The process of swinging reflection events through arcs to construct approximate reflector segments spawned a number of mechanical devices that migrated reflection records. They allowed the migration of picked events from nonzero-offset traces. However, they were all based on the same principle of swinging events over a restricted range of angles. This process was formalized by Hagedoorn (1954).

Digital migration

Seismic recording, processing, and migration became digital in the 1960s. Digital processing emphasized the discrete sampling of signals, in both time and space. It also allowed reflection records to be treated as wavefields, and wavefield algorithms could be applied to them. Wave-equation migration methods arose, based on differential equations, integral solutions to the wave equation, or mapping in the Fourier domain (Berkhout, 1982; Yilmaz, 1987). These methods are in use today. They have different realms of validity and different efficiencies. One of the methods, integral (Kirchhoff) migration, deserves mention. This technique is the direct descendant of pencil-and-paper migration. In Kirchhoff migration, samples on the recorded input traces are swung out over a range of angles. The earlier techniques could consider only isolated events, because constructing the envelopes corresponding to all reflection events of a record would produce an uninterpretable mess. However, including the wave equation as an essential part of the process allowed all samples to be swung out. Constructive and destructive interference, a natural consequence of treating the samples as components of a wavefield, caused reflection events to appear on the image, not as envelopes, but as waveforms moved to reflector locations.

Poststack migration

The first digital migrations were performed on computers with limited memory and processing capability. Migrating all traces of a two-dimensional (2-D) reflection survey involving hundreds of source locations, each with tens of receiver locations, would have taken months on early computers. So it became necessary to make use of the intermediate process of CMP stack to reduce the number of traces to be migrated. As mentioned above, this process performs time ("normal moveout," or NMO) corrections to traces with nonzero source-receiver offset. These corrections are time shifts, different for each sample, intended to produce equivalent zero-offset traces to be summed, or stacked, together. The quality of the normal-moveout process depends on the stacking velocity, which determines the time shift to be applied to each sample of each nonzero-offset trace. In order to stack together traces in a domain where the velocity varies as little as possible, it is desirable to sort the input traces from their original recorded common-shot configuration to a set of records where each record has a common source-receiver midpoint – thus the term common-midpoint stack. The stacking velocity for a common-midpoint gather is taken to be the velocity at the midpoint location. This velocity can vary with time down the zero-offset trace of the record. For each value of time, it is a type of average velocity. When all the traces in a CMP gather have been NMO-corrected and summed (stacked) together, the CMP gather has been replaced with a single, zero-offset, trace. The NMO/stack process is illustrated on a single reflection event in Figure 2. The ensemble of zero-offset traces, from all CMP gathers indexed by their midpoint locations, is a stacked record ready to be (poststack) migrated.

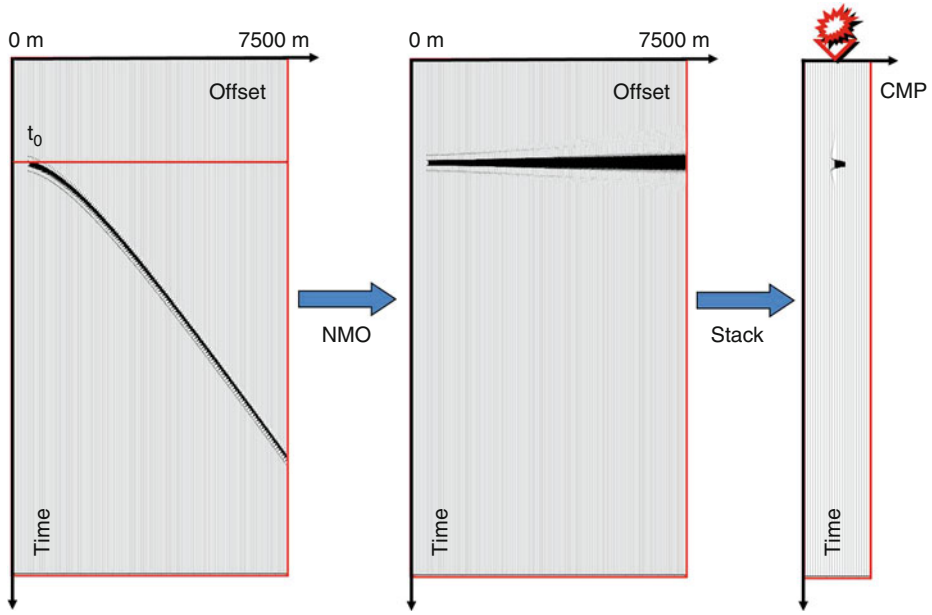
The CMP stacking process makes several approximations that are incompatible with the physics of wave propagation inside the earth. For example, sorting into CMP records and assuming that the seismic velocity does not change for all traces within a record ignores the lateral variability of the actual velocity, and it assumes that the reflectors inside the earth are locally flat below each midpoint location. These approximations were not usually damaging in earlier times, when drilling prospects were in shallow, relatively simple geology. As shallow targets were drilled, leaving deeper prospects under complex overburden with complex velocity behavior, the approximations broke down. Since about 2000, migration performed without CMP stacking (prestack migration) has become commonplace.

