and order 1–13. (See also entry *Geomagnetic Field, IGRF*).

Reduction to pole (RTP) transform

The external field of a magnetic body varies substantially as a function of the local geomagnetic inclination (see *Magnetic Anomalies, Interpretation*). The simplest relationship between the magnetic field and source magnetizations occurs at the geomagnetic poles where the field orientation is vertical (see *Geomagnetic Field, Global Pattern*). At the geomagnetic poles, induced anomalies due to steeply dipping bodies are essentially positive and are centered above the bodies. The reduction to pole transform is a fast Fourier transform (FFT) filter applied to replicate the field variations expected in a vertical field. The RTP transform is unstable when applied to low geomagnetic inclination fields (this is generally perceived to be a problem at inclinations of less than 30°). The severity of the problems depends on data quality



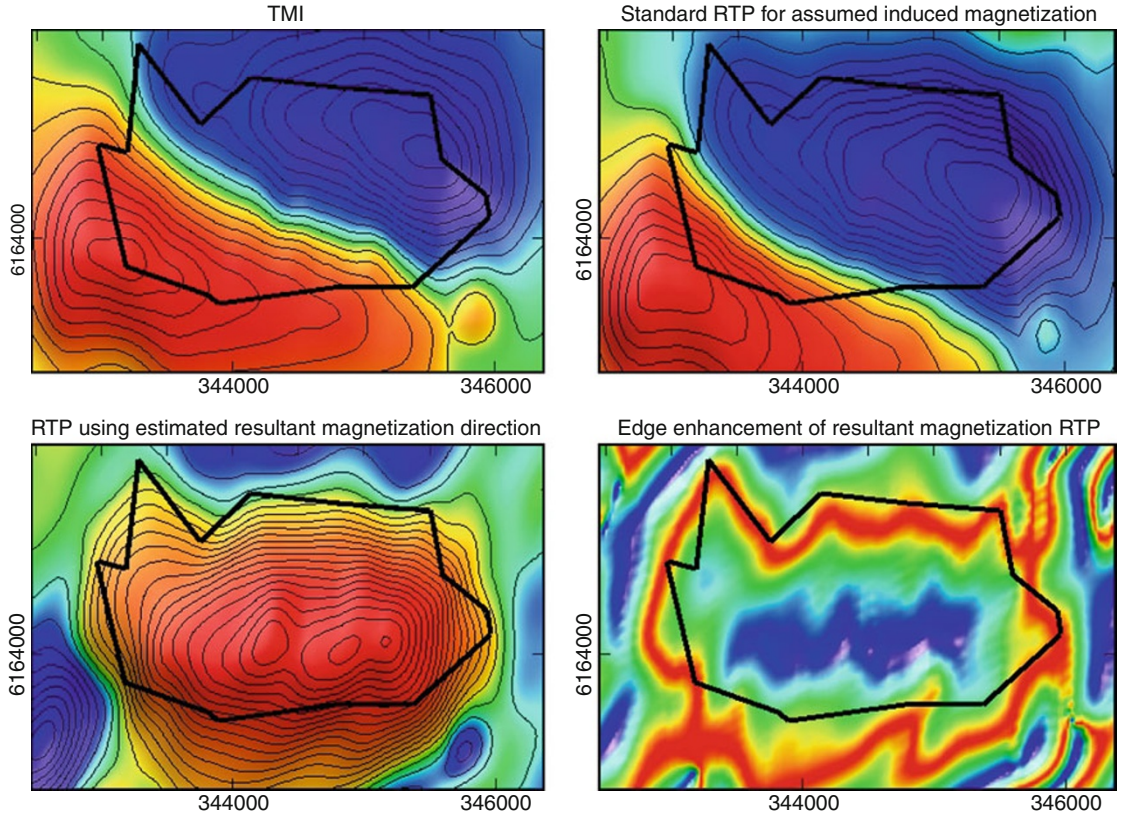
Magnetic Data Enhancements and Depth Estimation, Figure 1 Example aeromagnetic profile over a synclinal fold in the Frew River area of the Northern Territory of Australia (data courtesy of the Northern Territory Geological Survey and Geoscience Australia). The TMI image on the right shows a "string of pearls" pattern. The top track of the profile data on the left shows a vertical derivative enhancement of the measured TMI (*black*) and model computed TMI (*red*). The model shown below was generated by inversion to match these filter enhancements. The mismatch of the measured and model computed TMI in the center track requires addition of a background or "regional" field. The filter enhancement provides higher resolution for the inversion than is available from the primary TMI data.

and sufficiency of sampling, and these problems arise in particular with any apparent North–South trending features in the data. Several methods can be used to overcome low inclination RTP problems, as reviewed by Li (2008). In one approach, the RTP filter can be distorted to reduce the instability. The output of the transform is not strictly valid, but may have the desired characteristics of a steep inclination field. Another approach is to use an equivalent source technique (Guspi and Novara, 2009). The reduction to equator (RTE) transform also provides a partial alternative to RTP at low geomagnetic inclinations. The RTE transform shifts anomalies North–South to be directly above the source magnetizations, but the East–West elongation which is a natural characteristic of anomalies at low geomagnetic inclinations will be slightly amplified. Note that RTP or RTE transforms should not be used in modelling or inversion studies, as forward modelling algorithms readily incorporate the local geomagnetic field direction (although RTP images may help to approximately locate bodies in starting models).

The commonly used RTP transform requires that the direction of magnetization be in the local direction of the geomagnetic field, and for bodies with substantial remanent magnetization (see *Remanent Magnetism*) in a different direction this transform is invalidated. If however the resultant magnetization direction (the vector addition of induced and remanent magnetizations) is known from palaeomagnetic studies, magnetic moment analysis (Helbig, 1963; Schmidt and Clark, 1998; Phillips, 2005), or inversions of the magnetic field data, then an alternative RTP operator can be used which allows for separate specification of the geomagnetic field and the magnetization direction (Figure 2). All FFT filters have potential pitfalls, in part because of the fundamental assumption that the fields repeat infinitely beyond the sampled area. The FFT transform requires some processing to address level shifts between opposite edges of the sample area, and to pad the sample area with a smooth extrapolation. However well this is done, the output around the margins of the data is less reliable than in the center. This problem is of particular concern with the RTP transform, especially at the northern and southern edges of the data, and for longer wavelength field variations that are migrated furthest by the RTP transform.

The pseudo-gravity transform

Gravity and magnetic fields are linked by the common fundamental theory of potential fields (see *Magnetic Methods, Principles*), as described by Poisson's relationship (Baranov, 1957). If the direction of magnetization is consistent, and if there is a constant ratio between density and magnetization, then the RTP magnetic field and the vertical gradient of the gravity field are identical. For any but the simplest geological system, there is no such reliable linkage between magnetization and density, but



Magnetic Data Enhancements and Depth Estimation, Figure 2 The *top right* image is of a TMI anomaly over the Black Hill Norite in South Australia which is dominated by remanent magnetization (data courtesy of the Department of primary Industries and Resources South Australia). The contour interval is 200 nT, and the outline is of the source body derived from a staged inversion of the TMI data using a resultant magnetization direction determined from magnetic moment analysis. The *top right* image is of a standard RTP transform using an incorrect assumption that magnetization is in the geomagnetic field direction. The *bottom left* image is an RTP which correctly incorporates the resultant magnetization direction to produce a compact, positive anomaly centered over the source body. The *bottom right* image is an edge enhancement based on the tilt filter, applied to the resultant magnetization RTP. The maximum in this filter approximately matches the edge of the computed model.

nevertheless Poisson's relationship provides a basis for converting a magnetic field to an equivalent gravity field expression. This transform includes an inverse vertical derivative operation, which amplifies the expression of longer wavelength components of the field. The pseudo-gravity transform is sometimes used to apply analysis and processing techniques developed for gravity data to the magnetic field data, but this must be done with care. For instance, the pseudo-gravity transform accentuates the longer wavelengths of the field, but if the data from a small survey area is transformed, those longer wavelengths are not sufficiently sampled.

Enhancements of magnetic data

Enhancement of magnetic field data applies to any operation designed to highlight field variations due to a selected source of magnetization. These operations include application of various filters and also selection of display options such as histogram normalization and sun-shading.

Image display of magnetic field data

The display of magnetic field data is not an operation in the sense that it changes values of the data, but nevertheless it is highly significant in determining how the data is perceived, and how easily geological information can be recovered from it. Magnetic field data generally has much sharper variations than gravity data across the same area, with much of the amplitude range in only a small subset of the data. For this reason, magnetic field data is often displayed using a histogram equalized color stretch, devoting equal areas of the image to each color band. This form of imaging provides a much improved representation of detail across the complete range of the data. Histogram equalization does however have the drawback that it is difficult to appreciate the true amplitude range of features or to compare the relative amplitudes of different features.

Another important enhancement tool in image display is the use of sun shading. This process involves the addition of shadows and highlights to an image to mimic the illumination of the data surface by a light source. These highlights and shadows reveal features of shorter wavelength and more subtle amplitude variation than can be easily recognized in the color mapping of the amplitude values. With a vertical light source, the highlights appear along the axes of minima and maxima. However, light sources are generally set to moderate or low inclinations to produce a stronger, directional enhancement of features trending perpendicular to the illumination direction. Illumination applied parallel to the flight line direction minimizes the expression of any residual leveling errors.

Vertical continuation of the field

The amplitude of a magnetic field above a source varies with elevation as an exponential function of wavelength. This relationship can be readily exploited with FFT filters to recompute the field at a higher elevation ("upward continuation") or lower elevation ("downward continuation"). Upward continuation attenuates the field through an increased separation from the magnetization. Conversely, downward continuation towards the source or sources amplifies field variations. Upward continuation is inherently stable and acts as a smoothing filter, whereas the amplification of field variations due to downward continuation becomes unstable at depths approaching the source depth, or shallower if there is any shorter wavelength contamination of the data. Vertical continuation of a magnetic field is an enhancement filter because it preferentially accentuates the fields due to sources of different elevation. Methods, including equivalent source computations can be used for continuations in which the input and/or output surfaces are irregular (Hansen and Miyazaki, 1984; Pilkington and Urquhart, 1990). Upward continuation is useful for attenuation of fields from shallow magnetizations to focus on deeper sources, as the effect of the filter can be properly compensated by changing the elevation at which the model field is computed.

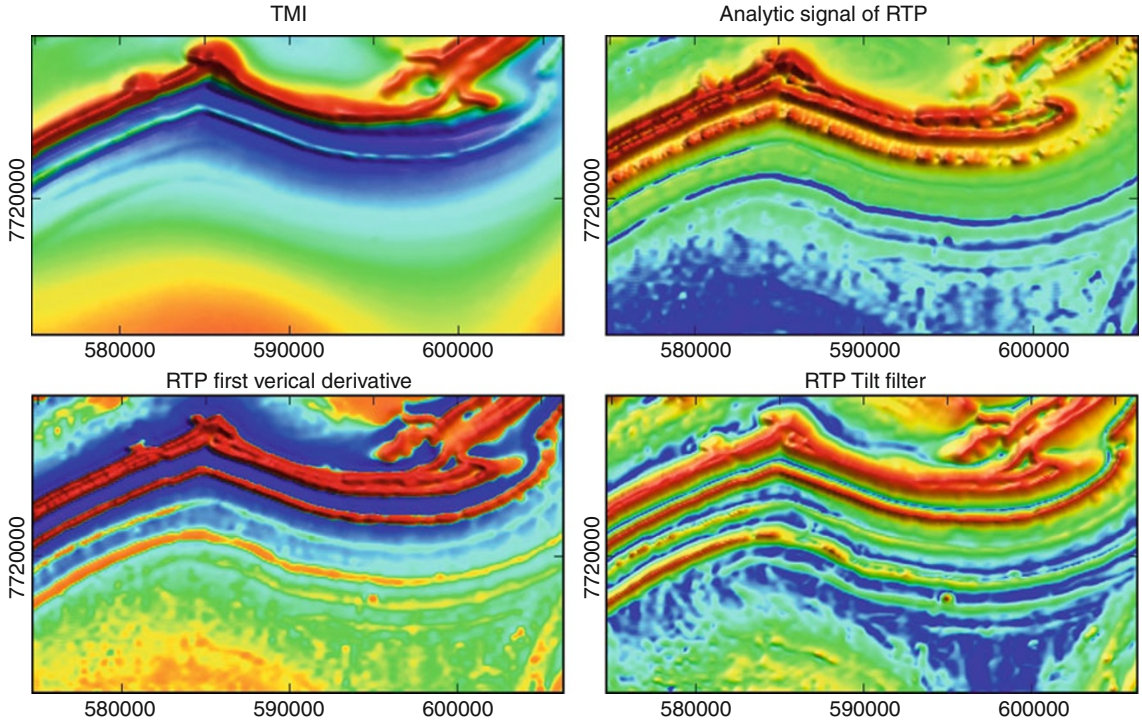
Vertical gradients of the field

Vertical gradient (or alternatively named "vertical derivative") filters preferentially amplify short-wavelength components of the field at the expense of longer wavelengths (Figure 3). Vertical gradient filters are generally applied to gridded data using FFT filters, and are therefore influenced by the characteristics of the gridding operator. Vertical gradient filters can also be applied to profile data on the assumption that the horizontal gradient measured along the profile is the only horizontal gradient. In some cases, this is a poor approximation, but for highly elongate anomalies, and with profiles approximately perpendicular to those anomalies, the approximation may be acceptable. If, furthermore, the magnetic sources are shallow compared to the line spacing of the survey, then there may be considerably more short-wavelength detail in the profile data than can be preserved through the gridding process. Vertical gradient profile filtering can be used to retain and enhance the shortest measured wavelengths during modelling and inversion by matching the outputs of the filter applied identically to the measured and computed fields (Figure 1). The second vertical derivative is a more extreme enhancement of a magnetic field. As such, it provides a more distinctive amplification of fields from shallow sources, but simultaneously is more sensitive to any short-wavelength artifacts in the data. In the event that a derivative of the field unacceptably accentuates noise or shallow magnetizations, the data can be preconditioned with a mild upward continuation before applying the derivative filter.

Bandpass and matched filters

The general relationship between depth of a source and the wavelength of its magnetic field can also be exploited to enhance the expression of sources from particular depths through bandpass filtering. Short-wavelength field variations can only be generated by shallow sources, so high pass filtering attenuates the expression of deep sources, and conversely, low pass filtering tends to attenuate the expression of shallow sources. However, bandpass filters rarely, if ever, provide a comprehensive separation of magnetic fields from different sources, so their outputs are not suitable for modelling or inversion studies (unless the identical filter is applied to the forward computed model fields).

The power spectrum display of a magnetic field commonly consists of segments which approximate to straight lines, the slope of which may be a function of the depth to the assemblage of sources whose field contributions dominate that part of the spectrum (Spector and Grant, 1970). The inspection of a power spectrum can support selection of cutoff wavelengths for bandpass filtering, with the taper of the filter also very important. Filters should not truncate abruptly nor should they target too narrow a band of wavelengths. Size, shape, and depth extent of bodies also strongly influence their magnetic field power spectrum, and the analysis by Spector and Grant is valid only statistically and for an assemblage of bodies. With some bandpass filtering, the transform back into the space domain has been claimed to localize fields from sources at particular depths, with terms such as "depth slice" and "pseudo-depth slice." These filters may produce images which are useful for interpretation, but any claims that they effectively invert the magnetic field data to supply a 3D mapping of magnetization are untenable. Nor does fitting a straight line to a segment of a power spectrum prove the effective wave-number separation of field contributions from sources at any particular depth, as implied by classifying these filters as matched filters. The combination of spectral characteristics and spatial localization supplied by wavelet processing (see *Wavelet Analysis*) promises considerable advantages over FFT methods,



Magnetic Data Enhancements and Depth Estimation, Figure 3 (All images are histogram equalized). The *top left* image shows TMI over the Frew River area of the Northern Territory of Australia (data courtesy of the Northern Territory Geological Survey and Geoscience Australia). The *bottom left* image is of the vertical gradient of TMI. This enhancement reveals weak anomalies across the center of the image which are poorly imaged in the TMI data. The *top right* image is the modulus of the analytic signal, which also enhances the expression of shallow magnetizations. The tilt filter image in the lower right is the most extreme enhancement and provides the best expression of weak, near-surface magnetizations across the lower gradient southern half of the area.

and some wavelet processing methods are now being used, particularly for localizing edges of magnetization in multi-scale edge detection.

Regional-residual separation

Potential fields are additive, and the magnetic field near the surface of the earth generally contains contributions from multiple crustal magnetizations. Separation of field variations from different sources is interpretive and nonunique, with no general analytic solution. One class of field separations is to remove local features of sharp curvature in the field ("anomalies" or "residuals") from broader, lower curvature variations due to deeper or more distant sources (the "regional"), a process termed "regional-residual" separation. Regional-residual separation is most reliably performed in cases for which the fields to be separated have quite different characteristics; if the characteristics of the fields are similar, their separation becomes more interpretive and less certain. Regional fields are also due to geological structures, but which are too deep or distant to be of immediate interest in a specific project. For modelling studies, the regional separation should be adjustable during the modelling, as a better realization of this separation emerges as the model is developed.

The modulus of the analytic signal

The modulus of the analytic signal (Nabighian, 1972, 1984; Roest et al., 1992; Hsu et al., 1996), commonly referred to simply as the analytic signal, is a popular gradient enhancement, given by:

$$\text{analytic signal of TMI} = \sqrt{\left((\partial \text{TMI}/\partial x)^2 + (\partial \text{TMI}/\partial y)^2 + (\partial \text{TMI}/\partial z)^2\right)} \quad (1)$$

For compact or thin bodies, the modulus of the analytic signal peaks approximately over the center of the body (Figure 3), for wider bodies over their edges. It is only weakly sensitive to magnetization direction, and indeed the two-dimensional case with only one horizontal gradient is independent of magnetization direction. The modulus of the analytic signal of TMI has much lower sensitivity to the inclination of the geomagnetic field than the original TMI data, and provides a means to analyze low latitude magnetic fields without the concerns of the RTP operator (Macleod et al., 1993; Rajagoplan, 2003). Source parameters such as depth can be estimated from statistics of the filter output, but these more advanced applications are more appropriately classified as interpretation, rather than enhancement processing.

The tilt filter

The tilt filter (Miller and Singh, 1994; Dentith et al., 2000; Verduzco et al., 2004; Salem et al., 2008) has also become a popular enhancement with an output given by:

$$\text{Tilt of TMI} = \tan^{-1}\left(\frac{\frac{\partial \text{TMI}}{\partial z}}{\frac{\partial \text{TMI}}{\partial h}}\right) \quad (2)$$

where

$$\partial \text{TMI}/\partial h = \sqrt{\left((\partial \text{TMI}/\partial x)^2 + (\partial \text{TMI}/\partial y)^2\right)} \quad (3)$$

As a ratio of gradients, the filter output retains no amplitude information, and the degree of enhancement of this filter is variable according to the local amplitude of the field gradients. In areas of low gradient, there is no signal to enhance, but the output of the filter is defined at all places; so it is important that tilt images be interpreted with reference to the original data (Figure 3). The tilt filter and analytic signal are both expressions of horizontal and vertical gradients, and as such, there are clearly linkages between them in their tendency to amplify field variations from shallow sources, highlight the location of subvertical edges (after RTP transform), and to provide estimates of depth to magnetization contrasts according to their sharpness of variation.

Multi-scale edge detection ("worming")

Local maxima in the horizontal gradients of a magnetic field can be analyzed using wavelets as a function of the depth to magnetization, with the advantage that wavelet functions can be selected for direct compatibility with potential field characteristics (Hornby et al., 1999; Ridsdill-Smith and Dentith, 1999; Vallée et al., 2004). Multi-scale edges defined by the wavelets have some affinities to different wavelength components separated in Fourier analysis, with the detail from shallow sources mostly carried in the small-scale edges, and broader, large-scale edges providing more information about deeper sources. Multi-scale edges can also be derived from mapping the migration of maxima in the horizontal gradients of the field at different levels of upward continuation (Holden et al., 2000; Lahti and Karinen, 2010). Wavelets are intrinsically linked to the analytic signal and tilt filter gradient functions, Euler deconvolution, and to other curvature functions previously used to map source edges (Blakely and Simpson, 1986; Grauch and Cordell, 1987).

Analytic derivation of magnetic source parameters

Nonuniqueness in interpreting a distribution of magnetization from study of a measured magnetic field precludes any definitive analytic solution of this problem. However, the interface between analytical processing operations and interpretation is blurred by methods that impose either implicit or explicit conditions on the distribution of magnetization and reduce the interpretation problem to one with much more accessible and restricted solutions. The most common of the imposed conditions is that magnetized bodies have depth and strike extents that can be summarized by a structural index. This factor is linked to the curvature of the magnetic field and its attenuation with increasing source depth and therefore must be supplied or derived for estimation of source parameters.

Automatic mapping of source magnetization distributions has been one of the most prolific subjects of geophysical publication over many years, but those methods that have achieved widespread acceptance and use can mostly be classified into a small number of groupings, namely; Wener deconvolution, Euler deconvolution, the Naudy method, and the source parameter imaging ("SPI") method. The fundamental assumptions of the various methods are necessarily similar, and in many cases identical, but nevertheless there are some practical differences that might lead to advantages in applying certain methods in certain circumstances. In all cases, the key factor for successful application of automated source detection and parameter estimation is the suitability of the geology. If the geology provides discrete, homogeneous, well-separated, moderate to strong magnetizations, in simple and predictable geometries, and with an absence of any additional magnetizations that would produce overlapping field variations, then any of the automated source estimation methods should work well. If however the geology results in irregular and indistinct distributions of magnetization, then there is no basis for the successful application of any of the methods, and they can only lead to fictitious and misleading results. This leads to a common dilemma in the interpretation of any data; whether to set strict quality conditions and accept just a few solutions of apparently high validity, or whether to relax the quality conditions to generate a more comprehensive set of solutions. In practice, validity of solutions is commonly evaluated from their quality coefficients, by clustering of solutions and their internal consistency, or simply by visual inspection and judgement as to whether the magnetic field anomaly the solutions are derived from is reliable and suitable. The ability to rapidly generate source parameter estimates from automatic or semiautomatic methods is always in part offset by the time and discretion required to evaluate and interpret the reliability and usefulness of those results. All automated source depth estimators also have in common that they are dependent on the quality and sufficiency of the magnetic field data. A concise review of magnetic depth estimation methods and practical advice on their application is given by Li (2003).

The Werner method

The Werner method of automatically generating magnetic source solutions from profile magnetic field measurements (Werner, 1953; Hartman et al., 1971) is often referred to as Werner deconvolution. It is not a true deconvolution, but solves for simple geological structures by solution of linear equations applied to profile data

sampled within a moving window. The equations are specified for bodies of nominated structural index. Ku and Sharp (1983) developed a two-stage approach in which the Werner solutions were subsequently submitted to a Marquardt inversion. Hansen and Simmons (1993) extended the Werner method by adapting it to run on an analytic signal transform of the data, and to detect and solve for multiple sources, and Hansen (2005) extended the Werner method to a three-dimensional multiple source analysis.

The Naudy method

The Naudy method (Naudy, 1971) is an elegant approach to finding and solving for magnetic sources from analysis of profiles of magnetic field data. As a window is moved along a magnetic field profile, the data is split into symmetric and asymmetric components about the center of the window. Firstly, the reference anomaly is computed for a target body of the nominal type and specified properties (primarily depth) and a correlation coefficient is derived between that target curve and the processed field data curves. A coefficient value beyond a set threshold flags a possible solution, which is then fed to a second stage inversion process that searches for the optimum source parameters. This operation can be repeated to scan the data across a range of target depths. A key advantage of the Naudy method is that the second stage inversion supplies bodies that can then be delivered into a modelling package for more detailed testing against the data they were derived from, and as a starting model for more interpretive studies. The Naudy method has been extended by Shi (1991) to run on the vertical derivative, and by Almond and Fitzgerald (1998) to adjust for the trend of source bodies automatically estimated from accompanying grid data.

Euler deconvolution

Euler deconvolution solves for Euler's homogeneity equation within a moving window assuming that the field variation within the window is due only to a single source body with a defined value of structural index. Thompson (1982) used a one-dimensional window along a profile, and Reid et al. (1990) extended the analysis to a two-dimensional window of grid data. Sources of error are that the structural index value used may be inappropriate and that the field variation within the window may be due to more than one source, and, as a consequence, the solutions themselves require interpretation. There have been numerous adaptations of the method to try to estimate the appropriate structural index for each solution (e.g., Barbosa et al., 1999) and also to analyze clusters of solutions (e.g., Silva and Barbosa, 2003; Ugalde and Morris, 2010). Euler deconvolution has also been extended to application with the modulus of the analytic signal (Salem and Ravat, 2003; Keating and Pilkington, 2004; Florio et al., 2006) and to solution for multiple sources (Hansen and Suciu, 2002). Other implementations of the Euler homogeneity equation to derivatives of the magnetic field that derive structural index as an integral part of the analysis are termed "extended" Euler methods (Mushayandebvu et al., 2001; Davis et al., 2010). Nabigian and Hansen (2001) have shown that the extended Euler method is a unification of Euler deconvolution and the Werner method. Thurston and Smith (1997) applied Euler's homogeneity equation to expressions of the complex analytic signal in a method termed source parameter imaging (SPI) which recovers source estimates for dipping 2-D contacts and dipping 2-D thin sheets from gridded magnetic field data. This method was further extended to include horizontal cylinders and automatic discrimination between different source models by Smith et al. (1998). These hybrid methods benefit from relationships discussed for simple analytic signal and tilt filter transforms as discussed in the section above on enhancement of magnetic field data, but these methods also require recovery of higher derivatives of the magnetic field, and ultimately it is the validity of those higher derivatives in the presence of noise and processing artifacts that determines the usefulness of these sophisticated methods.

Summary

A substantial toolbox of methods exists to process and enhance magnetic field data, and these capabilities are continuously being extended as computing power and speed increase. Most of the methods require careful inspection of the data to select optimum parameters and to detect any undesirable characteristic in the outputs. Enhancement operations, in particular, are selected and designed for a specific interpretational objective, and different enhancements can be applied to the same data for different objectives. Operations such as gridding and visualization are an integral part of processing and enhancement, and also require careful attention to avoid misrepresentation of data. There is an arbitrary delineation between methods such as multi-scale edge detection, which is described here as an advanced enhancement, and automatic depth estimators, such as Euler deconvolution, which attempt a marginally greater level of discrimination and represent a transition into interpretation. The current trend of automatic source depth estimation is towards ever greater sophistication using high-order derivatives of the field, but these methods place ever greater stress on the validity of the data, such that the derived parameters require careful evaluation.

MAGNETIC DOMAINS

Susan L. Halgedahl

Definition

Magnetic domain. A magnetic domain is a region in which the magnetic spins of atoms or molecules are aligned. Many magnetic particles consist of two or more magnetic domains, each of uniform magnetization separated by narrow zones called domain walls, in which the spins change orientation from one domain to the next.
NRM (natural remanent magnetization). The magnetic moment (per unit volume of per unit mass) acquired by a rock in nature.
TRM (thermal remanent magnetization). The magnetic moment acquired by a rock as it cools from the Curie temperature in the Earth's field.

Introduction

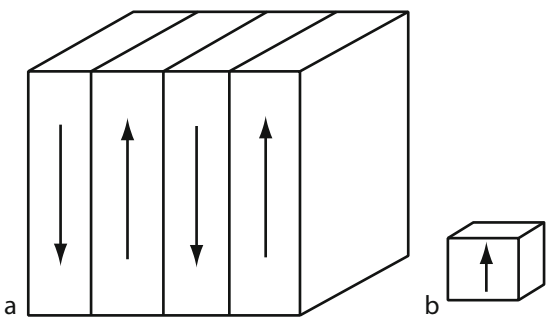
The existence of a paleomagnetic record attests to the ability of magnetic minerals in rocks to preserve their natural remanent magnetizations over geologic time. The building block of *Remanent Magnetism* is the magnetic domain, a region where the magnetic spins are aligned in the same direction. In the early days of paleomagnetism, it was thought that the stable components of natural remanent magnetization (NRM) mainly resided in extremely small magnetic mineral grains that occupied the single-domain (SD) state. However, it is now recognized that, due to their very small size and scarcity, SD particles may not be the major carriers of NRM in many rocks. Instead, it is more likely that much of NRM is carried by grains that, by virtue of their larger sizes, are subdivided into several domains (Figure 1). Adjacent domains are separated by domain walls, the transition regions where magnetic spins change direction from one domain to the next.

Remanences carried by SD assemblages can be highly stable, because destroying the remanence requires rotation of the particles' magnetic moments across strong energy barriers. In contrast, remanences carried by particles with two or more domains usually owe their stability to pinning of walls at crystal defects; these energy barriers are overcome more easily than those controlling SD grains. But another necessary criterion for paleomagnetic stability over geologic time is that a grain's overall domain state resists drastic reorganization caused by the changing physical/chemical conditions affecting the rock, such as moderately elevated temperature, moderate pressure, and some chemical alteration. For this reason, we discuss both theories and experiments to investigate how domain structure depends on grain size, applied field, and temperature in natural magnetic minerals and their synthetic analogues. (See detailed treatments of these subjects in standard texts such as Chikazumi (1964), Cullity (1972), Stacey and Banerjee (1974), and Dunlop and Ozdemir (1997)).

Classical Models of Magnetic Domain Structure

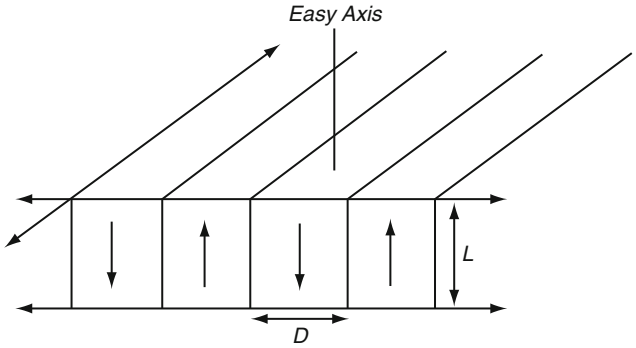
Exchange Energy

Models of magnetic domain structure are based on three energies: exchange energy, anisotropy energy, and magnetostatic energy. Magnetostatic energy is the fundamental reason why particles subdivide into two or more domains because, in so doing, this energy is reduced. However, this



Magnetic Domains, Figure 1 Illustrations of (**a**) a multidomain cube containing four domains and (**b**) a single-domain cube of uniform magnetization.

subdivision carries an energy "price": the energy of domain walls. In most classical theories, the first two energies above make the largest contributions to the surface energy of the wall. From seminal calculations, Heisenberg (1928) predicted the existence of the exchange interaction, which determines whether adjacent magnetic spins are aligned parallel or antiparallel with respect to each other in a specific substance. In a relatively few materials, this interaction leads to a configuration of lowest energy when neighboring spin vectors are aligned. This gives rise to the rare phenomenon of spontaneous magnetization (M_s) and magnetic remanence. Such materials possess a Curie temperature, above which spontaneous magnetism vanishes, because (a) thermal agitation disrupts the alignment of adjacent spins, and (b) thermal expansion of the lattice increases spin–spin distances and thus weakens the exchange interaction.



Magnetic Domains, Figure 2 Illustration of the semi-infinite, magnetized plate of thickness *L*, whose magnetostatic energy was calculated by Kittel (1949). The plate contains domains of identical width *D*, with magnetizations perpendicular to the plate's surface. Walls are assumed to be infinitely thin.

Magnetic anisotropy energy

Magnetic anisotropy causes magnetic behavior to depend on the direction in which it is measured. In magnetite, for example, magnetocrystalline anisotropy results in a lower external field being required to saturate a crystal along the <111> directions than along <100>. Magnetocrystalline anisotropy arises from the coupling between spins and orbits of the electrons, so that work is required to rotate spins out of the directions of lowest energy ("easy" directions). "Easy" and "hard" directions depend on the specific material and its crystal structure. In cubic materials such as magnetite, the easy directions are along <111>, whereas in iron <100> are easy directions (e.g., for more comprehensive discussions, see Chikazumi (1964); Cullity (1972)).

Also due to spin-orbit coupling, the lattice of a ferromagnetic material will spontaneously strain below the Curie temperature. The inverse effect is that external stress and/or variable internal strain can rotate the spontaneous magnetization away from the easy direction given by crystalline anisotropy. Depending on the material and the stress direction, applied stress may cause M_s to rotate either toward the stress axis or toward the direction perpendicular to the axis of stress.

Magnetostatic energy

Magnetostatic energy is the work, per unit volume, required to assemble a population of magnetic "free poles" into a particular geometric configuration. A simple but highly relevant case was addressed by Kittel (1949), who analyzed a semi-infinite plate of thickness L containing lamellar domains of uniform width D, with spontaneous magnetizations normal to the plate surface (Figure 2). Kittel obtained $E_m = 1.705\ M_s^2 D$, where E_m is the magnetostatic energy, per unit area of plate surface (erg/cm^2, in cgs). Kittel's calculations were refined by Rhodes and Rowlands (1954), who addressed finite, rectangular grains. Their results produced "Rhodes and Rowlands" functions, which yield the total magnetostatic energy of rectangular grains of specified axial ratios.

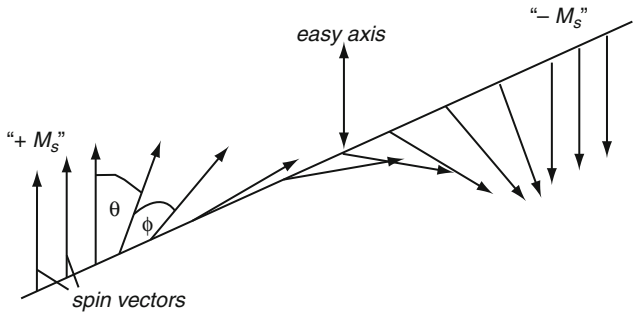
Energy and width of the domain wall

A domain wall is the transition region where the spontaneous magnetization changes direction from one domain to the next, so that each domain is distinct from a wall. (Micromagnetic theories relax this assumption and will be discussed in later.) The two most important energies contributing to the wall's energy and width are exchange energy and anisotropy energy, the latter due either to magnetocrystalline anisotropy or stress. The magnetostatic energy of the wall itself also plays a role; this energy was first analyzed by Amar (1958) and grows especially important when the wall width approaches that of the particle.

In the simplest models, spins in a wall reach an equilibrium configuration when magnetic anisotropy and exchange energies are balanced. For the 180° "Bloch" wall shown in Figure 3 in which spins rotate through 180°, the energy per unit area of wall surface is $E_w = 2\pi (AK)^{1/2}$, where K is the magnetic anisotropy constant due to magnetocrystalline anisotropy and/or stress and A is the material's exchange constant. Note that a submicroscopic change in either A or K can change the local wall energy. Such local changes constitute "wall pinning" sites, where wall motion is impeded by either an energy barrier or an energy trough. The width of a 180° wall is $\delta_w = \pi (A/K)^{1/2}$. In magnetite, values predicted for E_w and δ_w are approximately 0.9 erg/cm^2 and 0.3 μm, respectively (e.g., see Dunlop and Ozdemir, 1997).

Domain width versus grain size

For the magnetized plate illustrated in Figure 2, domain width D can be calculated for the lowest energy state by minimizing the sum of magnetostatic and wall energies per unit volume of material; this gives the half-power law $D = (1/M_s)\ (E_w L/1.705)^{1/2}$ (Kittel, 1949).



Magnetic Domains, Figure 3 Illustration of spins in a 180° Bloch wall. θ is the angle between a spin and the easy axis of magnetization; ϕ is the angle between adjacent spins.

Magnetic minerals in rocks, however, rarely grow as thin platelets. Moskowitz and Halgedahl (1987) calculated the number of domains versus grain size in rectangular particles of $x = 0.6$ titanomagnetite ("TM60": $Fe_{2.4}Ti_6O_4$) containing planar domains separated by 180° walls. Magnetostatic energy, including that from the walls' moments, was accounted for (Rhodes and Rowlands, 1954; Amar, 1958), and it was assumed that grains occupied states of absolute minimum energy. Their calculations yielded two principal results: (1) particles encompassing a wide range of grain sizes could contain the same number of domains, and (2) a plot of N (number of domains) versus L (grain thickness) could be fitted well by a power law $N \propto L^{1/2}$. It follows that domain width D also follows a half-power law in L. Thus, the general type of functional dependence of D on L is the same for both finite, rectangular grains and semi-infinite plates.

Single-domain/two-domain transition size d_o

Grains containing only two or three domains can rival the remanences and coercivities of SD grains, and such particles are often referred to as being "pseudosingle-domain" (PSD). A particle may favor a two-domain over a SD state because the magnetostatic energy associated with two domains is much lower than that for saturation. However, below d_o the energy price of adding a wall is too great to result in a state of minimum energy. At d_o, the total energy of the two-domain state and the SD state are equal. PSD grains can be common in many rocks and, in terms of interpreting rock magnetic behavior, it is important to know the grain sizes corresponding to the onset of PSD behavior in various magnetic minerals.

This transition size depends on the material's magnetic properties, its state of stress, the particle shape, and temperature. Moskowitz and Banerjee (1979) calculated total energies of SD, two-domain, and three-domain cubes of stress-free magnetite containing lamellar domains at room temperature. Magnetostatic energy of the walls was included in their calculations (Amar, 1958). They obtained $d_o \approx 0.08$ μm. Similar calculations for TM60 by Moskowitz and Halgedahl (1987) yielded $d_o \approx 0.5$ μm for unstressed particles at room temperature. Raising the stress level to 100 MPa shifted d_o upward to 1 μm.

Domains and domain walls near crystal surfaces

In relatively thick crystals, domains and domain walls may change their geometric styles near and at crystal surfaces, in order to lower the total magnetostatic energy with respect to that of the "open" structure shown in Figure 2. The particular style depends largely on the dominant kind of anisotropy, as well as on the relative strengths of magnetostatic and anisotropy energies. When $2\pi M_s^2/K >> 1$ in a uniaxial material, prism-shaped closure domains bounded by 90° walls may completely close off magnetic flux at the crystal surface (Figure 4a). Because closure domains greatly reduce magnetostatic energy, the "body" domains can be several times broader than predicted for the "open" structure.

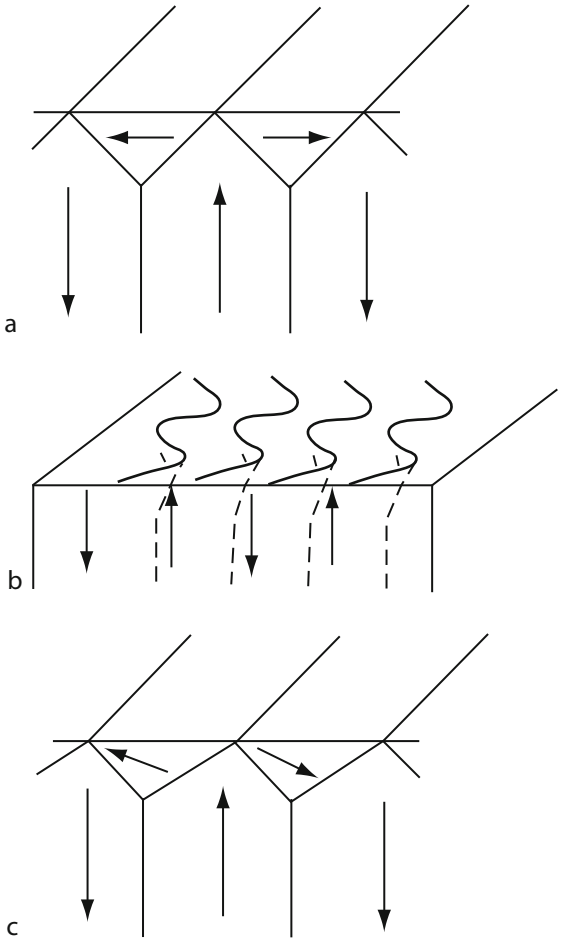
When $2\pi M_s^2/K << 1$ in a uniaxial substance, a large amount of anisotropy energy results when M_s is perpendicular to the "easy" axis, making the style of surface closure shown in Figure 4a energetically unfavorable. Instead, walls that are planar within the body of the crystal can become wavy at the surface (Figure 4b). In extremely thick crystals, wavy walls can alternate with rows of reverse spikes. These elaborate surface domain structures lower magnetostatic energy by achieving a closer mixture of "positive" and "negative" free magnetic poles (e.g., see Szymczak, 1968).

Large crystals governed by cubic magnetocrystalline anisotropy also reduce surface flux through prism-shaped closure domains at the surface. When <100> are easy directions, as in iron, closure domains are bounded by 90° walls (Figure 4a). When <111> are easy directions, as in magnetite, closure domains are bounded by 71° and 109° walls (Figure 4c).

Temperature dependence of domain structure

Understanding how domain structure evolves during both heating to, and cooling from, the Curie point is crucial to understanding the acquisition and thermal stability of thermal remanent magnetization (TRM). If the number of domains changes significantly during cooling from the Curie point in a weak field, it is reasonable to hypothesize that TRM will not become "frozen in," or blocked, until the overall domain structure reaches a stable configuration.

According to Kittel's original model (Figure 2), grains will nucleate (add) domain walls and domains with heating in zero field, if the wall energy drops more rapidly with increasing temperature than does the magnetostatic term. Energy-wise, in this first case, a particle can "afford" to add domains with heating. Conversely, during cooling from the Curie point, a grain will denucleate (lose) domains and domain walls if wall energy rises more quickly than does the magnetostatic energy with decreasing temperature. If wall energy drops less rapidly with



Magnetic Domains, Figure 4 Three styles in which domains and domain walls may terminate at a crystal surface. (**a**) Prism-shaped surface closure domains at the surface of a material which is either uniaxial, with $2\pi M_s^2/K >> 1.0$, or cubic, such as iron, whose easy axes are along <100>. Here, 90° walls separate closure domains from the principal "body" domains that fill most of the crystal. Arrows indicate the sense of spontaneous magnetization within the domains. (**b**) Wavy walls at the surface of a uniaxial material with $2\pi M_s^2/K < 1.0$. Waviness dies out with increasing distance from the surface. (**c**) Prism-shaped closure domains at the surface of a cubic material, such as magnetite, whose easy directions of magnetization are along <111>. Closure domains and body domains are separated by 71° and 109° walls.

increasing temperature than does the magnetostatic term, then the opposite scenarios apply. This predicted behavior relies on the assumptions that the particle is able to maintain a global energy minimum (GEM) domain state at all temperatures and that the total magnetostatic energy of the walls themselves can be ignored.

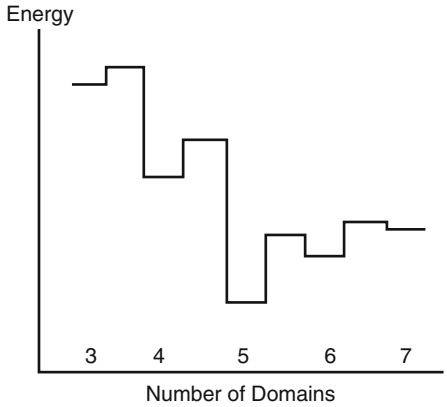
Using Amar's (1958) model, Moskowitz and Halgedahl (1987) calculated the number of domains between room temperature and the Curie point in parallelepipeds of TM60. As discussed earlier, they investigated two cases: dominant crystalline anisotropy (zero stress) and high stress ($\sigma = 100$ MPa). In TM60 grains larger than a few micrometers, most of their results gave an increase in the number of domains with heating. Exceptions to this overall pattern were cases in which walls broadened so dramatically with increasing temperature that they nearly filled the particle and rendered nucleation unfavorable. During cooling from the Curie point in zero field, the domain "blocking temperature" – the temperature below which the number of domains remained constant – increased both with decreasing grain size and with internal stress.

Micromagnetic models

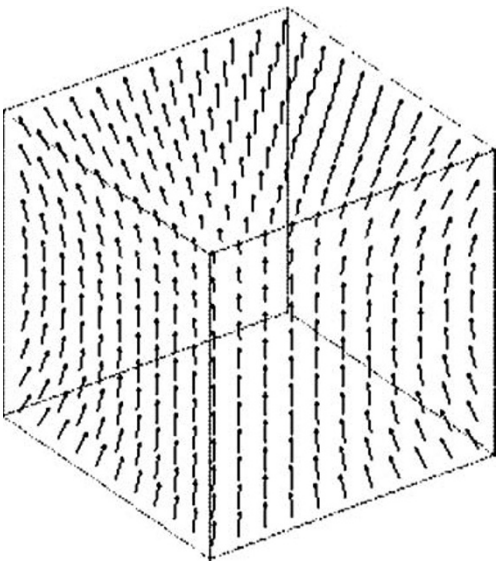
In contrast to classical models of magnetic domain structure, micromagnetic models do not assume the presence of discrete domains. Instead, they allow the orientations of M_s-vectors to vary among extremely small subvolumes, into which a grain is divided. A stable configuration is obtained numerically when the grand sum of exchange, anisotropy, and magnetostatic energies over all subvolumes is minimum. In rock magnetism, micromagnetic models have focused on magnetite, and they assume unstressed, defect-free crystals.