Prestack migration

Dropping the NMO/stack process from the migration flow eliminated some problems, but it made the velocity estimation problem more complicated. NMO velocities were useful for migration as well as stacking. These velocities were not necessarily accurate, but they provided a guide for the velocities to be used in migration. Using a rough estimate of velocity, poststack migration generates plausible migrated images, even if they lack the resolution required for interpretation of subtle targets. Accurate prestack migration, on the other hand, requires the velocity to be estimated without a prior stacking velocity analysis. New tools, consistent with wave propagation inside a geologically complicated earth, were needed for this task. These tools have been under development since the 1980s, but are not yet completely satisfactory. Unlike NMO/stack, they allow arbitrary velocity structure inside the earth, and there is no "locally flat" assumption.

2-D, 3-D, wide-azimuth 3-D acquisition and migration

Early seismic reflection profiles were acquired along 2-D lines, both land and marine. On land, a line of receivers was laid out, and shots were fired into the earth at locations along the line. As the shot locations moved along the line,



Seismic, Migration, Figure 2 NMO and CMP stack illustrated on a single reflection event.

receivers were picked up from the back end of the spread and placed at the front. Marine data were acquired using a vessel towing a linear array of receivers (a streamer), firing at regular locations along the line. 2-D processing assumes that the subsurface of the earth is invariant in the direction perpendicular to the line direction. When this assumption is violated, "out-of-plane" reflectors (not vertically below the acquisition line) contribute energy to the reflection records; 2-D migration cannot map this energy to its correct locations. For this reason, 3-D acquisition became commonplace in the 1970s and 1980s. On land, the receivers were laid out in a 3-D pattern (patch) that could be repeated as in 2-D. Gradually, the receiver patch became larger (thousands of meters on a side), with a wider range of azimuths, or compass directions of vectors joining the source and receiver locations. Today, the recording patch often contains several thousand receivers. Wide-azimuth marine acquisition is more difficult than land because it is physically impossible for a single vessel to tow the large number of streamers required. However, adding a second vessel as a source vessel alongside the first vessel at a large lateral distance produced data over a wide range of azimuths as for land.

Moving from 2-D to 3-D enabled the accurate migration of geologically complex structures such as salt bodies and overthrust structures, and it altered the economics of migration. In the initial days of 3-D seismic data, 2-D prestack migration was available but not commonly applied because it was still too computationally expensive. A fortiori, 3-D prestack migration was not yet feasible. In 3-D, the numbers of input and output locations are increased by an order of magnitude over 2-D, increasing migration cost by two orders of magnitude.

Deep crustal imaging

Most migration projects are performed by the oil and gas industry for hydrocarbon exploration, whose target depths rarely exceed 10 km. However, solid-earth geophysicists acquire and migrate seismic data to map crustal structures tens of kilometers deep. Imaging very deep targets with cumulative overburden effects such as wavefield scattering and absorption presents added challenges, and migration cannot be expected to be successful as often as it is for hydrocarbon exploration (Warner, 1987).