Moon and Merrill (1984, 1985) were the first in rock magnetism to construct one-dimensional (1D) micromagnetic models for defect-free magnetite cubes. Not only did they calculate the energies resulting from different numbers of domains within a grain of given size, but they also calculated the energy barriers associated with nucleation and denucleation of domains and domain walls. Their major breakthrough was the discovery that a particle can occupy a range of local energy minimum (LEM) domain states. Each LEM state is characterized by a unique number of domains and is separated from adjacent states by energy barriers. As illustrated in Figure 5, the GEM state is the configuration of lowest energy but, owing to the energy barriers between states, a LEM state can be quite stable as well.

Several authors have extended micromagnetic calculations for magnetite to two dimensions (2D) and three dimensions (3D) (e.g., Williams and Dunlop, 1989, 1990, 1995; Newell et al., 1993; Xu et al., 1994; Fabian et al., 1996; Fukuma and Dunlop, 1998; Williams and Wright, 1998). These models yield a variety of exotic, nonuniform configurations of magnetization, such as "flower" and "vortex" states. Analogous to Moon and Merrill's results, these models produce both LEM and GEM states, although with very different spin structures from those of 1D models. For example, Figure 6 illustrates a "flower" state in a cube magnetized parallel to the z-axis. The flower state is reminiscent of a classical SD state of uniform magnetization, except that the M_s-vectors are canted at and near the crystal surface. In relatively large cubes of magnetite – for example, 4 or 5 μm – both 2D and 3D models yield configurations closely approaching those of classical domain structures expected for magnetite, such as "body" domains and closure domains at



Magnetic Domains, Figure 5 Diagram illustrating the relative energies and energy barriers associated with local energy minimum (LEM) domain states. Each LEM state is characterized by a unique number of domains and is separated from adjacent states by nucleation and denucleation energy barriers. In this diagram, the global energy minimum, or GEM, domain state has five domains.



Magnetic Domains, Figure 6 Illustration of a "flower" state obtained through three-dimensional micromagnetic modeling of a cube largely magnetized along the cube's z-axis.

the surface (e.g., Xu et al. 1994; Williams and Wright, 1998). In submicron magnetite undergoing hysteresis, magnetization reversal can occur through LEM–LEM transitions (e.g., flower to vortex state) (e.g., Williams and Dunlop, 1995).

Dunlop et al. (1994) used 1D micromagnetic models to investigate LEM states in stress-free magnetite particles during TRM acquisition. Their study was motivated by experimental results reported earlier by Halgedahl (1991) (see discussions below). Dunlop et al. (1994) calculated the energy barriers for all combinations among SD/two-domain/three-domain transitions during cooling from the Curie point of magnetite in a weak external field. According to their results, after acquiring TRM under conditions of thermal equilibrium, populations would be overwhelmingly biased toward GEM domain states, and an individual particle should not exhibit a range of LEM states after several identical TRM runs.

Using renormalization group theory, Ye and Merrill (1995) arrived at a different conclusion. According to their calculations, short-range ordering of spins just below the Curie point could give rise to a variety of LEM states in the same particle after replicate coolings.

Experimental studies of magnetic domains

Methods of imaging domains and domain walls

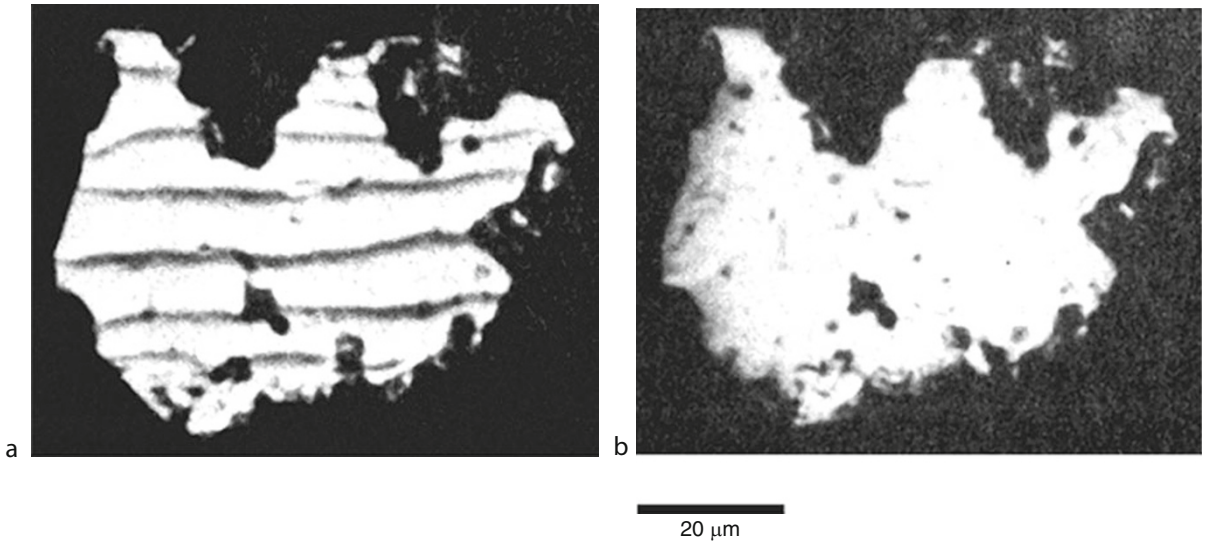
Rock magnetists have mainly used three methods to image domains and domain walls: the Bitter pattern method, which uses liquid magnetic colloid to image walls, with a resolution limit of about 1 μm (e.g., see details in Halgedahl and Fuller, 1983); the magneto-optical Kerr effect (MOKE), which images entire domains from the rotation of the polarization plane of light reflected by a magnetized specimen (e.g., Hoffmann et al., 1987; Worm et al., 1991; Heider and Hoffmann, 1992; Ambatiello et al., 1999); and magnetic force microscopy (MFM), which can image magnetic features as small as 0.01 μm through the voltage induced in a vibrating magnetic needle situated very close to a particle's surface (Williams et al., 1992; Proksch et al., 1994; Moloni et al., 1996; Pokhil and Moskowitz, 1996, 1997; Frandson et al., 2004). Two other methods – transmission electron microscopy (TEM) and off-axis electron holography – have been used in some studies of magnetite, most notably magnetotactic bacteria and magnetite intergrowths in ulvospinel (Dunin-Borowsky et al., 2001; McCartney et al., 2001; Harrison et al., 2002).

Styles of domains observed in magnetic minerals of paleomagnetic significance

In rock magnetism, the majority of domain observation studies have focused on four magnetic minerals, all important to paleomagnetism: pyrrhotite (Fe_7S_8), titanomagnetite of roughly intermediate composition (near $Fe_{2.4}Ti_6O_4$, or TM60), magnetite (Fe_3O_4), and hematite (Fe_2O_3).

Owing to its high magnetocrystalline anisotropy constant and relative insensitivity to stress, pyrrhotite behaves magnetically as a uniaxial material. When studied with the Bitter colloid method, pyrrhotite often exhibits fairly simple domain patterns which suggest lamellar domains separated by 180° walls (Figure 7a) (Soffel, 1977b; Halgedahl and Fuller, 1983).

Despite being cubic, intermediate titanomagnetites rarely, if ever, exhibit the arrays of closure domains, 71°, and 109° walls predicted from theories. Instead, these minerals often display very complex patterns of densely spaced, curved walls (Appel and Soffel, 1984, 1985).



Magnetic Domains, Figure 7 Bitter patterns on a particle of natural pyrrhotite (**a**) after demagnetization in an alternating field of 1,000 Oe and (**b**) in an apparently SD-like state after acquiring saturation remanence in 15 kOe.

However, some grains do exhibit a simple array of parallel walls, such as that shown in Figure 8a (e.g., Halgedahl and Fuller, 1980, 1981), but it is not unusual to observe wavy walls alternating with rows of reverse spikes (Halgedahl, 1987; Moskowitz et al., 1988). Both simple and wavy patterns suggest a dominant, internal stress that yields a uniaxial anisotropy, although the origin of this stress is still unclear.

Small magnetite grains grown in a synthetic rock-like matrix with the glass-ceramic method (Worm and Markert, 1987) generally display simple arrays of straight walls (e.g., Worm et al., 1991; Geiβ et al., 1996) (Figure 8b). In such samples, there appears to be a paucity of closure domains, perhaps the result of high internal stress generated by quenching during synthesis.

In contrast, domain images obtained from large crystals of natural magnetite and small magnetite grains in a variety of rocks reveal 180°, 71°, and 109° walls and closure domains, in accordance with theory (Bogdanov and Vlasov, 1965, 1966; Smith, 1980; Boyd et al., 1984; Ozdemir and Dunlop, 1993, 1997, 2006; Ozdemir et al., 1995; Ambatiello et al., 1999). Evidently, internal stress is low in these natural magnetites, so that magnetocrystalline anisotropy is dominant.

To date, domain studies on hematite have been limited to large (e.g., 100 μm to 1 mm) platelets. Even large crystals such as these contain very few walls and a fairly simple domain structure, owing to hematite's weak spontaneous magnetization (about 2 emu/cm^3) and low magnetostatic energy (Figure 8c) (Halgedahl, 1995, 1998).

Number of domains versus grain size

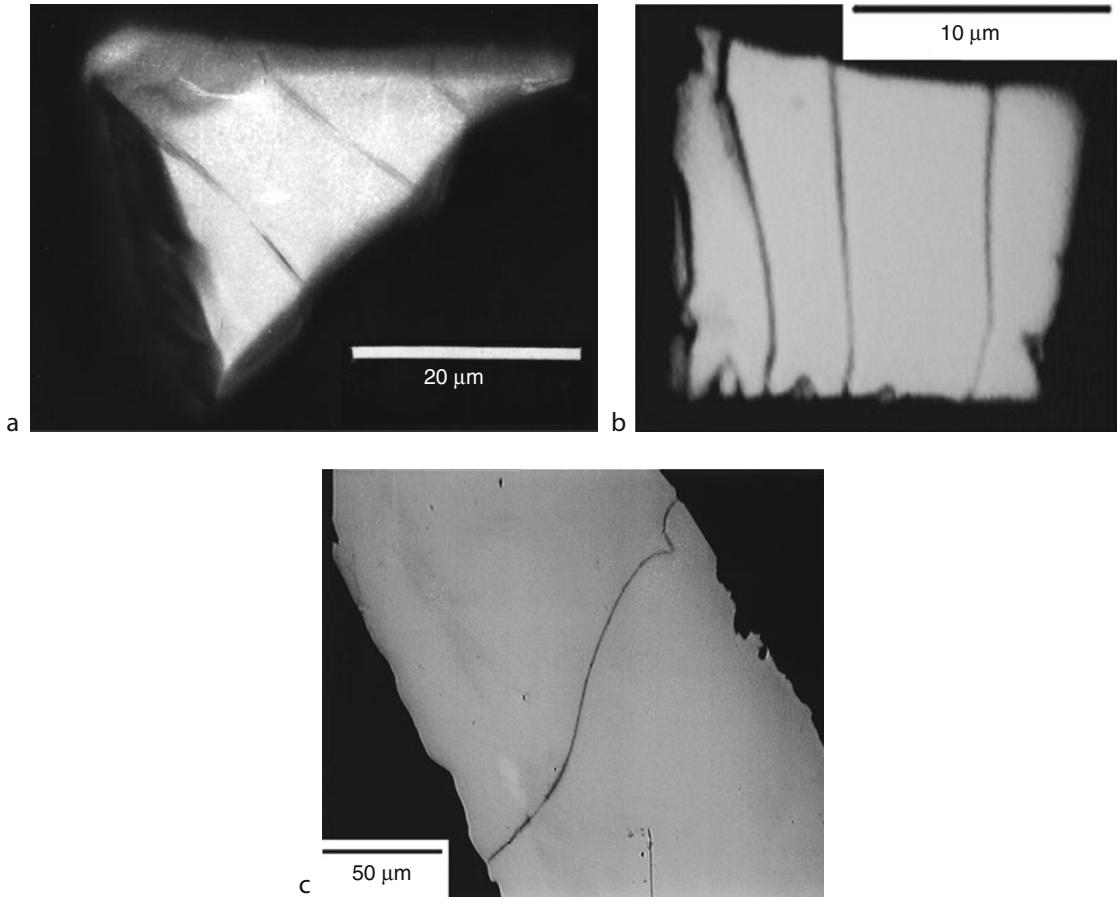
Both Kittel's original model of domains in a semi-infinite platelet and calculations for finite grains by (e.g., Moskowitz and Halgedahl, 1987) lead to the prediction that domain width $D \propto L^{1/2}$, where L is plate or particle thickness. These predictions are supported by domain studies of natural magnetic minerals which generally yield a power-law dependence of D on L, although the power may differ somewhat from 0.5.

Soffel (1971) was the first to study the grain-size dependence of the number of domains in a paleomagnetically important magnetic mineral. From Bitter patterns on grains of natural, intermediate ($x \approx 0.55$) titanomagnetite in a basalt, he determined that, on average, both D and N (number of domains = L/D) $\propto L^{1/2}$, where L was average particle size. His results yielded a single domain/two domain transition size of 0.6 μm and a wall energy density of about 1 erg/cm^2 for this composition.

Similarly, from Bitter patterns on natural pyrrhotite in a Bavarian diabase, both Soffel (1977b) and Halgedahl and Fuller (1983) found that $D \propto L^{0.40}$ to $D \propto L^{0.45}$, depending on the magnetization state. For this pyrrhotite sample, the SD boundary fell between 1.5 and 2 μm. Geiβ et al. (1996) obtained $D \propto L^{0.45}$ from Bitter patterns on synthetic magnetite particles grown in a glass-ceramic matrix (Worm and Markert, 1987). They obtained a SD/two-domain transition size for magnetite of approximately 0.25 μm.

Domain wall widths

When studied in the scanning electron microscope (SEM), patterns of dried magnetic colloid afford high-resolution views of domain walls. Moskowitz et al. (1988) applied this method to polycrystalline pellets of synthetic titanomagnetite substituted with aluminum and magnesium ($Fe_{2.2}Al_{0.1}Mg_{0.1}Ti_{0.6}O_4$: "AMTM60"). Dried Bitter patterns on unpolished surfaces were virtually identical



Magnetic Domains, Figure 8 (**a**) Bitter pattern on a grain of intermediate titanomagnetite ($x \approx 0.6$) in oceanic basalt drilled near the Mid-Atlantic Ridge. (**b**) Bitter pattern on a grain of magnetite synthesized with the glass-ceramic method. In this particular state of magnetization, the grain contains four walls, whose lengths are commensurate with the particle's length. Note that one wall is pinned very near the particle's extreme left-hand edge. The small triangular patterns at the lower edge of the particle represent walls which enclose small reverse spike domains. (**c**) Bitter pattern of a wall on a very large (approximately 150 μm width, 1 mm length) platelet of natural hematite from Elba, Italy. At most this platelet exhibits only 1–2 principal walls, although small edge domains are often observed. Apparently, the wall is bowing around a defect near the upper right-hand edge of the photograph. Only a small part of the crystal surface is shown.

in style to those common to materials controlled by strong uniaxial anisotropy. Patterns indicated closely spaced stripe domains, sinusoidally wavy walls, and nested arrays of reverse spikes. Measurements from SEM images yielded wall widths between 0.170 and 0.400 μm.

Very high resolution images of domains and domain walls in magnetite have been obtained with MFM. The first images were reported by Williams et al. (1992), who recorded a magnetic profile across a 180° wall on a {110} surface of a large natural magnetite crystal. Spins within the wall reversed their polarity of rotation along the length of the wall, demonstrating that walls in real materials can be much more complex than those portrayed by simple models. Using MFM, Pokhil and Moskowitz (1996, 1997) made a similar finding in glass-ceramic magnetite. Segments of opposite polarity were separated by Bloch lines, the transition regions where polarity changes sense. The number of Bloch lines within a wall varied among repeated alternating field (AF) demagnetization treatments. Thus walls, like particles, can occupy LEM states.

Owing to its high-resolution capabilities, the MFM can provide estimates of wall width. Proksch et al. (1994) obtained MFM profiles across a 180° wall on a {110} surface of natural magnetite, thus obtaining a wall width of about 0.21 μm.

Experimental evidence for local energy minimum (LEM) domain states

In their study of Bitter patterns on natural pyrrhotite, Halgedahl and Fuller (1983) noted that grains of virtually identical size could contain very different numbers of domains, despite these same particles having undergone

the same magnetic treatments. Moreover, they found that an individual particle could arrive in very different domain states – that is, with different numbers of walls – after different cycles of minor hysteresis.

These observations led Halgedahl and Fuller (1983) to the conclusion that a particle could occupy domain states other than the ground state. Subsequent domain observation studies by Halgedahl on AMTM60 and by Geiβ et al. (1996) on magnetite provided strong evidence for LEM states in other magnetic minerals.

LEM states and thermomagnetic treatments

A particularly unexpected type of LEM state in pyrrhotite and intermediate titanomagnetite is a SD-like state that certain particles can occupy after being saturated in a strong external field, even though these same particles readily accommodate walls in other states of magnetization. Bitter patterns on intermediate ($x \approx 0.6$) titanomagnetite in oceanic basalt and on natural pyrrhotite in diabase were studied during hysteresis by Halgedahl and Fuller (1980, 1983). In states of saturation remanence, most particles in a large population contained one or more walls, as expected on the basis of previous theories (Figure 7a). However, several tens of percent of the finer (5–15 μm) particles appeared saturated after the maximum field was shut off (Figure 7b). Halgedahl and Fuller (1980, 1983) proposed that grains that failed to nucleate walls could make a substantial contribution to saturation remanence. Particles in SD-like states remained saturated, until nucleation was accomplished by applying a back field of sufficient magnitude, and this nucleation field dropped off with increasing grain size L according to a power law in $L^{-1/2}$. Similarly, Boyd et al. (1984) reported Bitter patterns on natural magnetite grains carrying saturation remanence, and these patterns suggested SD-like states. These results were surprising, in view of magnetite's strong tendency to self-demagnetize.

Subsequent domain observations and hysteresis measurements of hematite platelets from Elba, Italy demonstrated that, after exposure to strong fields, even large crystals could arrive in states of near-saturation. Back fields were necessary to nucleate principal domains, and, similar to pyrrhotite, these nucleation fields also followed a power law in $L^{-1/2}$ (Halgedahl, 1995, 1998).

Results from titanomagnetite and pyrrhotite suggesting SD-like states were interpreted by Halgedahl and Fuller (1980, 1983) in light of previous theoretical and experimental work on high-anisotropy, industrial magnets. In such materials, nucleation of walls is an energetically difficult process, because the internal demagnetizing field, which triggers nucleation, may be too weak to overcome the anisotropy field, which hinders nucleation (Brown, 1963; Becker, 1969, 1971a, b, 1976). Such particles may require an external back field, which aids the demagnetizing field in order to nucleate walls and accompanying domains.

The style of domain structure and the range of LEM states that a particle can occupy can depend on thermomagnetic history. From Bitter patterns on natural, polycrystalline pyrrhotite, Halgedahl and Fuller (1981) discovered that crystallites displayed arrays of undulating walls on their surfaces after acquiring TRM in a weak external field. By contrast, after AF demagnetization in a strong peak field the same crystallites exhibited planar walls. Evidently, cooling locked in a high-temperature configuration of walls whose curved shapes promoted lower magnetostatic energy than would a planar geometry.

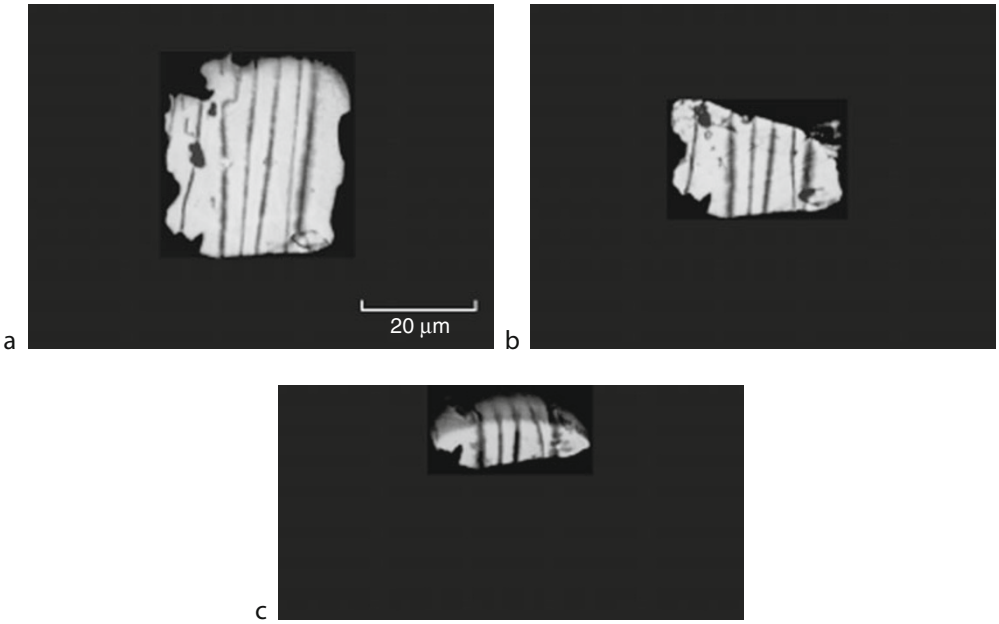
As indicated by Moon and Merrill's theoretical results for magnetite, a particular LEM state can be stable across a broad range of grain size. This prediction is born out by experiments by Halgedahl and Ye (2000), who investigated the effects of mechanical thinning on domain states in natural pyrrhotite. Individual pyrrhotite grains in a diabase were mechanically thinned and their Bitter patterns observed after each thinning step. Despite some grains being thinned to about one-fourth of their initial diameter, the widths of surviving domains and positions of surviving walls remained unaffected (Figure 9). Neither nucleations nor denucleations were observed, although calculations indicated that thinning would cause significant changes in GEM domain states.

Bitter patterns on crystallites of polycrystalline AMTM60 were studied after many replicate TRM acquisition and AF demagnetization experiments (Halgedahl 1991). In each particle, the number of domains varied from one experiment to the next, defining a distribution of LEM states. For states of weak-field TRM, this distribution could be broad and could include single-domain-like states (Figure 10). After replicate AF demagnetizations, however, typical distributions were narrow and clustered about a most probable state, possibly the GEM state.

Evolution of magnetic domain structures at elevated temperatures

The manner in which domain structure evolves with temperature carries clear implications for TRM. Cooling-induced nucleations and denucleations of walls/domains could trigger sudden changes of the internal demagnetizing field. As a result, preexisting walls which survive a domain transition could be dislodged from imperfections where they were pinned initially at higher temperatures.

The first Bitter patterns observed on magnetite above room temperature in the Earth's field were made by Heider et al. (1988), using hydrothermally recrystallized crystals. Depending on the particle, Bitter patterns could be followed to approximately 200°C, above which temperature the patterns grew too faint to discern. Surprisingly, heating to very moderate temperatures drove certain walls across much of a particle; in some cases, denucleation occurred. Upon cooling, walls reassembled in a similar, though not identical, arrangement to that observed initially at room temperature. In some cases, repeated thermal cycling between room temperature and about 200°C produced different numbers of domains in the same particle.



Magnetic Domains, Figure 9 Bitter patterns on a grain of natural pyrrhotite in a diabase before and after mechanical thinning. (**a**) Initial state, before thinning. (**b**) After thinning the particle to about one-half of its original length along a direction parallel to the trends of the Bitter lines. (**c**) Final state, after the particle has been thinned to about one-fourth of its original length.

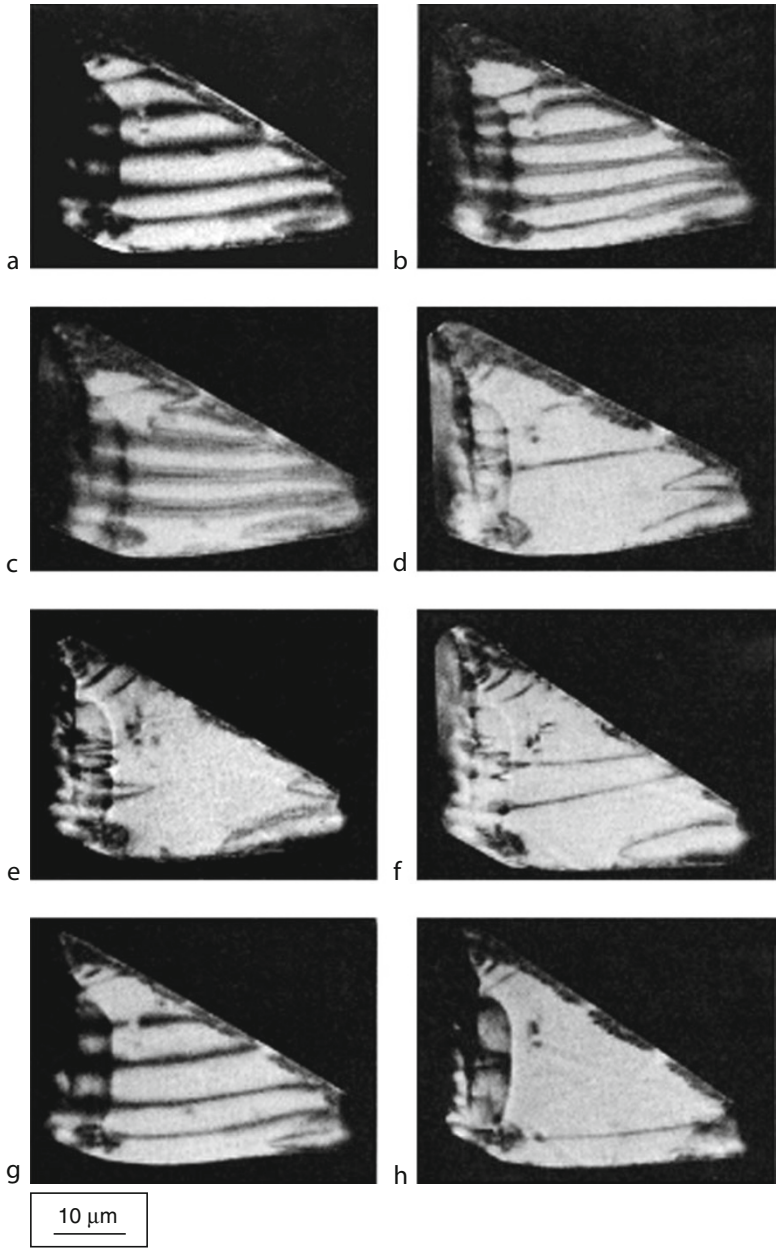
Ambatiello et al. (1999) used the MOKE to study domain widths versus temperature in several large (several mm) crystals of natural magnetite. At room temperature, {110} planes were dominated by broad lamellar domains that terminated in closure domains at crystal edges. On {111} planes, they found complex, nested arrays of very small closure domains, which finely subdivided the main closure structure. Domain widths generally increased with heating, and such changes were thermally reversible. To explain their results, these authors hypothesized that heating promoted an increasingly finer subdivision into small domains near the crystal surface; this would reduce magnetostatic energy with heating and thus cause broadening of body domains (also see Muxworthy and Williams, 2006).

Bitter patterns observed at elevated temperatures on natural, intermediate titanomagnetites were reported by Soffel (1977a), Metcalf and Fuller (1987a, b, 1988), and Halgedahl (1987). During heating, patterns gradually faded to obscurity, with few significant changes in domain structure. Remarkably, some titanomagnetite particles studied by Metcalf and Fuller (1987a, b, 1988) displayed no Bitter lines after cooling from the Curie point in the Earth's field. This observation provided evidence for Halgedahl and Fuller's (1983) earlier proposal that weak-field TRM acquired by populations of PSD grains could, in part, be attributable to particles which failed to nucleate walls during cooling.

The possible importance of LEM states to TRM acquisition was raised by work on synthetic, polycrystalline AMTM60 with a Curie point near 75°C (Halgedahl, 1991). As shown in Figure 10, replicate TRM experiments often produced different numbers of domains in the same particle. Some of these states suggested that the particle was entirely saturated, with no visible Bitter lines, or nearly saturated, with only small spike domains at grain boundaries. Patterns that evolved during cooling revealed that denucleation was one mechanism by which a particle arrived in a final LEM state. Denucleation occurred either through contraction of large, preexisting spike domains, or by straight walls moving together and coalescing into spikes. Often, spikes would collapse altogether. In some cases, denucleation left behind large volumes which, apparently, contained no walls, although walls were present elsewhere in the grain. In other cases, denucleation left behind a grain that appeared nearly saturated, but for small edge domains. These results led to the idea of trans-domain TRM (Halgedahl, 1991).

Magnetic domain structure in magnetite at low temperatures

Magnetite undergoes two types of transitions at low temperatures, which can profoundly affect domain structure and remanence (e.g., see detailed discussions in Stacey and Banerjee (1974); Dunlop and Ozdemir (1997)). At the isotropic point (approximately 130 K), the first magnetocrystalline anisotropy constant, K_1, passes through zero as it changes sign from negative at temperatures above the transition to positive below it. At the



Magnetic Domains, Figure 10 Bitter patterns on a crystallite of titanomagnetite ("AMTM60": see text) after each of eight replicate TRM acquisition runs in the Earth's field.

Verwey transition, T_v (approximately 120 K), magnetite undergoes a crystallographic transition from cubic to monoclinic.

Thus at 130 K domain walls should broaden dramatically, because wall width is proportional to $K_1^{-1/2}$. It follows that, by passage through 130 K, walls may break free of narrow defects which pinned them at other temperatures. At the Verwey transition, the easy axis of magnetization changes direction. In multidomain and pseudosingle-domain magnetite, these thermal passages may cause demagnetization and complete reorganization of domain structure. Low-temperature demagnetization has proved useful in removing certain spurious components of NRM which are surprisingly resistant to thermal demagnetization above room temperature. Thus it is important to determine how these transitions affect domains.

Using an MFM specially adapted to operate at low temperature, Moloni et al. (1996) were the first to image domains on {110} magnetite planes at temperatures near

the two transitions. As the crystal was warmed from 77 K to a few degrees just below T_v, the domain structure disappeared entirely below the instrument's noise level, evidently undergoing a complete reorganization near the crystallographic transition.

MAGNETIC GRADIOMETRY

Harald von der Osten-Woldenburg
National Heritage Department, Regional Government of Baden-Wuerttemberg, Esslingen am Neckar, Germany

Definition

Magnetometer. Instrument with a single sensor that measures magnetic flux density.
Magnetic gradiometer. Pairs of magnetometers with sensors separated by a fixed distance.

The earth's magnetic field at any point on or near the earth's surface is the vector sum of the contributions from the primary field due to the dynamo in the earth's liquid core and the crustal field from the magnetic mineral content of local rocks. This vector has both an orientation and an amplitude. Slight changes in any direction influence the orientation and amplitude. Introduce a highly magnetic rock formation into an otherwise homogenous host, and the local magnetic vector will change. In a three-dimensional world, there are nine (3×3) spatial gradients forming a tensor which defines the anomalous field.

On the conceptual design of gradiometers

A gradiometer is a special measuring instrument that consists of more than one (usually two, rarely three or four) magnetometers. The differences between the readings of the sensors are seen as an approximation to the gradient of the magnetic field along their alignment. The (usually) two magnetometers of a gradiometer are arranged either vertically or horizontally. The distance of the two sensors can vary between several decimeters (for archaeological or environmental mapping) and several kilometers (for research of the deeper-lying geological structures of the Earth's crust, see *Magnetic Methods, Airborne*) depending on the field of application.

Magnetometers

Quantum magnetometers (see also *Magnetometers*) and saturable-core magnetometers are generally suitable for use in gradiometers. Alongside the fluxgate saturable-core magnetometers, cesium vapor magnetometers have become a standard in many areas (aeromagnetic survey, marine geophysics, environmental geophysics, and archaeological prospection) due to the improved noise signal levels against the Overhauser magnetometers or the helium-cooled sensors (Nabighan and Asten, 2002).

Fluxgate gradiometers measure a single component of the Earth's magnetic field (usually the vertical component), while gradiometers consisting of quantum magnetometers (i.e., proton precession and cesium vapor sensors) measure the component of an anomaly in the direction of the Earth's ambient magnetic field, as this is much larger than the anomaly itself (Blakely, 1996). Additionally, fluxgate magnetometers are directionally sensitive and subject to a temperature-related drift, and therefore often have to be recalibrated during measurements.

Instead of using a pair of different magnetic field sensors and differentiating their outputs in order to derive a magnetic gradient value, a single sensitive element can be used for measuring directly a magnetic gradient. This is done by the use of a stiff metallic string clamped at both ends and pumped with an AC current, the frequency of which is tuned to the second eigenmode of the string. The string is excited at that eigenmode in the presence of a quasi-static magnetic gradient. Then, the corresponding mechanical displacements of the string can be measured by the use of an inductive technique with an instrumental noise envelope of less than $\pm 10^{-12}$ m, per 1 s measurement interval (Veryaskin, 2001).

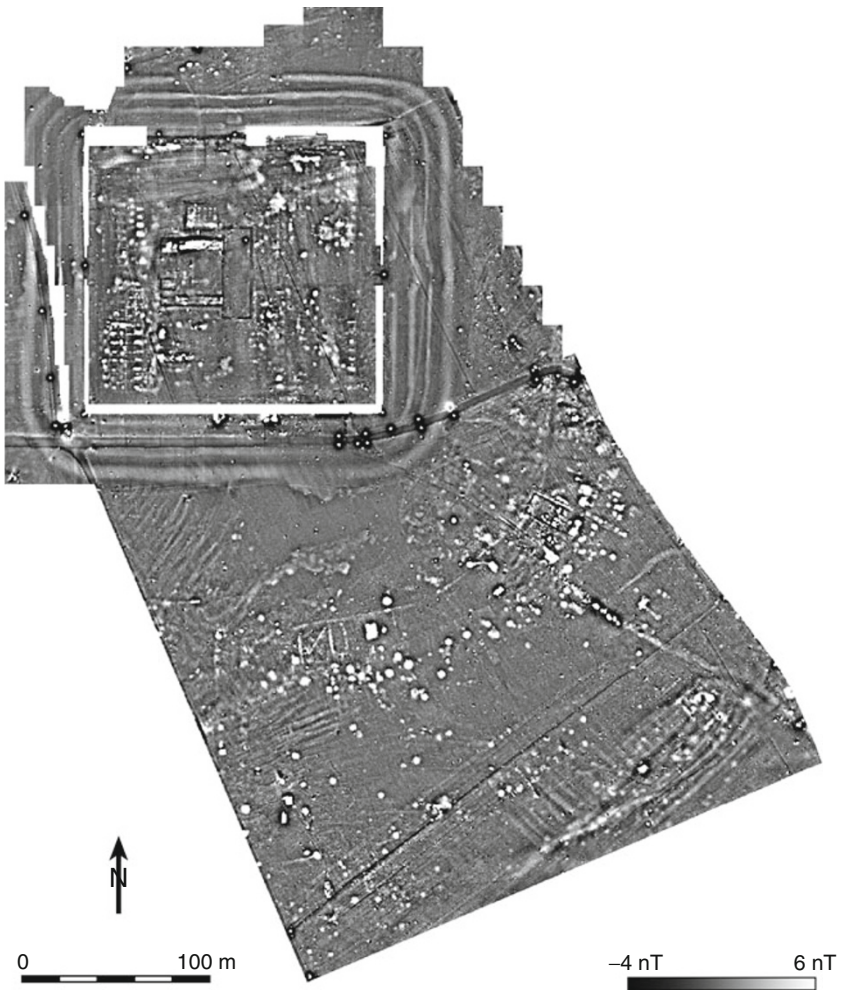
Advantages and limitations

In measurements with a gradiometer, the measured signal amplitude of the magnetic anomaly of an interfering body decreases by the power of three or four depending on the distance between the two sensors. A gradiometer is therefore somewhat less sensitive to deeper-lying features than a total-field magnetometer, where the signal amplitude of an anomaly decreases by the power of three depending on the distance of the sensor to the interfering body. However, gradiometers react very sensitively to interfering features close to the surface and possess a higher spatial resolution in small-scale structures than total-field

Magnetic Gradiometry, Figure 1 The four-channel fluxgate gradiometer of the Institute Dr. Foerster, Reutlingen, Germany. Measurements in a grid of 0.05 by 0.06 m are possible with this device. The two fluxgate sensors are 0.65 m apart.

magnetometers. The variability in time of the Earth's magnetic field and other sources of interference that are far enough away from the gradiometer, and whose influence on the sensors is equal or at least of a similar level during gradiometer measurements, can be eliminated – or at least significantly reduced – by subtracting the simultaneous readings of the two sensors from one another. An advantage of gradient measurements, arising from the ambiguity present in all potential field measurements, is the suppression of broad regional changes in the magnitude of the magnetic field – the long wavelength component. With gradiometer measurements, the local variations are enhanced, making small and weakly magnetic targets recognizable. Gradiometer surveys are particularly useful in areas that are geologically complex. Due to the resulting difference, the magnitude of the anomalies is, however, smaller than the amplitude that one would achieve with a total-field magnetometer. This means that a total-field magnetometer can detect anomalies of smaller and deeper-lying features which cannot be detected by a gradiometer. Fluxgate gradiometers are very sensitive to their position in relation to the magnetic vector field: an ever so slight change in the inclination of the instrument during measurements can lead to incorrect results (Schmidt and Clark, 2000).

The use of vertical gradiometers for magnetic mapping effectively removes the time variations in the magnetic field map without having to establish base stations, networks, or tie lines and is the only insurance against elimination of the high-frequency component that contains the small or weakly magnetic targets. Gradiometers have shown that they can offer a high degree of immunity from



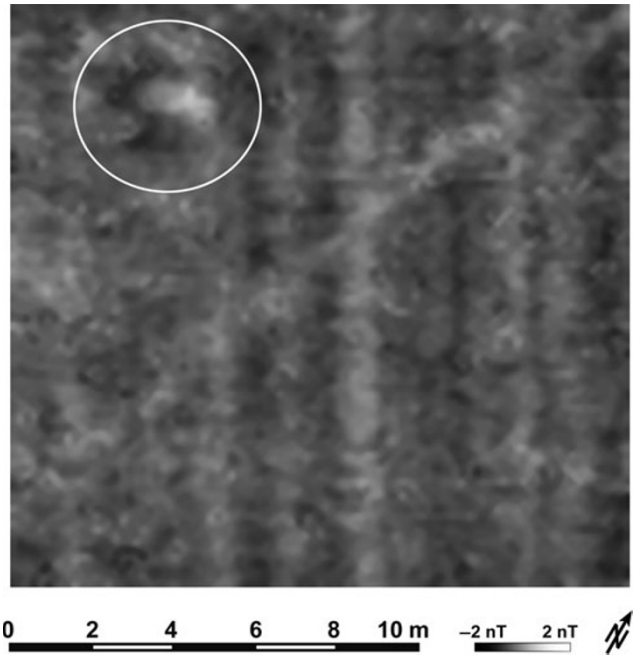
Magnetic Gradiometry, Figure 2 Archaeological survey: Magnetic gradiometer map of the Roman fort in Rainau-Buch, Baden-Württemberg, Germany. Four defensive trenches surround a fort measuring 140 by 150 m. In the center one can recognize the foundations of a stone building (principia), as well as several wooden barracks with their hearths. South of the fort is the adjacent settlement. Magnetic anomalies show the position of streets, stone buildings, cellars, and pits.

diurnal and minor magnetic storm activity in the ambient magnetic field; they can enhance near-surface, small, or weakly magnetic anomalies.

Areas of application

Vertical axial gradiometers are used for measuring the vertical differences (the vertical gradient) in the vertical component of the Earth's magnetic field. This configuration is commonly used for ground-based geophysical surveys in the field of environmental geophysics, in areas with complex geology and archaeological prospecting, as the influences of deeper-lying interferences can be suppressed by this setup of the sensors. For practical reasons, the distance between the sensors of a gradiometer used for ground-based surveys lies somewhere between 0.5 and 1 m. As a rule, the ground penetration and detection ranges to about one to two meters below the surface. Deeper detection can be achieved if the interfering body is accordingly large and strongly magnetized. Fluxgate gradiometers are commonly found in environmental geophysics and in archaeological prospecting (Figure 1). Surveys can be conducted at faster rates, and the highest requirements for spatial resolution of the smallest archaeologically relevant features can be met with measurement grids of 0.05 by 0.06 m without the fluxgate sensors influencing each other. Sometimes, these very small measuring intervals are necessary in archaeological prospecting in order to achieve the best possible spatial resolution of archaeological features (von der Osten-Woldenburg et al., 2006). The magnetic gradiometer map of a Roman fort and its adjacent settlement (Figure 2) that was obtained with a measurement grid of 0.25 by 0.25 m, shows a large number of diverse, often very characteristic anomalies which allow conclusions to be drawn on the position, shape, and size of defensive trenches, centrally located staff buildings with stone foundations, wooden barracks with their hearths, as well as buildings (stone-foundation buildings, street layouts, cellars, and pits) of the settlement adjacent to the fort.

Magnetic gradiometry is also employed in forensic geophysics, even if the radar method has been established as the standard procedure (Cheetham, 2005). However, certain general conditions such as a sufficient distance to the iron cores of reinforced concrete, fences, and other metal constructions must be provided, and it must be ensured that there is no metal refuse in the ground itself. The procedure is identical to that of archaeological prospecting: research is undertaken in small-scale, near-surface survey as the burials themselves are usually close to the surface. The human body only has a small measure of magnetic susceptibility, so a direct detection of the remains by magnetic gradiometry is not possible. But the excavation of a grave and the disruption of strata leads to disturbances of the layers of soil close to the surface that are usually magnetically homogenous, and the refilling of the grave with the excavated material – in which the magnetic particles are now statistically aligned – usually generates weak geomagnetic anomalies, often smaller than 2–3 nT (Figure 3). The displacement of soil with a significantly higher susceptibility by the human body can intensify this effect.



Magnetic Gradiometry, Figure 3 Forensic geophysics: Detection of a burial at the edge of a field (marked by a *circle*). The linear anomalies are produced by drainage pipes and geological structures in the substratum.

Axial gradiometers are also used in aeromagnetic surveys (see *Magnetic Methods, Airborne*), i.e., by helicopter for the detection of ordnance remains close to the surface (Doll et al., 2006), in the prospection of mineral deposits (see *Magnetic Methods, Surface*) and for research of anomalies in the Earth's magnetic field and deeper-lying geological structures of the Earth's crust (see *Magnetovariation Studies*) from stratospheric balloons with a base length of sensors as far as 6 km apart (Webers et al., 2009).

Transverse and longitudinal gradient magnetic measurements are applied in aeromagnetic surveys (Hogg, 2004), in marine geophysics, and space exploration (see *Magnetic Methods, Satellite*). The distance of the magnetometers from one to the other can range from 1.5 m (e.g., in cable and pipeline survey, or for detecting smaller metallic objects) to more than 500 m (for the detection of magnetic sediments close to the surface, shipwrecks, and the prospecting of mineral deposits), depending on the required area of application.

Summary

Magnetics belong to the most commonly used methods for prospecting in applied geophysics when attempting to

infer the position, geometry, and physical parameters of a body of interference or geological structure through the measurement of magnetic anomalies (Schmidt and Clark, 2006).

Gradiometers with two vertically arranged magnetometers that are positioned between 0.5 and 1 m apart, and which measure the vertical gradient and vertical component of the Earth's magnetic field have distinct advantages over total-field magnetometers, especially in ground-based magnetic measurements in environmental geophysics (surveying of contaminated sites, examination of building construction sites, archaeological research of former settlements): they offer a high resolution in smaller features which is, however, gained at the cost of a lesser penetration of the ground in comparison to measurements made with total-field magnetometers. Additionally, they are very sensitive to close-by sources of interference. Background interference (such as the variability in time of the Earth's magnetic field and other nearby sources of interference) can be eliminated or significantly reduced by subtracting the simultaneous readings of the two sensors in the gradiometer arrangement.

Introduction

Making measurements from the air of the Earth's magnetic field is a well-established geophysical survey method. The normal practice is to measure the scalar amplitude of the magnetic field in the survey area, this being referred to as the total magnetic intensity (TMI), the name reflecting the fact that the measurements represent the resultant of all the magnetic fields, of whatever source, in the vicinity of the measurement. The major contributions come from the geomagnetic field and the fields due to magnetic rocks in the upper crust, the latter being the fields of interest.

Initially used to infer the depth to magnetic rocks beneath nonmagnetic cover in sedimentary basin studies and for identification of major lineaments, the products from aeromagnetic surveys have evolved to now be a reliable means of creating detailed maps of the near-surface geology. Current developments in aeromagnetics are mostly related to the increasingly sophisticated inference of the 3D distribution of magnetism in the Earth's crust using inverse modeling methods.

Comprehensive accounts of aeromagnetic data, acquisition, processing, and interpretation are proved by Gunn (1997) and Reeves (2005).