Time migration, depth migration

Seismic traces are recorded in time, with a particular event occurring at different times on traces with different lateral positions. The CMP stack produces a composite section, with a trace at each position. Although migration is used to image reflectors inside the earth, the CMP stack itself provides a crude image. With its collapse of many seismic records into one, and its use of redundancy (fold) to suppress noise, the CMP stack produces images that can sometimes be interpreted without migration. If the CMP stack is migrated with the depth axis on the migrated image replaced by time, events on the unmigrated stack and the migrated stack can be compared directly, helping with interpretation. Such a migration, called "time migration," is opposed to the more natural "depth migration."

This fact has caused a diversity of approaches to migration. Geophysical interpreters often prefer time migration, but structural geologists and engineers usually prefer depth migration. Structural geology deals with space (depth) and how space is filled with material; geologists and engineers are concerned with the physical dimensions

of a potential hydrocarbon trap. Even if a migrated image is interpreted in time, in principle it is preferable to perform the migration and display the final image in depth. In practice, however, there are valid arguments against this statement.

First, time migration is sometimes more robust than depth migration; that is, it is often easier to produce an interpretable image with time migration than with depth migration, even if the image is known not to be accurate. This is because time and depth migration treat velocity differently. Time migration, following procedures developed for NMO/stack, uses what is best called an imaging velocity field, i.e., one that best focuses the migrated image. At each image location, this velocity is an average of the seismic velocity values in the overburden above the image depth. The imaging velocity is free to vary spatially. In essence, time migration performs a constant-velocity migration at each image location, where the constant can change from point to point. The imaging velocity field that produces the best image need not be consistent with any possible field of actual velocities inside the earth, and any attempt to convert the imaging velocities to a field of geologically possible earth velocities can fail. For example, assuming that the imaging velocities are root-mean-square velocities and using the Dix (1955) equation to invert these to interval velocities often produces physically impossible values. This inconsistent handling of velocity allows time migration to be robust. Second, the precision implied by depth migration is not always justified. A migrated image purports to show locations of reflectors and diffractors inside the earth, but often the locations are incorrect. It is easy to see that this can happen for time migration, which is not precise because of its inconsistent handling of velocity. For depth migration, the implied accurate positioning of reflectors assumes a correct migration velocity, which is an interval velocity field, i.e., a field of local velocities. Using accurate interval velocities allows depth migration to image more accurately than time migration can, but using inaccurate interval velocities can degrade image coherence that the less precise velocities of time migration often preserve.