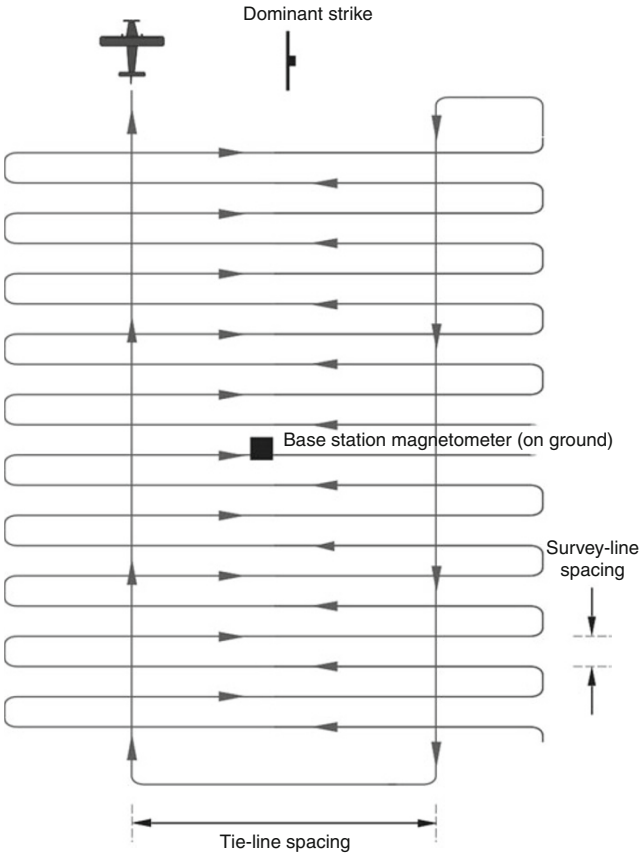
Making magnetic measurements from the air

Airborne magnetic data are acquired as a series of parallel "survey" or "flight" lines and more widely spaced orthogonal "tie" lines (Figure 1). The purpose of the tie lines is to create repeat measurements at the locations where they cross the flight lines, which are required during processing of the data (see below).

An advantage of making magnetic measurements from the air is that unless the survey area is small, typically less than a few square kilometers, it is much faster and cheaper to acquire the data than for a ground-based survey. The main disadvantage is that variations in topography, especially if the terrain is rugged, may seriously affect the ability to position the aircraft as would be preferred and also affect the individual measurements in a hard to predict way.

Equipment

Airborne measurements are routinely made using fixed-wing aircraft and helicopters. Surveys using fixed-wing aircraft are about a factor of four times cheaper than helicopter surveys, but helicopters have the advantage of



Magnetic Methods, Airborne, Figure 1 Schematic illustration of the flying pattern used in aeromagnetic surveys.

being able to fly lower and better maintain a consistent ground clearance in rugged terrain, but have the disadvantage of being less stable survey platforms.

To reduce effects of magnetic fields originating in the aircraft the magnetic sensor, usually a cesium vapor magnetometer (see *Magnetometers*), is located as far as possible from the main body of the aircraft and hence the magnetic fields associated with ferrous components and electric currents. For fixed-wing aircraft the magnetic sensor is mounted in a "stinger" located aft of the aircraft. In helicopters the sensor may be in a "boom" that positions the magnetometer in front of the aircraft or it may be within a towed "bird." The bird is a bomb-like device suspended on a cable beneath the aircraft. A "compensation" system within the aircraft is used to further reduce the effects of magnetic fields originating from the aircraft.

In addition to carrying one or more magnetometers, the survey aircraft also measures terrain clearance using an altimeter and GPS position and time. One or more "base station" magnetometers are also deployed on the ground to measure temporal changes in the magnetic field in the survey area to enable such variations to be removed from the data (see below).

The importance of source-sensor separation

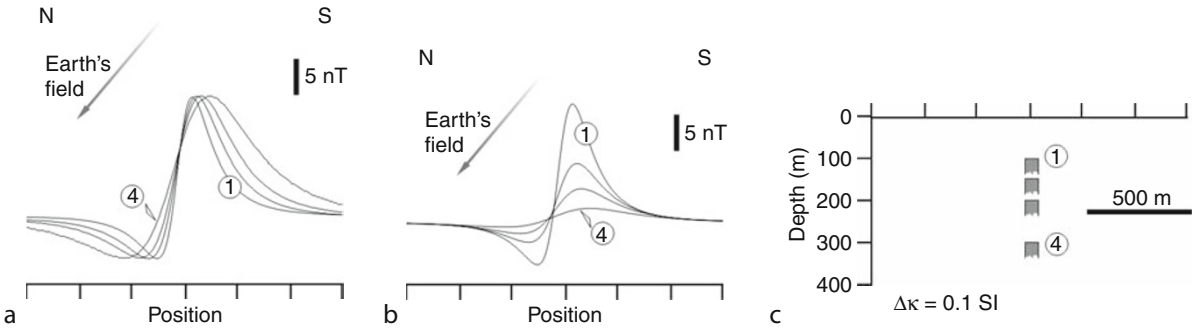
An important source of noise in aeromagnetic data is associated with changes in distance between the magnetic sensor and the magnetic materials. Any changes in this distance will create variations in TMI, which could easily be confused with those caused by changes in the local geology. As the distance increases the measured magnetic field variation decreases in amplitude and increases in wavelength (Figure 2b). The wavelength increase is most easily seen when the amplitude decrease is removed by rescaling the individual profiles so they have the same peak-to-peak amplitude (Figure 2a).

Ideally the survey aircraft maintains a constant ground clearance during the acquisition of the data, referred to as "drape" flying. In practice, aircraft are subject to the effects of wind and turbulence and the inaccuracies of human control. In addition, all aircraft have a limited ability to maneuver, especially climb. Figure 3 shows the flight path of a fixed-wing aircraft across a ridge and adjacent areas. When short wavelength variations in topography (B on the diagram) are encountered, the aircraft cannot respond quickly enough to maintain the separation and positive relief will bring the magnetic sources closer to the sensor, with a corresponding increase in the amplitude of the magnetic field (c.f. Figure 2), and vice versa. When large topographic features are encountered (A on the diagram) the aircraft will inevitably vary its ground clearance because of its limited ability to climb and to a lesser extent descend. If, as is the normal case, alternate flight lines are flown in opposite directions, adjacent parts of survey lines will have markedly different ground clearance adjacent to topographic features. This will introduce spurious variations into the data.

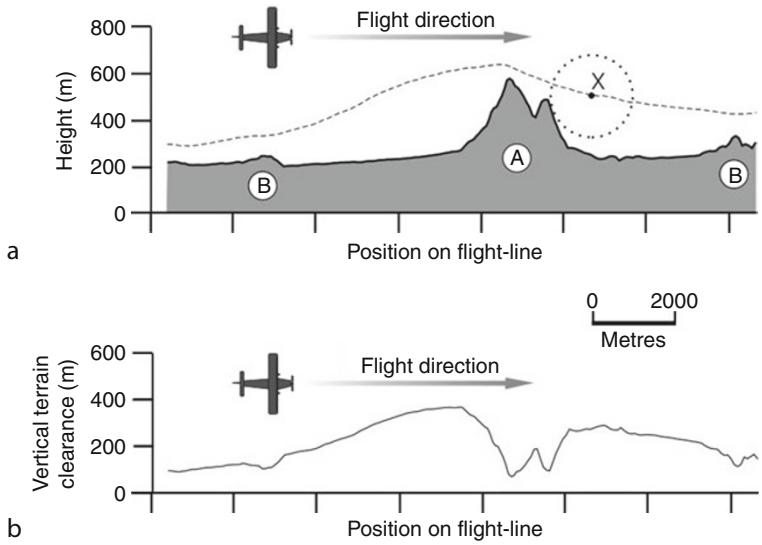
Current practice is to "program" a preplanned flight path for the aircraft, which the pilot follows using a real-time display. This program accounts for the terrain and the aircraft's performance. The aim is to achieve the best "loose drape," whereby terrain clearance effects are minimized as far as is practical. Note that even if a perfect drape was achieved, the effects of terrain would not be totally removed because even in the ideal scenario there are still the effects of variations in the distances to magnetic materials because it is not just the materials directly below the aircraft that are influencing the measurements. The measurement at X in Figure 3 will be affected more by the magnetic materials to the side than beneath because of the lesser distance to these materials, although this scenario only occurs in severe terrain.

Survey design

Sampling theory requires individual measurements of TMI to be spaced at a maximum of half the wavelength of the shortest wavelength of variation. Economic and safety factors mean this is rarely practical and some aliasing of responses is the norm. This is not necessarily a major problem since during qualitative interpretation of the data it is relative changes in amplitude and texture



Magnetic Methods, Airborne, Figure 2 Profile of total magnetic intensity across a dyke-like magnetic body. The four profiles correspond with the bodies at different depths in (**c**). The profiles in (**b**) represent variations in TMI. In part (**a**) the amplitudes have been normalized to the profile with maximum amplitude (shallowest source).



Magnetic Methods, Airborne, Figure 3 Example of the flight path of a fixed-wing survey aircraft across rugged topography. (**a**) Topographic and altimetry profile, (**b**) vertical terrain clearance. (Based on data in Flis and Cowan, 2000).

that are used, and in fact accurate definition of the variations is only required when specific anomalies need to be analyzed quantitatively (see *Magnetic Anomalies, Interpretation*) and often there is a follow-up, more detailed, survey of the area of interest to improve anomaly characterization.

Survey specifications

The survey geometry, illustrated in Figure 1, requires definition of three key parameters: the survey line spacing and orientation and the flight height. Typical values of two of these variables for different survey types are given in Table 1. Note that the tie-line spacing is a dependent variable, typically being set to ten times the survey line spacing, although this may be reduced to five times or less for high resolution surveys.

The survey line spacing controls the cost of the survey, which for fixed-wing aircraft is based on the total length of lines flown. The total line length of a survey in terms of the survey area and line spacing can be estimated from the equation below (Brodie, 2002).

$$\text{Total line length} = \frac{1000\left(1+\frac{\Delta_{\text{Survey lines}}}{\Delta_{\text{Tie lines}}}\right).\text{Survey area}}{\Delta_{\text{Survey lines}}}$$

Where $\Delta_{\text{Survey lines}}$ and $\Delta_{\text{Tie lines}}$ are the survey- and tie-line spacings in meters, respectively, the total line length is in kilometers, and the survey area is in square kilometers.

To this cost must be added nonproduction costs such as mobilization and "stand by" costs associated with factors outside the acquisition company's control, for example, bad weather, magnetic storms. With helicopter surveys the time spent in the air is also taken into account, and

Magnetic Methods, Airborne, Table 1 Typical survey specifications for aeromagnetic surveys

Survey line spacing (m)	Tie-line spacing (m)	Flight height (m)	Sampling ratio: Survey/Tie line[a]	Shortest along-strike wavelength sufficiently sampled
50	500	40	7.5	100
100	1,000	50	15	200
200	2,000	60	30	400
400	4,000	80	60	800

[a]assumed flight speed is 240 km/h (67 m/s) and 10 Hz sampling resulting in a 6.7 m along survey line sampling interval. These parameters are typical for a survey with a fixed-wing aircraft.

may be significant in mountainous areas where weather conditions severely restrict data acquisition both in terms of flying time and location (Mudge, 1996).

It is clear from Figure 2 that the lower the flight height the greater will be the amplitude of the targeted responses and also the shorter the wavelength of variation, and hence the greater the ability to resolve adjacent features. Figure 2 implies the lowest possible flight height should be used, but safety considerations mean flight heights are some tens of meters. "Crop-duster" fixed-wing aircraft or heliborne surveys may fly lower but ultra-low flying is not necessarily an advantage from a technical point of view since it means maintaining consistent terrain clearance is more difficult. Besides, there may be very shallow magnetic sources whose anomalies mask those of deeper, more significant variations (Doyle and Lindeman, 1985).

Reid (1980) showed that accurate definition of a TMI anomaly requires the sample spacing to be a maximum of half the source-sensor separation. The combination of the rate at which the aircraft's magnetometers make a measurement (typically 0.1 s) and the velocity of the aircraft (typically 220–280 km/h for a fixed-wing aircraft) result in an along flight line sample spacing of about 7 m for fixed-wing aircraft. Helicopter surveys with a 0.1 s sampling typically have a 4–5 m spacing, but the trend is to employ faster sampling magnetometers, reducing this spacing to even less. The important outcome from the above is that the along-line sampling exceeds the requirements of sampling theory for practical flight heights and the variations in TMI in the direction of the flight path can be considered as more than adequately characterized. The same is not true for variations in the directions perpendicular to the survey line direction because, as shown in Table 1, the spacing of these lines is very much greater than the along-line sampling interval. Note that since anomaly wavelength decreases with source-sensor separation, a low flight height combined with wide survey lines will lead to greater aliasing in the direction perpendicular to the survey lines. This is reflected in the parallel increase in flight height with line spacing in Table 1.

Conventionally airborne geophysical surveys are flown with the flight lines oriented perpendicular to the dominant geological strike direction. The rationale for this is that there will be shorter wavelength variations across strike than parallel to strike, and hence the greatest sampling density should be in the strike-perpendicular direction. For elongate anomalies the short wavelength variation parallel to strike is small, so significant aliasing does not occur. In practice economic considerations dictating the survey line spacing mean, there is inevitably some aliasing of TMI variations in the direction perpendicular to the survey lines.

Even if there is some variation in the strike across the survey area, and there is also a conflict caused by variations in stratigraphic and structural strike, it is best to use a single-line orientation. If this is not the case the data are very difficult to process into an easily interpreted form.

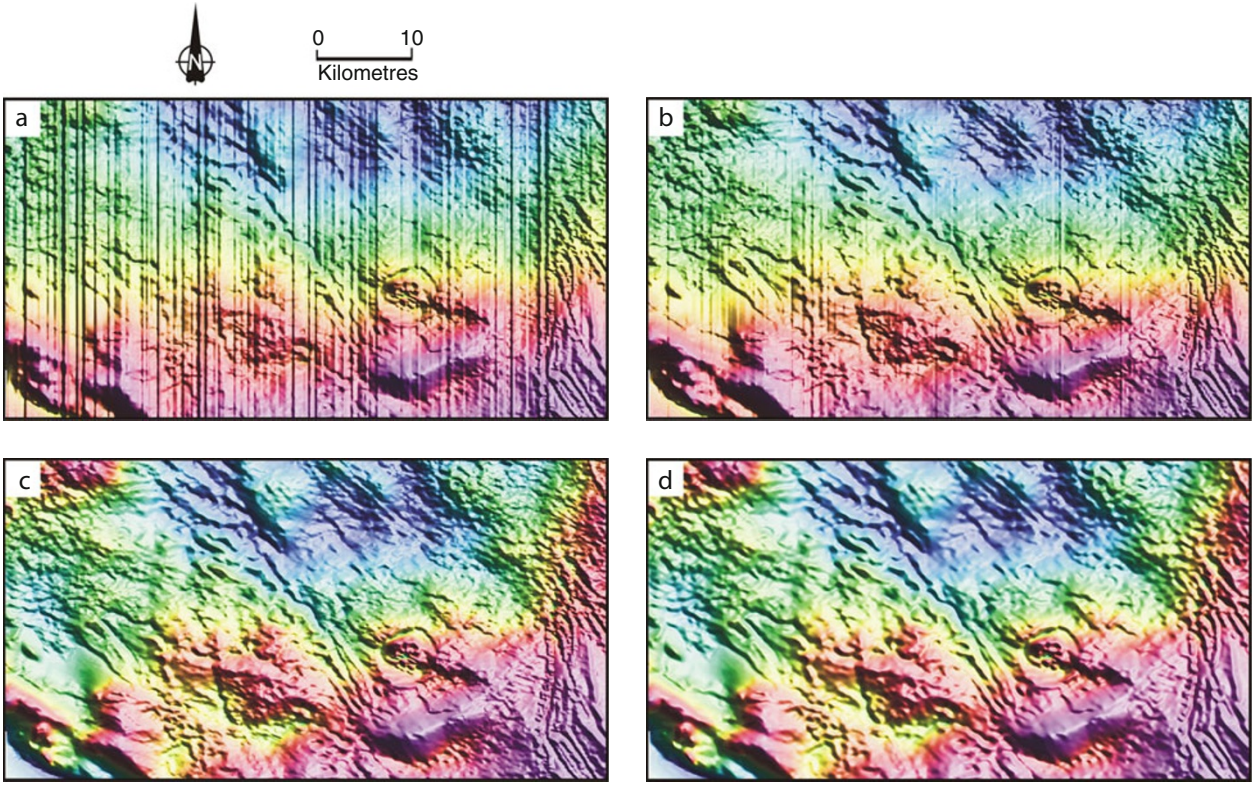
For surveys in equatorial regions the east–west elongation of magnetic responses associated with low declinations ($<30^\circ$) means it is always preferable to fly surveys with north–south survey lines.

Data processing

The term data processing refers here to the removal of noise prior to enhancement (see *Magnetic Data Enhancements and Depth Estimation*) and interpretation of the data (see *Magnetic Anomalies, Interpretation*). The aim of the processing is to create an instantaneous "snap shot" of TMI variations across the survey area with the contribution from the geomagnetic field removed. It is normal practice to complete at least preliminary processing in the field to ensure that the data are of acceptable quality.

The main source of noise in aeromagnetic data is temporal changes in the Earth's magnetic field, which occur during the course of the survey and hence from the mobile sensor's perspective are indistinguishable from lateral variations in TMI due to the geology of the survey area. It is to determine such variations that the repeat measurements inherent in the survey/tie-line geometry are required (Figure 1), along with the TMI time series recorded by each base station.

The removal of the noise is achieved in a series of steps. Figure 4 shows a raster display of an aeromagnetic dataset after each of the processing steps described below. Figure 4a shows the data after compensation for aircraft-related effects. Note the dominant characteristic is a north–south striping (corrugations) with a wavelength approximately equal to twice the line spacing; this being primarily the result of the temporal changes in the geomagnetic field during the survey and deviations of the aircraft from the ideal flight path.



Magnetic Methods, Airborne, Figure 4 Gridded TMI data from an aeromagnetic survey in Australia. The colors represent changes in amplitude (hot colors high, cold colors low) and the intensity represents a shaded relief presentation designed to highlight north–south trending features. (**a**) Data after compensation for magnetic fields originating in the aircraft. (**b**) As for (**a**) but with correction for temporal variations in the geomagnetic field as measured by a base station magnetometer. (**c**) As for (**b**) but with international geomagnetic reference field removed and tie-line leveling corrections applied. (**d**) As for (**c**) except for microleveling. Images created by Cowan Geodata Services.

Correction for temporal changes in the geomagnetic field

The Earth's magnetic field varies in intensity at a range of time scales; see *Geomagnetic Field, Theory*. Of significance to aeromagnetic surveys are magnetic storms (during which surveying must be discontinued) and micropulsation and diurnal variations. Micropulsations are variations in the geomagnetic field that last from a few seconds to a few minutes. They change in both phase and amplitude over distances comparable to survey dimensions. Diurnal variations have periods of 24 h and magnitudes of up to about 50 nT.

The principal means of removing micropulsation and diurnal variations is the base station magnetometer readings (the base station readings also allow the recognition of the onset of a magnetic storm). The readings in the aircraft and base station are time synchronized. In theory the variation at the (stationary) base station should represent geomagnetic field variations that occur during the course of the survey, and subtracting the base station readings from the time equivalent survey reading should leave a residual dataset free of the temporal variations. However, this is an imperfect process since the amplitude and phases of the changes vary with location. To counter this multiple base stations may be used for large surveys. The subtraction causes a base line shift in the data but this is unimportant since it is relative variations in TMI that are required for interpretation of the data (see *Magnetic Anomalies, Interpretation*). Often an average intensity of the magnetic field in the survey area is added to each measurement to return the data to closer to likely absolute values. Figure 4b shows the magnetic dataset after corrections for temporal changes in the geomagnetic field derived from a base station dataset. The degree of striping in the data is significantly reduced, although it is not eliminated.

Removal of geomagnetic field

It is normal practice to remove spatial variations in TMI caused by the geomagnetic field as defined by the International Geomagnetic Reference Field (IGRF), see *Geomagnetic Field, IGRF*. The wavelengths of variation of the field are very large compared to survey dimensions, and subtraction from the observed data will not usually significantly affect variations of interest. Nevertheless it is standard practice to remove such variations and it is computationally trivial to do so.

Tie-line leveling

Ideally the processing described above will mean the TMI measured along the survey- and tie-lines at their cross-over points will be identical. In practice, there will always be mismatches because of the imperfect aircraft compensation, spatial variations in diurnal and micropulsation related changes, but also because there are uncertainties in the aircraft's position, that is, where the cross-over occurs within the datasets. Differences in elevation between the survey- and tie-line measurements are the main source of error.

The minimization of the differences at the cross-over points is referred to as "leveling." Various approaches are used but normally there is an initial estimate of the extent to which location errors are responsible for the differences. Once these are accounted for the remaining differences at each line intersections are used to adjust the amplitudes along the survey lines. The most common method involves fitting a smooth function to the differences and using this to estimate leveling "corrections" at each measurement point along the survey lines. Figure 4c shows the magnetic data after removal of the IGRF (minimal effect) and tie-line based leveling. Corrugations in the data are now all but invisible.

Microleveling

Microleveling is a loosely defined term for making adjustments to the data when the processing stream outlined above is complete and artifacts appear to remain in the data. The details of these methods are mostly proprietary but are all various forms of low-pass filtering. The filter characteristics are often defined by the flight and survey line spacing, for example, Minty (1991). Microleveling is usually applied after the data have been gridded (see below), and the correction so derived used to adjust the individual survey measurements prior to re-gridding. Figure 4d shows the example magnetic data after application of a commercial microleveling process. There is some improvement in the lateral continuity of anomalies.

Gridding

By far the most common form of display and input to enhancement oriented processing operations are data projected on to a regular grid. Gridding the data is a compromise between honoring detailed sampling along the survey lines and producing smooth interpolation into areas between lines where no readings have been made. The grid cell size, that is, distance between interpolated locations, is conventionally between 1/3 and 1/5 of the survey line spacing. The loss of information in the survey line direction is balanced by an acceptable degree of reliability of interpolated points located between the survey lines. Nevertheless, especially with greater survey line spacing, aliasing frequently causes laterally continuous features to appear as a series of adjacent sub-circular features, referred to as "beads." This effect becomes worse as the trend of the anomalies approaches that of the survey lines.

Discussion of data processing

The processing described above is a combination of processes with a basis in field measurements and processes requiring the judgment of an expert processor, because it is not practical to collect the necessary data to process the data perfectly. There is no way to reliably judge the accuracy of the final measurements, but an accuracy of ± 1 nT is often quoted for individual points in the gridded datasets.

Summary

Mapping variations in TMI allows variations in rock magnetism in the upper crust to be mapped, from which geology may be inferred. The main sources of noise in magnetic data are temporal changes in the geomagnetic field and variations in the distance between magnetic sources and the magnetometer caused by changes in aircraft altitude. Temporal changes are accounted for by comparing survey data with readings contemporaneously recorded by a magnetometer on the ground. Discrepancies in repeat readings at the same location allow any remaining temporal change noise to be removed along with corrections for variations in survey altitude. The resulting data are projected on to a regular grid for display as raster images.

Definition

The term "Magnetic Methods" in geophysics generally refer to the collection of techniques, which aim to interpret the structure of the Earth's crust based on the physical property of magnetism.

Most commonly this term refers to those applications by means of which investigations are carried out regarding the subsurface structure and processes, guided by the presence of magnetic material in the Earth's crust.

Introduction: nature of magnetism

This article attempts a simple language description of how the material property of magnetism is exploited in geophysical terms to derive information regarding various aspects of solid Earth structure and processes.

Intuitively, magnetism makes us think of an iron bar, which aligns itself in the north–south direction. A magnetized bar has its power concentrated at two ends, its poles; they are known as its north (N) and south (S) poles, because if the bar is hung by its middle from a string, its N end tends to point northwards and its S end southwards. The N end will repel the N end of another magnet, S will repel S, but N and S attract each other. The region where this is observed is called the magnetic field. Either pole can also attract iron objects such as pins and paper clips because under the influence of a nearby magnet, each pin or paper clip becomes itself a temporary magnet, with its poles arranged in a way appropriate to magnetic attraction. If a much stronger/bigger bar magnet is placed near the suspended one, the latter will get aligned in a direction oriented towards the former, deviating from the original N–S direction.

Magnetic attraction occurs even when iron magnets are not evident. The Earth itself behaves like a giant weak magnet, which exerts its influence on a very wide range of magnetic materials. Out in space there is no magnetic iron, yet magnetism is widespread. For instance, sunspots consist of glowing hot gas, which are all intensely magnetic. Study of magnetism over the centuries by scientists like William Gilbert, Charles Coulomb, Hans Christian Oerstad, Andre–Marie Ampere, Michael Faraday, Heinrich Lorentz, and James Clerk Maxwell has led to the knowledge that electricity and magnetism are different manifestations of the same fundamental force field and are related to each other at microscopic and macroscopic scales.

Magnetism is caused by the flow of electric current in a conducting material. In space, on the Sun and in the Earth's core, electric currents are the only source of magnetism. Within magnetic materials, bulk magnetism is the result of the motion of electrons in an atom, which sets up a magnetic field around itself.

Components of the Earth's magnetic field

The Earth's magnetic field probably originated about 3.45 billion years ago and played a vital role in protecting the planet from damaging solar radiation, which may have stripped it of its atmosphere and water, making it completely unsuitable for life as we know it (Tarduno et al., 2010). Though the exact cause of the magnetic force continues to elude researchers, it is well established that electric currents, be on microscopic or macroscopic scales are linked to the existence of a magnetic field. The Earth's magnetic field, which is the strongest one among the rocky planets, extend 36,000 miles into space.

In solid earth geophysics, we deal with the following components:

1. The weak all-pervading geomagnetic field, generated by complex processes in the Earth's core, having a dipole and a non-dipole component (mainly represented by secular variations).
2. The smaller but often locally stronger magnetic fields generated by magnetic materials present in the crust and upper mantle of the Earth.
3. Motional induction in the ocean waters.
4. The magnetic field of the Sun, very strong but far away from the Earth, acting on the magnetospheric field.
5. Ionospheric fields, which are influenced by Earth's main field and also magnetospheric effects.

All these magnetic fields interact with each other and what we can sense and measure is a summation of all of their influences. The Geomagnetic field has a low amplitude but a very large radius of influence from the Earth's core to the magnetosphere. Near the surface of the Earth, it is influenced locally by the presence of magnetic material. Beyond the Earth and its atmosphere, the magnetosphere and ionosphere are strongly influenced by the interaction of particles and radiation coming from the Sun.

"Magnetic Methods" are implemented with an intention to remove the effects of the ambient Geomagnetic and solar magnetic fields from the measurements of magnetic force on the Earth's surface, isolate and study the local magnetic fields and use them to trace the sources of crustal magnetic material. This leads to the knowledge of the internal structure and processes operating in the Earth's crust as well as concentrations of magnetic ores in the crust.

Magnetic materials/rocks

For this method to be applied, materials found in the Earth's crust and upper mantle need to be categorized by their response to externally applied magnetic fields, in this case the Earth's magnetic field. When a material is influenced by a magnetic field, the magnetic forces of the material's electrons will be affected. This effect is

known as Faraday's Law of Magnetic Induction. Materials can react quite differently to the presence of an external magnetic field, depending on the atomic and molecular structure of the material and the net magnetic field associated with the atoms. The magnetic moments associated with atoms have three origins: electron orbital motion, the change in orbital motion caused by an external magnetic field, and the spin of the electrons. An understanding of the magnetic property requires quantum mechanical analyses. A working understanding can be acquired from the simplified concept of atomic structure given by Ernest Rutherford. In most atoms, electrons occur in pairs, which spin in opposite directions. So, when electrons are paired together, their opposite spins cause their magnetic fields to cancel each other. Therefore, no net magnetic field exists. Alternately, materials with some unpaired electrons will have a net magnetic field and will react more to an external field. Most materials can be classified as diamagnetic, paramagnetic, or ferromagnetic.

The magnetization of a material is expressed in terms of density of net magnetic dipole moments μ in the material. We define a vector quantity called the magnetization M by

$$M = \mu_{\text{total}}/V.$$

Then the total magnetic field B in the material is given by

$$B = B_0 + \mu_0 M$$

where μ_0 is the magnetic permeability of space and B_0 is the externally applied magnetic field. When magnetic fields inside materials are calculated using Ampere's law or the Biot–Savart law, then the μ_0 in those equations is typically replaced by just μ with the definition

$$\mu = K_m \mu_0$$

where K_m is called the relative permeability. If the material does not respond to the external magnetic field by producing any magnetization, then $K_{\text{m}} = 1$. Another commonly used magnetic quantity is the magnetic susceptibility which specifies how much the relative permeability differs from one.

$$\text{Magnetic susceptibility } \chi_m = K_m - 1$$

For paramagnetic and diamagnetic materials, the relative permeability is very close to one and the magnetic susceptibility very close to zero. For ferromagnetic materials, these quantities may be very large.

Another way to deal with the magnetic fields which arise from magnetization of materials is to introduce a quantity called magnetic field strength H. It can be defined by the relationship

$$H = B_0/\mu_0 = B/\mu_0 - M$$

and has the value of unambiguously designating the driving magnetic influence from external currents in a material, independent of the material's magnetic response. The relationship for B above can be written in the equivalent form

$$B = \mu_0(H + M)$$

H and M will have the same units, A/m.

Diamagnetic metals have a very weak and negative susceptibility to magnetic fields. Diamagnetic materials are slightly repelled by a magnetic field and the material does not retain the magnetic properties when the external field is removed. These are solids with all paired electrons resulting in no permanent net magnetic moment per atom. Diamagnetic properties arise from the realignment of the electron orbits under the influence of an external magnetic field. Most elements in the periodic table, including copper, silver, and gold are diamagnetic.

Paramagnetic metals have a small and positive susceptibility to magnetic fields. These materials are slightly attracted by a magnetic field and the material does not retain the magnetic properties when the external field is removed. Paramagnetic properties are due to the presence of some unpaired electrons, and from the realignment of the electron orbits caused by the external magnetic field. Paramagnetic materials include magnesium, molybdenum, lithium, and tantalum.

Ferromagnetic materials have a large and positive susceptibility to an external magnetic field. They exhibit a strong attraction to magnetic fields and are able to retain their magnetic properties after the external field has been removed. Ferromagnetic materials have some unpaired electrons so their atoms have a net magnetic moment. They get their strong magnetic properties due to the presence of magnetic domains. In these domains, large numbers of atom's moments are aligned parallel so that the magnetic force within the domain is strong. When a ferromagnetic material is in the unmagnetized state, the domains are nearly randomly organized and the net magnetic field for the part as a whole is zero. When a magnetizing force is applied, the domains become aligned to produce a strong magnetic field within the part. Iron, nickel, and cobalt are examples of ferromagnetic materials. Components with these materials are commonly inspected using the magnetic method. Ferromagnetic materials will undergo a small mechanical change when magnetic fields are applied, either expanding or contracting slightly. This effect is called magnetostriction.

In oxide crystals, the large oxygen ions keep the metal ions far apart, and exchange of electrons among them can only occur through indirect exchange, resulting in antiparallel directions of adjacent atomic magnetic moments, giving rise to antiferromagnetism which is weak and positive. Ilmenite is such a mineral, which becomes paramagnetic at room temperatures. Parasitic ferromagnetism occurs in minerals having defects in their lattices, like hematite. In spinel crystal structures, the indirect exchange process involves anitiparallel and unequal magnetization

of the sublattices, resulting in ferrimagnetism, which changes to paramagnetism beyond Curie temperature. The most important such minerals are magnetite, pyrrhotite, goethite (Lowrie, 1997).

Thus, an external magnetic field will strongly attract ferromagnetic materials, weakly attract paramagnetic materials, and weakly repel diamagnetic materials. Further details are given in *Magnetic Domains*; *Remanent Magnetism* and *Magnetic Anisotropy*.

Measurement of magnetic field and magnetic anomaly

The Earth's magnetic field varies in strength and direction over time and space as a result of the varying degrees of interactions of the causal fields. Each of the components of the magnetic field, mentioned above, influence and is influenced by the presence of the other components. This makes the study of the Earth's magnetic field interesting and challenging. Sensors are designed to record the total effect of the Earth's magnetic field and also to track the variations of one or more of the components. Many different kinds of magnetometers have been developed over the history of study of magnetism, details may be checked up on in *Magnetometers*. Near-Earth and near-polar satellites measure the magnetic field from space.

The compilation and processing of all such measurements have allowed the magnetic field of the Earth to be mapped successfully (www.ngdc.noaa.gov/IAGA/vmod/igrf.html, http://smsc.cnes.fr/html-images/solid_earth.htm). Details of such techniques are to be found in *Magnetic Methods, Satellite*; *Magnetic Methods, Surface*; *Geomagnetic Field, Measurement Techniques*. The International Association of Geomagnetism and Aeronomy (IAGA), through many participating agencies of magnetic field modelers and the institutes involved in collecting and disseminating magnetic field data from satellites and from observatories and surveys around the world, generates the standard mathematical description of the Earth's main magnetic field, which contain the contributions of all the sources listed above.

A key concept in Magnetic Method is that of magnetic anomaly. An anomaly is a deviation from a normal. Hence, embedded in the word "anomaly" are the concepts of the *ideal* and the *real*, which is different from the ideal. In the case of the magnetic field of the Earth, the ideal field is visualized as that produced by currents within a homogeneous outer core, which is essentially contained in the International Geomagnetic Reference Field (IGRF), see *Geomagnetic Field, IGRF*; *Geomagnetic Field, Theory*; *Geomagnetic Field, Global Pattern*. This Main Field itself changes with time and the IGRF needs to be redefined periodically.

At any given point of time the IGRF is overlayed by the effects of secular variations and geomagnetic jerks, by variations in solar activity and crustal magnetization, which varies from place to place within the magnetic field (see *Geomagnetic Excursions*; *Geomagnetic Field, Secular Variation*). The standard technique of Spherical Harmonic Analyses (see *Spherical Harmonic Analysis Applied to Potential Fields*) enable the Main Field (dipole field, non-dipole field, and secular variations of each) to be quantified and separated from the total observed magnetic field. The higher order terms in the energy density spectrum represent the contribution to the total field by crustal magnetization. It is the aim of "magnetic methods" to isolate and study these contributions, which are generated by composition and structures of the Earth's crust under the influence of the ambient magnetic field.

Magnetic anomaly maps provide insight into the subsurface structure and composition of the Earth's crust. Anomalies trending parallel to the isochrons (lines of equal age) in the oceans reveal the temporal evolution of oceanic crust. Magnetic maps are widely used in the geological sciences and in resource exploration. Furthermore, the global magnetic map is useful in science education to illustrate various aspects of Earth evolution, such as plate tectonics and crustal interaction with the deep mantle. Distinct patterns and magnetic signatures can be attributed to the formation (seafloor spreading) and destruction (subduction zones) of oceanic crust, the formation of continental crust by accretion of various terranes to cratonic areas and large scale volcanism (both on continents and oceans). Anomaly maps depicting crustal magnetization represent the cumulative effects of the Earth's magnetic field from the time of formation of the rocks within the crust, through various stages of metamorphism and finally the present ambient field (see *Remanent Magnetism*). The Main Field of the Earth, generated from the core, changes its strength and direction over millions of years and these influences are superimposed in the magnetization patterns of the minerals in the rocks. Techniques of separating these (see *Remanent Magnetism*; *Paleomagnetism, Measurement Techniques and Instrumentation*) embedded signatures are available and yield information about the Earth's magnetic field of the past and the present.

The total magnetization of a rock is thus the summation of remanent and induced magnetizations, which have different directions and intensities. Hence, the resultant vector is not parallel to the present magnetic field. The Konigsberger ratio Q is defined as the ratio of the intensity of magnetization to that of induced magnetization. Commonly, values of Q are low for magnetic minerals on land because these minerals are dominantly multi-domain in structure, which are reoriented by changes of the ambient magnetic field. Also they frequently have high susceptibility and the Earth's present magnetic field can induce a strong magnetization. On the other hand, ocean basalts, which were formed by extrusion and rapid underwater cooling, have very high Q values because of the structure and size of the grains as a result of the quenching.

The component of induced magnetization can be neglected and interpretations made as if the magnetization is entirely remanent.

The variations of the magnetic field with altitude, latitude and longitude are dominated by the vertical and horizontal variations of the dipole field. The altitude correction is given by the vertical gradient of the magnetic field. The corrections for latitude and longitude are inherent in the reference field that is subtracted, or the latitude correction can be given by the north–south horizontal gradient of the magnetic field. In highly magnetic terrains, the disturbing effect of magnetized topography may require topographic corrections (see *Magnetic Data Enhancements and Depth Estimation*).

Interpretation of magnetic anomalies on land

By analyzing magnetic anomalies, geophysicists are able to learn about geologic structures, which may be buried beneath the Earth's surface. Geologic structures (such as faults or igneous intrusions) often produce small magnetic fields that distort the main magnetic field of the Earth. Volcanic rocks are the most prevalent magnetic lithology, and we expect high-amplitude, short-wavelength anomalies over volcanic terranes. Steeply dipping faults that offset subhorizontal units often produce magnetic anomalies that appear as linear trends on aeromagnetic maps. Latites, on the other hand, often are extruded from volcanic plugs and thus tend to produce intense, somewhat circular magnetic anomalies (often as magnetic lows, because the latites are generally reversely polarized). Metavolcanic rocks, gabbros, and some of the intrusive rocks can produce prominent magnetic anomalies.

The magnetic properties of sedimentary rocks, such as Paleozoic sequences of dolomite, limestone, and sandstone, are usually weak, such that the resulting magnetic anomalies are very small in amplitude and undetectable by airborne surveys. The Precambrian metasedimentary rocks are generally incapable of producing detectable magnetic anomalies, although there are some notable exceptions like the iron-rich metachert and metagraywackes.

Interpretation of magnetic anomalies in the oceans

The special characteristics of magnetisation of the oceanic crust was discovered in the 1950s, when large areas of oceanic crust were found to be characterized by long stripes of alternating positive and negative magnetic anomalies in the Pacific Ocean. On magnetic profiles perpendicular to the axis of a spreading ridge, these anomalies had a remarkably symmetric pattern on both sides of the ridge. Samples of pillow basalts dredged near to ridge crests have been found to possess moderate susceptibilities and large remanent magnetizations. The ocean basalts are able to account for most of the anomalies measured in the offshore. The oceanic crust formed at a spreading ridge acquires a thermoremanent magnetization in accordance with the geomagnetic field of the time of formation. While the polarity of the field remains constant, the crust formed carries the same signature. After a polarity reversal, freshly formed basalts acquire magnetization, which is parallel to the new field and opposite to the previous one.

In cases where oceanic magnetic anomalies have two sources, from the upper basalts and the lower gabbros, the two contributions will be a little out of phase spatially because of the curved depth profiles of cooling isotherms in the oceanic crust. The net effect will be an asymmetry of inclined magnetization directions on opposite sides of the ridge, which needs to be carefully resolved during interpretation. There are contrary view, which need to be established.

Locally anomalies of the continent-ocean margins are interpreted in terms of variations of the crustal composition.

Summary

The physical phenomenon of magnetism is one of the oldest subjects of study by humans. Simplified concepts, on the basis of which this property can be used to gather knowledge about the internal structure of the Earth forms the essence of this article. Details of each aspect have been dealt with in other articles of this volume.

Definition

Magnetic field. A vector force field produced by moving electrical charges (electric currents and magnetized material).
Satellite. A compact body orbiting another body in space, and, in this case, human-made container carrying equipment for measuring magnetic fields (magnetometers) and the direction of its sensors.

Introduction

Magnetometers (qv) onboard Earth-orbiting satellites measure precise near-Earth magnetic fields in space from sensors mounted on booms to reduce interference from the spacecraft's magnetic fields. Since the dawn of the age of the Earth-orbiting satellites, the POGO series (three missions during 1965–1971, periapsis (lowest altitude) of about 400 km, scalar only, Cain (2007)), Magsat (6 months during 1979–1980, alt. 325–550 km, Langel et al. (1982)), CHAMP (2000–2010, alt. 300–450 km, Lühr et al. (2009)), Ørsted (1999–2010+, alt. 650–850, Olsen (2007)) and Ørsted-2/SAC-C (2000–2004, alt. ~700 km, Olsen (2007)) satellites have made significant contributions to the field of geomagnetism. The Swarm mission (2011 onward) is a three-satellite constellation, at altitudes below 400 km and above 530 km, and will likely lead to an order of magnitude better resolution on the measured magnetic fields due to the possibility of simultaneously measuring certain external fields in different locations and the ability of measuring magnetic gradients (Friis-Christensen et al., 2006). The magnetic fields sensed in the near-Earth environment primarily originate from the Earth's core field dynamo, lithospheric magnetic fields from rocks' ferromagnetic components, and ionospheric fields and magnetospheric fields of different origin in addition to their electromagnetic-induced counterpart in the conducting mantle, crust, and the oceans. It is possible to model (or simulate) and separate all these components and study their characteristics, but this is difficult to do so precisely, for localized, rapidly time-varying fields due to sampling inadequacies. Slowly varying components like the core field and the nearly static components from the lithosphere can be isolated well with long period observations (i.e., core field models (e.g., POMME-6.0, Maus et al., 2009) and lithospheric field models (e.g., MF6, Maus et al., 2008) from CHAMP and Ørsted satellites). A continuous model of certain aspects of these magnetic fields from POGO to CHAMP/Ørsted satellite era, including the ground magnetic observatory data, has also been achieved for quiet external field conditions (Sabaka et al., 2004).

Two primary types of *Magnetometers* (qv) used aboard satellites are scalar and vector; the scalar magnetometers typically measure total magnetic field intensity (magnitude), whereas the vector magnetometers measure fields in a particular orientation (magnitude, typically, in three orthogonal directions) relative to a baseline. Vector measurements are essential for separating fields above and below the observation plane (Backus, 1970); vector measurements also reduce a particular non-uniqueness in the interpretation of scalar magnetic anomalies close to the magnetic equator (Backus, 1970; but see also, Maus and Haak, 2003).

Polar orbits (orbital inclinations $>80°$) of these satellites allow near-global coverage of the magnetic field observations. The relative position of the satellite with respect to Earth is always changing. For precision measurements (<1 nanotesla or nT) with vector magnetometers (fluxgate type), the knowledge of the attitude (direction) of the sensors is necessary within a few arcseconds and is derived from star cameras (modern satellites have multiple-head star cameras for cross-check and backup). Vector magnetometers are relative instruments and may also drift with time, meaning their baseline changes with time. Thus, their field is calibrated against scalar magnetometers (rubidium, cesium, helium, Overhauser proton precession magnetometers) onboard.

Sources of errors

The current magnetometer instrument accuracy is high (error of < 0.1 nT) (Nielsen et al., 1995) and the magnetic field measurement precision, which include errors in the sensor attitude determination, are also small (± 1 nT) (Olsen et al., 2003). The main difference in the processing of the satellite-borne magnetic data, from those of aeromagnetic/marine/ground surveys for crustal studies (qv *Magnetic Methods, Airborne*) is in the determination and treatment of external fields. External fields are dynamic and, since the satellite flies through the ionosphere, the ionospheric fields cannot be separately monitored for the purpose of their removal as in the case with the magnetic surveys close to the Earth's surface. Spatial and temporal models are necessary of different sources of fields, such as the core field, the lithospheric field, and the ionospheric and magnetospheric fields from a plethora of different phenomena that also involve Earth-Sun interactions. Many of these fields overlap in space and time and with only a few simultaneous observations there can be no perfect isolation of these different sources of fields. The imperfection matters most to the analyses and interpretation of crustal/lithospheric fields because these fields at satellite altitude are relatively small (a few nT and hence the signal-to-noise ratio is low) and contain coalesced effects of individual sources of geologic/tectonic features as a result of the high observation altitude. Also, the magnetic effects of all geologic features of small dimensions are attenuated below the noise level of the observations (Ravat et al., 2002) and information about these features

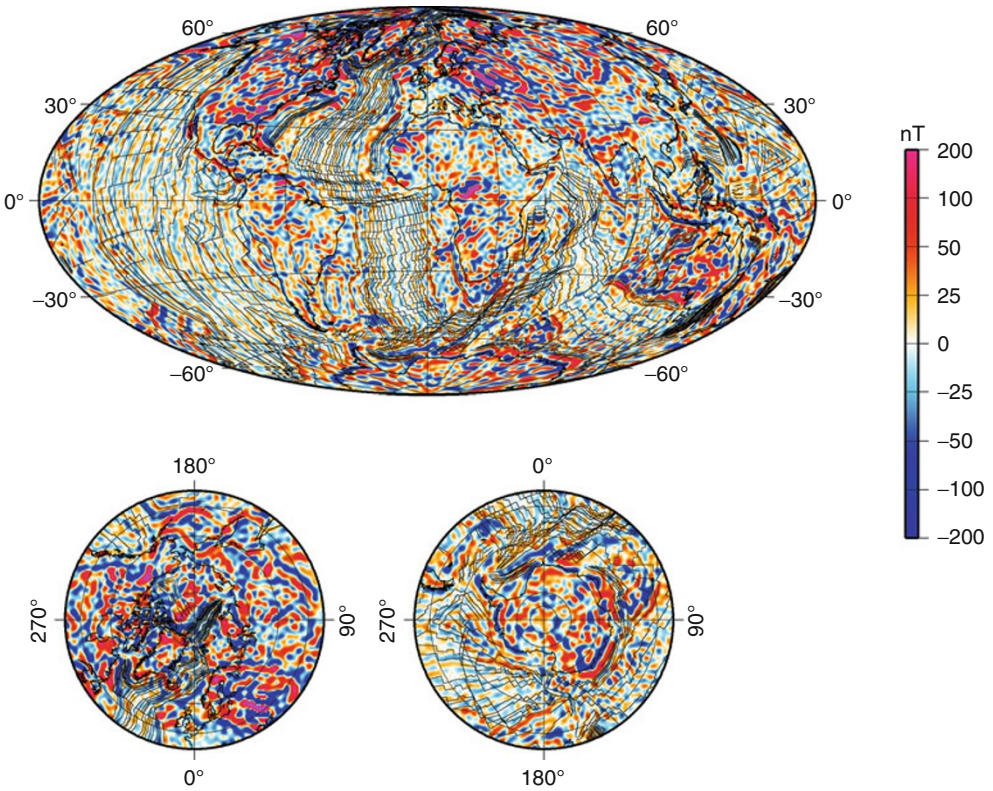
cannot be recovered. To minimize these difficulties for isolating the lithospheric fields, the data are selected from the quietest external field conditions; these quietest external fields are modeled to the best of one's capability, and the remaining external fields are filtered out (Ravat et al., 1995; Langel and Hinze, 1998; Maus et al., 2008). The ability of selecting a large amount of local night-time data (less ionospheric field contribution) at low altitude during geomagnetic quiet conditions (solar minimum) during the epoch of the CHAMP satellite has led to an order of magnitude advance in the determination of the global long-wavelength magnetic fields.