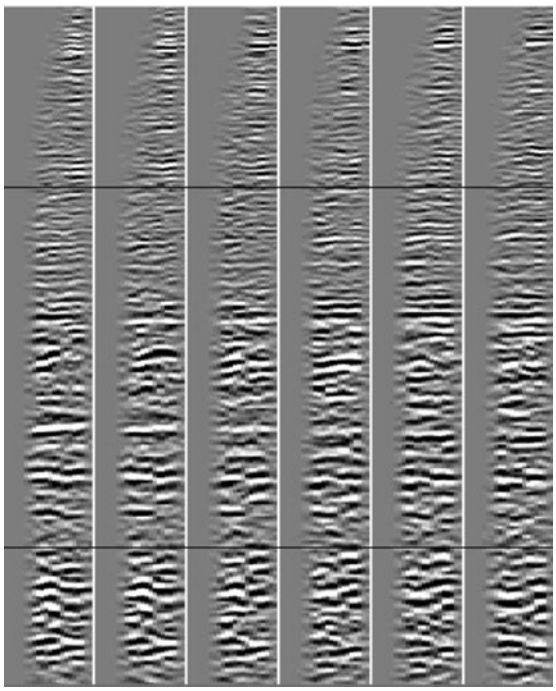
Purposes of migration

Strucural imaging

The primary goal of seismic migration is to correct distortions present in recorded seismic records, due to uncollapsed diffraction energy, geometric effects, or velocity effects. Even in areas of fairly flat geology, diffracted energy from abrupt fault terminations can obscure deeper reflection events, making their interpretation difficult. Therefore, collapsing unwanted diffraction energy to scatterer locations is important. Geometric and velocity effects are caused by complicated geologic structures. Familiar examples are "bowtie" signatures on stacked records converted by migration into synclines, and broad anticlinal structures converted by migration into narrower, steeper structures. Other examples include complicated water bottoms, complicated salt geometry, thrusted structures, heavily faulted areas, and gas-charged sediments. In these, reflector geometries or lateral velocity variations cause wavefield distortions that must be corrected before the image can be interpreted.

Velocity estimation

Poststack migration is performed using a velocity field that is specified beforehand. The velocity can be derived from NMO velocity analysis or from an assumed geologic model. It is difficult to analyze a poststack migrated image for velocity errors. By contrast, we can analyze prestack migration for velocity errors. To do this, one performs prestack migration separately on all the input records, with individual images that overlap considerably. In the overlap areas, the different images can be checked for consistency by sorting the migrated traces into common-image-point gathers (CIGs), which are the migration analog of NMO-corrected unmigrated CMP gathers. Within a CIG, each trace refers to a single surface location, imaged from a different input record. As an example, Figure 3 shows six CIG's from a land survey, referring to images below six different locations on the earth's surface. Each CIG displays migrated traces from different source-receiver offsets. If all the individual migrations have imaged one particular event at the same depth, the images are



Seismic, Migration, Figure 3 Prestack depth migration common-image gathers from six different locations on a survey from Western Canada. Each of the gathers contains traces from migrations of data with offsets ranging from 0 m to 4,500 m. The events on the gathers are flat except at the greatest depths, indicating that the velocity field is largely correct.

consistent at that location. That is the case in this example: except at the greatest depths, most of the events on each CIG appear flat. If the different migrations image a particular event at different depths, the images will be inconsistent, and the event will not appear flat on a CIG. In order to make the images consistent for such an event, the migration velocity will need to be adjusted in the overburden above the event location.

For prestack depth migration, the velocity estimation problem is to build an interval velocity field that makes the migrated events appear flat on all the CIGs. This is usually posed as an algebraic inverse problem, called seismic tomography, involving the interval velocity field, the reflector locations, and the raypaths from the reflectors to the source and receiver locations. This problem is solved iteratively for velocity model refinements. In order to avoid converging to an unrealistic model, tomography usually needs to be constrained, using partial knowledge of the seismic velocities and reflecting horizon locations. This biases the solution, and it can result in incomplete event flattening on the CIGs. Tomography is widely used, but it usually produces velocity models with limited spatial resolution

Increasingly, seismic velocities are recognized as anisotropic: at each location, seismic velocity varies with direction. Including anisotropy makes velocity estimation more difficult, but anisotropy is usually needed to produce accurate images. The most common assumption for anisotropy is transverse isotropy, often with a tilted axis of symmetry (TTI).

Currently, almost all migrations are performed before stack, and migration is used to estimate velocity (imaging velocity for time migration, interval velocity for depth migration).

Migrated amplitude analysis for rock property determination

In the 1980s, researchers observed that careful handling of amplitude terms within migration algorithms produced migrated amplitudes that are proportional to reflection coefficient values at rock boundaries. This observation is the basis of true-amplitude migration (Bleistein, 1987). Migrated amplitudes are now often analyzed in terms of angle-dependent reflection coefficients at rock boundaries. The reflection coefficients can be used to estimate the types of rock above and below each interface, and whether the rocks can bear hydrocarbons. This endeavor has had some success in areas of moderate velocity and structural complexity, but less success below areas of high complexity, such as below salt.

Imaging conditions

Isochron imaging

Pencil-and-paper migrations were performed by swinging reflection events to their migrated locations, which are the envelopes of all possible swing locations. Kirchhoff migration can be performed the same way, with the wave equation canceling the energy away from the envelopes and leaving only images of reflectors. The time of a sample on an input trace is the sum of time from the source to a reflector plus time from the reflector to the receiver; Kirchhoff migration acts by placing the sample at all subsurface locations (isochrons) that share the same two-way travel time.

Isochron imaging, useful in describing Kirchhoff migration, is plausible and correct, but it is not a wavefield concept, and cannot be applied to all migrations based on the wave equation. These require more general treatment, which is different for poststack and prestack migration.

Poststack migration – exploding reflector model

The CMP stack simulates a zero-offset record, where energy has been excited and recorded at the same location. It can also be considered as a single wavefield from a far-fetched experiment. Suppose all the reflectors and diffractors inside the earth exploded at the same instant (time zero), sending energy in all directions; some of the energy would emerge at the earth's surface at later times to be recorded at the receiver locations. Suppose also that the propagation velocity of the wavefield from the exploding reflectors is exactly one-half the actual propagation velocity inside the earth. Then the recording time for an event from an exploding reflector is the same as the two-way zero-offset reflection time, with the actual velocity, from the same reflector. This thought experiment (Loewenthal et al., 1976) provides the basis for a poststack migration imaging principle, breaking migration into two parts: downward continuation and imaging. The first part expresses the wavefield at one depth in terms of the wavefield at a shallower depth. As the wavefield moves down, time decreases towards zero (the time of the explosion). The second part picks off the downward-continued wavefield at each location when the time reaches zero. The result of the process is a snapshot of the reflectors in the act of explosion.

Reflected wavefield amplitude normalized by source wavefield amplitude

For prestack migration, downward continuation is useful, but exploding reflectors and zero-time imaging are not. As in poststack migration, the wavefield from the many receiver locations is downward continued into the earth and backwards in time. Likewise, the wavefield from the source location is downward continued, but forward in time so that it can interact with the receiver wavefield at actual reflection times. If the two downward-continued wavefields intersect at a location at a particular time, the process has captured the instant of reflection at that point. At that location and time, the receiver wavefield amplitude equals the source wavefield amplitude times the value of the reflection coefficient at the location (possibly zero, if the location is not on an actual reflector). That is, the migrated image at that location is the receiver wavefield divided by the source wavefield.

Deconvolution and cross correlation imaging conditions

Some migration techniques are applied in the time domain, others in the frequency (ω) domain. For frequency-domain methods, a precise statement of the prestack migration imaging principle is that reflectors exist inside the earth where downward continued source and receiver wavefields are in phase, and the reflection strength is the ratio of the two wavefields. For a single frequency, there is complete uncertainty about the location of a reflector; only by adding the results from many frequencies can reflector positions be precisely determined. Thus, the prestack-migration imaging principle can be written as

$$R(\mathbf{x}) = \int \frac{U(\mathbf{x};\omega)}{D(\mathbf{x};\omega)} \mathrm{d}\omega, \tag{1}$$

where $R(\mathbf{x})$ is reflection strength at location $\mathbf{x}$, U is the downward-continued receiver wavefield, and D is the downward-continued source wavefield. The quotient can cause stability problems when the source wavefield D becomes weak. To overcome instability, note that if both numerator and denominator are multiplied by the complex conjugate of D, denoted D^*, the phase of the denominator will disappear (the denominator becomes a positive real number). Instability, caused by the nearly vanishing denominator DD^*, can be eliminated by replacing the denominator with a constant value, leaving the modified imaging condition

$$R(\mathbf{x}) = \int U(\mathbf{x};\omega) D*(\mathbf{x};\omega) \mathrm{d}\omega. \tag{2}$$

Equations 1 and 2 migrate events to the same locations, but migrated amplitudes obtained using Equation 2 are different from those obtained using Equation 1. Imaging conditions (1) (*deconvolution*) and (2) (*crosscorrelation*) were introduced by Claerbout (1971).