Overall characteristics of the geomagnetic field

Over 99% of the magnetic field measured at the satellite altitude originates from the Earth's core dynamo and only a fraction of a percent arises from the ferromagnetic components in the lithosphere (±20 nT at 350 km elevation, ±200 nT when downward continued to the Earth's surface). The core field varies in intensity from 24,000 nT at the geomagnetic equator to over 65,000 nT at the geomagnetic poles. It is convenient to represent the global field measured from satellites in terms of spherical harmonic coefficients. The core field dominates the longer wavelengths (>2,800 km) represented by the spherical harmonic coefficients of degree < 14, whereas the lithospheric field (i.e., magnetic anomalies) dominates in the complementary shorter wavelength part of the field. The features of the core field and its temporal changes (on the order of < ±150 nT/year) reflect the fluid flow processes in the outer core (Holme, 2007; Whaler, 2007). In addition, satellite magnetic-field data provide the spatial and temporal coverage necessary to study the conductivity variations within the Earth, and the phenomena of geomagnetic jerks (sudden change in the second derivative of the field with time) and the variations in the length of the day (i.e., changes in the Earth's rotation rate) (Olsen, 2007). Examples of the interpretation of the satellite-derived magnetic anomalies are given in Ravat (2007) and Purucker and Whaler (2007), and their features and the current use are described below.

Features of the lithospheric satellite-derived magnetic field

Figure 1 shows the vertical component of the magnetic field measured by CHAMP satellite, downward continued to the surface of the Earth. For the following discussion, features of this field should be compared to the CGMW, Geological Map of the World (http://ccgm.free.fr/index_gb.html). Even though there is no observable continent-ocean boundary-edge effect in the data, statistics is no longer needed to



Magnetic Methods, Satellite, Figure 1 Vertical component of the lithospheric magnetic field at the Earth's surface from CHAMP MF6 magnetic field model from Maus et al. (2008), superimposed with isochrons of the ocean-age model by Müller et al. (2008).

differentiate between continental and oceanic magnetic variations observed on this map. The correlation of the features of the magnetic field with geologic provinces is strong. The magnetic field over the oceans is vastly smaller in amplitude except over the edges of the magnetic polarity quiet zones (qv *Geomagnetic Field, Polarity Reversals*) and many oceanic islands and plateau regions. Over the continents, where not attenuated due to rise in the Curie isotherm (qv *Curie Temperature*) from recent tectonic/magmatic events, the magnetic field over the Archean and Precambrian regions stands out in comparison to Phanerozoic lithosphere. Many of the oceanic North–South-oriented stripes parallel to North–South trending oceanic ridges are real in this map, but some could be an artifact of the pass-by-pass filtering and misleveling of base levels in adjacent satellite passes (see, e.g., the NW-SE trending South West Indian Ridge between Australia and Antarctica also has north-south features perpendicular to the ridge – the expectation here is that stripes should be parallel to the ridge). Overall, however, the MF6 magnetic anomaly field (Maus et al., 2008) is a vast improvement over its predecessors and amenable to quantitative geologic modeling and new geologic interpretations.

Modern uses of satellite-altitude magnetic anomalies

Despite their long-wavelength nature compared to near-surface magnetic-anomaly data, there are several advantages and uses of satellite-altitude magnetic anomalies of lithospheric origin: (1) Availability of vector data make it possible to minimize some of the instabilities near the magnetic equator (Backus, 1970); (2) Several magnetic surveys since the inception of the aeromagnetic and marine magnetic surveying in the 1940s have been processed using ad-hoc processing of long-wavelengths fields and processing with different IGRF core-field models (qv *Geomagnetic Field, IGRF*) that are piecewise continuous, and hence cause artifacts in regional compilations. These problems have led to spurious intermediate- and long-wavelengths to the extent that misinterpretation of lower-crustal magnetic features can occur (e.g., zones of regional magnetization, depth to Curie isotherm/magnetic bottom). These problems can be overcome by replacing the intermediate- and long-wavelength field by downward-continued satellite-altitude field in regional compilations (Ravat et al., 2002; Bankey et al., 2002). The long-wavelength CHAMP field has also been used to provide a common datum in the preparation of the World Digital Magnetic Anomaly Map (http://projects.gtk.fi/WDMAM/project/perugia/index.html, Korhonen et al., 2007); and (3) Several regions of the world have little or no coverage of magnetic anomalies; in these regions, the downward-continued magnetic field gives some idea of the intermediate- and long-wavelength anomaly field that could be useful in regional geologic interpretation.

The main limitation of satellite-altitude magnetic fields is that the magnetic effects of geologic sources have coalesced at satellite altitudes. High precision of the MF6 field has partly circumvented this issue by downward continuation of the field to the surface; however, the part of the short-wavelength signal that is in the noise level at the satellite altitudes cannot be recovered. Thus, only features of >350 km wavelength can be reliably mapped with the present satellite-altitude data. Another milestone to be achieved is the separation of the lithospheric field from the field attributed to the core of the Earth (spherical harmonic degree <14). The latter may pose challenges in the recognition of the continental and oceanic boundaries and a number of large cratonic regions of the world (as discussed by Purucker et al., 1998; however, this inference has been challenged by the study of Hemant and Maus (2005)).

Summary

Over the last decade, the availability of continuous time series of high-precision magnetic measurements from space (Ørsted, CHAMP and Ørsted-2/SAC-C satellites) has significantly advanced the knowledge of magnetic fields observed in the near-Earth environment compared to the previous space-borne magnetic observations. These magnetic fields are produced by many sources, ranging from the core of the Earth to the regions deep in the Earth's magnetosphere, and include also effects caused by the Sun's direct influence on the Earth. The newest CHAMP-based lithospheric field models (e.g., MF6, Maus et al., 2008) have a wealth of geologic information that can be used to improve regional and local magnetic survey compilations and decipher regional geologic characteristics difficult to assess from local or regional magnetic anomaly compilations or areas devoid of near-surface magnetic measurements on the Earth.

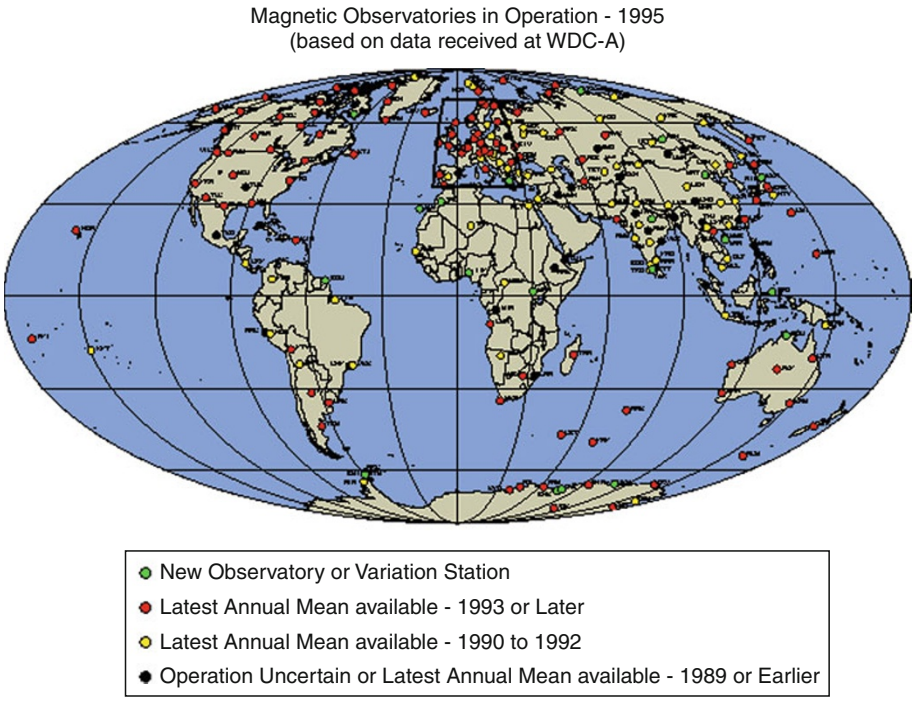
Definition

Magnetic observatory. Magnetic observatories continuously measure the Earth's magnetic field at fixed locations at the Earth's surface. They are designed to operate for several decades to stably record rapid and slow variations of the earth's magnetic field and report time-averaged values that estimate the form of the Earth's magnetic field. Since observatories started operating in the nineteenth century, the methods of measurement, reporting, and analysis have varied over region and time. After the International Geophysical Year (IGY – 1957–1958), the quality and organization of the data have been standardized, making spatial and temporal studies easier, more refined, and consequent models more accurate. The International Association for Geomagnetism and Aeronomy (IAGA) is the coordinating body for the magnetic observatories of the world, standardization of measurement, exchange of data, and presentation of models of the Earth's magnetic field. There are about 200 magnetic observatories reporting standardized data, and several more making continuous variation measurements (Figure 1).

INTERMAGNET. Classical torsion magnetometers, with analogue-photographic systems, were replaced in the 1980s by improved fluxgate magnetometers and digital data acquisition systems. More recently, a magnetic standard evolved by IAGA, INTERMAGNET (International Real-time Magnetic Observatory Network), has resulted in a network that provides one-minute values of the three components of the geomagnetic field, in near-real time. INTERMAGNET standards of measurement and digital reporting have been adopted by over 100 observatories, worldwide.

Observatory and semi-long-term measurements

Magnetic observatory data are used to report and study periodic and episodic variations that are classified by time scale and mechanism: Long term secular variation, 11-year solar cycle, annual, semi-annual, seasonal, and daily

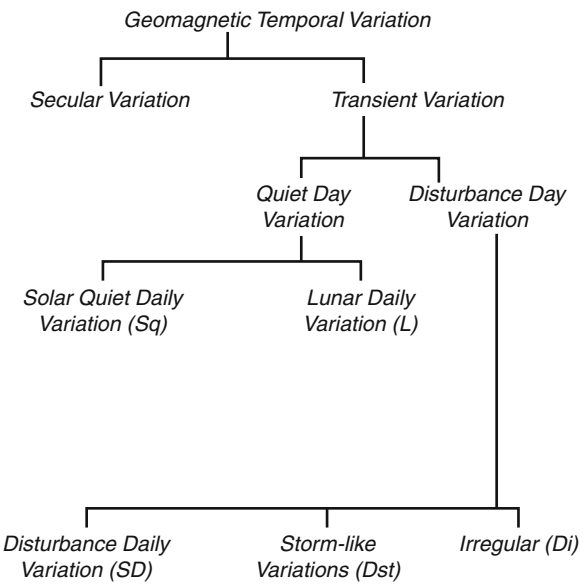


Magnetic Methods, Surface, Figure 1 Currently operating observatories, updated in 1996 (Jankowski and Sucksdorff, 1996).

variation and shorter transient variations classed as disturbances (Figure 2).

Observatory yearbooks often give the average solar daily variation for different months of the year, and even separately for quiet, disturbed and all days. Based on an analysis of magnetic activity by trained observers, and estimation of the activity indices (most commonly K), five quiet and disturbed days are selected for each month by the International Service of Geomagnetic Indices.

Magnetic variations have characteristics, varying over latitude and period attributed to different sources – solar activity from 11 years to 27 days; diurnal harmonics of ionospheric currents from 24 to 4 h; shorter events like sudden commencements, sudden impulses, substorms (bays) from −2 h to 1 min; magnetic pulsations, with small amplitude and short periods from 1 to 60 s. Hourly and daily variations are a measure of solar interaction with the Earth's magnetic field. This can be both solar radiation, interacting daily with the ionosphere or corpuscular streams interacting with the magnetosphere, manifested as disturbances. Regular solar daily variation is also a function of season, solar activity, and latitude. The variation of the magnetic field on magnetically quiet days is called the solar quiet day variation or Sq variation. Magnetic storms (∼day), substorms (∼hour), pulsations (∼min), sudden impulses, and solar flares are some of the transient disturbances. The longer, slower variations are obtained from monthly and annual means of observatory data. The trends seen in the data complied over the last 150 years have been used to produce spherical harmonic representation of the Earth's magnetic field that is internally



Magnetic Methods, Surface, Figure 2 Diagram showing the different types of geomagnetic variations (Okeke et al., http://www.saao.ac.za/∼wgssa/as4/fokeke.html).

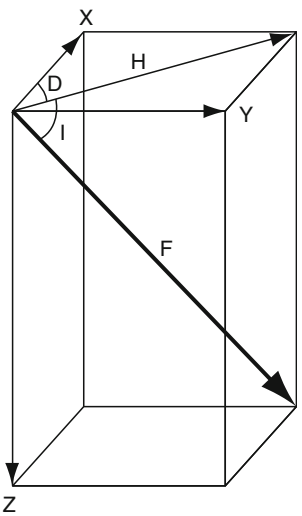
generated and its secular variation that are indicative of processes within the Earth's mantle and outer core. Definition of the main magnetic field and secular variation are currently supplemented by low-earth orbiting satellites (OERSTED,

CHAMP missions, for example). This is one of the fastest growing areas of study.

Magnetic measurements

Vector and scalar measurements: Magnetic measurements can be scalar (total field) or vector. To define the vector, three out of seven elements need to be measured simultaneously (Figure 3). Commonly, any three of these elements are measured in a magnetic observatory as variations, to fully define variations of the total magnetic field.

Absolute measurements: Most vector magnetometers used in magnetic observatories (earlier torsion, and recently fluxgates) usually drift in time due to several factors such as temperature variations, magnetic moment, and aging of the electronics. In order to periodically recalibrate the vector measurements, absolute measurements fully defining the magnetic field vector are performed, to complement continuous measurements, on a regular basis (typically once a week). Such measurements are made by a trained observer using a single-axis fluxgate magnetometer mounted onto a nonmagnetic theodolite and a scalar magnetometer. From which, the continuous measurements can be calibrated to a baseline defined by absolute measurements. Two types of data are available from observatories: preliminary data, which are made available in quasi-real time (less than 72 h), and definitive data, which are produced only once a year, typically a few months after the end of the calendar year. After reducing time variations to absolute baseline at a location, continuous observations of the vector magnetic field are produced at desired sampled intervals: minute, hour, day, month, year, etc. These data are available for all years going back to the start of observations at each observatory. The format for easy assimilation and distribution of this data are formulated by IAGA working groups – updated periodically since 1957–1958. This data is also available at World Data Centers for Geomagnetism, established in different countries, partly by their research institutions and partly funded by IAGA.



Magnetic Methods, Surface, Figure 3 Magnetic elements, defined in geographic and geomagnetic coordinates. (Jankowski and Sucksdorff, 1996).

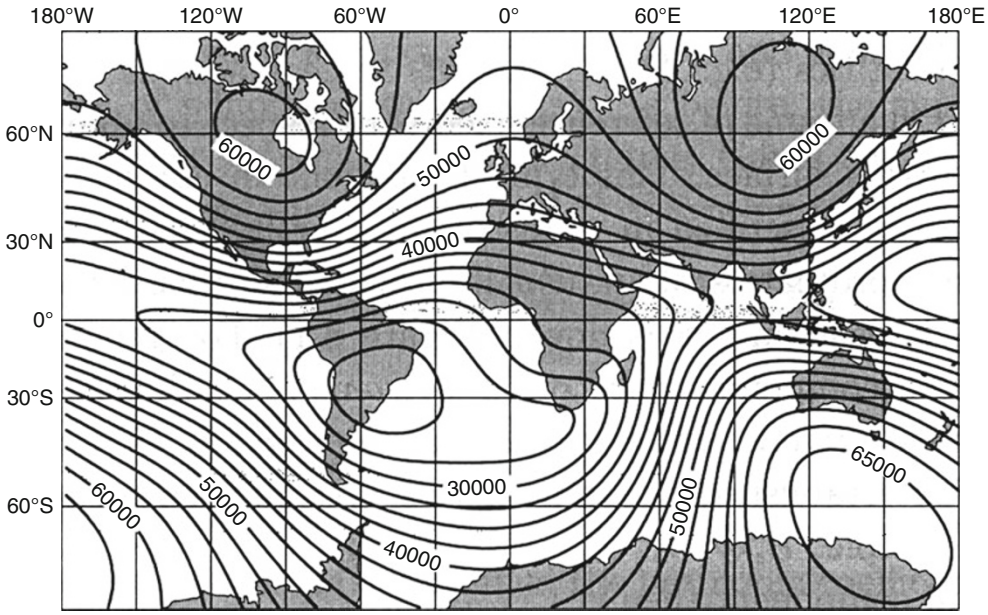
Products of observatory data

Magnetic field values at different points on the Earth, their variation on different timescales are obtained. The Earth's magnetic field has been approximated as a dipole and more accurately expressed as a spherical harmonic series, based on time-averaged means of observatory data, by Gauss, demonstrating that 95% of the field intensity is derived from inside the Earth and 5% due to external currents in the atmosphere (now known as magnetosphere). The magnitude of the magnetic field components varies from 0 to 60,000 nT. From variations of the magnetic field at regularly sampled intervals, much information can be extracted. The time-averaged values over months and years provide a data set approximating the potential field of the internally generated magnetic field. The absolute value of the field at a point on the Earth can therefore be estimated with accuracy of ~0.01%. These values define the shape of the Earth's magnetic potential field (Figure 4). This is termed the International Geomagnetic Reference Field, for a stated epoch (instant in time). Other data sets from magnetic surveys and satellites are added to refine the IGRF (see *Geomagnetic Field, IGRF*).

Secular variation: Variation in monthly and annual means defines the secular, slow change of the Earth's internal magnetic field. This has been mapped going back to about 300 years. Secular variation is, however, a small variation compared to absolute values and is determined as change over years of averaged variation. The change is as small as ~10 nT/yr. The pattern of secular variation places constraints on the theory of generation of the Earth's magnetic field and maps fluid flow in the outer core. It is also the only means of studying electromagnetic and thermal properties of the Earth's outer core (depth: 3,000 km) (see *Geomagnetic Field, Secular Variation*).

Solar radiation and quiet day variations

Daily variation at each observatory has contributed to the definition of solar-induced daily ionospheric currents (Sq). Variation with latitude and season has also been defined (Figure 5). These variations range between 10 and 100 nT, in each component. In this, diurnal variation is the most prominent. Monthly, seasonal, and annual variations are largely controlled by radiation (F10.7) from the sun. The effects of solar radiation on the ionosphere drive electric current loops in the ionosphere (height ~100 km). Study of these regular variations from both observatory data and in recent decades, from satellite data, has resulted in better models of the current loops and their variability. In addition, solar-induced disturbances affect the earth's magnetic field.



Magnetic Methods, Surface, Figure 4 Spatial variation of the Earth's magnetic field scalar (F), approximating a dipole field, over the Earth (After Jankowski and Sucksdorff, 1996).

Magnetic disturbances and solar activity

Study and classification of magnetic disturbances, the influence of sunspot activity, etc., were noted and a theory explaining these phenomena evolved, from a study of observatory data, during 1920–1940. This theory has since been corroborated from a direct observation of corpuscular radiation streams from the Sun and magnetospheric currents, by satellites. Magnetic disturbances are of varying time period from minutes to days. Magnetic storms are the most prominent among these with characteristics variations of ~100 nT. Short period events like bays, sudden commencement, and solar flares have amplitudes of ~10 nT [magnetic pulsations, storms].

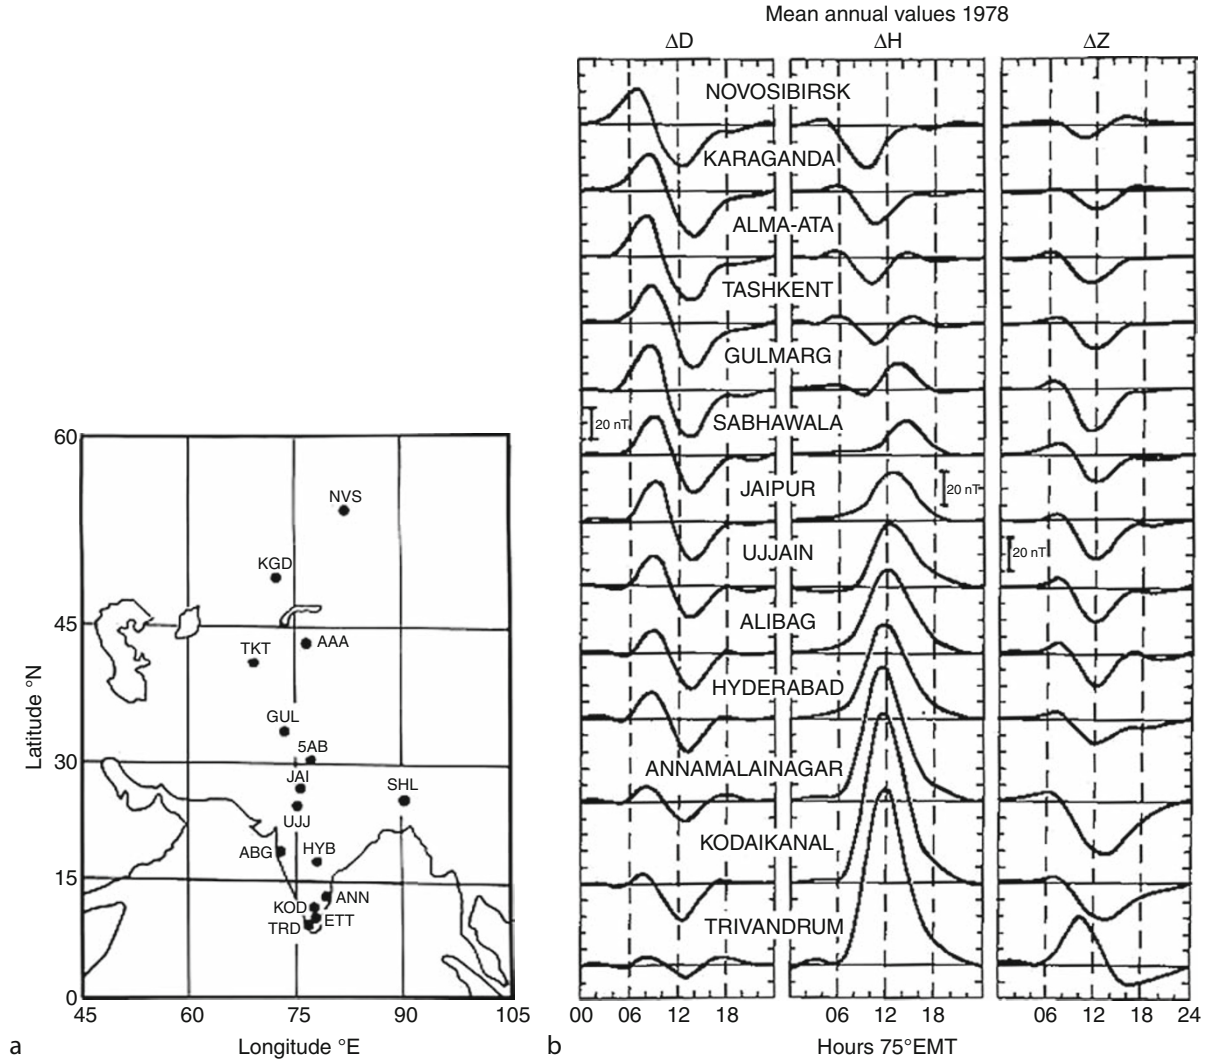
Each day's variations are analyzed and classified from quiet to disturbed, as a measure of magnetic activity in the earth's magnetosphere, in a manner that eliminates geographic difference. Geomagnetic indices were formulated as a composite of reported variations from observatories at different locations. These indices, and several new ones, continue to be reported and are updated, revised in accordance with discussion and resolutions passed by IAGA.

Uses of observatory data

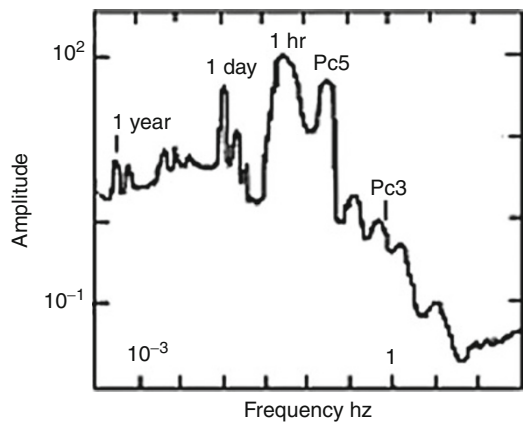
From the individual magnetic observatories established 150 years ago, and some earlier measurements, a pattern of global behavior of the magnetic field came to be defined. After the International Geophysical year (IGY), in 1957, studies of the earth's physical properties, time variations and mechanisms, intensified. Observatory data are useful in determining rapid, medium term as well as slow variations in earth's magnetic field. Each range of variations, studied for specific signals, contributes to the understanding of different processes (Figure 6).

Some of the phenomena being currently studied are:

1. Secular variation of the magnetic field at different places on the Earth. It is then expressed in spherical harmonic coefficients and included in the IGRF by adding time derivatives of coefficients. Knowledge of these variations is important in theoretical modeling of the geomagnetic dynamo. It is the only means of studying the motions of the electrically conducting fluid in the Earth's outer core, where the main geomagnetic field is generated. These data are also widely used to calculate time-varying core field models, often in combination with satellite magnetic data or historical data (see *Geomagnetic Field, Global Pattern*).
2. The regular variations of the magnetic field are related to rotation and/or orbital movements of the Earth, Sun, and Moon. The most prominent is the diurnal variation or solar daily variation, having amplitudes of the order of 10–100 nT(nanotesla). Solar radiation ionizes the higher atmosphere during the daylight hours, and the gravitational forces of the Sun and the Moon force the ionospheric layers in a tidal motion. So the ionized gas in the ionosphere moves in the magnetic field of the Earth, creating electric currents which are seen as daily variations in magnetic recordings. There are two well-known periodic variations, the solar daily variation and the lunar daily variation.
3. A global network is essential in monitoring the pattern of geomagnetic storms, local disturbances, mapping of



Magnetic Methods, Surface, Figure 5 Diurnal variation of the magnetic field, showing changes with latitude for solar quiet days (**a**) locations of observations (**b**) variations with latitude.



Magnetic Methods, Surface, Figure 6 An illustration of the wide spectrum geomagnetic variations (~1 s to 1 year) (Serson, 1983).

currents generated in the magnetosphere, and thereby, inferences about presence of charged particles, models of magnetic field lines.

4. Induced currents in the crust and mantle are caused by external variations of the earth's magnetic field. For each periodic and episodic event described above, a corresponding current is induced in the finitely conducting layers of the Earth. An estimation of these currents provides a measure of the electrical conductivity distribution within the Earth's crust and mantle. This has been applied as a tool to study the Earth's interior and a large volume of electromagnetic variation data has been collected solely to this purpose. In the past decade induced signals from satellite magnetic data have been used to model electrical conductivity distribution, over continents and oceans (see *Geoelectromagnetism*).

5. Ground observation networks provide calibration and control of magnetic survey satellites and complement detailed ground surveys of the magnetic field.
6. Magnetic pulsations –10 Hz to 600 s – are small amplitude variations generated at the boundary between magnetosphere and solar wind, under various dynamic conditions and transmitted through the magnetosphere and ionosphere, and carry signatures of the properties of these regions as well.

Land surveys

Magnetic surveys are conducted on land to determine changes in physical properties of subsurface rocks (viz., magnetic susceptibility). Magnetic field scalar (or vector) is measured using a suitable portable magnetometer at precisely determined points in the survey area. The measurements provide variation of the magnetic field strength over the area surveyed, at a desired sampling length (in m or km), depending on the extent or depth of anomaly expected. (*Magnetic Methods, Airborne; Magnetic Methods, Principles; Magnetometers; Magnetovariational Studies*) At the same time a record of temporal variations is made, at a central point in the survey area, or by tying up the survey to a nearby observatory. The field values, which could be scalar values of total field, or a component of the vector are then corrected for diurnal variation occurring during the survey. This is a crucial aspect of magnetic surveys. If the survey is over a sufficiently large region (∼100 km), IGRF values of the main magnetic field are also subtracted from the data points. The variation over the sampled points then indicates spatial changes, which are interpreted in terms of changes in magnetic properties of subsurface rocks. The variations found from this data are ∼100 nT and in the case of very large anomalies it maybe ∼1,000 nT. The accuracy of determining these anomalies depends on the accurate measurements, both at survey points and base stations. Most modern magnetometers can measure a spot value to 0.1 nT accuracy. But determining the anomalous value from this requires precise reduction of data. Errors of alignment, timing, and baseline values can affect subsequent analyses. Presence of man-made electromagnetic effects also affect surveys. Therefore, it is it is possible that errors of upto 2 nT are present. Fast surveys like marine and aeromagnetic are most effective in obtaining relative changes, rather than accurate estimation of magnitudes.

Most commonly, change in magnetic susceptibility indicates a change in composition of rock. In certain instances, in the study of crustal magnetization, it could indicate thermal changes (*Global Magnetic Anomaly Map*). Since the amount of ferromagnetic minerals varies considerably, among different crustal rocks, magnetic surveys are a quick and effective method for detecting subsurface variation in rock type. Magnetic surveys are a viable method to obtain information regarding the crystalline basement over areas of sedimentary cover. The method has also been used to provide information on upper crustal structure and thermal state, along major geotransects. The results of magnetic surveys are presented in the form of contour maps of intensity of total or any field component. The anomaly maps are prepared after subtraction of the IGRF, and do not contain any signatures of the dipole field of the earth, including averaged crustal effects. Such maps/data grids can be modeled as a simple potential field caused by the anomalous susceptibility distribution alone. This is the utility of magnetic surveys. Modeling of these potential fields is considerably advanced, with inversion over two and three dimensional bodies possible (see *Magnetic Anomalies, Interpretation*).

The most significant change in magnetic properties occurs at Curie point, the depth varies considerably in different tectonic settings. Therefore, large-scale magnetic surveys provide significant inputs to deep crustal studies. Mapping of spatial magnetic variation provides information about the thickness of the basement rock beneath sedimentary basins/supracrustal rocks and thermal state of the crust of that region.

Marine magnetic surveys

Methods of marine magnetic surveys are more elaborate, since instruments have to be towed behind a vessel and data collection is challenging. However, principles of analysis are similar. These methods map the variation in thickness of the oceanic crust – which consists of uniform magnetic material (basalt). In the case of marine magnetic surveys, the errors in measurement are greater, since the vessel tows the magnetic sensor, it is liable to more movement, making accurate measurement of position and magnetic value more error-prone. The magnetic anomalies arising from distribution of magnetic basalt on the ocean floor are at a distance of 1–5 km from the measuring platform (ocean surface). From a careful elimination of errors due to wave noise, position tracking, and instrument noise, long track of marine magnetic anomalies have been recorded. Over several decades, measurements have been made in the campaign mode, and latest measurements with better instruments have been tallied with older measurements, so that a maximum amount of data could be utilized. The amplitude of marine magnetic anomalies is ∼100–1,000 nT, after removal of IGRF values. The geometry of marine magnetic anomalies is striking, they trend in parallel lines and follow a long linear track across the oceans. This feature has been recognized as bands of basalt that have been added to the ocean floor in different ages, creating new ocean floor, for over 200 million years. Significant variations in marine magnetic measurements have been attributed to pulses of ocean-floor formation. These pulses belonging to different epochs have been identified by adjacent stripes of differing magnetization of the ocean floor – a significant discovery of the phenomenon of "seafloor spreading" (*Paleomagnetism, Magnetostratigraphy*).

Principles of survey measurement

The measurement of spatial variation of magnetic field depends on determining the value at a spot, obtaining the position, and time of measurement, and eliminating temporal variation, during the period of the survey, at each location. For this, data have to be reduced to a time epoch in contrast to observatory measurements, which provide time variations at a fixed point. The objectives of a survey govern the use of specific magnetic instruments, surveying parameters (for example, observation elevation and data spacing), and the coordinate system used for the analysis of the data. For geological interpretation either total field scalar or vector measurements are suitable. But mapping of internally induced currents – in the crust, for tectonic studies, or in the mantle and outer core, for studies of the deep interior – requires vector measurements. Instruments used vary from torsion magnetometer, to fluxgate, proton precession, SQUID, etc. The precision of most modern instruments is between 0.1 and 1.0 nT.

The residual, after removing temporal variation, is the variation in potential caused by deflection of field lines, through a volume of subsurface that has nonuniform magnetic properties.

Instrumentation technologies

The principles of magnetometers are:

1. Torsion magnetometers measure the opposing force to the magnetic field – as in torsion fiber suspended magnetometers and deflection measurements. This was the oldest and mostly accepted method for nearly 200 years. Examples: Quartz horizontal magnetometer (QHM), Balance magnetometer Zero (BMZ), Kew Magnetometer, La Cour/Eschenhagen variometers, and others.
2. Flux measurement, amplified and measured in a ferrite sensor, with appropriate hysteresis – fluxgate magnetometers. Accuracy of fluxgate magnetometers can be adapted to different ranges of measurement. When mounted in triaxial mode, they are give reliable values of the field. The Magnetometers are sensitive to temperature variation and internal noise, but these have been minmized by improved design. They are suitable for observatories, satellites, and unmanned vector measurements.
3. Magnetic Theodolite: Estimating opposing force to the magnetic field as applied to a sensor of finite magnetic moment – using an oscillating magnet and theodolite, an old, classical method for absolute values – several instruments are still in use as secondary standards. A modern version of this is the Declination Inclination magnetometer. Thus uses a singly fluxgate counted on a theodolite. This is adjusted to a null position to find the inclination of the magnetic field. In conjunction with total field measurement, this would result in vector components. The theodolite also gives azimuth and declination measurements. Since it is a null observation, accuracy is good. This has been adopted at standard for modern magnetic observatories and is increasingly used for surveys also.
4. Precession: Based on the frequency of precession of hydrogen atoms (protons) after a strong external field is applied. Precession frequency is proportional to the ambient field. This is the most stable accurate method at present. Counting of frequency is very accurate with improved digital time stamping. The proton precession magnetometer measures only the scalar of total field intensity. An improvement of the same principle is the Overhauser magnetometer, which stimulates precession almost continuously and thereby produces a steady signal that is a measure of ambient field. This magnetometer is now chosen for most remote, continuous, and surveying operations.
5. Optically pumped magnetometers: The principle is of optical excitation of cesium (or other) gas, with a focused beam of coherent light. Zeeman splitting effect produces splitting of the lines emitted by the sample gas. The frequency of split is proportional to the ambient magnetic field.
6. Induction coil magnetometers: These operate on the simple principle of measuring the output of a coil of many windings around a ferrite core. The signal is proportional to the derivative of the magnetic field. The induction coil has good response of a wide frequency range of measurement. This is used for rapid variation, e.g., pulsations, magnetotellurics, etc.

Summary

The shape, strength and variations of the Earth's magnetic field, have been studied over 500 years. Starting from measurements, repeated in time, at different places on earth, a model of the Earth's magnetic field, in space and time has been built up. Magnetic observatories are places where long time series of accurate measurements of the magnetic field are made, analysed and disseminated to institutions and persons seeking this information. Variations in different period ranges provide information about diverse processes, affecting the magnetic field. Short period variations (∼min, hr) are indicative of disturbances in the magnetosphere caused by the Sun's corpuscular streams and magnetic fields, medium-term variations (∼day, year) describe effects of the sun's radiation and long-term variations (∼year, decade, century) provide insights into the nature of the Earth's internal magnetic field, its origin, and modification in the Earth's outer core (secular variation). Closely spaced measurements on the Earth's surface are used in studies for resource exploration, tectonics and mapping the formation of the oceanic crust.

The form of the Earth's magnetic field is defined every five years, collating all available measurements as the IGRF. This also provides estimates of secular variation. The vast quantity of data collected about spatial and temporal variations of the Earth's magnetic field, has resulted in increasingly accurate models of processes on the Sun, in space and on and within the Earth.

Definition

Magnetic Modeling usually refers to the process of developing models of the Earth's magnetic field based upon measured magnetic data. A model may be as simple as recognizing that an anomaly is likely caused by a buried iron object, or it may involve sophisticated data processing and/or inversion to mathematically build a range of plausible models.

Introduction

When either a ground observatory or a satellite takes a geomagnetic field measurement, it represents the superposition of many sources. The greatest contribution is generated from the dynamo action within the fluid, iron-rich core of the Earth, known as the core field. Although depending upon the altitude and location of the measurement, the data may have sizeable contributions from the static lithospheric field being largely generated from rocks and remnant magnetism within the Earth's crust. Internal in origin are also small magnetic signals produced by the electrical currents associated to the water flow in oceans. On the other side, the external field sources originate in the ionosphere and magnetosphere. These sources include the daily solar quiet variations, the ring current variations, and the many other atmospheric current systems (e.g., the field-aligned currents and the auroral and equatorial electrojets). When modeling Earth's magnetic field one must also take into account the currents induced in the Earth from these external fields. Sporadic magnetic storms and pulses, which have short-term effects, also play a role in the measured magnetic field values.

An important feature of the geomagnetic field is its variability on many different timescales, from less than a second to millions of years (Mandea and Purucker, 2005). The knowledge of the Earth's magnetic field relies on various data sources, ranging from rock magnetization measurements to direct magnetic field measurements, from historic magnetic measurements to recent high-quality data provided by magnetic observatories and the magnetic satellites as MAGSAT, Ørsted, CHAMP, and SAC-C (Mandea et al., 2010a). A combination of ground and continuous satellite measurements allows the core magnetic field and its time variation to be described with a very high resolution in space and in time, on global scale (e.g., (Lesur et al., 2010; Olsen et al., 2010)). On the other side, recent dynamo simulations have also contributed to the understanding of the core field geometry and its dynamics, and temporal changes (Christensen and Wicht, 2007; Wicht et al., 2010).

The geomagnetic field changes in space and time, therefore magnetic observations must continually be acquired, on ground and near-Earth's space. The magnetic observations are performed in different ways and at various platforms. Geomagnetic observatories have provided the highest quality data, however with a very uneven spatial distribution. To increase the spatial density regionally, repeat station surveys are conducted by many teams, but at a national scale, only. Over the last decade, magnetic satellites have offered a uniform, global coverage, but face problems of altitude control and ambient current in the surrounding plasma.

This very brief description of the sources contributing to magnetic observations, suggests how challenging it is to obtain a reliable mathematical description of magnetic field for the modeling process. New mathematical tools need to be developed to accurately describe magnetic data. Depending on the available data and the base functions, those models can be global or regional, static or time dependent. The mathematical description of the different kinds of field models, their physical backgrounds, and applicability are vast subjects, and cannot be covered in detail here. The main aim of this contribution is to give to the reader a basic support and information for more detailed readings.

Global field modeling

Spatial and temporal description

The geomagnetic field is a global phenomenon, so the most obvious approach is to describe it on the whole Earth's surface. The magnetic field, following the Maxwell equations is source-free, so it can be written:

$$\nabla \times \vec{H} = \vec{J} + \frac{\partial \vec{D}}{\partial t} \tag{1}$$

$$\nabla \cdot \vec{B} = 0 \tag{2}$$

where $\vec{H}$ is the magnetic field, $\vec{B}$ is the magnetic induction, $\vec{J}$ is the current density, and $\partial\vec{D}/\partial t$ is the electric displacement current density. In a region without magnetic field sources, for example from the Earth's surface up to about 50 km, it is reasonable to assume that $\vec{J} = 0$ and $\partial\vec{D}/\partial t = 0$, so $\nabla \times \vec{H} = 0$, meaning that the vector field is conservative in the region of interest, and the magnetic field $\vec{H}$ can be expressed as $\vec{H} = -\nabla V$, where V is a scalar potential. Because $\vec{B} = \mu_0\vec{H}$ above the Earth's surface (where $\mu_0 = 4\pi \times 10^{-7}$ H m^{-1}), it follows that $\nabla \cdot \vec{H} = 0$ and that V has to satisfy Laplace's equation:

$$\nabla^2 V(\theta, \phi, r) = 0 \tag{3}$$

We underline that in geomagnetism the magnetic induction $\vec{B}$ is traditionally called "magnetic field." We use the same notation in the following. In spherical coordinates (θ, ϕ, r), which are the geocentric co-latitude, longitude, and radial distance, Laplace's equation takes the form:

$$\frac{1}{r}\frac{\partial^2}{\partial r^2}(rV) + \frac{1}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial V}{\partial\theta}\right) + \frac{1}{r^2\sin^2\theta}\frac{\partial^2 V}{\partial\phi^2} = 0 \tag{4}$$

Equation 4 solutions are products of three expressions (the first is to be only a function of r, the second, only a function of θ and the third, only a function of ϕ) and can be solved by separation of variables. A completely general solution is provided by spherical harmonics, and can be written in such a form to express two important contributions in the potential field: a part, V^{int} describing the internal (core and lithospheric) sources, and a part, V^{ext}, describing the external (mainly magnetospheric) sources:

$$\begin{aligned} V &= V^{\text{int}} + V^{\text{ext}} \\ &= a\sum_{n=1}^{N_{\text{int}}}\sum_{m=0}^{n}\left(g_n^m\cos m\phi + h_n^m\sin m\phi\right)\left(\frac{a}{r}\right)^{n+1}P_n^m(\cos\theta) \\ &\quad + a\sum_{n=1}^{N_{\text{ext}}}\sum_{m=0}^{n}\left(q_n^m\cos m\phi + s_n^m\sin m\phi\right)\left(\frac{r}{a}\right)^{n}P_n^m(\cos\theta), \end{aligned} \tag{5}$$

where a = 6371.2 km is a reference radius, (θ, ϕ, r) are geocentric coordinates, P_n^m are the associated Schmidt normalized Legendre functions, N_{int} is the maximum degree and order of the internal potential coefficients g_n^m, h_n^m, and N_{ext} is that of the external potential coefficients q_n^m, s_n^m.

Some of the base functions show special characteristics and are named individually:

- Zonal functions are characterized by $m = 0$ and are independent of longitude.
- Sectorial functions, are defined by $n = m$, so there are no zero crossings in latitude.
- Tesseral functions vary with both latitude and longitude.

The Gauss coefficients can be interpreted in terms of "sources." The first term, g_1^0, is associated with the geocentric dipole oriented along the vertical axis, that is, axis of the Earth's rotation, with dipole moment $g_1^0 4\pi a^3/\mu_0$. The next two terms, g_1^1, h_1^1, characterize the geocentric dipoles oriented along the two last orthogonal axis. The magnitude of the *geocentric dipole* is given by $M = (4\pi a^3/\mu_0)\left(\left(g_1^0\right)^2 + \left(g_1^1\right)^2 + \left(h_1^1\right)^2\right)^{1/2}$, and presently is tilted at roughly 11° from the rotation axis. The potential for a dipole falls off as r^{-2}, and the strength of the field components as r^{-3}. Similarly, for $n = 2$, the terms represent the *geocentric quadrupole* (potential falls off as r^{-3}, and the strength as r^{-4}), for $n = 3$ the terms represent the *geocentric octopole* (potential falls off as r^{-4}, and the strength as r^{-5}), and so forth.

The first three Gauss coefficients $\left(g_0^1, g_1^1, h_1^1\right)$ represent the *dipole* field, while the remaining terms represent the *non-dipole field*. The lowest degree terms correspond to the largest wavelength features of the field, and is dominated by zonal harmonics. The first Gauss coefficient has a cos θ dependence, so at distance r the "wavelength" of the associated magnetic feature is $2\pi r$. Generally speaking, the term g_n^m has a wavelength of $2\pi r/\left(n+\frac{1}{2}\right)$ (Backus et al., 1996).

To describe only the part of the geomagnetic field with sources beneath the Earth's surface, only the part V^{int} of Equation 5 is used. However, this first term of Equation 5 describes both the core and lithospheric fields. It is possible to separate sources originating in the core from those originating in the lithosphere (Lowes, 1966) by computing

the mean square value of the field over the Earth's surface produced by harmonics of a given n:

$$W_n = (n+1)\sum_m \left(\left(g_n^m\right)^2 + \left(h_n^m\right)^2 \right). \tag{6}$$

Variation of W_n depends on degree n, it is known as the power or Lowes–Mauersberger spectrum, and Figure 1 shows its behavior. The steep part of the spectrum ($n \leq 13$) is clear and indicates the signature of the long wavelengths of the core field, the transition degrees ($n = 14$–15) can be attributed to signals from both the core and the lithospheric sources, and the higher degrees ($n \geq 16$) are dominantly lithospheric in origin.

The above description in terms of spherical harmonics is used to characterize static or snapshot fields. Considering the definition of the components X, Y, and Z of the magnetic field (in the northward, eastward, and radially inward directions) and the definition of the spherical polar coordinates (Merrill et al., 1996), it is apparent that $X = -B_\theta$, $Y = B_\phi$ and $Z = -B_r$. For a given epoch, the components of the geomagnetic field are obtained from the model coefficients using the internal part of Equation 5, as derivatives of potential:

$$\begin{aligned} B_\theta &= -\frac{1}{r}\frac{\partial}{\partial\theta}(V^{\text{int}}) \\ &= -\sum_{n=1}^{N_{\text{int}}}\sum_{m=0}^{n}\left(g_n^m\cos m\phi + h_n^m \sin m\phi\right)\left(\frac{a}{r}\right)^{n+2} \\ &\quad \times \frac{\partial}{\partial\theta}P_n^m(\cos\,\theta) \end{aligned} \tag{7}$$

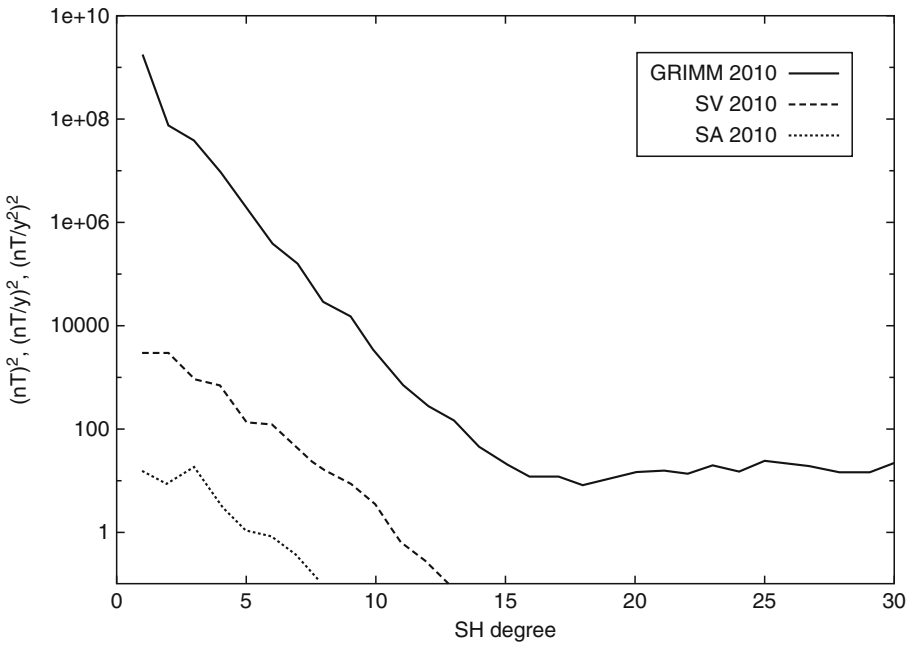
$$\begin{aligned} B_\phi &= -\frac{1}{r\,sin\,\theta}\frac{\partial}{\partial\phi}(V^{\text{int}}) \\ &= \frac{1}{sin\theta}\sum_{n=1}^{N_{\text{int}}}\sum_{m=0}^{n} m\left(g_n^m \sin m\phi - h_n^m\cos m\phi\right)\left(\frac{a}{r}\right)^{n+2} \\ &\quad \times P_n^m(\cos\,\theta) \end{aligned} \tag{8}$$

$$\begin{aligned} B_r &= -\frac{\partial}{\partial r}(V^{\text{int}}) \\ &= -\sum_{n=1}^{N_{\text{int}}}\sum_{m=0}^{n}(n+1)\left(g_n^m\cos m\phi + h_n^m\sin m\phi\right)\left(\frac{a}{r}\right)^{n+2} \\ &\quad \times P_n^m(\cos\,\theta) \end{aligned} \tag{9}$$

Traditionally, the system of coordinates used in geomagnetism consists of the north, east, and center components (sometimes denoted X, Y, Z).

Since the geomagnetic field changes in space and time, the Gauss coefficients are also time-dependent. In order to model time variations of internal origin, the *secular variation*, about 1 year of continuous observations is needed. This variation is often assumed to be constant over short timescales, and can be introduced by adding a secular-variation potential, V_{sv}, truncated to $N_{\text{sv}}^{\max}$:

$$\begin{aligned} V_{\text{sv}} = a\sum_{n=1}^{N_{\text{sv}}^{\max}}\left(\frac{a}{r}\right)^{n+1}\sum_{m=0}^{n}(t-T_0)\left(\dot{g}_n^m\cos(m\phi)\right. \\ \left. + \dot{h}_n^m\sin(m\phi)\right)P_n^m(\cos(\theta)) \end{aligned} \tag{10}$$



Magnetic Modeling, Theory and Computation, Figure 1 The power spectrum obtained from the GRIMM model: the steep part of the spectrum ($n \leq 13$) indicates the core field contribution, the transition degrees (n = 14–15) can be attributed to both core and lithospheric contributions, and the higher degrees ($n \geq 16$) describe the lithospheric contribution. Units are in nT^2.

where $\dot{g}_n^m$, $\dot{h}_n^m$ denote the time derivative of the internal Gauss coefficients, T_0 the reference time (i.e., the epoch of the core field model), and t is the considered time.

The time dependence of the core field coefficients $\left\{g_n^{m(t)}, h_n^m(t)\right\}$ up to a given degree n can also be described by temporally more complex functions, for example, B-splines. Generally, in the geomagnetic field modeling process, the cubic (i.e., order 4) B-splines (Bloxham and Gubbins, 1985; Jackson et al., 2000; Olsen et al., 2006; Wardinski et al., 2008), or higher order B-splines (Sabaka et al., 2004; Lesur et al., 2008; Olsen et al., 2009) are used. Splines of order 4 result in a piecewise linear representation of $\partial_t^2 \vec{B}$, which is not favorable for studying rapid core field changes and geomagnetic jerks. Higher order splines result in a smoother representation of $\partial_t^2 \vec{B}$ and are therefore preferable. In order to be able to describe rapid field temporal variations of the core field, a 6-month knot separation is recommended. Recently, due to a decade of high-resolution, high-precision satellite magnetic data, the secular acceleration can also be described, by coefficients $\ddot{g}_n^m$, $\ddot{h}_n^m$, denoting the second time derivative of the Gauss coefficients.

Inverse problem and implementation

To obtain a geomagnetic model and thereafter the field component description, an inverse problem needs to be solved, for which the standard model estimation technique is summarized below.

The aim is to describe a given dataset in terms of a series of parameters. The data can be assembled in a data vector $\mathbf{d}$ of length N

$$\mathbf{d}^{\mathbf{T}} = (\mathbf{d_1}, \mathbf{d_2}, \ldots, \mathbf{d_N}). \tag{11}$$

The model is defined by a set of M parameters assembled in a model vector of length M

$$\mathbf{m}^{\mathbf{T}} = (\mathbf{m_1}, \mathbf{m_2}, \ldots, \mathbf{m_M}). \tag{12}$$

The basic assumption is that the data are related to the model parameters through a function $\mathbf{F}(\mathbf{m})$, leading to the relation:

$$\mathbf{d} = \mathbf{F}(\mathbf{m}), \tag{13}$$

which, for linear (or linearized) problems, reduces in a matrix form:

$$\mathbf{d} = \mathbf{A}\mathbf{m} \tag{14}$$

where $\mathbf{A}$ is an $N \times M$ matrix of coefficients, independent of data values and model parameters. In the case of spherical harmonics analysis, the data often consist of three components of the magnetic field vector. The Gauss coefficients define the parameter vector $\mathbf{m}$. The $\mathbf{A}$ matrix elements contains M base functions evaluated at N data positions – that is, spherical harmonics (or their gradients) and their radial dependences.

Generally, more data are available than parameters to be resolved, so $N \geq M$. In this case, the above equation cannot be satisfied for every data, the inverse problem is overdetermined and has no exact solution. Hence, model parameters are sought such that the above equation is solved approximately. The least square method minimizes the sum of the squares of the errors in order to find a solution. The usual solution to this problem is given by:

$$\mathbf{m} = \left(\mathbf{A}^{\mathbf{T}}\mathbf{W}\mathbf{A}\right)^{-1}\mathbf{A}^{\mathbf{T}}\mathbf{W}\mathbf{d} \tag{15}$$

as long as the inverse matrix $\mathbf{G}^{-1} = \left(\mathbf{A}^{\mathbf{T}}\mathbf{W}\mathbf{A}\right)^{-1}$ exists. To define the weight matrix $\mathbf{W}$, it is observed that the magnetic data from different platforms, and at different times, can be affected by different error sources and these error sources can even be correlated. The covariance matrix $\mathbf{C_d}$ associated with these errors must be estimated, inverted, and then used as weight matrix, that is, $\mathbf{W} = \mathbf{C_d^{-1}}$. For uncorrelated data, the covariance matrix is diagonal. In practice, this is rarely the case, but for computational simplicity diagonal covariance matrices are often used.

Inverse problems are sometimes ill-posed – that is, some parameters or combination of parameters are not resolved by the data. In that case, the inverse of $\mathbf{G} = \left(\mathbf{A}^{\mathbf{T}}\mathbf{W}\mathbf{A}\right)$ does not exist, or is numerically difficult to estimate. It results that small errors in data values can lead to considerable changes in the parameters. The error amplification must be controlled by appropriate measures in the solution process: inverse problems can be regularized by introducing regularization matrices in space and time. A solution in the least square sense writes now:

$$\mathbf{m} = \left(\mathbf{A}^{\mathbf{T}}\mathbf{W}\mathbf{A} + \lambda_t\mathbf{\Lambda_t} + \lambda_s\mathbf{\Lambda_s}\right)^{-1}\mathbf{A}^{\mathbf{T}}\mathbf{W}\mathbf{d}. \tag{16}$$

It corresponds to a minimum of the functional:

$$\Phi = (\mathbf{d} - \mathbf{A}\mathbf{m})^{\mathbf{T}}\mathbf{W}(\mathbf{d} - \mathbf{A}\mathbf{m}) + \lambda_t\mathbf{m}^{\mathbf{T}}\mathbf{\Lambda_t}\mathbf{m} + \lambda_s\mathbf{m}^{\mathbf{T}}\mathbf{\Lambda_s}\mathbf{m} \tag{17}$$

The choice of λ_t and λ_s damping parameter values is a difficult, and often computationally intensive task. If criteria exist to determine these parameters, they are often unpractical to establish, and therefore the parameters choice often depends on the modeler skills, interests, and a priori knowledge on the solution. The same formalism is used to impose constraints on the model solution.

The models developed are more and more complex due to the high quality of the recent satellite data, and to the overall progress in data acquisition techniques and quality. This combined with the developments of new mathematical tools, and better insight on the physical process underlying the generation of the magnetic field, has led to the developments of complex codes that use up-to-date numerical techniques.

From a computational view point, when large datasets are used, the most time-consuming step in building a model is to compute the matrix $\mathbf{G} = (\mathbf{A}^{\mathbf{T}}\mathbf{W}\mathbf{A})$. Typically, a parallel computing environment is necessary to compute this matrix in a reasonable amount of time, that is, less

than a few days. Often, a re-weighted least-square approach is needed to reach the best solution, requiring the evaluation of **G** numerous times. In comparison, inverting the matrix takes only few minutes for models with 10–20 thousands of parameters. Overall, several months are needed by a trained modeler to derive a robust model of the Earth's interior magnetic field.

Potpourri of recent global models

An important prerequisite for deriving more precise and higher resolution models of the geomagnetic field is the availability of high-quality measurements. Under the assumption of suitable data, the modeling task may be separated in a few crucial steps. The first one is linked to data selection, as in each single measurement all contributions exist, and the wish is to minimize the external ones. In the second, the inversion of magnetic measurements (as shown before) to obtain a mathematical description of the field distribution is foreseen, and finally a control of the final model is needed.

Here, some of the most recent models are listed, and the interested reader can find more information on the specified web sources. Firstly, models based on the last decade of satellite data are indicated, thereafter models covering a longer period of time.

The International Geomagnetic Reference Field (www.ngdc.noaa.gov/IAGA/vmod/IGRF-10) IGRF is an internationally agreed series of global spherical harmonic models of the Earth's core magnetic field, and it is provided by the IAGA Division V-MOD. The Gauss coefficients are considered linearly time dependent for 5-year intervals (Finlay et al., 2010).

The GRIMM series (GFZ Reference Internal Magnetic Model) (www.gfz-potsdam.de/portal/gfz/Struktur/Departments/Department+2/sec23/topics/models/GRIMM2) by Lesur et al. (2008, 2010) are based on CHAMP satellite data and observatory hourly means. GRIMM-2 covers the period 2001–2010 and aims at describing the very rapid variations of the core field. One of its special characteristic is the use of full vector satellite data at high latitudes at all local times, for a better separation into the contributions generated by the ionosphere and field aligned currents on one hand, and, contributions generated by the Earth's core and lithosphere, on the other hand.

The CHAOS models (www.space.dtu.dk/English/Research/Scientific_data_and_models/Magnetic_Field_Models.aspx) derived by Olsen et al. (2006, 2009) as well as Olsen and Mandea (2008) are based on satellite and observatory data, with an interest to the subdecadal timescales variations. As GRIMM series, the advantage of these series of models is the fact that they are able to describe the field itself, but also its secular variation and acceleration.

The MF series (www.geomag.us/models/MF6.html), with the last version published by Maus et al. (2008), is a model built to mainly describe the global lithospheric field. The last published version, MF6 estimates the lithospheric magnetic field to spherical harmonic degree 120, which corresponds to 333 km wavelength resolution. The very last version MF7 is now available.

Some geomagnetic field models cover longer period of time, from decades to centuries, as:

The CM4 model (core2.gsfc.nasa.gov/cm/), as the fourth version of the Comprehensive Model, has been developed by Sabaka et al. (2004). This model relies on POGO, MAGSAT, Ørstedt, and CHAMP satellite data and observatory hourly means and is continuous through the time span from 1960 to 2002. The spherical harmonic expansion goes to degree and order 65 with the secular variation represented by cubic B-splines with 2.5-years knot spacing through degree and order 13.

The C^3 FM (www.gfz-potsdam.de/portal/gfz/Struktur/Departments/Department+2/sec23/topics/models/C3FM), as Continuous Covariant Constrained-end-points Field Model Wardinski and Holme (2006), is a time-dependent model, between 1980 and 2000 with Gauss coefficients expanded in time on a basis of cubic B-splines. This model is constrained to fit field models from two satellites (MAGSAT in 1980 and Ørsted in 2000) and to fit both magnetic observatory and repeat station secular variation for the period in between. The model reveals a short-term secular variation on subdecadal timescale with a higher spatial resolution than previously resolved.

The gufm (www.epm.geophys.ethz.ch/cfinlay/gufm1.html) model of Jackson et al. (2000) provides a complete picture of the evolution of the core magnetic field, from 1590 to 1990. This time-dependent model is based on a massive compilation of historical observations of the magnetic field, originating from observations taken by mariners engaged in merchant and naval shipping, as well as survey data, observatory data (which runs back to the mid-nineteenth century), and data from the POGO and MAGSAT satellites.

The CALSK series (www.gfz-potsdam.de/portal/gfz/Struktur/Departments/Department+2/sec23/topics/models/CALS7K) are based on archeo- and paleomagnetic data and give a global description of field evolution further back in the past, although with lower spatial and temporal resolution. Continuous spherical harmonic models on millennial timescales give estimates of spatial field structure up to spherical harmonic degrees around 4 and temporal variations in the order of 100 years. The longest continuous and regularized spherical harmonic model to date goes back 7 kyrs (Korte and Constable, 2005).

Some models together with online calculators or source codes are available. The interested reader can find on the German Research Centre for Geosciences web site (www.gfz-potsdam.de/portal/gfz/Struktur/Departments/Department+2/sec23/topics/models), the British Geological Survey web site (www.geomag.bgs.ac.uk/gifs/igrf_form.shtml), or the National Oceanic and Atmospheric Administration web site (www.geomag.org) good overviews on a number of field models together with user-friendly calculators. Figures 2 and 3 show maps of the

core field components and their secular variation for the northward, eastward, and radially inward direction at the Earth's surface in 2010 from the field model GRIMM-2 (Lesur et al., 2010).

Regional field modeling

To describe the magnetic field at regional scales, different methods have been proposed during the last decades,

starting with the Spherical Cap Harmonic Analysis proposed by Haines (1985) and the related translated origin spherical cap harmonic analysis (De Santis, 1991; Korte and Holme, 2003). The spherical cap harmonic analysis permits the use of data from only a region of the Earth while satisfying the constraints of potential field theory. Indeed, the region to be studied has to be defined by a spherical cap and satisfies the zero curl and divergence conditions. The method is claimed to be valid over any spherical cap at any altitude above the Earth's surface. On the basis of these assertions, the method has been widely used for constructing regional magnetic maps (De Santis et al., 1997; Korte and Haak, 2000). However, difficulties occur when using this approach. The main one appears as a failure to correctly model the radial dependence (i.e., that the models cannot be continued and data acquired at different altitudes cannot be simultaneously inverted). In order to solve this difficulty, Thébault et al. (2004) have re-posed this method as a boundary value problem within a cone extending above the reference surface, thereby allowing satellite data to be downward continued to the Earth's surface.

Some different basis functions, such as harmonic splines Shure et al. (1982), or with more local support, wavelet-like functions (Holschneider et al., 2003; Lesur, 2006), are better suited to describe datasets with variable resolution over the area of interest. Only these two approaches are summarized in the following. Schott and Thébault (2010) provide a detailed overview of various regional modeling approaches, and the interested reader is advised into this paper.

Harmonic splines

A detailed description of harmonic splines can be found in Shure et al. (1982), and a very recent revisited approach with an application for the Southern African continent magnetic data in Geese et al. (2010). The main interest of this representation is that it offers a smoothness property to the derived field model.

The method considers the magnetic field as expressed as the gradient of a scalar potential, as shown in the previous section. Using the spherical harmonics Y_n^m of degree n and order m, the internal part of the global magnetic field can be written as

$$B = -\nabla a \sum_{n,m}^{N} g_n^m \left(\frac{a}{r}\right)^{n+1} Y_n^m(\theta,\phi) \tag{18}$$

with $Y_n^m(\theta,\phi)$ being the Schmidt normalized spherical harmonics. An alternative representation of the field is given by:

$$B(\theta,\phi,r) = -\sum_i \alpha_i \nabla F_i^{Nr}(\theta,\phi,r) \tag{19}$$

$$F_i^{Nr} = a \sum_{n,m}^{N} f_n (n+1) \left(\frac{a}{r}\right)^{n+1} \left(\frac{a}{r_i}\right)^{n+2} \times Y_n^m(\theta_i,\phi_i) Y_n^m(\theta,\phi) \tag{20}$$

$$f_n = \frac{2n+1}{4\pi n^2 (n+1)^4} \tag{21}$$

With this choice of parameter f_n values, the modeled magnetic field minimizes the quantity:

$$\int_\Omega \left|\nabla_h^2 B_r\right|^2 \mathrm{d}\omega \tag{22}$$

In the framework of regional analysis, in order to insure a fit to the data, it is necessary to introduce for the representation of the magnetic field two further sets of functions similar to Equation 20. This gives:

$$B(\theta,\phi,r) = -\nabla\left(\sum_i \alpha_i^r F_i^{Nr}(\theta,\phi,r) + \sum_i \alpha_i^\theta F_i^{N\theta}(\theta,\phi,r) + \sum_i \alpha_i^\phi F_i^{N\phi}(\theta,\phi,r)\right) \tag{23}$$

$$F_i^{N\theta} = a \sum_{n,m}^{N} f_n \left(\frac{a}{r}\right)^{n+1} \left(\frac{a}{r_i}\right)^{n+2} \times \frac{\partial}{\partial\theta} Y_n^m(\theta_i,\phi_i) Y_n^m(\theta,\phi)$$

$$F_i^{N\phi} = a \sum_{n,m}^{N} f_n \left(\frac{a}{r}\right)^{n+1} \left(\frac{a}{r_i}\right)^{n+2} \frac{1}{\sin\theta} \times \frac{\partial}{\partial\phi} Y_n^m(\theta_i,\phi_i) Y_n^m(\theta,\phi). \tag{24}$$

This model is equivalent to the harmonic spline model presented in Geese et al. (2010) and Shure et al. (1982).

An example of a recent application of this approach is found in Geese et al. (2010). The investigated area is the Southern African continent where the geomagnetic field is weaker and changes more rapidly compared to other regions of the Earth. The regional dataset, consisting of repeat station surveys and observatory annual means, has been used in the described system of representation. The regional field model covers the time span from 1960 to 2002 and gives a detailed view of the changes of the geomagnetic field in this region.

Wavelet analysis

The wavelet frames and the recent work by Holschneider et al. (2003); Freeden and Michel (2004); Chambodut et al. (2005) have brought the use of wavelet frames for constructing regional potential field models. In particular on the sphere, the used functions should satisfy the following properties: (1) harmonic prolongation must be easily computable; (2) function itself has to be numerically easy to compute; (3) functions must be localized on the sphere.

The indicated requirements lead to constructions based on the Poisson kernel of spherical functions. A Poisson wavelet at a given point on the unit sphere is expressed as:

$$\psi_a^k(\vec{x}) = N_a^k \sum_n (an)^k e^{-an} Q_n(\cos\ \mu) \tag{25}$$

where N_a^k is a normalization constant and μ is the angle between the wavelet position and the data point position. The Q_n function is defined by:

$$Q_n(\cos\ \mu) = (2n+1)P_n(\cos\ \mu), \tag{26}$$

that can be expressed easily in terms of products of spherical harmonics.

The wavelet is defined by three parameters: scale a, position, and order k. The scale a is a measure of the wavelength of the wavelet without dimension, and order k characterizes the global shape of the wavelets (number of oscillations). The wavelets on the sphere may also be considered as a restriction on the sphere of a function that is harmonic outside and that has singularities inside it. The main characteristic of a wavelet is its relatively well-localized amplitude on the sphere, hence well adapted to regional modeling, while spanning a relatively limited range of wavelengths.

Recently, a few implementations of the wavelet representation for potential fields have been done. For example, Panet et al. (2006) have applied the wavelet method to improve a global, but low-resolution gravity field model, by using regional high-resolution data. Over the same area of interest, French Polynesia, a lithospheric magnetic field model based on CHAMP satellite data has been computed, applying the same approach. The regional field models allow authors to suggest that the origin of the volcanism in this region may be controlled by lithospheric weakness due to the regional stress field.

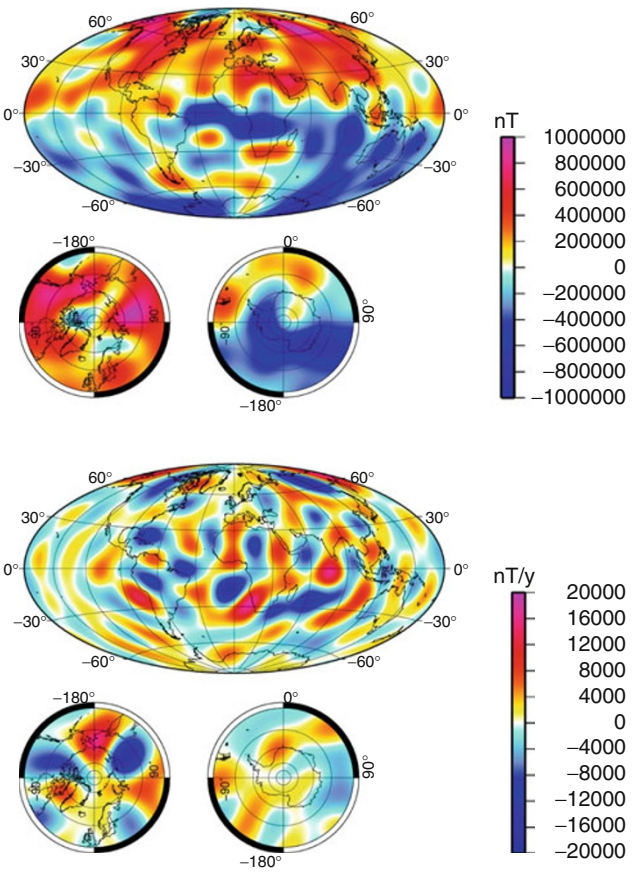
Interpretation

The geomagnetic field models, at global and regional scales, play an important role in our modern world. The Earth's magnetic fields can be used as a tool in screening our planet and understanding it deep interior structure and processes. Moreover, these models can be used for some specific applications, as in navigation, petroleum industry, in technological systems submitted to large geomagnetically induced currents, in satellite operations, or exploration geophysics. From this list, which is far to be complete, two examples are given, one linked to interpretation of the magnetic field and its secular variation at the core mantle boundary, and one linked to the lithospheric field.

Core magnetic field at core–mantle boundary

As described above, models of the magnetic field generated inside the Earth are dominated for the long wavelengths by the core field, and for the shorter wavelengths by the lithospheric field. The longest wavelengths of these models – roughly up to spherical harmonics of degree 14 – can therefore be used to try to understand the generation process of the core field. Results from seismological observations have shown that the core can be separated in two regions; a solid inner core of radius estimated at 1,220 km and a liquid outer core in the spherical shell extending up to 3,485 km. This liquid outer core is very conductive and made mainly of liquid iron in convection, which in the presence of a magnetic field, can regenerate this field, balancing its natural decay due to ohmic dissipation. This process is known as the geodynamo. The best way to retrieve information about the dynamics of the core, and the fluid motions at the top of the core is through magnetic data acquired at, or above, the Earth's surface. The magnetic field models are therefore downward continued, through the mantle, to the core mantle boundary (CMB) assuming that the mantle is an insulator. In principle, only the radial component of the magnetic field can be derived just below the CMB, because of the unknown jump of the electrical conductivity across the CMB, associated with a discontinuity of the magnetic field components tangential to the boundary.

An image of this vertical down component of the core magnetic field just below the CMB is shown in Figure 4, together with its expected time derivative. These images



Magnetic Modeling, Theory and Computation, Figure 4 Map of the core field vertical down component (Units in nT) and its secular variation (Units in nT/year) at the core–mantle boundary, for year 2010 and from the field model GRIMM-2. Molleweide projection is used.

correspond to a magnetic field model truncated to spherical harmonic degree 13. Contributions from shorter wavelengths may considerably modify these images, but these contributions are unknown, being hidden by the lithospheric field or the noise, at the Earth's surface. However, considerable information can be readily extracted from these maps. One can see that the core field has a much more complex structure at the CMB than on the Earth's surface (Figure 2). In particular, the presence in the southern hemisphere of a large patch of reverse orientation of the magnetic field – the field there is oriented toward the core interior, whereas in a simple dipole approximation one would expect the field to be oriented outward. This patch and its evolution has attracted scientists' attention over the last decades because it is associated with the weakness of the Earth's field in the South-Atlantic region, it contributes significantly to the decrease of the strength of the Earth's dipole field component, and it has sometimes been thought as an early stage of a reversal process (Hulot et al., 2002; Olsen and Mandea, 2008) regarding the secular variation, it is obviously concentrated at midlatitudes and high latitudes of the northern hemisphere. It is extremely weak under the Pacific ocean and southern part of the southern hemisphere.

The combination of the Maxwell equations leads to the so-called induction equation. Under the frozen-flux approximation, which neglects the diffusion in front of induction (Roberts and Scott, 1965), the radial component of this equation writes:

$$\frac{\partial}{\partial t} B_r = -\nabla_h \cdot (B_r U_h) \tag{27}$$

where B_r is the radial component of the magnetic field, U_h is the horizontal component of the flow under the CMB, and ∇_h is the tangential gradient on the sphere. This equation simply shows that the main source of secular variation is the advection of the field lines by the flow. Since radial component of both the field and its secular variation can be estimated at the CMB, this equation provides a way to get some information on the flow at the top of the liquid outer core, for large spatial wavelength and relatively short timescales. By combining this equations with constraints derived from the equations of fluid dynamics and/or magnetohydrodynamics, it is possible to derive physical properties of the outer core and shed light on unexplained phenomenon as geomagnetic jerks (Mandea et al., 2010b) or contributions to the variation of the length of the day.

Lithospheric magnetic field over the Arctic region

The magnetic signature of the lithosphere is related to all the processes that affected and shaped the figure of our planet. To first order, the remanent magnetic contributions are canceled out at large wavelength and the induced part dominates above continental domains. The exact contribution of the remanent magnetization is actually difficult to estimate, unless the physical properties of the magnetic sources are known through rock sampling and analysis. It is possible to estimate what is their relative contribution by using global forward approaches, mostly relying on the distribution of the vertically integrated magnetization. A simple estimate is based on the lateral magnetization contrast associated with the boundary between oceanic and continental domains. Indeed, the abrupt boundaries between the thin oceanic crust and the thicker continental crust translates into a large-scale magnetic signal which sometimes occur in the proximity of continental margins, and also above continental and oceanic basins. This does not suffice to explain all the observed magnetic anomalies. Those interested in the crustal magnetic field are referred to some recent reviews, like Langlais et al. (2009).

Generally speaking, the lithospheric magnetic field reflects the magnetization associated with minerals cooling down below their Curie temperature in the presence of a magnetic field. Above the Curie temperature, the magnetization vanishes, and minerals exhibit then paramagnetic susceptibility, with little effect compared to magnetization. Therefore, rocks are essentially nonmagnetic at temperatures greater than the Curie temperature characterizing their main magnetic minerals constituents. Taking into account a normal geothermal gradient, sources of the measured magnetic signal are then restricted to some maximum 30–40 km depth, excepting the old cratonic areas where the Curie depth – depth at which the temperature reach the Curie temperature – may be deeper. Methods to estimate depth to the bottom of magnetic sources from magnetic data are based on the spectral analysis of magnetic anomalies (Spector and Grant, 1970; Blakely, 1995; Bouligand et al., 2009).

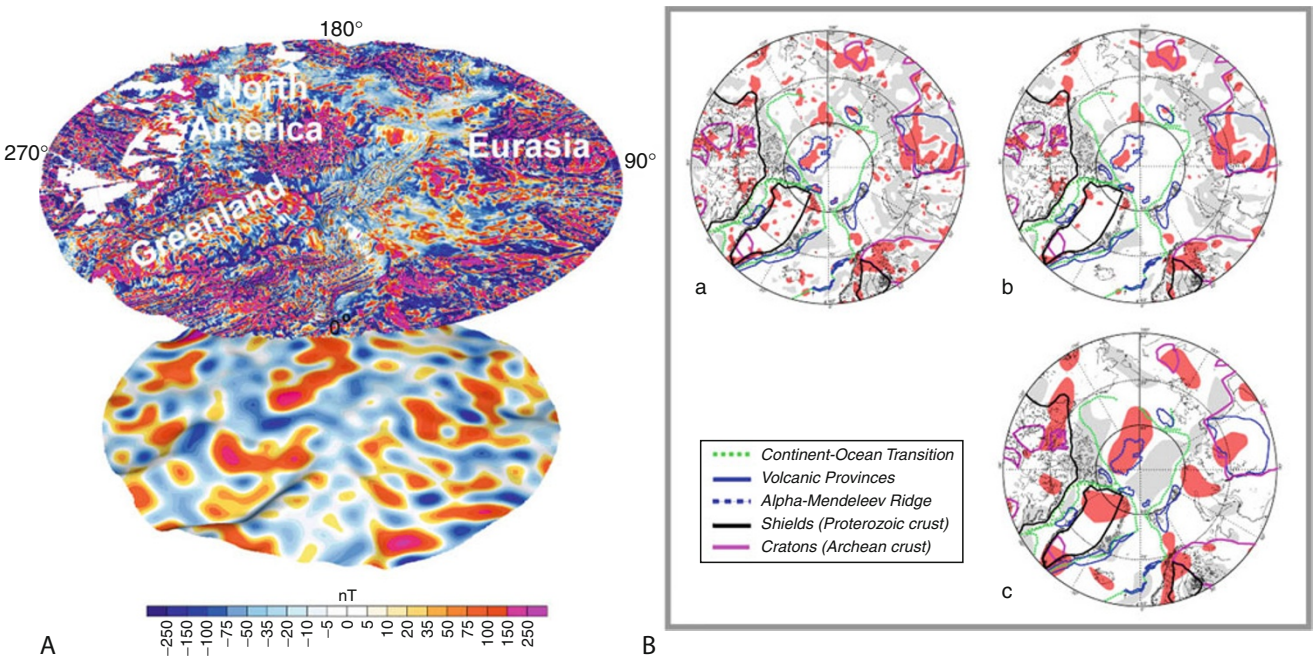
It is important to note here that another source for the deep crustal magnetism has been suggested in the last decade. This is the magnetism resulted from chemical interfaces, or lamellar magnetism. This concept shifted the paradigm of having magnetic rocks only above the Curie temperature (580) depth and can be the source for old, deep-seated crust on Earth and other planets (Robinson et al., 2002).

For a comprehensive example of how the most prominent magnetic anomalies observed in the global compilations of ground and satellite magnetic data (like the World Digital Magnetic Anomaly Map WDMAM, Korhonen et al., 2007) can be analyzed, see Mandea and Thébault (2007). In this contribution we present an example of regional magnetic anomaly modeling and the suggested interpretation, over the Arctic area.

In the last decade, the Arctic region became a frontier for scientific discoveries and exploration studies. All circum-Arctic nations embarked on a quest for collecting new data and deciphering the structure and evolution of the Arctic crust and lithosphere. In the same time, due to the inaccessibility and harsh climate of this area, satellite data plays a crucial role for the Arctic science. Along with bathymetric, gravimetric, and seismological studies, acquisition, processing, and interpretation of magnetic data are vital components for the understanding of

lithospheric architecture. The last couple of years have been favorable not only for data acquisition at high latitudes (due to low solar activity), but also for concerted efforts to gather and assemble regional datasets. Besides the World Digital Magnetic Anomaly Map (Korhonen et al., 2007) and similar global compilations (Hamoudi et al., 2007; Hemant et al., 2007; Maus et al., 2008), a higher resolution map for the Arctic region (upward 60° North) is currently available to the scientific community (Gaina and the CAMP-GM group, 2011) and, together with a satellite lithospheric model (Maus et al., 2008), is used here as a brief example into the Arctic magnetic anomaly interpretation.

Figure 5A shows the difference between magnetic anomalies recorded closer to Earth's surface, which display the magnetic signature of bodies in the Earth's crust, and magnetic anomalies measured from satellites (in this case at about 350 km), which image thicker than normal and/or deeply buried magnetic bodies. By upward continuing the magnetic data collected closer to the surface (either shipborne or airborne), a first-order estimation of shallow versus deep-magnetized bodies can be made. Figure 5B shows the higher and lower magnetic anomalies obtained by upward continuing the magnetic gridded data of the Arctic (CAMP-GM without using the satellite data) at 60 and 100 km, that roughly correspond to the lower continental crust and upper mantle. In addition, the MF6 lithospheric model (Maus et al., 2008) is shown at 350 km altitude. The magnetic signature of the boundary between the continental and oceanic crust cannot be detected anymore in the upward continued data or from satellite altitude, even for volcanic margins (note the volcanic areas outlined by blue lines along the eastern coast of Greenland and western coast of Eurasia). The oldest continental crust, usually found in the cratonic areas and as Proterozoic accreted crust, generates the largest positive magnetic anomalies. This crust contains large and deep volcanic bodies in the North American shield, Greenland, the Baltic shield in Eurasia, and the Siberian platform in NE Asia, which are imaged by the satellite data (Figure 5B). One of the most striking feature in the Arctic domain is the strong magnetic anomaly close to the north pole that correlates with a large, igneous oceanic plateau called the Alpha Mendeleev ridge. The age and exact origin of this Large Igneous Province is not known, although numerous studies speculate on an episode of Cretaceous



Magnetic Modeling, Theory and Computation, Figure 5 (**A**) 3D image of the Circum-Arctic grid of magnetic anomalies compiled from aeromagnetic datasets (Gaina and the CAMP-GM group, 2011) draped on bathymetry and topography of the Arctic (IBCAO, (Jakobsson et al., 2008)). Lower panel shows the lithospheric magnetic model based on satellite data (MF6, (Maus et al., 2008)) downward continued at the geoid height. The MF6 grid is draped on the Bouguer anomaly of the Arctic that has been upward continued in such a way that the major relief corresponds to areas of thick crust (mainly under continental, cratonic area or large volcanic provinces) or thin crust (under the oceanic basins or highly extended continental crust). (**B**) Minimum (gray) and maximum (red) amplitude of magnetic anomalies of the Arctic (CAMP-GM) upward continued at 60 and 100 km (**a** and **b**, respectively) and magnetic anomalies from satellite data at 350 km altitude. Lower map shows major boundaries between different lithospheric domains that may contribute to magnetic anomalies. Regions of thick, old Archean crust and adjacent accretionary crust are characterized by regional metamorphism and plutonic intrusions that have strong magnetic anomaly signatures.

volcanism that affected an old oceanic crust or a partially continental crust. The intensity and extent of the magnetic anomalies recorded by aircrafts or satellites point toward a very thick, volcanic crust, but, as in the case of other oceanic Large Igneous Provinces, only deep sea drilling will be able to reveal the true nature of the underlying crust at the core of the Arctic.

Summary

To model and interpret the Earth's magnetic field, two ingredients are crucial: global high accuracy, high-resolution data and reliable mathematical tools. Starting with the next years, a trio of satellites, Swarm mission, will be launched for a unique view inside the Earth. This mission will provide the most detailed data yet on the geomagnetic field of the Earth and its temporal evolution, giving new insights into improving our knowledge of the Earth's interior and climate. The Swarm constellation satellites will be placed in three different polar orbits, two flying side by side at an altitude of 450 km and a third at an altitude of 530 km. These measurements, together with those provided by magnetic observatories, shipborne or airborne instruments, are valuable data essential for modeling the geomagnetic field and its interaction with other physical aspects of the Earth's system.

Definition

Electromagnetic pulsations. Geomagnetic field oscillations having periods of 0.2–600 s.
Magnetic storms. Global disturbances in the geomagnetic field lasting from half to several days.
Magnetospheric substorms. A set pattern of disturbances occurring in the magnetosphere, lasting for a period of approximately one to a few hours, in response to an enhanced coupling between the solar wind and the geomagnetic field.

Electromagnetic pulsations

The Earth's magnetic field varies over time scales spanning many orders of magnitudes, from hundreds of thousands of years to a fraction of a second. The variations on the long periods, from hundreds of thousands to tens of years, are believed to be due to the geodynamo processes. The shorter period variations, from about 22 years to a fraction of a second are thought to be caused either directly or indirectly by the solar output. The shortest period oscillations in the geomagnetic field varying from about ~0.2 to 600 s are called electromagnetic pulsations

or simply magnetic pulsations. The frequencies of magnetic pulsations fall in the range of ultra-low-frequency (ULF) electromagnetic waves. The amplitudes of these electromagnetic pulsations decrease as their time periods decrease (or their frequencies increase). At the longest time periods, magnetic pulsations can have amplitudes of several hundreds of nT, whereas at the shortest time periods, their amplitudes are fractions of a nT. Magnetic pulsations have been detected on the ground by magnetometers and in the magnetosphere by in situ satellite magnetic and electric field sensors.

Classification of magnetic pulsations

Magnetic pulsations observed on ground have been classified into two broad classes depending on the waveform and period. This has been done formally by the International Association of Geomagnetism and Aeronomy (IAGA) (Jacobs et al., 1964). Pulsations with quasi-sinusoidal waveform are called pulsation continuous (Pc), and those with an irregular waveform pattern are called pulsation irregular (Pi). Each main class is subdivided into period bands that roughly isolate a particular type of pulsation as shown in Table 1. During disturbed geomagnetic conditions like substorms and magnetic storms, giant magnetic pulsations, called Pc6 or Ps6, are observed with periods ranging from ~600–900 s.

Generation mechanisms of magnetic pulsations

Magnetic pulsations observed on the ground or in space are produced by a variety of plasma processes occurring in the magnetosphere and the solar wind (McPherron, 2005).

The magnetosphere is the region of space where the Earth's magnetic field is confined by the solar wind plasma emanating from the Sun. A schematic of the three-dimensional view of the magnetosphere is shown in Figure 1. It shows various important plasma regions as well as the current systems. Fluctuations in these currents arising from various plasma waves and instabilities excite the magnetic pulsations. Therefore, changes in the plasma and magnetic fields in the solar wind can have dramatic effects on the type of waves seen at a particular location at Earth.

Observations show that continuous pulsations sharing the same frequency range may differ, for example, in their polarization, harmonic structure, or spatial occurrence dependence, and thus can have different generation mechanisms. There are two main mechanisms for the long-period (Pc3–Pc5) magnetic pulsations. The first one is based on field-line resonance theory where a monochromatic surface wave is excited by some plasma instability (e.g., Kelvin–Helmholtz, drift mirror mode, etc.) at the magnetopause. This instability resonantly couples with a shear Alfvén wave associated with local field-line oscillations (Chen and Hasegawa, 1974). The second mechanism is based on cavity modes where global fast modes are excited throughout the entire magnetospheric cavity in response to sudden impulses in the solar wind (Kivelson and Southwood, 1985). The cavity modes couple to field-line resonances that drive currents in the ionosphere producing magnetic pulsations. However, some daytime Pc3–Pc5 pulsations are believed to be driven directly by the solar wind pressure fluctuations. Short-period-pulsations (Pc1 and Pc2) are generated locally in the equatorial region of the magnetosphere by an electromagnetic ion cyclotron instability. The instability is driven by a temperature anisotropy of the energetic protons from the ring-current and plasma-sheet regions. On the other hand, coupling of global cavity modes to field-line resonances is considered as a likely mechanism for the generation of irregular magnetic pulsations (Cheng et al., 1998). Nighttime Pi2 pulsations are probably excited by earthward propagating fast-mode waves launched at substorm onset by large-scale magnetic reconfiguration associated with cross-tail current disruptions.

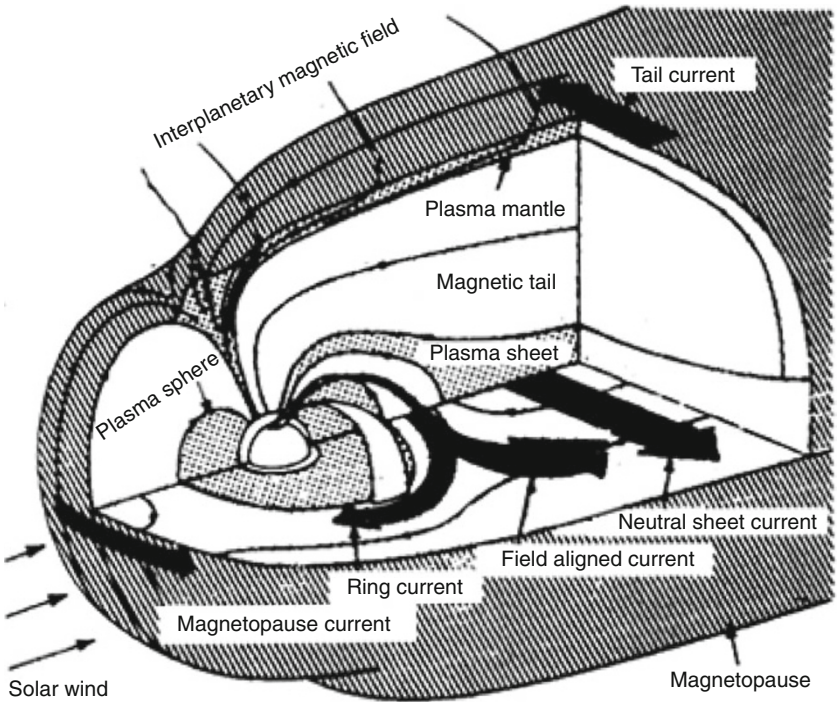
Substorms and magnetic storms

Substorms and magnetic storms are geomagnetic activity phenomena. A substorm (Akasofu, 1964) is composed of a set sequence of evolution of ionospheric auroral forms and magnetospheric disturbances that typically last from ~30 min to 1 h. There are often many substorms in a day. During substorms there is an explosive release of stored magnetotail energy directed toward the midnight sector magnetosphere. This results in the excitation of discrete auroras that become widespread, intense, and much more agitated than normal. The Earth's magnetic field gets disturbed due to intensified field-aligned currents and auroral electrojets. The ultimate source of energy for substorms is the solar wind.