Migration techniques

Integral (Kirchhoff) migration

Kirchhoff migration is the digital embodiment of the earliest migration heuristics, and it has a basis in the downward continuation of wavefields: the wavefield at depth is an integral of the recorded wavefield (Schneider, 1978). The mathematical physics of this operation requires amplitude and phase manipulations of the recorded wavefield, yielding various expressions for poststack and prestack migration with different recording configurations. For example, shot-record Kirchhoff migration is expressed as

$$I(\mathbf{x};\mathbf{x_s}) = \int \mathrm{d}\mathbf{x_r} \int \mathrm{d}t W \frac{\partial U(\mathbf{x_r};\mathbf{x_s};t)}{\partial t} \delta[t-(t_s+t_r)], \tag{3}$$

where $I(\mathbf{x}, \mathbf{x_s})$ is the migrated image at location $\mathbf{x}$ due to a source at $\mathbf{x_s}$, $\mathbf{x_r}$ are the receiver locations, W is a weight function, U is the recorded wavefield, δ is the Dirac delta function, and t_s and t_r are travel times from $\mathbf{x_s}$ and $\mathbf{x_r}$ to $\mathbf{x}$. The integral accumulates data samples from the receiver locations into the image at $\mathbf{x}$. Alternatively, Equation 3 allows an input sample at time $t_s + t_r$ from receiver location $\mathbf{x_r}$ to be smeared out into the isochron surface.

Kirchhoff migration is flexible, allowing the accumulation of trace values from any subvolume of the recorded traces into any subvolume of the image. This has made Kirchhoff migration very popular. However, complicated velocity models used in many depth migration projects have shown its accuracy limits, which are due mostly to a reliance on asymptotic ray theory to provide travel times and amplitudes.

Beam migration

In its simplest form, beam migration is a Kirchhoff migration with the integral over the recording surface broken into two stages: first, the domain of integration is divided into a number of overlapping regions; second, a directional decomposition of the data within each region is performed. This decomposition produces a set of local plane waves, over a range of angles, emerging within each region. Each of these local-plane wave data components is mapped back into the earth using raypaths sent in the directions of the emerging plane waves. A more complete description (Hill, 2001) uses Green's identity to downward continue the wavefields, with Gaussian beams as Green's functions. Gray et al. (2009) provide an elementary physical explanation of this complicated method, which is generally more accurate than Kirchhoff migration because it naturally allows several arrivals from each wavefield to accumulate at any image location (which is difficult for Kirchhoff migration). It has many of the flexibilities of Kirchhoff migration, but, like Kirchhoff migration, relies on asymptotic ray theory.

One-way wave-equation migration (OWEM)

Strictly speaking, applying the term "wave-equation migration" solely to migration methods that downward-continue wavefields recursively one depth step at a time is an abuse of terminology. This usage excludes Kirchhoff and beam migrations, implying that they do not derive from the wave equation, which is not true. This usage has become entrenched.

Downward continuing a wavefield from one depth to the next requires that the wavefield is propagating either up or down, but not both at once. (The wavefield can propagate laterally, but up or down is a distinguished direction.) Further, it requires an appropriate (upgoing or downgoing) wave equation. In the simple constant-velocity case, the one-way solution can be obtained easily. The two-way wave equation for wavefield P (acoustic, ignoring elastic effects such as mode conversion) is

$$\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} - \frac{1}{v^2}\frac{\partial^2}{\partial t^2}\right) P = 0. \tag{4}$$

When this equation is expressed in the frequency/horizontal wave number domain, it factors into separate equations for upgoing and downgoing wavefields. Analytical solutions of these equations provide phase shifts that perform downward continuation. Once the downward-continued wavefields have been inverse Fourier transformed from wave number back to space, they can be combined and summed over frequency using Equation 1 or 2 to produce the migrated image (Gazdag, 1978). This method, phase-shift migration, can accurately image dips up to 90°. Its only limitation is the lateral invariance of the velocity field. It has proven successful in imaging salt flanks in marine sedimentary basins. Beneath the salt flanks, where significant velocity contrast has occurred, the phase-shift image is inaccurate.