Magnetic storms (Gonzalez et al., 1994) are driven directly by solar drivers like coronal mass ejections (CMEs) and flares, and Corotating Interaction Regions (CIRs) associated with fast streams emanating from coronal holes (Tsurutani et al., 1995, 2006). The cause of magnetic storms is long intervals of southward interplanetary magnetic fields that considerably enhance the efficiency

Magnetic Storms and Electromagnetic Pulsations, Table 1 Classification of magnetic pulsations

	Continuous pulsations					Irregular pulsations	
	Pc1	Pc2	Pc3	Pc4	Pc5	Pi1	Pi2
Period range (s)	0.2–5	5–10	10–45	45–150	150–600	1–40	40–150
Frequency range (mHz)	200–5,000	100–200	22–100	7–22	2–7	25–1,000	7–25



Magnetic Storms and Electromagnetic Pulsations, Figure 1 Schematic three-dimensional view of the earth's magnetosphere formed by the interaction of solar wind from the Sun (from the left) with the geomagnetic field. Small arrows indicate the direction of the magnetic field lines. *Thick arrows* show the direction of electric currents. Various current systems present in the magnetosphere are shown.

of magnetic reconnection process, leading to strong plasma injection from the magnetotail toward the inner magnetosphere. This leads to intense auroras at high-latitude nightside regions and at the same time intensifies the ring current, which causes a diamagnetic decrease in the Earth's magnetic field measured at near-equatorial magnetic stations.

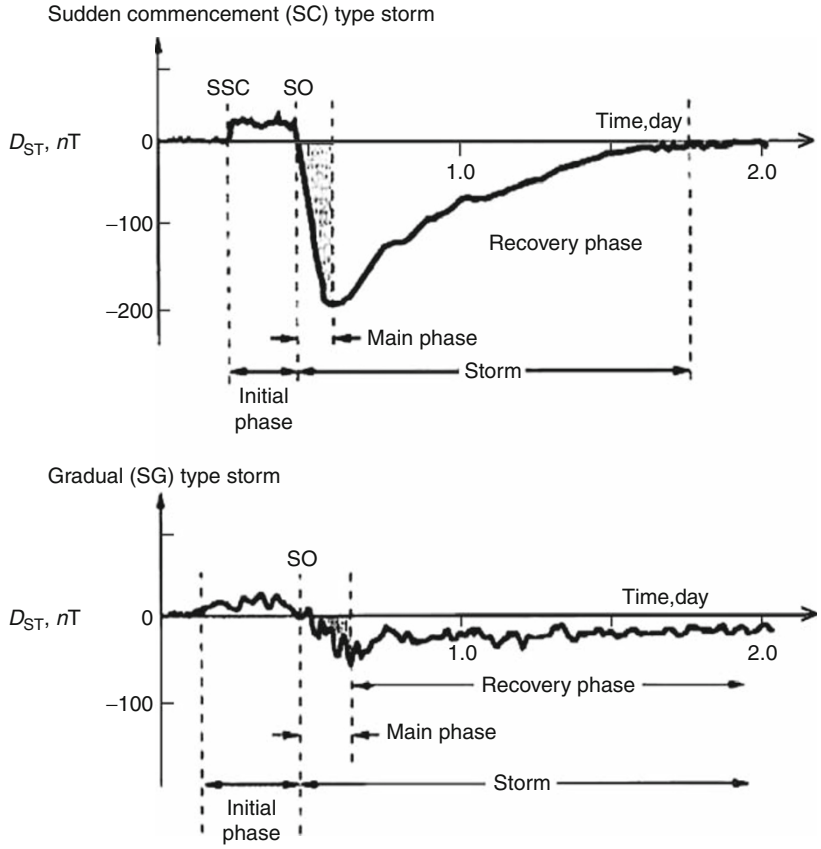
The *sudden commencement* (SC) storms are characterized by a sudden increase in the horizontal magnetic field intensity shortly before the main phase (see top panel of Figure 2). This sudden increase in magnetic field strength is caused by the interplanetary shock compression of the magnetosphere. The period between the sudden commencement and the storm main phase is called the *initial phase*. However, all magnetic storms do not have an initial phase. A geomagnetic storm not accompanied by a SC is called a *gradual geomagnetic storm* (SG) type (bottom panel of Figure 2). The *main phase* where the horizontal components of the low-latitude ground magnetic fields are significantly depressed over a time span of one to a few hours is caused by intensification of the ring-current energetic ions injected into the inner magnetosphere (L ~2–7). This is followed by a *recovery phase*, which may extend for ~10 h or more, associated with the decay of the ring current. The intensity of a geomagnetic storm is expressed in terms of the disturbance storm time index (Dst) or SYM-H (basically the same as Dst except the higher time resolution) index, which is a measure of the intensity of the ring current.

Relationship between magnetic pulsations and substorms and magnetic storms

The magnetospheric magnetic field configuration and plasma populations undergo drastic changes during substorms and magnetic storms. This directly affects the magnetic pulsations that are generated internally, for example, Pc1 and Pc2 by electromagnetic ion cyclotron instability, Pc3 and Pc4 by drift mirror instability, and Pi1 and Pi2 associated with the formation of substorm current wedges. Ps6 magnetic pulsations are also generated during substorms. Injection of energetic oxygen ions during magnetic storms tend to reduce the frequency of the long-period-pulsations, especially Pc5s. Further, the ULF wave power increases substantially during magnetic storms. On the other hand Pc5 magnetic pulsations are considered as a possible factor that can accelerate electrons to relativistic energies during magnetic storm recovery phases.

Magnetic storms and society

Intense (Dst < -100 nT) and super-intense (Dst < -500 nT) geomagnetic storms create hostile space weather conditions that can be hazardous to Earth-orbiting spacecrafts



Magnetic Storms and Electromagnetic Pulsations, Figure 2 Schematic of a magnetic storm sudden commencement (SC) driven by an ICME (*top*) and gradual (SG) type caused by a CIR (*bottom*). All storms may not have initial phases. (Slightly modified from Tsurutani et al., 2006.)

as well as technological systems at ground. Some adverse effects are malfunctioning and even failure of sensitive instruments and satellite command systems due to high fluxes of relativistic "killer" ~MeV electrons, satellite communication failures, satellite data loss and navigational errors, and loss of low earth-orbiting satellites caused by an expanded upper atmosphere. The elevated radiation level is a threat to astronauts and jetliner passengers. Geomagnetically induced currents can cause damage to power-line transformers and corrosion of long pipelines and cables.

Conclusions

Electromagnetic pulsations and magnetic storms form an important component of space weather. The ground-based measurements of magnetic pulsations and magnetic storms offer a unique and simple way of monitoring the conditions in the magnetosphere and solar wind. These measurements can also be utilized for geophysical surveys to probe the subsurface conductivity structure of the Earth.

Definition

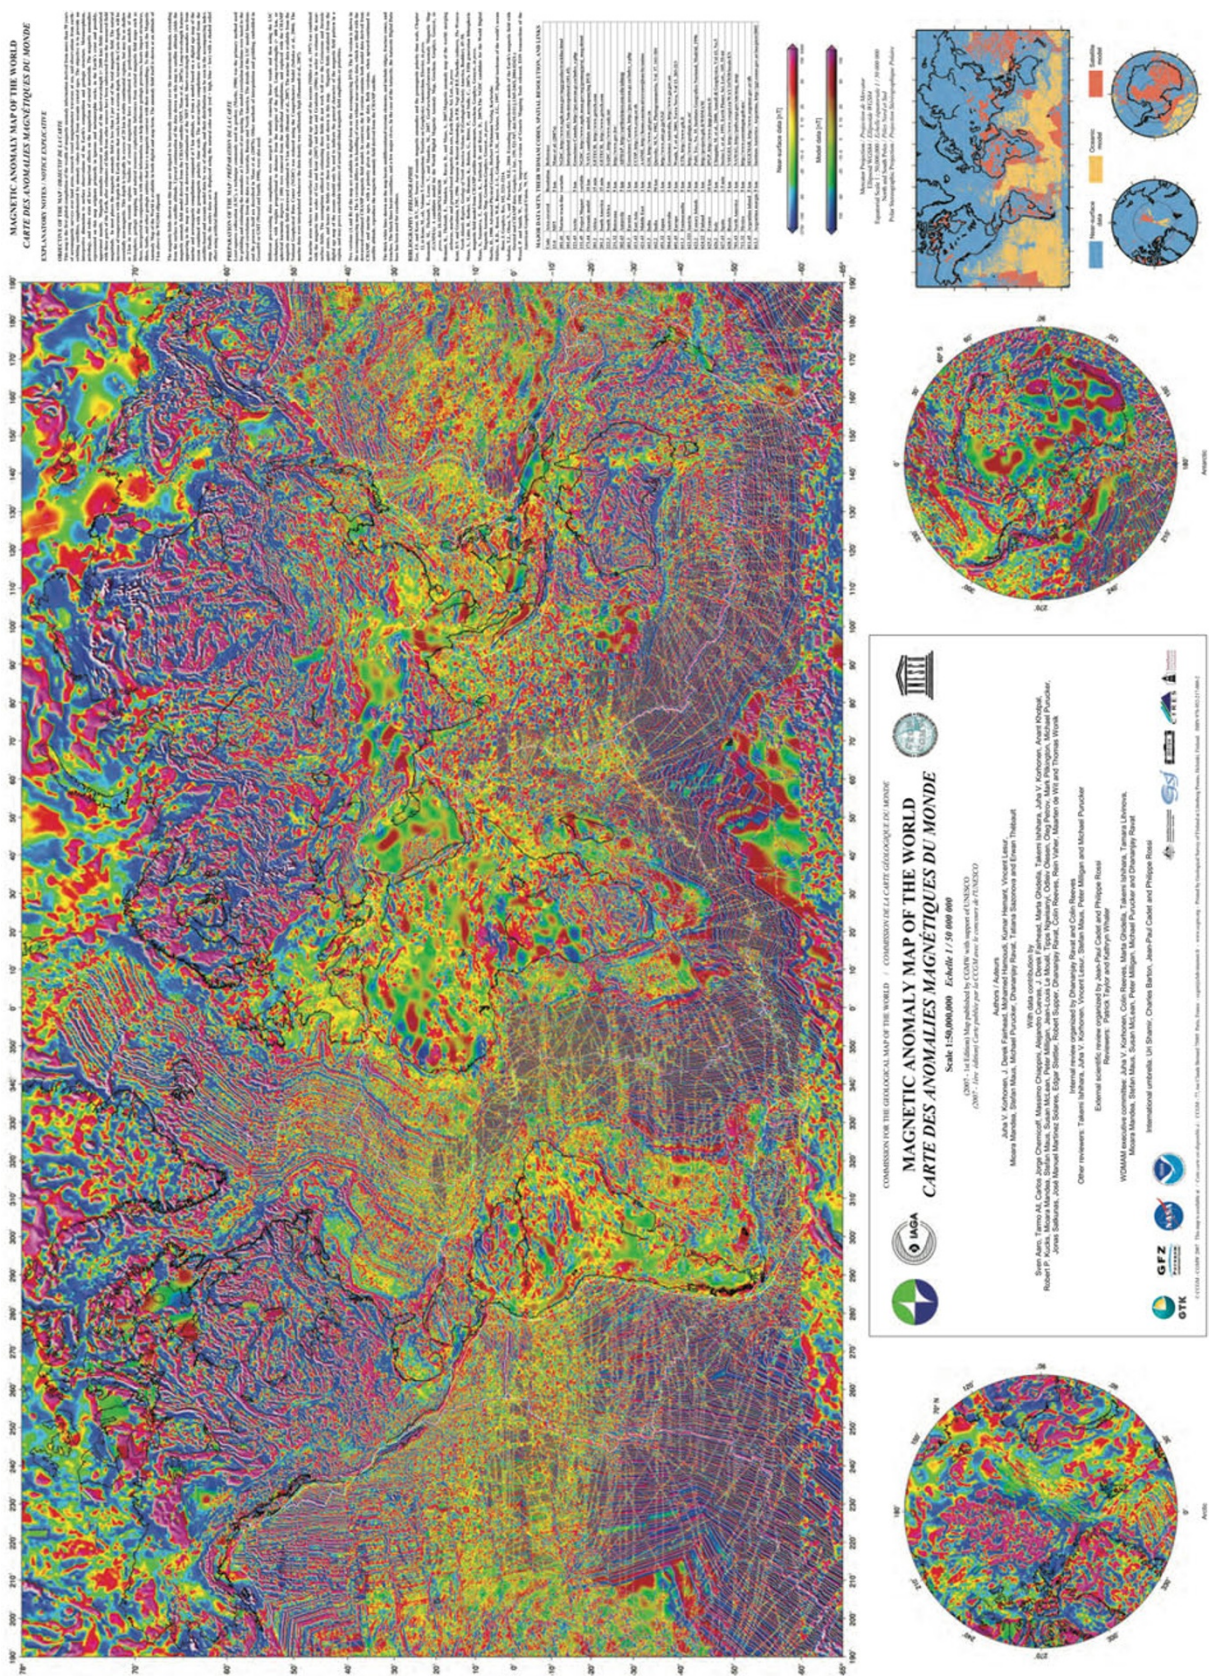
Global Magnetic Anomaly Map is an international effort to integrate near-surface and downward-continued spaceborne maps of the magnetic anomaly field. These global maps are available as grids, and find use in geologic and tectonic interpretation.

Introduction

Magnetic data have been collected from magnetometers towed by aircraft and ships for many decades now. Magnetic anomaly maps derived from regional airborne (see *Magnetic Methods, Airborne*) and marine surveys are beneficial to our understanding of the subsurface structure, chemical composition, and geodynamics of the Earth's crust (see *Earth's Structure, Continental Crust*) and lithosphere (Purucker and Whaler, 2007). Maps derived from marine surveys were instrumental in the discovery of sea-floor spreading and in the development of the theory of plate tectonics. Continental anomaly maps derived from aeromagnetic surveys interpreted with other geophysical information are used to delineate geologic and tectonic provinces and structures like faults, dikes, and lineations (see *Magnetic Anomalies, Interpretation*). These maps are also widely used, for example, in natural resource exploration, in estimating the thermal state of the earth's lithosphere (see *Lithosphere, Continental: Thermal Structure*), and the magnetic characterization (see *Remanent Magnetism*) of volcanic surfaces and deep interiors on both continents and oceans.

Satellite missions (see *Magnetic Methods, Satellite*) have also made significant contributions in enhancing our knowledge of the Earth's magnetic field (cf. Langel and Hinze, 1998). Satellite data are acquired and processed in three-dimensional spherical coordinates; hence, the derived magnetic anomaly maps are on a global scale. The satellite data are measured typically 400–750 km away from the causative sources in the Earth's lithosphere, lack sufficient resolution of geological features smaller than 400 km in wavelengths, but find extensive use in studying the long-wavelength anomalies. In comparison, magnetic anomaly maps prepared from data recorded near the surface (~few kilometers) and therefore near to the sources resolve short-wavelength-anomaly features better (see *Magnetic Anomalies, Interpretation*). There are, however, many geologic problems that could be better solved with the use of the self-consistent global magnetic anomaly maps that take advantage of the strengths of each data set while bypassing its limitation. For example, repeated rifting (see *Continental Rifts*) and movement of tectonic plates (see *Plates and Paleoreconstructions*) over hundreds of millions of years have made once adjacent landmasses drift (see *Continental Drift*) to completely different regions of the world. Reassembly requires consistently prepared magnetic anomaly maps over the entire globe consisting of both short and long wavelengths. The world digital magnetic anomaly map (WDMAM) derived from merging near-surface magnetic data and a global satellite model will aid evaluation of hypotheses about geologic origins of tectonic rifts, fracture zones that run across the continents, and tectonic history of many regions.

The WDMAM is the magnetic field defined on a grid of 3 arc-min angular grid resolution at an altitude of 5 km above the World Geodetic System 1984 (WGS84) reference ellipsoid (Figure 1) (Korhonen et al., 2007). The world magnetic anomaly map is the first international collaborative effort to compile magnetic anomaly information on a global scale. The map is derived from more than 50 years of aeromagnetic, shipborne surveys over land and sea, and it is supplemented by observations from earth-orbiting satellites. The global map shows the variation in strength of the magnetic field (see *Geomagnetic Field, Global Pattern*) after the Earth's dipole field and, external field sources like magnetosphere and ionosphere have been subtracted from the measured field. The remaining variations in the field (few hundreds of nanoteslas (nT)) are due to changes in the magnetic



Magnetic, Global Anomaly Map, Figure 1 The World Digital Magnetic Anomaly Map published by Commission for the Geological Map of the World (CGMW) in July 2007. The map is shown in Mercator Projection and is at an equatorial scale 1:50,000,000. (Courtesy: Korhonen et al., 2007.)

properties of the crustal rocks. In most places, the magnetic anomaly field is less than 1% of the main magnetic field of the Earth.

The magnetic fields derived in this map are internally consistent within the measurement domain, extending from the Earth's surface to satellite altitude (<750 km). The map comprises both the short- and long-wavelength anomalies from different sources. Short-wavelength anomalies are derived from merging continental compilations and marine track line data. Long-wavelength features in this global map are based on a downward-continued grid of the MF5 model, a model derived from CHAMP satellite magnetometer measurements. In oceanic regions where the data gaps exist, the digital age map of the ocean floor (Müller et al., 1997) was combined with the geomagnetic polarity time scale (Gee and Kent, 2007; Kent and Gradstein, 1986) (see *Geomagnetic Field, Polarity Reversals*) to estimate the total field anomaly at 5 km altitude.

The global magnetic anomaly map is available in both digital and print form. Two versions (A and B) of the map are available on DVD. The B version is shown in Figure 1. The map is displayed in natural colors (red = positive values, blue = negative values) and produced from Generic Mapping Tools (GMT) (Wessel and Smith, 1991). The A version differs in its handling of areas with data gaps, which are filled with the downward-continued MF5 model. The map images and the DVD version of the WDMAM 2007 are available at http://ftp.gtk.fi/WDMAM2007/.

Early developments

Magnetic surveys have been carried out on land, sea, and from the air over all continents and oceans. The patchwork of aeromagnetic surveys over the continents and the tracks of oceanographic survey vessels across the oceans, together, make up an enormous but distinct body of data. This incomplete and nonuniform coverage of near-surface data has recently been supplemented by reliable maps from earth-orbiting satellites such as CHAMP (http://www-app2.gfz-potsdam.de/pb1/op/champ/). These satellite-derived models (see *Magnetic Methods, Satellite*) provide uniform coverage over the globe that can help resolve uncertainties in near-surface compilations produced by stitching together disparate sets of data. A new initiative was therefore required to combine these near-surface anomaly maps into a reliable global compilation and make it more accessible for geological mapping, educational purposes, and future research.

The original data is held by a large number of individual organizations around the world and, in some cases, is still commercially used and politically sensitive. In 1977, the International Association of Geomagnetism and Aeronomy (IAGA) (http://www.ngdc.noaa.gov/IAGA/vmod/) realized the importance of magnetic anomaly mapping for geologic and tectonic interpretation (see *Magnetic Anomalies, Interpretation*) and noted the existence of numerous airborne and marine magnetic data. They began a concerted international effort to bring the global magnetic anomaly data set into place alongside other worldwide databases to maximize its use. Through a series of resolutions in 1979, 1995, and 1997, the WDMAM task force was constituted by IAGA at the International Union of Geodesy and Geophysics General (IUGG) Assembly in 2003 to prepare a roadmap to complete the work. The job of the task force included (1) cataloging existing data compilations that cover significant areas of the Earth, (2) negotiating access to such data at a resolution sufficient for a global compilation, (3) producing a preliminary paper map at the IAGA Assembly in Toulouse, France, July 2005, and (4) while addressing the main scientific and practical issues, producing a digital magnetic anomaly map of the world for the 24th IUGG General Assembly, Perugia, Italy, July 2007.

The WDMAM task force urged various organizations and custodians of data to release nonsensitive versions of the classified or confidential aeromagnetic and marine track line digital data to the public domain for the WDMAM project. The organizations holding the data responded to the call and made near-surface data available for the first version of the WDMAM map. In June 2006, a call for submission of WDMAM candidate models was issued. In November 2006, five models were submitted for evaluation. Five teams at the National Geophysical Data Center (NGDC), NASA's Goddard Space Flight Center (GSFC), Geological Survey of Finland (GTK), GeoForschungsZentrum, Potsdam, Germany, and the University of Leeds, UK produced candidate models for the WDMAM project (http://projects.gtk.fi/WDMAM/project/). After careful evaluation, the candidate model developed by NGDC was selected as a base map for representing anomalies over continents while the GAMMA model was selected for oceans. The first version of the official WDMAM was unveiled at the 24th IUGG General Assembly in Perugia, Italy, in July 2007 by the Commission for the Geological Map of the World (CGMW). The United Nations Educational, Scientific and Cultural Organization (UNESCO) kindly supported and provided the funding for the printing.

Aeromagnetic and marine compilations

The first airborne surveys were done over former Soviet Union in 1936 and the first maps of the total intensity were published at 1:2.5 million scale in 1974. These maps were later digitized and made available at 1 and 3 arc-min grid resolution from the NGDC magnetic data archive (http://ols.nndc.noaa.gov/plolstore/plsql/olstore.prodspecific?prodnum=G01284-CDR-A0001). More recently, another magnetic compilation for Russia compiled by the A.R. Karpinsky Russian Geological Research Institute is available as a 5 km resolution of the data grid (VSEGEI, http://www.vsegei.ru/WAY/247038/locale/EN).

The first ever North American continental-scale compilation was derived by merging magnetic anomaly maps

of USA, Canada, and surrounding waters. The map was released in 1987 as a part of the Decade of North American geology. The map had erroneous long-wavelength features, which revealed shortcomings and pitfalls in stitching together residual intensity maps reduced from measured data using different IGRF models (see *Magnetic Data Enhancements and Depth Estimation*). After correcting for these erroneous long wavelengths using Comprehensive Model (CM) (Sabaka et al., 2002), the improved maps for USA and Canada, in addition to the aeromagnetic compilation for Mexico, were combined to produce the revised North American magnetic anomaly map (Bankey et al., 2002). The Arctic and North Atlantic magnetic compilation including nearby landmasses was produced from a patchwork of shipborne and airborne surveys (Verhoef et al., 1996). Because the compilation had incorrect long wavelengths greater than 400 km, it was filtered before releasing the grid to the public domain.

Across the Atlantic, Wonik et al. (2001) prepared the first European compilation by merging magnetic data from North, West, and East Europe. The map retains the long-wavelength features but shows a poor correlation when compared with satellite data. However, there have been many developments in the last decade in the preparation of high-resolution magnetic compilations from marine and airborne surveys. The Geological Survey of Japan compiled the grid for East Asia in 2002. The fourth edition, but a significant improvement over its previous version, the high-resolution magnetic anomaly grid for Australia and its surrounding oceans was released (Minty et al., 2003). The noticeable feature of this map is its control over the long-wavelength anomalies, which was achieved by flying long aeromagnetic traverses around Australia. The maps for China have also been recently made available in digital form by the Chinese National Aerogeophysics Surveys. Another map that was digitized for WDMAM project is a combined map for China, Mongolia, and Russia produced in 1995 by the Geological Survey of Canada. This map also had long wavelengths greater than 400 km corrected. In addition, the Antarctic Digital Magnetic Anomaly Project (ADMAP) provided the continental-scale compilation over Antarctica (Golynsky et al., 2001). The map was derived from merging aeromagnetic and marine data with the satellite magnetic data.

In addition to these data in public domain, there have been efforts by industry-led consortia to produce maps for Africa, South America, and Middle East (http://www.getech.com/data/global_mag_margins.htm). Geological Survey of India also contributed the Indian magnetic compilation. Over oceans, NGDC's archives of track line data sets (http://www.ngdc.noaa.gov/mgg/geodas/geodas.html) were made available. In addition, the Project Magnet ocean traverse data were also available at http://www.ngdc.noaa.gov/geomag/proj_mag.shtml.

Table 1 summarizes the marine and airborne magnetic compilations made available by the WDMAM task force to produce the candidate models. The data density greatly varies between the Northern and the Southern hemispheres. The coverage is especially sparse over oceans in the southern hemisphere where some of the marine track line data were not available for the project. Missing data are noted over parts of the Arabian Peninsula, India, East Asia and many countries within Africa and South America. For processing the compilations, the datasets were grouped in three sets. The NGDC and Project Magnet marine and aeromagnetic track line data comprised the first set. Due to large errors and inconsistencies to be discussed later, the Project Magnet data was not used in the preparation of GAMMA candidate model. The second set included the gridded aeromagnetic and marine magnetic anomaly grids. The downward-continued MF5 model derived from the CHAMP satellite data made the third set. Of the track line profile data, the NGDC marine data and Project Magnet measurements together make 27 million points on 31,000 tracks. With scales ranging from country to continents, a total of 19 gridded data sets were made available.

The metadata information from the compilations, when available, shows the coverage to be in various projections and datums depending on their geographical representation on the globe. Hence, prior to applying any filtering or merging procedures, all grids were preprocessed and transformed from their local reference system to a common representation on the WGS84 global reference ellipsoid, using conversion formulas (Snyder, 1987). The software, Oasis Montaj, Geosoft© was used in the preparation of GAMMA model for upward continuation of the data, while the Leeds model was produced on the ESRI's ARCGIS (www.esri.com).

Satellite compilations

Several global models of the lithospheric magnetic field, based on satellite missions, have been produced in the last 4 decades (see *Magnetic Methods, Satellite*). Although spherical harmonic analyses of data gathered at satellite altitude are typically used to compute the magnetic potential, they follow two different philosophies. The comprehensive approach (CM4), proposed by Sabaka et al. (2004), uses POGO, Magsat, Ørsted, CHAMP, and SAC-C measurements (see *Geomagnetic Field, Measurement Techniques*) to derive a model that accounts for magnetic sources (see *Geomagnetic Field, Theory*) from the Earth's main field to the external field sources in the ionosphere and magnetosphere and their temporal variations, including the crustal magnetic field component up to spherical harmonic degree 60. In contrast to the comprehensive approach, the second philosophy strictly focuses on the lithospheric field representation. This approach requires careful data selection and processing to clean the data from non-lithospheric sources (see *Magnetic Methods, Satellite*). MF series of models are derived from CHAMP scalar and vector magnetometer measurements (http://geomag.org/models/index.html). The MF4 model used 4 years of CHAMP data and is derived up to

spherical harmonic degree 90. The map showed inconsistencies in the polar regions due to high data-noise levels. The use of localized basis functions by Lesur and Maus (2006) led to the derivation of MF4× model which showed improvement in lithospheric field at high latitudes. In 2007, the fifth generation of CHAMP models, MF5, was released (Maus et al., 2007a). MF5 extends to spherical harmonic degree 100 (400 km resolution) and showed a significant improvement, especially between 60° and 80° latitude, compared to previous models. After comparing the MF series of satellite compilations, the WDMAM committee, recommended using the MF5 model for the preparation of candidate models. Recently, using only 3 years of CHAMP measurements, the high-resolution MF6 model was derived (Maus et al., 2008). The MF6 model is able to resolve lithospheric magnetic field to degree 120, corresponding to 333 km wavelength. The MF6 model is also the first satellite-data-based global magnetic anomaly map to resolve the direction of oceanic magnetic lineations, which makes a helpful addition to the study of oceanic lithosphere (see *Lithosphere, Oceanic*) from space. The EMAG2 model uses the MF6 model to substitute the long-wavelength components.

Preparation of the global magnetic anomaly map

The NGDC candidate model (Maus et al., 2007b) uses the method of least-squares collocation (LSC) and line-leveling methods to generate a regular grid from irregularly spaced marine and aeromagnetic measurements. Other approaches for computing the candidate model include removal of a regional polynomial, iteratively adjusting a low-degree main field model for different epochs from each of the compilations, upward continuation of the data to 5 km above the WGS84 ellipsoid, and finally knitting, merging, and filtering them together (Hamoudi et al., 2007). Long wavelengths (>400 km or spherical harmonic degrees ≤100) were removed from the individual compilations, and replaced with the MF5 anomaly map of the total field downward-continued to 5 km altitude (Hemant et al., 2007). The following sections describe the preprocessing techniques and methods followed to derive the NGDC candidate model for WDMAM.

The WDMAM requires an accurate estimate of the crustal magnetic field on a 5 km angular resolution grid. Gridded data sets were mostly available in a 5 km grid or even had coarser resolution. In case of track line data, the resolution was variable (Table 1). Therefore, to prevent further loss of information during processing, all grids were decimated to 2.5 km angular resolution using the minimum curvature algorithm of GMT. Most of the compilations, in particular over the Northern Hemisphere, had overlapping regions. The compilations known to have higher accuracy or finer resolution were retained within overlapping parts by rejecting the coarser ones. In the process, the 15 arc-min GETECH data of South America and Africa were discarded whenever a higher resolution grid for the same region was available. Generally, the aeromagnetic surveys over the land are draped, meaning that they follow the surface topography at a constant altitude above terrain. Thus, the derived compilations from these surveys follow topography. Therefore, to accurately process the altitude information with respect to a geoid, a topographic model of the Earth was used.

The NGDC ETOPO-2 (http://www.ngdc.noaa.gov/mgg/fliers/01mgg04.html) surface elevation grid was linearly interpolated to the measurement positions and added to the terrain clearance of all draped surveys, to compute the measurement altitude above the geoid.

The continental-scale compilations (Table 1) are produced after stitching together many regional aeromagnetic anomaly grids (Ravat et al., 2002). These regional surveys are flown at different times and, hence, use different international geomagnetic reference field (IGRF) models (see *Geomagnetic Field, IGRF*) to reduce the measured data. The patchwork grids are therefore prone to offsets and edge effects and mismatch in anomaly shapes and strengths across overlapping regions. They also have the potential to introduce spurious anomalies. These edge effects were corrected by subtracting a linear 2D trend from all smaller sized grids.

It is well known that the genuine crustal anomalies of strengths ~500 nT can easily be contaminated by external field disturbances of amplitudes 100 nT. Thus, it has been a challenge to filter out short-wavelength noise from aeromagnetic and marine track line data. To filter these spurious signals, spatiotemporal variations of the magnetic field of strong but fast external field disturbances and those recorded by instruments on board relatively slow moving ships and aircrafts are compared by computing the along-track derivative of the magnetic field residual. As a selection criterion, if the derivative exceeded 100 nT/km, 20 preceding and following measurement points on a track were removed. This selection procedure removed about 3% of the marine track line profile data and 9% of the Project Magnet data, which possibly were affected by external field disturbances.

Methods

Line-leveling of data

In aeromagnetic surveys, inaccuracy in the measured positions of crossover points of acquisition, line to line differences in flying heights along adjacent tracks, and inadequate compensation for the magnetic field resulting from the aircraft leads to errors covering a region that extends beyond the line spacing in each direction (see *Magnetic Data Enhancements and Depth Estimation*; *Magnetic Methods, Airborne*). These errors are visible as linear anomalies parallel to the flight lines. If uncorrected, the computation of derivatives enhances these noise effects along the lines. This problem is common with acquiring aeromagnetic data. A common processing method to remove these errors is to line-level the data. A set of tie-lines perpendicular to, but spaced greater than that of the main survey lines is normally acquired for line-leveling. The line-leveling procedure computes differences in the field values at the crossover points of the survey and tie-lines, and corrections are applied to minimize these differences in the least-square sense (Reeves, 2005).

The track line data, both marine and aeromagnetic, used for the WDMAM project is also likely to have this kind of problem. These track line data are first corrected for the main field and external fields. Additional navigational errors, instrument biases, and disturbances from the unfiltered external field remain in the data causing uncertainty in the longer wavelength part of the magnetic field. The line-leveling technique addresses these remaining errors in the track line data by minimizing the differences between adjacent or crossing tracks (Maus et al., 2007b).

The technique defines a correction function for each track given by

$$f_j(d) = \sum_{k=0}^{M_j} b_{j,k} \cos\left(\pi k d / X_j\right). \tag{1}$$

Here, X_j is the great circle distance from the first to the last point of the jth track and M_j is the number of parameters required for the estimation of the correction function of this track. The algorithm assumes $M_j = \text{trunc}\ (X_j/400\ \text{km}) + 1$, to correct for offsets with half-wavelength greater than 400 km. The choice of 400 km wavelength is based on the minimum wavelength the MF5 model is able to resolve. To minimize the misfit between all adjacent tracks and the differences of the track line profiles to the gridded data, the parameters $b_{j,k}$ are estimated from inversion. The line-leveling algorithm then minimizes the distance-weighted misfit between all measurement locations. The weight function $W(r_{1,2},z_1,z_2)$ used here is given by

$$W\left(r_{1,2}, z_1, z_2\right) = \max\left(0, 1 - \frac{1}{R_s}\sqrt{\left(r_{1,2}^2 + 2(z_1 - z_2)^2\right)}\right). \tag{2}$$

where R_s is the search radius, $r_{1,2} = \left((x_2 - x_1)^2 + (y_2 - y_1)^2\right)^{1/2}$ is the horizontal separation and z_1 and z_2 are the vertical coordinates of two locations 1 and 2 in Cartesian coordinate system. In Equation 2, the vertical separation (z_1–z_2) is up-weighted by a factor 2 to account for the greater variability of a potential field in the vertical than in the horizontal direction. The weights proportional to the distance from the margins of the grids were chosen. A value of 0.01 on the margin and 1.0 at 200 km inland were used. Although the line-leveling technique was effective in minimizing the misfist between adjacent tracks, it also introduced spurious anomalies with half-wavelengths larger than 200 km. However, these spurious long-wavelength anomalies were later replaced by those from the MF5 model.

The implementation of the technique first required the decimation of 31,000 tracks of NGDC and Project Magnet data into 98,000 segments. These track line data were then line-leveled against each other by estimating 110,000 correction coefficients (b_{jk}) from one grand inversion. This procedure also minimized offsets where tracks overlapped with gridded data. The segments that were affected by strong external field disturbances were removed when

differences between two adjacent segments exceeded 550 nT and misfit against the gridded data exceeded 500 nT. The line-leveling and selection procedures further reduced the rms misfit between two adjacent segments from 380 to 130 nT and against the gridded data from 400 to 90 nT.

Least-squares collocation

LSC is a scheme for interpolation by the weighted average of the measurements similar to the method called Kriging. The weighted averages are obtained in a minimum-variance sense. The technique of LSC has been used to solve a wide variety of problems in physical geodesy (Moritz, 1980). It has been especially useful in certain satellite missions applications, such as in satellite altimetry and satellite-to-satellite tracking. The LSC method is discussed in Langel and Hinze (1998) and has been applied by Maus et al. (2007b) to compute the NGDC global magnetic anomaly. Since locations of the measurement points in both track line and gridded data are not on a regular grid, one requires an interpolation procedure to estimate the field at regular grid nodes.

Following Moritz (1980), the LSC method estimates vector components of magnetic anomaly field values, b, on a predefined grid from a given set of vector magnetic measurements, **c**, at nearby locations. The vector of measurements, **c**, is defined as the sums of the true anomaly vector, **a**, plus an associated noise vector, **e** (i.e., **c = a + e**). To estimate the value of $\underline{b}$, covariance matrices are first computed as follows:

$$V_a = E\left(aa^T\right), V_b = E\left(bb^T\right),$$

$$V_{b,a} = E\left(ba^T\right), V_d = E\left(ee^T\right),$$

where E indicates the expected value. The collocation requires the estimation of anomaly field $\underline{b}$ in the least-square sense from

$$\underline{b} = V_{a,b}^T V_c^{-1} c, \tag{3}$$

where $V_{b,a} = \left(V_{a,b}\right)^T$ and

$$V_c = E\left(cc^T\right) = V_a + V_d. \tag{4}$$

Here, it is assumed that **e** and **a** are uncorrelated, so that $V_{a,e} = V_{e,a} = 0$; and V_d is the error covariance matrix of measurement noise. The efficiency of the LSC method then lies in computation of the covariance matrices V_a, V_b and $V_{a,b}$ from properties of the true signal (**a**) and the estimation of V_d from the properties of the noise.

For a Cartesian approximation of the data volume, Langel and Hinze (1998) suggest approximate correlation functions V_2 and V_3 between two locations at (x_1, y_1, z_1) and (x_2, y_2, z_2) of the form

$$V_2\left(r_{1,2}, z_1, z_2\right) = V_0 \beta \left(r_{1,2}^2 + \left(z_1 + z_2 + \beta\right)^2\right)^{-1/2}, \tag{5}$$

where $\beta = r_c/\sqrt{3}$, and

$$V_3\left(r_{1,2}, z_1, z_2\right) = V_0 \beta^2 \left(z_1 + z_2 + \beta\right)\left(r_{1,2}^2 + \left(z_1 + z_2 + \beta\right)^2\right)^{-3/2}, \tag{6}$$

where $\beta = r_c/0.766$.

Here, the variance V_0 is a linear scale factor for the horizontal axis, while the correlation length r_c is a scale factor on the vertical axis. For magnetic anomaly fields, the use of one of these correlation functions for collocation depends on the variation of the function V_2 and V_3 with distance. Based on correlation functions for NGDC magnetic data, Australia and North America, empirically, it was determined that V_3 gives a better fit than V_2. From V_3, the values of V_0 and r_c are estimated to be 40,000 nT^2 and 15 km respectively.

The value of $\underline{b}$ from Equation 3 can then be estimated by computing the matrix $V_{a,b}$ given by (Maus et al., 2007b)

$$V_{a,b} = V_3\left(r_{a,b}, z_a, z_b\right), \tag{7}$$

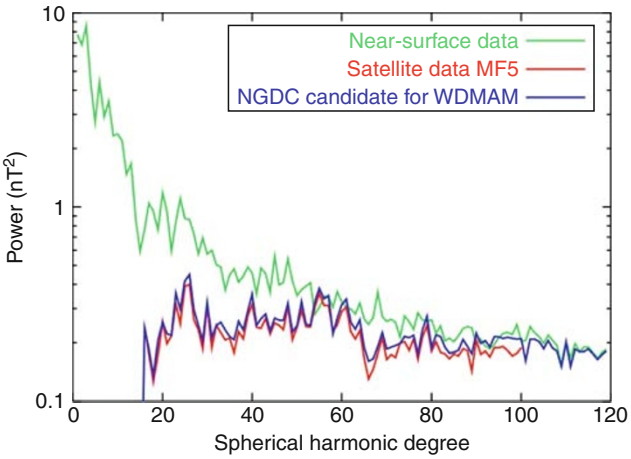
and the matrix V_c from Equation 4,

$$V_c = V_3\left(r_{1,2}, z_1, z_2\right) + E\left(ee^T\right), \tag{8}$$

are evaluated for all pairs of estimation (b) and measurement (a) locations. The error covariance matrix of measurement noise $E(ee^T)$ arise due to differences between adjacent tracks and between a track and a gridded data, which undermine all other sources of errors in the data. After line-leveling, it was assumed the uncorrected difference is 25 nT and the error covariance matrix was set to 625 nT^2 for data pairs from the same set, and 0 nT^2 for data pairs from different sets. The line-leveled data were finally merged with the gridded data using the LSC method. This grid is called the final merged grid.

Merging satellite models

Finally, the NGDC candidate model was derived by combining the final merged grid with MF5 by computing the magnetic potential. As a first step, the magnetic potential of the line-leveled data was computed to spherical harmonic degree 120. The degree correlation (cf. Langel and Hinze, 1998) between this model and MF5 was shown to be about 0.6 at degree 100. This high correlation offered some validation of high-degree coefficients of MF5. The correlation suggests that CHAMP satellite data is able to resolve many small-scale features beyond degree 100, which could be crustal in origin. The power spectra (Figure 2) of line-leveled data show excess power at low-degree. This is possibly caused by unremoved main field in continental-scale grids and by erroneous long-wavelength anomalies introduced in stitching together small-scale grids. At high degrees, the line-leveled data has 10% more power than MF5. Again, considering the different data sources and their uncertainties and various data processing steps and corrections, the disagreement in power is judged small. Following a good spectral agreement between the line-leveled and MF5



Magnetic, Global Anomaly Map, Figure 2 Power spectra of the near-surface (*line-leveled*) data, MF5 satellite model, and the final NGDC candidate model computed from spherical harmonic. (Courtesy: Maus et al., 2007a.)

model at degree 100, a sharp cutoff was used to substitute the long wavelengths of the near-surface data with the MF5 model. The substitution is carried out by subtracting the near-surface model to degree 100 from each grid cell and then adding the prediction from MF5. The final NGDC candidate model for WDMAM is a 3 arc-min angular grid of the total intensity anomaly at 5 km above the WGS84 geoid. The digital grid of the NGDC candidate for WDMAM also referred to as EMAG3 model is available at http://geomag.org/models/wdmam.html and additional plugins can be downloaded from http://www.getech.com/downloads/WDMAM for visualization in NASA World Wind.

Other candidate models for WDMAM

There were four other candidate models for WDMAM. Two of those models, the GAMMA model produced by GeoForschungsZentrum, Potsdam (Hamoudi et al., 2007) and the Leeds model derived by the team at University of Leeds, Leeds (Hemant et al., 2007) are published. These models are described next.

The GAMMA model

Most techniques were designed to improve the compatibility of the overlapping areas of neighboring grids. Hamoudi et al. (2007) applied different procedures to improve this incompatibility. These procedures are useful and easy to implement if only few grids are used, for they require only first order estimation of improved long-wavelength values.

Prior to processing, the gridded and track line data were statistically analyzed to check for their self consistency. For a pure anomaly field, one expects a symmetric distribution with zero mean. A skewed anomaly distribution not centered on zero possibly indicates some more or less severe contamination of other magnetic field contributions. In this respect, Russian, East Asian, and European compilations showed large anomaly intensity means. The standard deviation of anomaly distribution was usually between 100 and 200 nT for continents but could be as large as 930 nT on oceans. Oceanic magnetic anomalies of remament origin have amplitudes larger than on continents but such a wide distribution can only be explained by noise, bad tracks and outliers in the data. Another criterion, based on the arithmetic sum, highlighted some bias in marine, Russian, Australian, and East Asian compilations. These statistics were used to provide the available data and compilation with a quality flag.

The next procedure devoted to the analysis of data compatibility in the overlapping regions was based on visual inspection. By binning the data on a coarse grid, the spurious isolated points or track lines could be easily identified and manually removed. Other track lines, having consistent values but suspicious behavior, like a few Project Magnet data crossing the African continent or possibly biased data offshore Senegal were removed. Some GETECH South American and African compilations showed unusual shapes like over Bangui. Considering that these grids were coarser than any others, it was decided to allow them a low weight in the final process. Similarly, the Indian grid based on repeat stations showed poor resolution, so magnetic map boundaries of Qureshy (1982) on the eastern coast were applied. The European grid showed unexpected geographical shifts by a few kilometers, in particular over Germany, so the grids were used for analysis only when no other data were available in that region. In general, most grids suffered from edge effects, possibly resulting from some kind of filtering at the last stage of their production. Some of these errors were identified but could not be systematically corrected due to lack of complete metadata information.

The third procedure was to carry out an arguably homogeneous correction for the core magnetic field. It has been customary to correct all aeromagnetic surveys with IGRF/DGRF core field models (see *Geomagnetic Field, IGRF*; *Magnetic Anomalies, Interpretation*). Older surveys were corrected for more inaccurate core field models, particularly for those carried out at epochs when rapid core field variations were not yet identified (see *Geomagnetic Field, Secular Variation*). The core field correction was thus often followed by two-dimensional polynomial fitting or a Cartesian Fourier filtering. The DGRF models or polynomial fitting parameters were added to such old surveys whenever they were known, and a more recent core field model correction such as CM4 was (Sabaka et al., 2004). When the core field models were unknown, a better solution was found by trials and errors. A DGRF core field model for different epochs was added to each of these surveys and the CM4 was removed. When it improved the statistics (arithmetic mean, histogram of residuals), this correction was deemed fruitful. This procedure was not applied only for the Russian grid because it was outside of the CM4 time span (1960–2002). This procedure was shown to improve the data statistics by lowering the mean

intensity anomaly toward zero and the continuity in overlapping areas between adjacent compilations and other artifacts caused by the different model biases. For countrywide compilations with a clear knowledge of the acquisition date, in France, Italy, and Spain, this procedure provided a better way to correct for secular variation between different compilations. For some other surveys, however, for which the exact epoch and corrections were poorly known, a regional polynomial adjustment was necessary. In order to avoid Cartesian distortion due to the Earth's curvature a regional second order polynomial from all grids in the WGS84 geographic reference was removed. This polynomial fitting was not applied to the Australian grid, where the long-wavelength control was good, or to compilations over geographic poles (Arctic and Antarctic grids), where the processing procedure was based on using Cartesian reference frame instead. After this correction, the grids were shown to have the expected properties characterizing the anomaly field with the average anomaly intensity and an arithmetic sum zero (Table 2).

The fourth step consisted in upward continuation of the data to the desired altitude of 5 km. Marine track line data sets were also upward continued to mitigate effects of the sharp transition at the ocean-continent boundaries. Grids smaller than 2,000 km width, like Argentina, Austria, Fennoscandia, Italy, France, Mexico, and Spain, were upward continued to 5 km altitude above the geoid without any further processing. However, larger compilations (>2,000 km) were first split into 2,000 × 2,000 km^2 and upward continued individually. This dimension corresponds to the maximum size for which the Earth's curvature can be neglected (Nakagawa et al., 1985). After upward continuation, the edge effects between adjacent grids were not significant.

The preliminary processing discussed earlier reduced the large discontinuities but did not fully remove them. The Grid-knitting tool of GeoSoft was used to smooth the transition between adjacent grids. Some spurious wavelengths were created but were filtered out later. Merging large compilations with small compilations includes a risk, because the adjustment is better constrained by the large compilation even if the small one has apparently a better quality. Before merging the grids, compilations with comparable grid sizes were generated and more weight was given to the grid showing the best statistical properties. Therefore, French, Italian, and Spanish grids were first merged together, followed by building a second grid, the Finland, Fennoscandian, European, and Austrian grids. These two new compilations were merged together and the grids from Russia, Eurasia, Middle East, Antarctica, and North America were successively added to the compilation. The remaining grids that did not overlap with the grids listed above were simply added in the corresponding geographical areas. This generated a 3′ × 3′ global grid using GMT.

Magnetic, Global Anomaly Map, Table 2 Statistics after preprocessing of gridded and track line data (Courtsey: Hamoudi et al., 2007)

Grid name	Number of points in the grid	Minimum anomaly intensity	Maximum anomaly intensity	Standard deviation	Arithmetic mean
Africa and South America	65,030	−1,032	701	66	3.E − 08
Antarctica	969,479	−894	2,113	128	6.E − 05
Arctic	2,225,311	−2,604	5,528	171	−5.E − 05
Argentina inland	571,585	−3,150	1,480	107	−1.E − 07
Argentina margin	44,056	−137	318	44	6.E − 09
Australia	23,636,550	−8,743	18,882	209	8.E − 04
Austria	4,240	−55	137	27	0.E + 00
Canary Islands	328,077	−400	456	87	1.E − 05
India	625,898	−4,001	7,109	102	8.E − 06
Eurasia	1,758,876	−916	1,034	123	4.E − 05
Europe	664,626	−1,712	7,983	179	1.E − 06
Fennoscandia	78,862	−526	1,254	158	6.E − 09
Finland	420,121	−2,110	3,974	240	2.E − 05
France	7,560	−111	251	29	0.E + 00
Italy	36,603	−747	1,402	79	2.E − 09
Mexico	79,699	−562	876	86	−1.E − 07
Middle East	4,915,299	−5,446	2,408	101	5.E − 04
North America	63,447,385	−22,567	26,232	191	3.E − 02
Russia	1,061,053	−1,046	9,545	349	5.E − 05
South Africa	12,324,191	−14,642	11,341	176	−1.E − 04
East Asia	3,554,249	−340	2,196	85	6.E − 05
Spain	81,501	−97	242	20	0.E + 00
Magnet Project	7,814,111	−2,000	2,000	89	0.E + 00
Marine Data	19,455,835	−2,000	2,000	148	1.E − 04

Finally, the spurious intermediate wavelengths introduced by the merging were filtered out by a spherical harmonic transformation. The wavelengths larger than those corresponding to spherical harmonic degree 100 were filtered out of the global grid and were replaced with those from the downward-continued MF5 model. The candidate model along with accompanying documentation is available at http://www.earthref.org.

The Leeds model

To check for inconsistencies in the gridded data, the strength of total field intensities across the two overlaying grids are compared. Within the overlapping regions of Eurasia and Europe, total field intensities disagree in strength by 10–200 nT. At the grid boundaries, these intensities vary by 100–150 nT. These differences indicate possible errors in the long-wavelength content of the two grids. The discrepancies could also be attributable to the relative difference in the anomaly strength and resolution of the original grid. These differences are also observed between the Arctic and the North American compilations. Continental and oceanic compilations also show discontinuities in many regions.

For minimizing differences in the anomalies between various grids, a low-pass Gaussian filter with a cutoff wavelength of 400 km is applied in the 2-D space domain using GMT software (Wessel and Smith, 2004). The cutoff wavelength is set to 400 km because the longer wavelengths are later substituted from the MF5 model, which is robust up to spherical harmonic degree 100 (~400 km). The filtered output is a long-wavelength grid (>400 km) and strongly resembles a satellite-derived magnetic anomaly map. The short-wavelength grid is computed by subtracting the long wavelengths from the original grid and show finer details of the regional geology and structure of the crust (Figure 3).

To analyze the systematic errors in the long wavelengths between adjacent overlapping grids, the difference in the long wavelengths are computed. A visual inspection shows differences in the anomalies exceeding hundreds of nT and often show a lack of continuity across two or more grids. Because, it is difficult to judge the trustworthiness of an overlapping long-wavelength grid, it was best suited to replace the filtered long wavelength with a reliable satellite model.

Techniques that merge two adjacent compilations often employ a weighted average of different-order surfaces such that the two adjoining maps are seamless within the merging area. These processes modify the grids within the overlaying regions and near the edges and alter the strength and pattern of anomaly features. In this process, anomalies are modified, or at times genuine crustal anomaly features are even entirely eliminated. The merging technique applied to merge short-wavelength magnetic anomaly data minimizes abrupt changes along boundaries of overlapping grids. Using the MOSAIC toolbox (http://www.esri.com/), the grid values within the overlapping regions were determined from Hermite Cubic functions (Franke, 1982) and the short-wavelength grids merged.

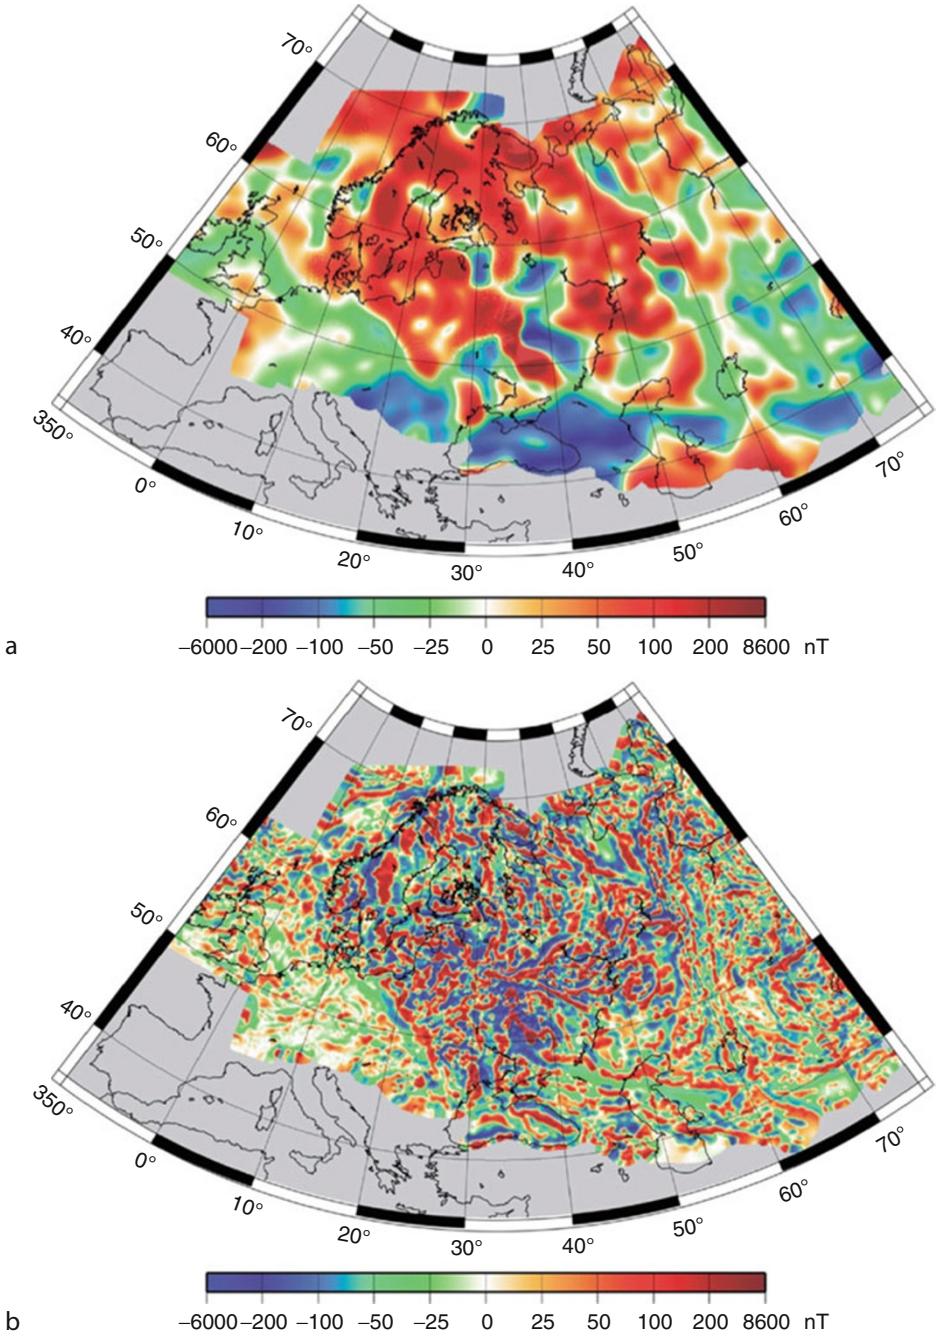
The short-wavelength anomaly differences between grids vary substantially; hence, it is difficult to prescribe the order of precedence for merging. However, the quality of an individual compilation is also reflected in the long-wavelength differences. Therefore, the order of precedence of the grid merging was based on the difference between long wavelengths and the quality of the parent grid. Thus, the short-wavelength grids were merged in the following order: Australia, North America, Austrian, Canary Island, East Asia, Eurasia, Europe, Arctic, Spain, Fennoscandia, France, Russia, Argentina margin and inland, South Africa, Antarctica, Italy, India, Middle East, Africa and South America, NGDC track line, and Project Magnet data. The grids were merged beginning with the highest precedence. The accuracy and reliability of the merged grid is assessed by investigating the effect of merging on the continuity of anomaly patterns across two or more grids and the effects on the anomaly shapes and strengths within and near the grid boundary. The differences for the merged European and Eurasian grid ranged from ± 100 to 200 nT and $< \pm 100$ nT for the remaining grid. A small difference of 8 nT was noted between Australian and East Asian grids indicating consistent anomaly patterns between the pair.

Finally, the total field anomalies of the short-wavelength-merged magnetic anomaly map were added to the downward-continued total field anomaly of the MF5 model to produce the candidate model of the LEEDS-WDMAM. The candidate model is archived at http://earthref.org/cgi-bin/ado.cgi?n=736&dbms=ERDA.

Earth magnetic anomaly grid (EMAG2)

As an improvement to the WDMAM, track line data were added in the southern oceans, where the data gaps were significant. For WDMAM, these, gaps in the ocean were filled with magnetic anomalies computed from ocean age model and geomagnetic polarity time scale. EMAG2 (Maus et al., 2009) was extrapolated into the unsurveyed areas using directional gridding based on the ocean age model of Müller et al. (2008). To further enhance the accuracy of the model over oceans, instead of using precompiled ocean magnetic anomaly grids, original track line data were used where available. Line-leveling algorithm was the primary method to minimize crossover errors. The new Arctic compilation (Circum-Arctic Mapping Project) was used instead of the old Arctic compilation. A new crustal magnetic field model derived from CHAMP data, the MF6 model (Maus et al., 2008), is used for EMAG2 to correct the long-wavelength anomaly field (wavelengths > 330 km) replacing the MF5 model used for WDMAM model.

EMAG2 is 2 arc-min grid defined at a height of 4 km above the geoid. The ocean data includes NGDC's GEODAS marine data archive, Antarctic Digital Magnetic Anomaly Project data (Golynsky et al., 2001), and

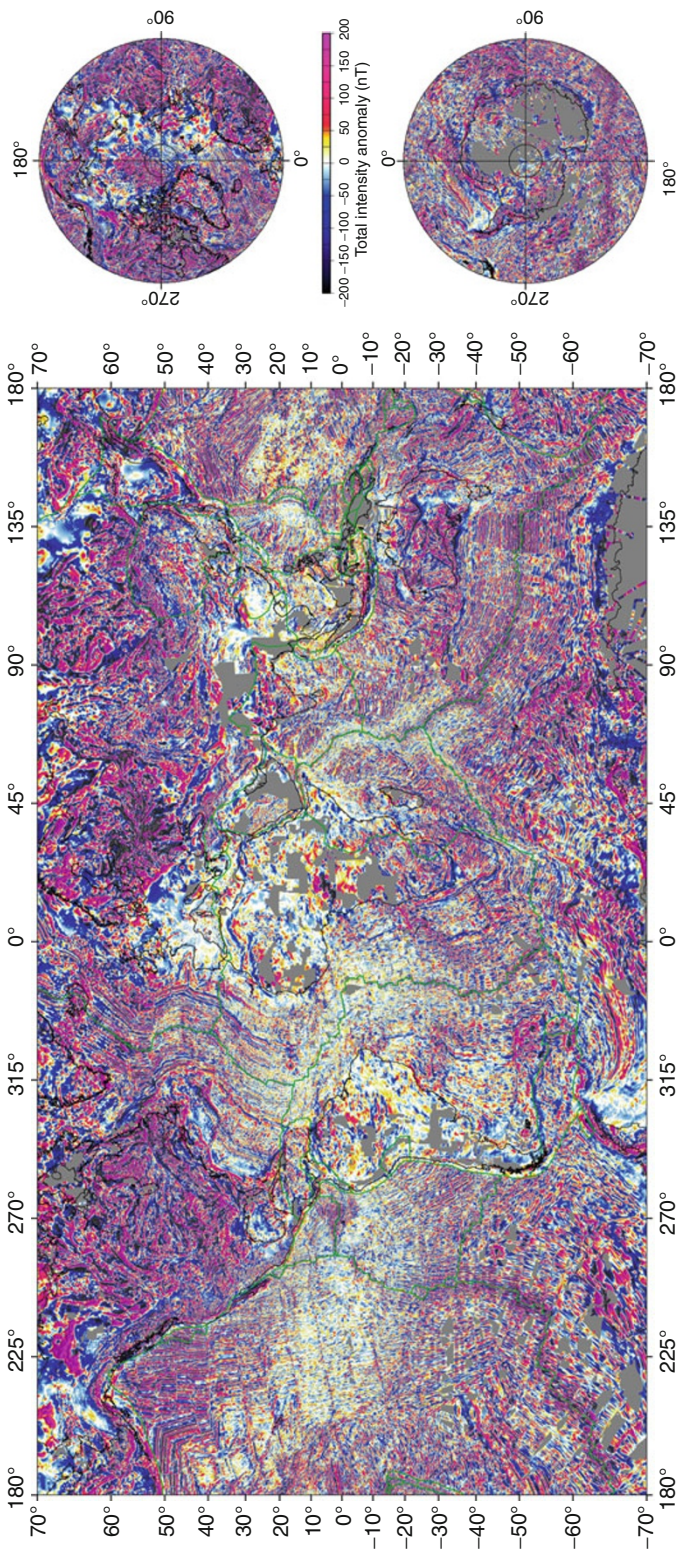


Magnetic, Global Anomaly Map, Figure 3 The effect of Gaussian filtering on the European magnetic compilation is demonstrated. Long-wavelength anomaly features (wavelengths greater than 400 km) in (**a**) resemble a typical satellite-based lithospheric magnetic field model at satellite altitude. The short-wavelength anomalies shown in (**b**) reflect geologic and tectonic features in detail. (After Hemant et al., 2007.)

the Project Magnetic Airborne data of the Naval Research Lab (NRL).

The line-leveling algorithm remains the same as described earlier. However, the search radius was reduced from $R_s = 100–8$ km in order to minimize the crossover effects in processing the track line data. In addition, the number of correction coefficients per track is now $N_i = \text{trunc}\,(X_i/300\ \text{km}) + 1$. These efforts reduced the crossover errors from 92 to 70 nT and reduced the RMS misfit to the merged grid from 121 to 97 nT.

The least-squares collocation method requires estimation of the correlation function. No new correlation



Magnetic, Global Anomaly Map, Figure 4 The Earth Magnetic Anomaly Grid (EMAG2) shown in Mercator projection and polar stereographic projection. (Courtesy: Maus et al., 2009.)

functions were computed for land areas as the gridded compilation remained the same. Notable changes for oceans, however were made. For instance, for Australia, 100 m terrain clearance was used. Due to the inclusion of more accurate grids and original marine and airborne surveys, the assumed variance V_0 was reduced from 40,000 to 33,000 nT and the correlation length r_c from 15 to 14 km.

The methodology of LSC was slightly modified for EMAG2. The correlation analysis now considered the anisotropy of oceanic magnetic anomalies. Track line data, just the way it was processed for NGDC candidate model, were first divided into small windows but along the constant heading direction of the track. Next, for each track, the azimuth for every pair of measurement points was calculated and compared with the direction of the oceanic isochrons at the locations of both points. The pair was removed from further processing if they met one of the following criteria: (1) the azimuth of the isochrons was not well defined, (2) the azimuth differed by more than 5° between the points, or (3) the topographic gradient between the two points exceeded 3%. The NGDC ETOPO-2 bathymetry values were used to compute the topographic gradient. This gradient could detect and remove the magnetic anomalies due to sea-mounts, which otherwise would appear as noise. The anisotropic correlation function was then computed in 10° directional bins; from 0° (parallel) to 90° (perpendicular, i.e., in the spreading direction) to the isochrons. This anisotropic correlation model allowed the LSC method to be used as a directional gridding algorithm.

From the analysis of covariance function in the isochron direction, it was noted that the function value reduced too rapidly. Furthermore, extrapolating the field far from a track line, made the function reduce to zero. This produced erroneous stripes parallel to the track lines. To stabilize the covariance function, the correlation length was doubled when gridding the ocean areas. This made the anisotropy of the oceanic field in EMAG2 to be smoother than it perhaps is.

EMAG2 also suffers inaccuracies from the oceanic crustal age model due to errors in the estimated ocean isochrons. This error could easily have contaminated those estimated oceanic magnetic anomalies of EMAG2, where the uncertainties in isochron age are large. To reduce these uncertainties, empirically, the anisotropy factor was increased four-fold for all oceanic isochrons of age <140 Ma and a linear reduction to a factor 2.25 for ages >150 Ma was used. This procedure helped reduce the errors in EMAG2 within the oceans, in particular over the older crust.

For compiling the final EMAG2 grid (Figure 4), the portion of the original total field anomaly up to degree 120 is replaced by that of the MF6 model. A spectral comparison between the original and modified grids shows a slight discrepancy above degree 120. This is perhaps due to the leakage of long-wavelength power into shorter wavelengths. But the overall comparison generally validates the power content in EMAG2. The EMAG2 grid can be downloaded from http://earthref.org/cgi-bin/er.cgi?s=erda.cgi?n=970 or from http://geomag.org/models/EMAG2.

World digital magnetic anomaly map 2011

The WDMAM is an ongoing project, with plans to produce updates of the map and grid every 4 years. As part of these updates, it is envisaged that more organizations will make additional data available for WDMAM 2011, in particular over regions where large data gaps exist. The call for candidate models for WDMAM 2011 has been announced. WDMAM 2011 will represent the total intensity of the magnetic field at an altitude of 2.5 km above the geoid at a resolution 2.5 km. The teams interested in deriving the candidate models are required to register by April 2010 and submit their models by October 2010. The WDMAM executive committee will choose one candidate as a basis for WDMAM 2011, and will define necessary adjustments required before submitting the manuscript to the CGMW. The final manuscript will consist of a grid file and a map image plus a short explanation. The CGMW will organize a scientific review of the submitted WDMAM 2011 manuscript and will print the map at a 1:50 million scale. Finally, the selected candidate model will be released as the WDMAM 2011 map at the IUGG General Assembly in Melbourne, Australia in July 2011.

Summary

In summary, with methods discussed above, it will be possible to regularly update the WDMAM model without excessive effort to reliably synthesize a map that accurately represents the world's magnetic anomalies. This would also require information on the long-wavelength field in order to continuously improve representation of the world magnetic anomalies. The upcoming Swarm mission of the European Space Agency (http://www.esa.int/esaLP/LPswarm.html) will considerably improve the lithospheric magnetic anomaly maps by providing highly accurate measurements of magnetic field gradients and further improve the long-wavelength anomalies in next generations of WDMAMs and EMAGs. It is our hope that these global magnetic anomaly maps will enjoy widespread usage, and inspire further aeromagnetic and marine surveys, thus helping to produce maps having truly global coverage. Finally, the WDMAM would not have existed without the willingness of institutions to constantly revise and release their national-scale compilation.

Definition

Magnetometers are devices/instruments that measure magnetic field/magnetic flux density in particular Earth's magnetic field either vectorially or scalarly.

Introduction

First measurements of magnetic field intensity have been introduced by Carl Friedrich Gauss (Kaufman et al., 2009) in 1834. He has established a number of magnetic observatories to continuously measure magnetic field of Earth (see *Geomagnetic Field, Measurement Techniques*; *Geomagnetic Field, Secular Variation*). Prior to that, compasses were in use for several centuries mostly for navigation but with no knowledge of the causes of magnetic needle behavior. Since Gauss' times, many methods of magnetic field measurement have been developed but there are two pillars of magnetometry discovered and developed in the twentieth century:

1. Fluxgate magnetometers for measurement of components of the vector of magnetic field (Primdahl, 1979; Korepanov et al., 2007)
2. Scalar, quantum magnetometers with high precision of measurement and a possibility of measurements in motion (Abragam, 1961; Alexandrov and Bonch-Bruevich, 1992; Hrvoic, 2004; Hrvoic, 2008)

Presently, absolute measurements of magnetic field direction by optical methods (DI-Flux or DIM) based on fluxgate technology and the scalar measurements (Proton precession, Overhauser or Potassium) of its magnitude set up the limits of precision of the magnetic field vector measurement.

Magnetometry is a mature science/technology with myriad of applications. The need for better, more precise, smaller magnetometers fuels continuous research in the field.

This review will be treating separately vector and scalar magnetometers describing their principles of operation and main features, and with the view of their application in different fields of geophysical exploration.

Scalar magnetometers with their high precision and absolute accuracy now dominate measurements in mineral and oil exploration, volcanology, ordnance detection, archeology and partially magnetic observatories while vector magnetometer's role is limited to magnetic observatories, partially space measurement (Acuña, 2002) (see *Equatorial Electrojet*; *Magnetic Methods, Satellite*), and in vertical gradiometers for archeological research (see *Archaeomagnetism*). Scalar magnetometers are used to calibrate fluxgates. Some experiments with tensor measurements also include fluxgates and/or SQUIDs (Supercooled Quantum Interference Devices) (Clark, 1993).

All modern magnetometers are computerized instruments with nonvolatile memory for display, storage, and review of data.

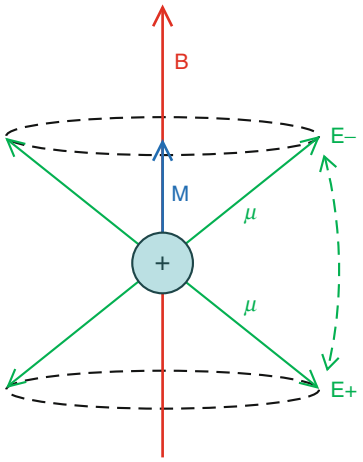
Scalar (quantum) magnetometers

Advent of scalar magnetometers in the second part of the twentieth century made a substantial contribution to measurement of both vector and scalar values of magnetic field. They offer precession frequency as a measure of magnetic field. Scalar magnetometer's sensitivities are determined only by achievable quality of precession signal, value of gyromagnetic constant, width of the spectral line (or time of decay of the precession signal), and signal-to-noise ratio. Scalar magnetometers have high sensitivity and accuracy of readings, virtually no drift with temperature or time. Measurements depend very weakly on sensor orientation or movement allowing for measurement in motion.

Proton, Overhauser, and Alkali metal (optically pumped) magnetometers are now overwhelmingly used in mineral/diamond/oil exploration, weapons detection, volcanology, archeology, magnetic observatories. Most of the current research is done in variations of optical pumping, and the progress in the last 25–30 years is phenomenal. Sensitivities have been improved from some *nT* to fractions of *pT*, perhaps four orders of magnitude, far exceeding requirements for ground (see *Magnetic Methods, Surface*), airborne (see *Magnetic Methods, Airborne*), or marine surveys. Speed of readings increased from perhaps once per second to tens and hundreds of readings per second limited only by increasing noise and/or possibility to usefully store a flood of data. With the development of instrumentation, the use of gradiometers with two or more sensors has increased (see *Magnetic Gradiometry*). It improves the quality of surveys, determination of depth of the anomaly producing body, following the direction and depth of the buried pipelines or electrical power lines etc.

Scalar magnetometer consists of a sensor, separated by a cable from electronics (to avoid its stray magnetic fields). Electronics has an analogue part that generates precession signal from the sensor and digital microprocessor based on part that controls the operation; measures Larmor frequency; converts it into units of magnetic field; and displays, stores, and/or outputs the data. Review of data is often possible (Figure 1).

Magnetometers, Figure 1 Overhauser magnetometer – sensor, cable and electronics console.



Magnetometers, Figure 2 Magnetic moment μ of a proton (or electron) precesses around magnetic induction *B*. Resulting magnetization *M* is collinear with *B* and static. Components orthogonal to *B* are averaged out. Coupling energy $E = -\mu B$.

Global positioning plays a big role in geophysical ground and airborne surveys. In stationary measurements, GPS provides precise timing (1μs accurate pulses referenced to Greenwich standard time).

Background physics

Scalar magnetometers are all based on a spin of subatomic particles – electrons and protons (Abragam, 1961; Schumacher, 1970).

Spinning charged particles make magnetic dipoles. The dipoles are precessing around ambient (applied) magnetic field following Quantum Physics rules (Figure 2).

Precession frequency is proportional to magnetic flux density:

$$\omega_0 = \gamma B$$

ω_0 is an angular precession frequency (Larmor frequency), B magnetic induction (flux density), and γ gyromagnetic constant.

Spinning protons (electrons) orient themselves in magnetic field. Only two angles of orientation are allowed: acute (lower energy level) and obtuse (higher energy level).

Since individual particles precess at random phases, their dipolar magnetic field in the plane perpendicular to the magnetic field is averaged out. A projection of the dipolar magnetic fields in the direction of the applied magnetic field is static. Since orientation at the acute angle to the direction of the field is more populated than the one at the obtuse angle, a minute "polarization" of precessing particles creates a magnetization M_0 collinear with magnetic induction B:

$$M_o = \frac{N\gamma^2 h^2 / 4\pi^2 B}{4kT\mu_o}$$

N is the number of particles, γ gyromagnetic constant, h Planck's constant, T absolute temperature, k, μ_0 constants.

When placed in the flux density B, M_0 will reach its "thermal equilibrium" exponentially with the "longitudinal" time constant T_1.

When deflected by about 90°, it will precess around the field by the Larmor frequency and decay exponentially by the "transversal" time constant T_2. (Time constants T_1 and T_2 depend on the aggregate state of the assembly of spinning particles. In liquids and vapors, they may be several seconds long, while in solids, T_2 time is only in milliseconds and the precession signal disappears very quickly. This is why all scalar magnetometers have liquid or gaseous sensors.) Particles at the lower energy level can accept energy in the form of magnetic field at Larmor frequency and flip to the higher energy level. Leveling of the two energy level populations eliminates M_0. This is saturation of the precession spectral line. Proportionality constant, the gyromagnetic constant (not always a constant), is precisely determined to better than one part per million accuracy only for protons in water (Hrvoic, 1996):

$$\gamma_\rho = 0.2675153362 \mathrm{rad}/nT$$

Magnetization M_0 is too small to produce detectable precession signal when deflected in the plane of precession. All scalar magnetometers therefore need to increase polarization and magnetization M and thus increase the sensitivity of the instrument. Polarization is increased in different ways:

- By temporarily increasing B to few hundreds Gauss (Proton magnetometers)
- Transferring thermal equilibrium polarization of electrons to protons in liquid sensors (Overhauser magnetometers)
- Using light polarization in alkali metals, and ^{4}He magnetometers

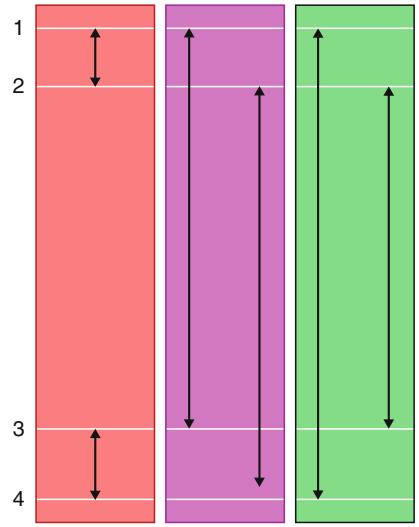
Proton magnetometers

Proton magnetometers are the oldest scalar magnetometers. The first commercial units were produced in early 1960s as portable instruments. In continuation, airborne instruments appeared with optimized speed of readings and sensitivity, large sensors, etc. Later development of Overhauser and optically pumped magnetometers has eliminated Proton magnetometers from airborne surveys. However, they remain very popular in various ground surveys and observatories.

Proton magnetometer's sensor contains liquid rich in protons and polarization/pick-up coil. Polarization is done by increasing flux density B for a time comparable with T_1 of the sensor liquid. Electrical current passing through polarization coil creates strong magnetic field that polarizes protons of the sensor liquid. The coil is usually immersed in liquid to maximize the coupling. Alternatively, omnidirectional toroidal coil is used. Polarization field of few hundred Gauss must be roughly at the right angle to the measured field. Its removal must be fast to leave the newly formed magnetization in the plane of precession. Practical portable Proton magnetometers achieve about $0.1nT$ sensitivity at a few seconds cycle, somewhat less in once per second measurements.

Overhauser magnetometer

Overhauser effect originates from double resonance experiments in metals (Overhauser, 1953). Russian and French scientists have greatly contributed to the development of modern Overhauser magnetometers based on nitroxide free radicals (Abragam, 1961; Pomerantsev, 1968). Practical realization of the magnetometer is as follows: Sensor liquid containing protons is placed in an RF resonator. It has small concentration of a Nitroxide free radical – stable chemical with one unpaired electron. The unpaired electron is dwelling close to the nitrogen nucleus, in its magnetic field of some 24 Gauss. Its electron paramagnetic resonance frequency in the Earth's magnetic field is about 30,000 times higher than the one of protons. Unpaired electrons couple with the protons of the sensor, creating a four energy level system (Figure 3). Coupling can be either scalar or dipole – dipole. If one of them predominates, saturating electron resonance at some 60 MHz, transfers part of electron magnetization to protons. Increased proton polarization (magnetization) needs a 90° deflection to be turned in the plane of precession. The deflection can be either pulsed ($\pi/2$ pulse) or stationary by applying a weak rotating magnetic field of Larmor frequency in the plane of precession. Transferred magnetization is far superior to any achievable by proton magnetometers and the measurement does not need to be interrupted for polarization; RF saturating field can be present continuously. In pulsed mode, repeated $\pi/2$ pulses interrupt measurement by about 25–30 ms. Low power consumption, no warm-up delay, higher sensitivity ($10pT$ for one reading per second), absolute accuracy, reasonable speed of readings (up to five readings per second), and omnidirectional sensors make Overhauser magnetometers very convenient and attractive for magnetic observatories, volcanological exploration, marine surveys, and base stations for airborne surveys. Oersted and CHAMP magnetic satellites use continuous Overhauser magnetometers as reference to vector measurement of magnetic field.



Magnetometers, Figure 3 Four energy levels combined electron–proton system. Transitions 1–4 (weak scalar coupling) and 2–3 (dipole-dipole coupling) involve combined transitions of electrons and protons. 1–3, 2–4, 1–2, and 3–4 are independent transitions of electrons and protons.

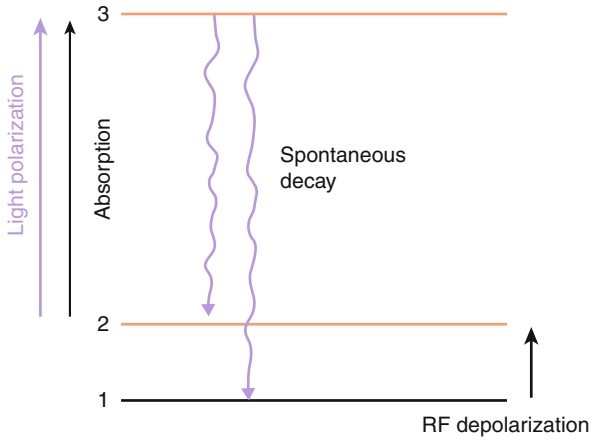
Optically pumped magnetometers

This is the latest to be discovered and the most potent family of magnetometers. It consists of elements of the first column of the table of chemical elements. In gaseous form, alkali metals have an unpaired electron in their valence shell.

Gaseous sensor is subject to a circularly polarized light (D_1 line) (Happer, 1972). Polarization process lifts electrons from a higher energy level to a metastable state from which electrons fall back to both levels.

Eventually, all electrons are in the lower energy level while the upper one is depleted. Absorption of light is then reduced and the sensor is more transparent. Rotating RF magnetic field of the Larmor frequency will depolarize the sensor and increase absorption of the light (Figure 4).

As a result, the polarizing light will be modulated by the Larmor frequency. Its detection produces an electrical signal for the measurement of magnetic field. Helium 4 magnetometers that have two valence electrons need a weak discharge to lift one of them in a metastable state. Laser-pumped Helium 4 magnetometer has sub pT sensitivity. Due to the influence of nucleus (strong scalar coupling with valence electrons), all Alkali metal magnetometers have a number of spectral lines in their EPR spectrum (Breit and Rabi, 1931).



Magnetometers, Figure 4 Optical polarization (lifting an electron from upper energy level to a metastable state) and depolarization (lifting electrons from lower to upper energy level) result in modulation of optical beam by Larmor frequency.

Potassium spectral lines are well spaced and the operation of Potassium magnetometer can be based on a single narrow spectral line. This ensures very high sensitivity and the absolute accuracy similar to the one of Proton/Overhauser magnetometers. Cesium and rubidium lines are very close to each other, and they overlap and make a relatively wide composite single line. Operation of the magnetometer in self-oscillating mode is at the peak of the composite line. Problem is that the position of the peak depends on an angle between sensor axis and magnetic field direction. A heading error due to this effect can be reduced by a "split beam" technique, which symmetrizes the composite line. Reduction of the heading error to some nT or even a fraction of nT is possible. However, the split beam technique reduces the sensitivity by about one order of magnitude. Absolute accuracy of only few nT can be achieved by Cs and Rb magnetometers.

Measurement of frequency

In the magnetic field of Earth (20–65μT), precession frequency of protons is an acoustic frequency in a range of some 850Hz–3kHz, while Alkali metal optically pumped magnetometers produce 70–450kHz, ^{4}He 280kHz to about 2MHz. Considering achieved precisions of measurement – one part per million or a small fraction of that for Proton and Overhauser magnetometers respectively and even few parts per billion for ^{4}He and ^{39}K or ^{41}K – we are resolving Larmor frequency to a millihertz precision. Times of all zero-crossings of precession frequency are taken, and an average period is measured by the least squares fit. Zero-crossing times must be understood as a phase information too (0°, 180°, 360°, etc.), and this allows measurement to the sub Hz precisions. Measurement of phase difference to obtain the frequency results in an unusual noise dependence on the speed of readings. Most of measurements concerned with the noise bandwidth specify noise as per square root of Hertz. Doubling the bandwidth increases noise by square root of two. Not so in precession frequency measurement. When we double bandwidth by doubling the number of readings per second the noise increases by two square roots of two or $2^{3/2}$ instead of $2^{1/2}$. Defining noise as per square root of Hertz is therefore deceiving, although it may be calculated correctly for a particular number of readings per second.

Another peculiarity of precession frequency measurement is a phenomenon of "outliers" or "spikes" that occur when a zero-crossing time is either missing or modified by a spike of phase noise usually showing lower value of magnetic field. Preponderance of outliers increases dramatically as signal/noise ratio of precession signal decreases.

Absolute accuracy and precision

Absolute accuracy of measurement can be determined directly for Proton (Overhauser) magnetometers only. Proton gyromagnetic constant gets periodically refined by national standards institutions of a number of major countries (NIST, USA; NPL, U.K; VNIIM, Russia; NIIM, China).

Absolute accuracy of better than one part per million is possible to achieve. Besides the precise gyromagnetic constant, it requires a number of conditions to be fulfilled: sensitivity must always exceed the absolute accuracy, frequency reference precision must be adequate, phase stability of the signal and time determination of a zero-crossing must be proper, chemical shift of the precession frequency of the sensor liquid must be taken into account (Hrvoic 1996). Since we measure frequency of rotating magnetic moment, rotation of the sensor in the plane of precession introduces error (rotational Doppler). This error, insignificant for optically pumped magnetometers, may be significant for Proton and Overhauser magnetometers (about 23nT offset for one cycle per second rotation of the sensor).

Alkali metal magnetometers have only potassium capable of high absolute accuracy (comparing its readings with Proton/Overhauser magnetometers) (Alexandrov and Bonch-Bruevich, 1992). Cesium and rubidium operate on lumped spectral lines, (and ^{4}He has a very wide spectral line) and their absolute accuracies are in few nT range.

Great majority of nowadays measurements do not require high absolute accuracy but only sensitivity and repeatability or relative accuracy of readings. Exceptions are magnetic observatories, space measurements, and perhaps some standards measurements derived from magnetic measurements (determination of electrical current standard for example).

Sensitivities of scalar magnetometers vary. Details depend heavily on particular design, but an order of magnitude can be assessed. Proton magnetometers are nowadays used for ground exploration or calibration of vector

magnetometers (fluxgates) only. Slow rate of readings can produce about $0.1nT$ sensitivity and absolute accuracy. Up to two readings per second are possible, but at this rate, the noise is in nT range. Overhauser magnetometers achieve $0.01nT$ at one reading per second, maximum rate five per second. High absolute accuracy Overhauser magnetometers are standard at magnetic observatories and very prominent in marine and ground surveys, and base stations for airborne surveys. Composite spectral line Alkali vapor magnetometers (Cesium, Rubidium) have similar sensitivity to Overhauser at one reading per second, but their top speed of readings is over 20/s. Their absolute accuracy is only few nT. Laser-pumped ^{4}He reaches sub pT sensitivities at one reading per second. Potassium has reached $0.05pT$ sensitivity at one reading per second. Practical potassium assemblies for ground and airborne surveys feature sub pT once per second and about $7–10pT$rms noise at ten readings per second. Like cesium and rubidium, maximum speed of readings exceeds 20/s. Increase of noise is rather a practical limit to a number of readings per second. Cesium magnetometers are prominent in airborne surveys while potassium covers top of the field, especially in gradiometry due to it's high absolute accuracy. Potassium is exclusively used in some new high sensitivity magnetic observatories and Earthquake study centers.

Vector magnetometers

Vector magnetometers are generally used for static measurements (observatories) or in vertical suspension (archeology) or rarely in the component airborne surveys where only computed total field may reach $0.1nT$ sensitivity, while components stay useless due to changes in aircraft attitude. In some recent attempt, accelerometers are used to account for attitude changes and apply corrections.

Main characteristics of most of the vector magnetometers are (except for SQUIDs):

1. Good sensitivity of measurement $0.1nT$ common, $0.01nT$ or somewhat lower (Korepanov et al., 2007) the best reported.
2. Very precise determination of the direction of measurement. One arc second change in direction means a fraction of one nT difference in readings, depending on an angle. In some orientations, vector magnetometers can resolve $0.01nT$ field and well below one arc second angle.
3. Relatively substantial temperature dependence ($0.1nT$/°C or more).
4. Relatively substantial time variation – aging ($2nT$ or more per year).

Consequences of the above are difficulties in orienting in the magnetic field and determination of the orthogonality of the three components. Due to their temperature dependence/aging, the vector magnetometers at the magnetic observatories need calibration by Proton/Overhauser magnetometers.

Fluxgate magnetometer

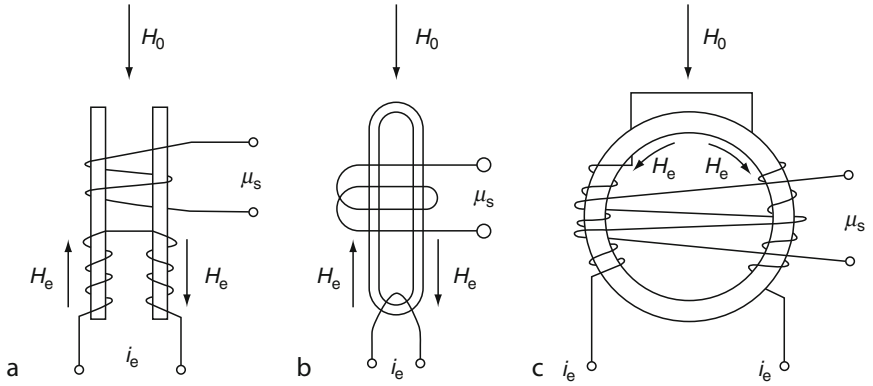
Main vector magnetometer today is the fluxgate. Its operation is based on nonlinearity of magnetic properties of steel (ferromagnetic material) (Primdahl, 1979). When placed in strong magnetic field, steel will lose its high magnetic permeability in saturation, i.e., relative permeability will fall from several hundreds to close to one. A coil is wound around a layered core of steel, and alternating current is driving the core to saturation in two opposite directions alternatively. When not saturated, the core will concentrate the magnetic flux of the applied magnetic field. When saturated, the flux will deconcentrate itself. Pick-up coil wound around the core will detect changes in the flux passing through the core. With no external magnetic field, the saturations on positive and negative sides will be symmetrical i.e. the pick-up voltage will have only odd harmonics. When the external magnetic field is present, the saturations become unsymmetrical and second harmonic appears in the pick-up voltage, its amplitude proportional to the strength of magnetic field. Phase detected second harmonic is then a measure of applied magnetic field in the direction of the core. It is convenient to use two pieces of the core with excitation windings in opposition and the pick-up coil encompassing both cores as this eliminates pick-up voltage due to the original driving current. Instead of double iron core, a ring or "racetrack" shaped cores can be used (Figure 5).

Today's fluxgates can achieve $0.1nT$/°C temperature coefficient with some nT per year aging. Composition of the iron cores plays a big role in the quality of fluxgates. Some recent new developments (Korepanov et al., 2007) claim better noise and aging characteristics.

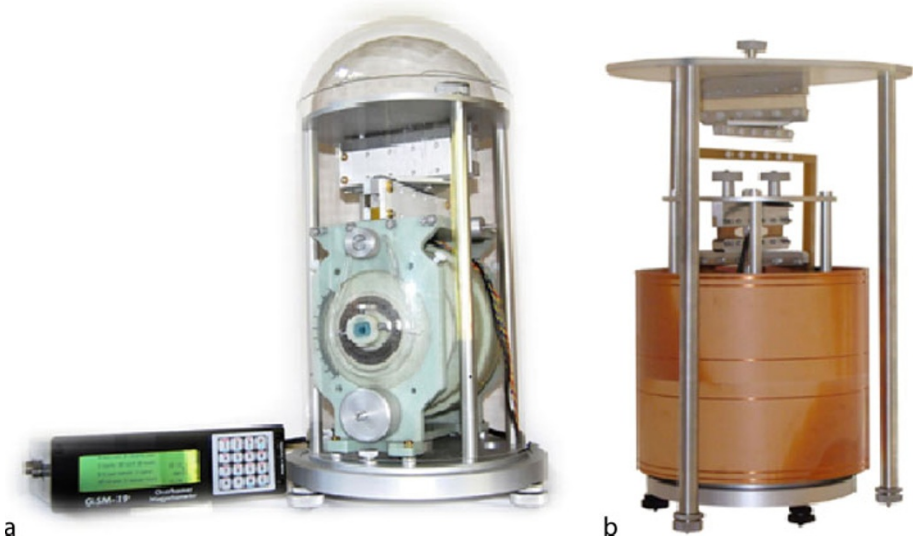
During the Second World War, a total field – oriented single fluxgate was used to detect submarines. ASQ-10 instrument had about $0.1nT$ sensitivity and the total field orientation of the sensor was kept by feedback electronics/mechanics.

Absolute measurement

Declination/Inclination magnetometer (DI-Flux or DIM) is a variation of fluxgate measurement (Jankowski and Sucksdorff, 1996). Fluxgate magnetometer sensor is mounted collinear with the optical axis of (nonmagnetic) theodolyte, in horizontal plane. Theodolyte is rotated, and two zero field angles are marked. The telescope is then reversed and two more zero readings determined. Magnetic north in arbitrary coordinate system is then calculated from angles of the four zero field measurements. The calculated angle is then referred to a known marker to determine true declination angle related to north direction. To determine inclination, the theodolyte is oriented in just determined magnetic declination vertical plane and four zero field positions are determined in that plane. Averaging will give the angle off horizontal, i.e., the inclination. Some attempts have been made (see *Geomagnetic Field, Measurement Techniques*) to automate absolute measurements.



Magnetometers, Figure 5 Excitation current drives the two cores (**a**) in saturation in opposite directions. Pick-up coil detects unsymmetry in saturation by measuring second harmonic. The cores can be connected at the ends to create "race track" (**b**) or ring core (**c**) shapes. Ring core allows for measurement of two orthogonal components, on one core.



Magnetometers, Figure 6 DIdD Overhauser/Potassium suspended system (**a**) and with external vertical coil to measure inclination directly (**b**).

Simplified version of DIM is the Declinometer. It has a suspended magnet on a torsionless fiber, a mirror attached to it at the right angle to its magnetic axis and in front of a telescope. The theodolyte is turned until the telescope becomes at right angle to the mirror. Direction of magnetic meridian is read from the base of the theodolyte. This is referenced to a known reference mark to determine real declination angle.

Weakness of this measurement is an angle mirror-magnetic axis of the magnet that has to be 90°. This is mitigated by using two magnets of different magnetic moments.

Quantum vector magnetometers

SQUID is a vector magnetometer of exceptional fT range sensitivity. It operates at cryogenic temperatures (liquid helium or liquid hydrogen) (Clark, 1993). It is used sporadically in geophysics for tensor calculations or short base gradiometers.

DIdD (Delta inclination delta declination) is a vector magnetometer with two orthogonal bias coils and a scalar magnetometer (Overhauser or Potassium) (Figure 6).

Coils are oriented at right angles to magnetic field direction, one in a horizontal plane, one in vertical magnetic declination plane. A sequence of four biased fields and one unbiased allows for determination of departures of the field from the preset one. Orientation of one bias coil in the vertical direction and the other in the horizontal East-West direction (now possible with the precise GPS direction determination or a North seeking gyroscope) will convert dIdD instrument into an absolute D and I instrument. Potassium magnetometer can provide

superior sensitivity and absolute accuracy. The stability of the instrument as for temperature and aging can be superior to the best fluxgates. This instrument is still in development. It is meant for use in the directional drilling for oil and minerals and possibly in a refined version for magnetic observatories.

Summary

Magnetic measurements are an essential part of geophysical exploration for minerals and oil, archeological, volcanological explorations, research of atmosphere, Sun's influence, crustal studies, earthquake research, etc. Scalar magnetometers are dominant in most fields. They are described in some detail – their physics, principles of operation, details of design, sensitivities and absolute accuracy. Vector magnetometers are essential in magnetic observatories, space measurements, and many scientific investigations. Fluxgate magnetometers and variations of absolute determination of magnetic field direction have been described in some detail. Quantum magnetometers as vector magnetometers are briefly described. Refinement of Potassium magnetometers may improve sensitivity of presently used scalar magnetometers by two orders of magnitude to sub *pT* range.

Magnetotelluric data processing: statistical estimation and analysis of impedance tensors and other transfer functions from measured electromagnetic time-series data.

Introduction

In the magnetotelluric (MT) method (see *Magnetotelluric Interpretation*), *data processing* generally refers to the initial analysis steps required to use naturally occurring time variations of electromagnetic (EM) fields measured at the surface to map the distribution of electrical conductivity within the Earth (see *Geoelectromagnetism*). The data are acquired as time series, generally including three components of the vector magnetic fields, along with the two components of the horizontal electric field. Earth conductivity variations have a relatively subtle effect on the raw EM data, which most directly reflect the temporal pattern of external source variations. Sophisticated data processing methods have been developed to extract the interpretable Earth conductivity signal from these data. Two distinct steps can be distinguished. In the first, time series processing methods are used to estimate frequency-dependent linear relations or transfer functions (TFs), relating magnetic and electric field components. In the second step, distortion and strike analysis, the full set of TFs is reduced to a simpler set, consistent with simplified one or two-dimensional models of Earth conductivity, typically allowing for shallow near-surface complications. After these data processing steps, TFs are inverted for conductivity, and the resulting images are interpreted in terms of composition, physical state, and Earth structure.

MT transfer functions

The basic assumption underlying the MT method is that the external source fields are spatially uniform, an approximation that can be physically justified provided the spatial scale of external magnetic fields at Earth's surface is large compared to the depth of penetration of the EM fields in the conducting Earth. Except at very long periods ($T > 10^4$ s), for which penetration depths in the Earth can exceed several hundred kilometers, and in the auroral zone where ionospheric current systems vary over short length scales, this assumption holds quite well for natural sources. Local cultural sources of EM noise have much shorter spatial scale, and will not always satisfy the uniform source assumption. These sorts of coherent noise, which violate the most fundamental MT assumption, represent the most serious obstacle to successful MT transfer function (TF) estimation.

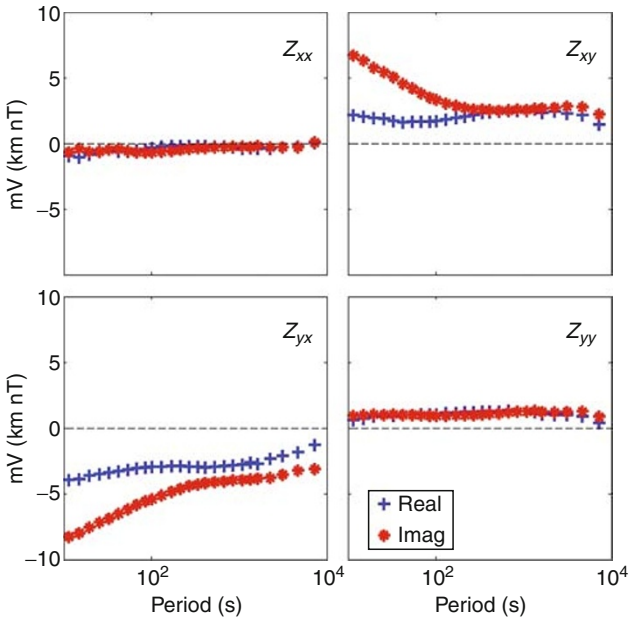
For periodic sources at a fixed frequency, the assumption of spatial uniformity implies that sources can be expressed as linear combinations of two simple modes: unit magnitude uniform sources linearly polarized North–South and East–West. This in turn implies a linear relationship (in the frequency domain) between the horizontal electric and magnetic field vectors measured at a single site.

$$\begin{pmatrix} E_x \\ E_y \end{pmatrix} = \begin{pmatrix} Z_{xx}(\omega) & Z_{xy}(\omega) \\ Z_{yx}(\omega) & Z_{yy}(\omega) \end{pmatrix} \begin{pmatrix} H_x \\ H_y \end{pmatrix} \tag{1}$$

The frequency-dependent 2×2 TF $Z(\omega)$ is referred to as the impedance tensor; see Figure 1 for an example. Equation 1 can be justified by the linearity of Maxwell's equations, and the assumption that all sources can be expressed as linear combinations of two linearly independent polarizations (Egbert and Booker, 1989). Under these circumstances, two independent field components (e.g., H_x and H_y at one location) uniquely determine all other EM field components at any nearby site. The uniform source assumption thus also justifies other sorts of TFs. In the other most important case, the vertical magnetic field component is related to the two horizontal components at the local site

$$H_z = \begin{pmatrix} T_x(\omega) & T_y(\omega) \end{pmatrix} \begin{pmatrix} H_x \\ H_y \end{pmatrix}. \tag{2}$$

Vertical field TFs, which are commonly estimated along with the impedance in most modern MT surveys, are referred to variously as the Tipper, Parkinson vector, or Wiese vector. Inter-station TFs, which relate horizontal magnetic fields at two sites, are also sometimes considered (e.g., Egbert, 2002).



Magnetotelluric Data Processing, Figure 1 Example of an impedance tensor, the 2×2TF relating horizontal electric and magnetic field components. Real and imaginary parts of the complex impedance components are plotted as a function of period. Note that the diagonal components of the impedance are relatively small; for the case of a 2D conductivity distribution, these components would vanish identically, if the impedance were expressed in the proper coordinate system.

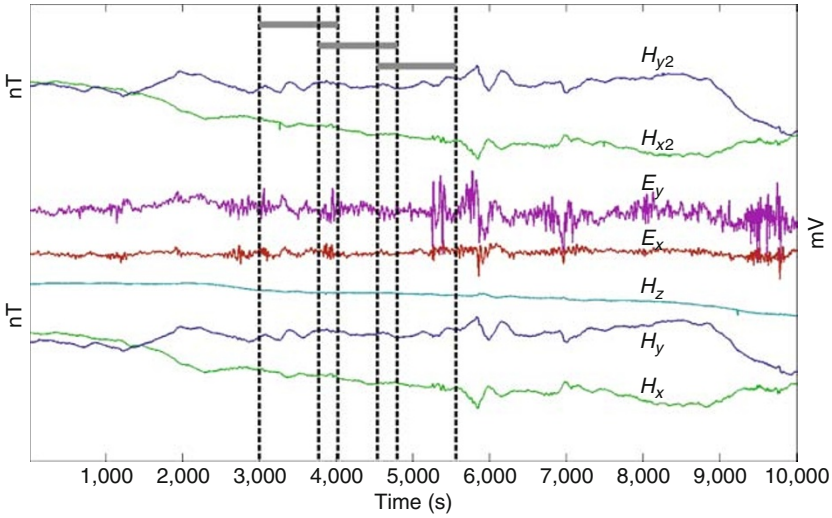
Least squares transfer function estimation

The earliest approaches to MT TF estimation were based on classical time series methods (e.g., Bendat and Piersol, 1971), applying a simple linear least squares (LS) fitting procedure in the frequency domain. To be explicit, consider estimating the MT TF between one component of the electric field (e.g., E_x) and the two horizontal magnetic field components H_x and H_y at a single fixed frequency ω. This TF corresponds to the first *row* of the usual MT impedance tensor. All of the discussion here and in subsequent sections applies equally to the second row of the impedance, and to the vertical field TF. Because all of the TFs are most succinctly described in the frequency domain as in (1–2), the first step in data processing is generally to Fourier transform the data. After possibly de-spiking and/or pre-whitening, time series for each component are divided into M short time windows, tapered, and Fourier transformed (Figure 2). Fourier coefficients for N frequencies in a band centered around ω are used for the TF estimate, for a total of $I = MN$ complex data. Estimates $\hat{\mathbf{Z}}$ of the TF (i.e., impedance elements) are then obtained for frequency ω by least squares (LS) fitting of the linear model

$$\begin{pmatrix} E_1 \\ \vdots \\ E_I \end{pmatrix} = \begin{pmatrix} H_{x1} & H_{y1} \\ \vdots & \vdots \\ H_{xI} & H_{yI} \end{pmatrix} \begin{pmatrix} Z_{xx} \\ Z_{xy} \end{pmatrix} + \begin{pmatrix} \varepsilon_1 \\ \vdots \\ \varepsilon_I \end{pmatrix}, \tag{3}$$

or in matrix notation

$$\mathbf{E} = \mathbf{HZ} + \varepsilon. \tag{4}$$



Magnetotelluric Data Processing, Figure 2 Example of time series collected with a long-period MT system. From bottom, three vector components of the magnetic field (measured with a fluxgate magnetometer), two colocated orthogonal horizontal electric field components (measured as the potential difference between pairs of electrodes separated by 100 m), and two horizontal components of the magnetic field at a distant remote site. Three overlapping data segments are indicated by the vertical dashed lines. Segments such as these are Fourier transformed to yield a series of complex Fourier coefficients for each data channel, which are then used for the various transfer function estimates discussed in the text. Longer segments are processed to get Fourier coefficients for longer period data, typically after low-pass filtering and decimating the time series.

With standard least squares (LS), this is accomplished by minimizing the sum of the squares of the residuals:

$$\sum_i |E_{xi} - (H_{xi}\hat{Z}_{xx} + H_{yi}\hat{Z}_{xy})|^2 = \sum_i |r_i|^2 \rightarrow \min \quad (5)$$

yielding

$$\widehat{\mathbf{Z}} = (\mathbf{H}^*\mathbf{H})^{-1}(\mathbf{H}^*\mathbf{E}) \quad (6)$$

where the superscript asterisk denotes the conjugate transpose of the complex matrix.

Robust estimation

The simple LS estimator implicitly assumes a Gaussian distribution for the errors ε_i in (3). This assumption often fails for MT data due to the non-stationarity of both signal and noise. Both can be highly variable in time, resulting in a marginal error distribution in the frequency domain that is heavy tailed and contaminated by outliers. As a result, the simple LS estimate all too frequently leads to very poor TF estimates with large error bars (Figure 3a). A number of MT processing methods have been proposed to overcome these difficulties, generally using some sort of automated screening or weighting of the data. Early efforts in this direction used ad hoc schemes, for example weighting data segments based on broad-band coherence between input and output channels. A more rigorously justifiable approach is based on the regression M-estimate (RME; Huber, 1981), a variant on LS that is robust to violations of distributional assumptions and resistant to outliers (Egbert and Booker, 1986; Chave et al., 1987). For the RME, the quadratic loss functional of (5) is replaced by

$$\sum_i \rho(|E_{xi} - (H_{xi}\hat{Z}_{xx} + H_{yi}\hat{Z}_{xy})|/\hat{\sigma}) = \sum_i \rho(|r_i|/\hat{\sigma}) \rightarrow \min \quad (7)$$

where $\hat{\sigma}$ is some estimate of the scale of typical residuals. LS is a special case of (7), with $\rho(r) = r^2$. By choosing the functional form for $\rho(r)$ so that large residuals are penalized less heavily than with the quadratic used for LS, the influence of outliers on the estimate can be substantially reduced. For robust estimation of MT TFs, the so-called *Huber* loss function (Huber, 1981)

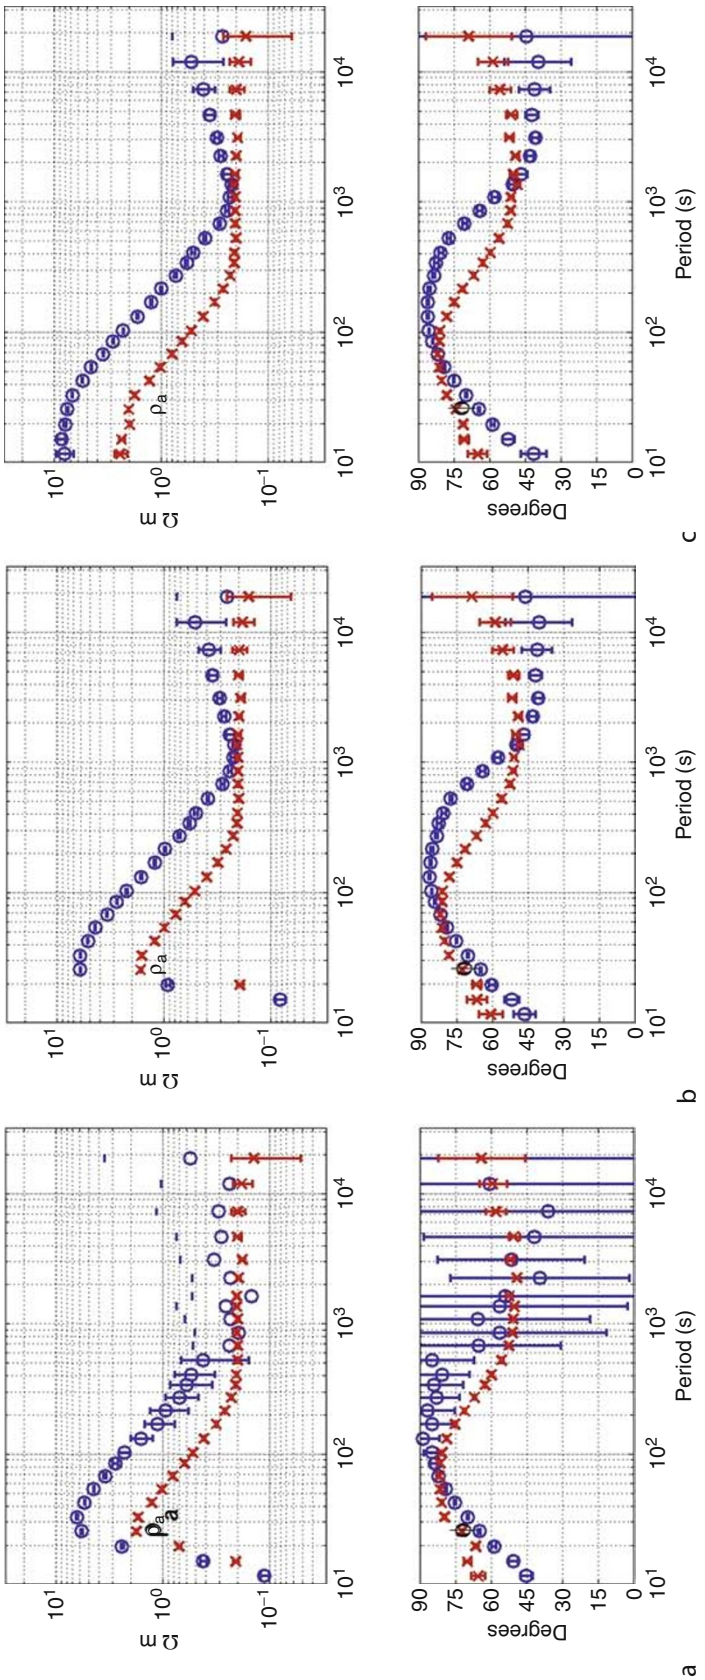
$$\rho(r) = \begin{cases} r^2/2 & |r| < r_0 \\ r_0|r| - r_0^2/2 & |r| >= r_0 \end{cases} \quad (8)$$

is commonly used with $r_0 = 1.5$.

The more general loss function of (7) can be minimized with an iterative scheme, which can be viewed as weighted LS, with weights determined from the data. Define the *influence function* $\psi(r) = \rho'(r)$ (the derivative of the loss function), and set $w(r) = \psi(r)/r$. Then, it is easily shown that the minimizer of (7) satisfies

$$\widehat{\mathbf{Z}} = (\mathbf{H}^*\mathbf{W}\mathbf{H})^{-1}(\mathbf{H}^*\mathbf{W}\mathbf{E}), \quad (9)$$

where $\mathbf{W} = \mathbf{diag}[w_1 \cdots w_I] = \mathbf{diag}[w(|r_1|) \cdots w(|r_I|)]$ is a diagonal matrix of weights. The RME thus corresponds approximately to the weighted LS problem



Magnetotelluric Data Processing, Figure 3 Comparison of TFs estimated from the same time series with three procedures described in the text (**a**) standard unweighted LS; (**b**) the regression M-estimate applied to data from a single site; and (**c**) the robust remote reference estimate. Here, apparent resistivities $\rho_a = (\omega\mu_0)^{-1}|Z|^2$ and phases $\phi = \tan^{-1}(Z)$ are plotted, computed from the dominant off-diagonal impedances Z_{xy} (*circles*) and Z_{yx} (*crosses*). The LS estimates are too noisy to be useful over much of the frequency range, while both of the robust estimates vary smoothly with frequency and have small error bars. However, the single site apparent resistivities of (**a**) and (**b**) are severely biased to low values for periods shorter than about 20 s. This bias is eliminated by the remote reference processing.

$\sum_i w(|r_i|)|r_i|^2 \rightarrow \min$. The weights depend on the normalized residuals $r_i = (E_{xi} - [Z_{xx}H_{xi} - Z_{xy}H_{yi}])/\hat{\sigma}$, and hence on the TF estimate, so an iterative procedure is required. Given an estimate of the TF, and of the error scale $\hat{\sigma}$, normalized residuals can be used to calculate weights, and the weighted LS problem can be solved for a new TF estimate. This procedure can be started from a standard LS estimate of the TF (and some robust estimate of error scale, for example, based on the median absolute deviation of residuals) and then repeated until convergence.

For convex loss functions (e.g., the Huber function of (8)), convergence of this procedure to the unique minimizer of (7) is guaranteed (Huber, 1981). For the Huber loss function in (8), the weights are

$$w(r) = \begin{cases} 1 & |r| > r_0 \\ r/r_0 & |r| \geq r_0 \end{cases}, \tag{10}$$

i.e., data corresponding to large normalized residuals get smaller weights. To allow for a sharp cutoff, with data exceeding a hard threshold discarded, the loss function $\rho(r)$ must be non-convex, and convergence of the iterative minimization algorithm cannot be guaranteed. The standard practice is to iterate with a convex loss function such as (8) to convergence, followed by a final step or two with a hard cutoff to completely discard extreme outliers. This completely automated procedure frequently results in significant improvements in TF estimates, as indicated by improvements in smoothness and physical realizability of apparent resistivity and phase curves (Figure 3b), and reproducibility of results.

More ad hoc schemes are also frequently used for down-weighting noisy or inconsistent data. These can be viewed as special cases of the weighted LS estimate of (9) but with weights now determined by some criteria other than residual magnitude. For example, in coherence weighting, broad-band coherence of input and output channels is used to down-weight time segments with low signal-to-noise ratios. Such methods can of course be combined with the RME.

Leverage

The RME can still be excessively influenced by a small number of data sections with large signal (or more typically noise) amplitude. In the terminology of linear statistical models, these large amplitude data are *leverage points*. For the LS estimate, the predicted data are

$$\hat{\mathbf{E}} = \left[\mathbf{H}(\mathbf{H}^*\mathbf{H})^{-1}\mathbf{H}^*\right]\mathbf{E} \tag{11}$$

with the matrix expression in brackets (which maps observed data to predicted) referred to as the "hat matrix." It is readily shown that the sum of the diagonal elements of the hat matrix satisfy $\sum_{i=1}^{I} h_{ii} = 2$, and that the individual diagonal elements h_{ii} can be interpreted as the fraction of total magnetic field signal power in the ith Fourier coefficient. Large values of h_{ii} indicate data points with inordinate influence on the TF estimates. In extreme cases, leverage points are used heavily to predict themselves, making the iterative RME ineffective. To deal with leverage points in routine MT processing, it is thus useful to include an additional weighting term (a function of the magnitude of h_{ii}) to reduce the influence of any observations of unusually large amplitude (e.g., Chave and Thomson, 1989).

Remote reference

The linear statistical model (4) is strictly appropriate to the case where noise is restricted to the output, or predicted electric field channels. Violation of this assumption results in the downward bias of estimated impedance amplitudes. These biases are proportional to the ratio of noise power to signal power, and can be quite severe in the so-called MT "dead bands" centered at frequencies 1–5 kHz and 0.1–1 Hz (examples of such biases are seen in Figure 3a, b, at periods shorter than 20 s). To avoid these bias errors, horizontal magnetic fields recorded simultaneously at a remote reference site are correlated with the EM fields at the local site (Gamble et al., 1979). Letting R_{xi} and R_{yi} be the Fourier coefficients for the two remote site components for the ith data segment, and $\mathbf{R}$ the corresponding $I \times 2$ matrix, then the remote reference analog of the LS estimate is

$$\hat{\mathbf{Z}} = [\mathbf{R}^*\mathbf{H}]^{-1}[\mathbf{R}^*\mathbf{E}]. \tag{12}$$

It is can be shown that the remote reference estimate is unbiased if noise at the remote site is not coherent with noise in magnetic and electric fields at the local site. Thus, the remote reference estimate can eliminate or significantly reduce the effects of coherent cultural EM noise, provided the reference site is sufficiently distant. Very large scale sources of cultural noise, in particular DC electric railways, still present a significant challenge to collecting high-quality MT data in many parts of the world. These sources can be coherent over large enough scales to contaminate both local and remote signals, but still have significant power at wavelengths which are short enough to violate the MT uniform source assumption.

To generalize the RME to remote reference, one can iterate the weighted analog of (12), i.e., $\hat{\mathbf{Z}} = [\mathbf{R}^*\mathbf{W}\mathbf{H}]^{-1}[\mathbf{R}^*\mathbf{W}\mathbf{E}]$, with the weights on the diagonal of $\mathbf{W}$ determined from the residual magnitudes, exactly as for the single site robust estimator. It is also useful to add some additional weighting to allow for outliers at the remote site, and as with the single site estimates, for leverage. When arrays of simultaneously operating EM instruments are available, more complex procedures, which use data from multiple sites to define the reference fields are possible (Egbert, 2002).

Error estimates

With a statistical approach to TF estimation, one also obtains error variances that define the precision of the TF estimates. These error bars are required to assess the

adequacy of fit of models derived by inversion, and thus play a critical role in the interpretation process. The covariance of the linear LS TF estimate of (6) is readily derived from standard theory, based on linear propagation of errors:

$$\begin{aligned}\mathbf{Cov}\left[\hat{\mathbf{Z}}\right] &= \hat{\sigma}^2[\mathbf{H}^*\mathbf{H}]^{-1} \\ \hat{\sigma}^2 &= (I-2)^{-1}\sum\nolimits_i |r_i|^2.\end{aligned} \tag{13}$$

where r_i are again the residuals. An analogous expression for the error covariance for the remote reference estimate is

$$\begin{aligned}\mathbf{Cov}\left[\hat{\mathbf{Z}}\right] &= \hat{\sigma}^2[\mathbf{R}^*\mathbf{H}]^{-1}[\mathbf{R}^*\mathbf{R}][\mathbf{H}^*\mathbf{R}]^{-1} \\ \hat{\sigma}^2 &= (I-2)^{-1}\sum\nolimits_i |r_i|^2.\end{aligned} \tag{14}$$

For both (13) and (14), the diagonal components of the 2×2 covariance matrices are the estimation error variances for the two impedance elements.

For the RME, variances of the estimates are complicated by nonlinearity, but asymptotic expressions (valid in the limit of large sample sizes) can be obtained from standard theory (Huber, 1981):

$$\mathbf{Cov}[\hat{\mathbf{Z}}] = \frac{(I-2)^{-1}\sum_i w_i|r_i|^2}{\left[I^{-1}\sum_i \psi'(|r_i|/\hat{\sigma})\right]^2}[\mathbf{H}^*\mathbf{H}]^{-1} \tag{15}$$

where r_i, w_i, $i = 1, \ldots, I$ and $\hat{\sigma}$ are the residuals, and weights and error scale from the final iteration, and the prime denotes the derivative of the influence function. An analogous asymptotic covariance for the robust remote reference estimates can be given with $[\mathbf{H}^*\mathbf{H}]^{-1}$ in (15) replaced by $[\mathbf{R}^*\mathbf{H}]^{-1}[\mathbf{H}^*\mathbf{H}][\mathbf{H}^*\mathbf{R}]^{-1}$.

As an alternative to asymptotic error estimates such as (15), the nonparametric jackknife method (Efron, 1982) has also been frequently used for computing TF error estimates (Thomson and Chave, 1991). The jackknife approach can also be applied to compute error bars for complicated nonlinear functions of TFs, which arise, for example, in some forms of distortion analysis. The jackknife approach significantly increases computational effort required for TF estimation, unless some approximations are used (Eisel and Egbert, 2001).

Strike and distortion analysis

As of this writing, MT data are most often acquired in profiles across a geologically appropriate strike, and the data are interpreted with two-dimensional (2D) Earth conductivity models that vary only with depth, and across strike, a reasonable approximation for many geologic structures. If the 2D assumption holds exactly, and the coordinate axes (used to give the components of the horizontal electric and magnetic fields) are chosen so that one of x or y aligns with the geoelectric strike (i.e., the direction along which there is no variation in conductivity), the diagonal components of the impedance tensor vanish.

$$\mathbf{Z}(\omega) = \begin{bmatrix} 0 & Z_{xy}(\omega) \\ Z_{yx}(\omega) & 0 \end{bmatrix}. \tag{16}$$

This special form only holds when the impedance is expressed in the proper coordinate system. Thus, once impedances are estimated, a key step in 2D MT interpretation is to determine an appropriate geoelectric strike where (16) holds approximately. The two off-diagonal components in this coordinate system (the transverse electric or TE mode, in which electric currents flow along the geologic strike, and transverse magnetic or TM mode, in which electric currents flow across the geologic strike; *Magnetotelluric Interpretation*), are then fit using 2D modeling and inversion programs.

Even if the 2D approximation is reasonably justified for large-scale deep structure, more complex (3D) small-scale near-surface complications in conductivity will occur. These near-surface features result in distortion of the impedance tensor, so that even when the correct regional strike is used to define the coordinate system, the impedance tensor does not have the simple form of (16). Most modern approaches to 2D MT interpretation allow for these distortion effects in strike determination, and subsequent inversion. Early approaches to strike determination, such as choosing the strike angle to minimize the magnitude of the diagonal components, without accounting for distortion effects are seldom used anymore.

In the limit where the penetration depth of the EM fields greatly exceeds the depth to the bottom of the near-surface distorting structures, the electric fields (only) are distorted in a static (frequency-independent) manner. Allowing for rotation of the measurement coordinate system by an angle θ, the distorted impedance tensor for a 2D Earth can be decomposed as

$$\begin{aligned}\mathbf{Z}(\omega)z &= \mathbf{U}\mathbf{D}\tilde{\mathbf{Z}}(\omega)\mathbf{U}' \\ &= \begin{bmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{bmatrix}\begin{bmatrix} D_{xx} & D_{xy} \\ D_{yx} & D_{yy} \end{bmatrix} \\ &\times \begin{bmatrix} 0 & \tilde{Z}_{xy}(\omega) \\ \tilde{Z}_{yx}(\omega) & 0 \end{bmatrix}\begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix},\end{aligned} \tag{17}$$

where $\mathbf{D}$ is the distortion matrix, which is real, and $\tilde{\mathbf{Z}}(\omega)$ is the undistorted 2D impedance, which carries all of the frequency dependence. It is readily verified that not all of the parameters in (17) are uniquely identifiable – e.g., the distortion parameter D_{xx} cannot be determined independent of the absolute level of the impedance $\tilde{Z}_{xy}$; only the product $D_{xx}Z_{xy}$ is uniquely determined. However, (17) provides a suitable model to determine an optimal geoelectric strike (defined by the rotation angle θ), and this has ultimately become the most common use for strike and distortion analysis in most 2D MT interpretations. Note that in principal the same $\mathbf{D}$ and θ should apply to all frequencies at one site, while the strike angle should be the same over all sites.

Nonlinear least-squares estimation schemes can be used to fit the parameters in (17) (e.g., Smith, 1995; McNeice and Jones, 2001). These are often applied site by site, for various subsets of frequencies, but impedances from multiple sites can also be fit simultaneously. Finding a consistent strike provides justification, and an optimal coordinate system, for 2D interpretation. Sometimes, the analysis is also used to eliminate sites, or frequency ranges, which are inconsistent with the generally preferred strike. Once the strike is determined and the impedance tensors are rotated, the off-diagonal components can be used as input for 2D inversion. Because the overall level of the impedance curves are still potentially effected by near-surface distortion, but the phases are not, it is common to fit phases more tightly, and relax fit to amplitudes (i.e., apparent resistivities). It is also possible to directly allow for distortion by introducing additional parameters at the inversion stage.

Summary

Data processing represents the first step in MT data interpretation, resulting in a reduction of the raw time-series data (approximately 10^6 observations) to frequency domain transfer functions such as impedances (a few hundred numbers). These transfer functions contain information about the response of the Earth to simple plane-wave sources, and provide input data for subsequent inversion and interpretation steps. Robust remote reference processing substantially improves reliability of transfer functions estimates. Except in areas of strong cultural noise (which unfortunately are increasingly common), modern processing produces smooth unbiased response curves. Distortion and strike analysis represents a further step in MT processing, essential for 2D interpretation of MT profile data. Such analysis is used to test for consistency with the assumed 2D geoelectric geometry, to estimate the strike, and to reduce the full impedance to the TE and TM mode responses appropriate to 2D interpretation.

MAGNETOTELLURIC INTERPRETATION

John F. Hermance
Department of Geological Sciences, Brown University, Providence, RI, USA

What is magnetotellurics?

The magnetotelluric (MT) method is a geophysical technique in which the time-varying electric and magnetic fields from distant natural or artificial sources are measured at the Earth's surface, and analyzed to determine the electrical properties of the subsurface.

Workers have known from the 1800s that naturally occurring transient voltages of significant magnitude observed on grounded telegraph wires were associated with rapid fluctuations of the geomagnetic field following *solar flares* and *auroral displays*. These natural voltage fluctuations – so-called telluric fields – have since been explained as the product of eddy currents induced in the finite conducting earth by transient magnetic field disturbances in the ionosphere and magnetosphere, even the global-wide propagation of radiated signals from lightning strokes in the distant atmosphere (see *Magnetic Storms and Electromagnetic Pulsations*).

Early work by Kato and Kikuchi, and Rikitake in Japan, and Tikhonov in the then, Soviet Union, laid the foundation for using these natural electric and magnetic field variations to study the electrical structure of the solid earth (see the collection of classic reprints by Vozoff, 1985; see also *Geoelectromagnetism*). However, it was the seminal paper by Louis Cagniard (1953) that first described the comprehensive procedure for using the ratio of the

horizontal electric – that is, the *telluric* – field to the horizontal *magnetic* field, for which he coined the name the *magnetotelluric method*.

Fundamental concepts: surface impedance and apparent resistivity

The magnetotelluric method, as generally employed by geophysicists, invokes several fundamental concepts from the theory of the propagation of electromagnetic waves. The first concept is the physical attribute known as the *electromagnetic wave impedance* of the medium (see *Magnetotelluric Data Processing*), provided by computing the ratio of the electric field intensity to the orthogonal magnetic field intensity. For example, Figure 1 shows an electromagnetic plane wave vertically incident on the earth's surface; the electric field is polarized in the x-direction, and, to be consistent with the Poynting vector $\mathbf{S} = \mathbf{E} \times \mathbf{H}$, the magnetic field is polarized in the y-direction. Alternatively, for the case where the electric field might be polarized in the y-direction, the magnetic field will be polarized in the $-x$-direction. The ideal natural field for magnetotellurics is one which is randomly polarized in *all* horizontal directions, so that usually both sets of electric and magnetic data, (E_x, H_y) and (E_y, H_x), will be employed, leading to two estimates of the *surface impedance*:

$$Z_{xy}^{(\mathrm{surf})} = \frac{E_x}{H_y} \text{ and } Z_{yx}^{(\mathrm{surf})} = -\frac{E_y}{H_x} \tag{1}$$

The impedance terms in Equation 1 can be looked upon as the coefficients of linear coupling relations between the electric and respective magnetic field components having the forms:

$$E_x = Z_{xy}^{(\mathrm{surf})} H_y \text{ and } E_y = -Z_{yx}^{(\mathrm{surf})} H_x \tag{2}$$

The subscripts on the impedance coefficients denote the ordering of the respective electric and corresponding orthogonal magnetic field components.

Under appropriate conditions, the *resistivity* of the uniform half-space in Figure 1 may be determined from the measured surface impedance, since the *characteristic impedance* that a wave encounters traveling through a homogeneous medium is given by $Z_{\mathrm{char}} = E_x/H_y = -E_y/H_x = \sqrt{i\omega\mu\rho_{\mathrm{Tot}}}$ where $i = \sqrt{-1}$, ω is the radian frequency ($\omega = 2\pi f$, and $f = 1/T$ is the frequency in Hz, where T is the period in seconds), μ is the free-space magnetic permeability ($\mu = 4\pi \times 10^{-7}$ henries/m), and ρ_{Tot} is the total resistivity that accounts for both ohmic and dielectric effects in the medium.

The latter expressions for the ratios of the electric field to its orthogonal magnetic field counterpart, can be rearranged to estimate the resistivity of the medium according to $\rho_{\mathrm{obs}} = (1/\omega\mu)\left|E_x/H_y\right|^2 = (1/\omega\mu)\left|E_y/H_x\right|^2$.

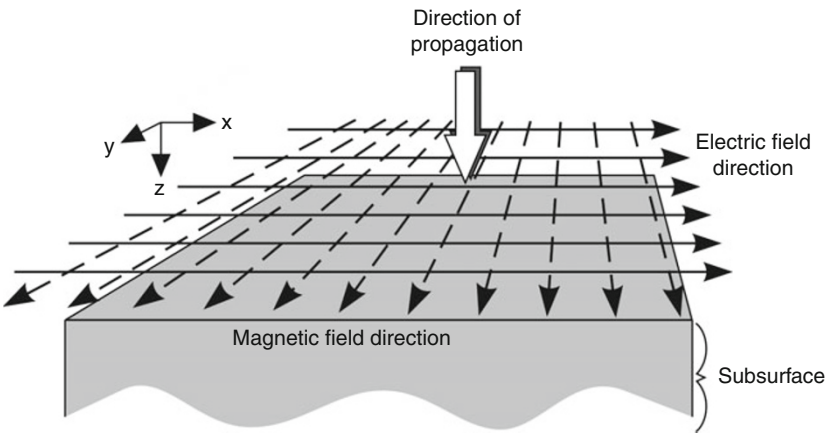
In general, however, the earth is *not* uniform, and as proposed by Cagniard (1953) in his classic paper, it is best to refer to the observed resistivity as an *apparent resistivity*, which might be determined using either combination of the respective field components, (E_x, H_y) or (E_y, H_x). The corresponding apparent resistivities are commonly referred to as *Cagniard pairs*, and are given by

$$\rho_{xy}^{(\mathrm{app})} = \frac{1}{\omega\mu}\left|\frac{E_x}{H_y}\right|^2 \text{ and } \rho_{yx}^{(\mathrm{app})} = \frac{1}{\omega\mu}\left|\frac{E_y}{H_x}\right|^2 \tag{3}$$

For a uniform earth as well as for a plane-layered earth, as discussed below, one should expect that $\rho_{xy}^{(\mathrm{app})} = \rho_{yx}^{(\mathrm{app})}$. Exceptions to the latter denote the presence of lateral heterogeneities, also discussed below.

Principles of depth sounding

The *skin depth* or *depth of penetration* of an electromagnetic wave impinging on a uniform conductor (the earth) is given by $\delta \cong 500\sqrt{\rho \cdot T}$ meters, where ρ is the electrical resistivity of the medium in Ohm.m, and T is the period (inverse of frequency) of the signal in seconds. The consequence of the *skin-depth effect* is that low frequency (long period) waves penetrate to greater depth in a given



Magnetotelluric Interpretation, Figure 1 Schematic of a uniform plane wave vertically incident on the earth's surface.

conductor than high frequency (short period) waves (see *Geoelectromagnetism*).

The intrinsic resistivity of typical earth materials varies over many orders of magnitude, depending on mineralogy, water content, and temperature (see *Electrical Properties of Rocks*). Figure 2 summarizes the range of characteristic depths of penetration over the typical range of earth resistivities and frequencies employed in magnetotellurics. As an aside, note in the upper right corner of the figure, the roll-over of the linear isolines for high frequencies and high resistivities due to dielectric effects coming into play.

The *apparent resistivity* as a function of increasing period can be determined using spectral analysis of the measured electric and magnetic time series (see Vozoff, 1985; see *Magnetotelluric Data Processing*). Then, from measurements of the apparent resistivity as a function of period, one can use the variable depth of penetration to electrically "probe" the earth to greater depth by progressively "tuning" the observed signals to progressively longer period.

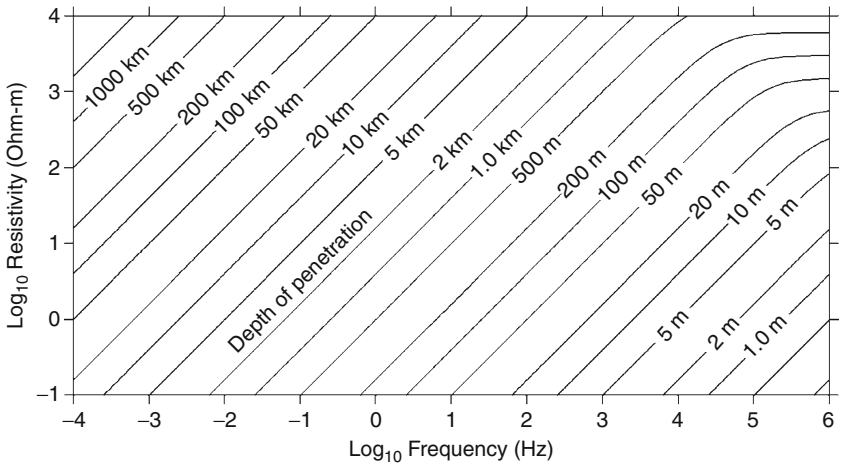
For conventional magnetotelluric applications, at the highest frequencies (≅1 MHz) and the lowest resistivities (close to that of seawater, 1/3 Ω-m, or lower), the signal (often from commercial or government radio transmitters, or, in the audio band, from distant lightning strikes) would penetrate to a few meters or few tens of meters depth. This range is useful for shallow geotechnical and groundwater investigations, and perhaps shallow geothermal work.

At the other end of the spectrum, at frequencies of a Hertz or lower ($T \geq 1$ s), workers usually rely on natural sources in the magnetosphere and ionosphere (such as micropulsations, magnetic substorms, and diurnal variations), (see *Magnetic Storms and Electromagnetic Pulsations*) to probe to depths of tens to hundreds of kilometers.

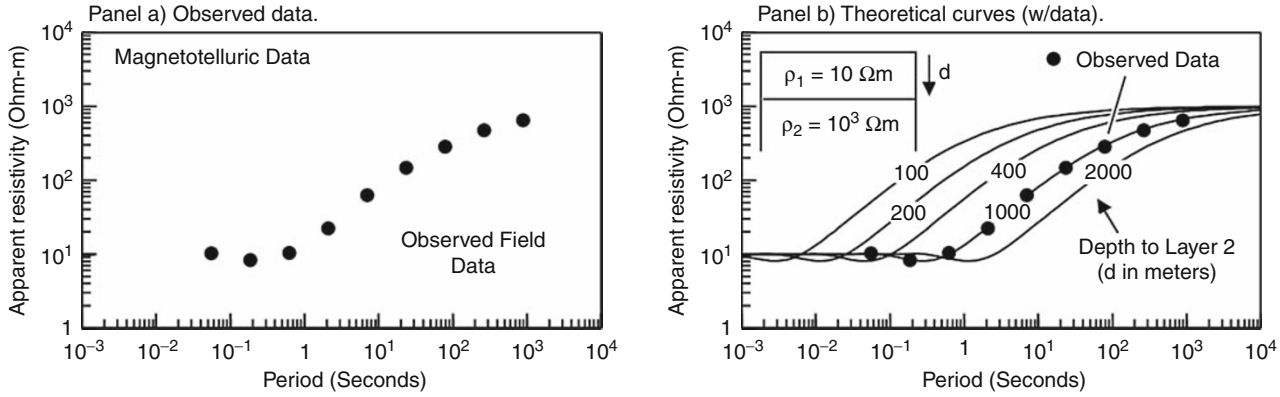
An example of the apparent resistivity that might be measured on the surface of a broad sedimentary basin as a function of period, as envisioned by Louis Cagniard in his 1953 paper, is shown in Figure 3. The exploration geophysicist would have in mind that the relatively conductive sediments are underlain at some unknown depth by more resistive crystalline or metamorphosed basement (see *Electrical Properties of Rocks*). At an early stage, in the exploration of such a basin, the interpreter would like to determine three types of information from the observed MT data: *first*, the physical properties of the sedimentary basin (ρ_1: the resistivity of layer 1); *second*, the depth d to the base of the sediments; *third*, the physical properties of the underlying basement (ρ_2: the resistivity of layer 2). From the various models seen in Figure 3b, a theoretical model with a surface resistivity of 10 Ω-m, underlain by a more resistive 1,000 Ω-m layer at a depth of 1,000 m, "fits" the observed data quite well. The mathematical framework through which one determines a model that best fits the set of observed data is known as *inverse theory* (see *Magnetotelluric Data Processing*; *Inverse Theory, Global Optimization*; *Inverse Theory, Linear*; *Inverse Theory, Monte Carlo Method*; *Inverse Theory, Singular Value Decomposition*).

Effects of lateral heterogeneities

Early workers discovered the effects of lateral heterogeneities on MT data when they found that the Cagniard pairs were unequal: $\rho_{xy}^{(\mathrm{app})} \neq \rho_{yx}^{(\mathrm{app})}$ in Equation 3. That is to say, the observed apparent resistivity often depended on the direction in which the respective E and H fields were measured, as well as on the location of the measurements relative to local geologic features. Consider, for example, the case of the simple 2D vertical contact shown in Figure 4. The observed apparent resistivities can be resolved into two principal modes: the incident electric source field may be polarized *perpendicular* to the strike of the contact, or it may be *parallel* to the strike of the contact in the y-direction.



Magnetotelluric Interpretation, Figure 2 Depth of penetration as a function of frequency and resistivity of the host medium for geophysical applications.



Magnetotelluric Interpretation, Figure 3 (Panel a) An example of field data from magnetotelluric measurements. (Panel b) Field data overlaid on a set of theoretical curves representing various combinations of model parameters, in this case the resistivity of each of two layers and the depth of layer 2.