Factoring the wave equation exactly into one-way equations works only for constant velocity. When velocity varies laterally, the factoring, again with z as a distinguished direction, is approximate, incurring kinematic (time) and dynamic (amplitude) errors. A number of methods downward continue wavefields using approximate one-way wave equations. The earliest of these used finite differences to discretize the equations, using low-angle approximations (e.g., Claerbout, 1970). Later methods generalized phase-shift migration to handle lateral velocity variations, and other methods combine aspects of finite-difference and phase-shift approaches. Development of these methods continues today. Because of the errors inherent in even the best one-way wave equations, none of the methods can be completely accurate.

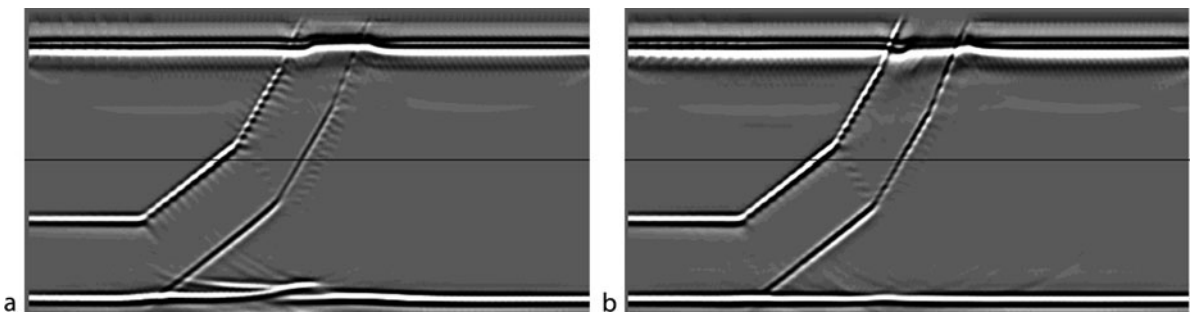
Two-way wave-equation migration (reverse-time migration)

Reverse-time migration (RTM) uses the full two-way wave equation 4. It does not operate by downward continuation of downgoing or upgoing wavefields. Instead, it takes the source and receiver wavefields at the recording surface and injects them into the earth by treating them as boundary values for the wave equation (McMechan, 1983), computing full wavefields inside the earth at each time step. The source wavefield is computed forwards in time, so successive wavefield snapshots show an expanding wavefront moving into the earth and interacting with reflectors and diffractors. The receiver wavefield is computed backwards in time (beginning with the final time sample on each trace of the recorded data), so successive snapshots show reflection events moving generally downward. Imaging is performed using a temporal version of the imaging condition (1) or (2). In principle, RTM is the most accurate migration method: it does not rely on asymptotic ray theory, and it suffers from neither the steep-dip nor the kinematic and dynamic errors of OWEM. Until recently, its use has been limited because it tends to be slower than other migration methods, and numerical approximations to the wave equation (e.g., low-order finite-difference approximations) produced errors (e.g., numerical dispersion) that other methods do not incur. However, modern computational hardware has both the speed and the memory availability to allow very good approximations to the wave equation, and high-quality RTM images are now the norm.

Migration examples

There are many reasons to migrate seismic data; we will need to be content with a few illustrations.

The first illustrates structural imaging in the presence of anisotropy. Figure 4 shows two images of a cross section designed to mimic the structural geology of a dipping thrust sheet, simplified to isolate the effect of anisotropy on image positioning and quality. The velocity is generally simple, with a constant velocity of 2,740 m/s outside the thrust sheet. The velocity complication lies in the thrust sheet, which is anisotropic (TTI), with a symmetry axis parallel to the boundaries of the sheet. In the thrust sheet, the velocity is 2,925 m/s in the direction of the symmetry axis, and higher in all other directions. Both images in Figure 4 are from prestack beam migration of the same input data set, which was generated by finite-difference elastic modeling (courtesy BP). In Figure 4a, anisotropy was ignored, and in Figure 4b, anisotropy was taken into account. The reflector below the dipping thrust sheet should be flat, as it is in Figure 4b. In Figure 4a, the flat reflector is pulled up beneath the thrust sheet, and is poorly imaged. The high-amplitude flat event cutting across the



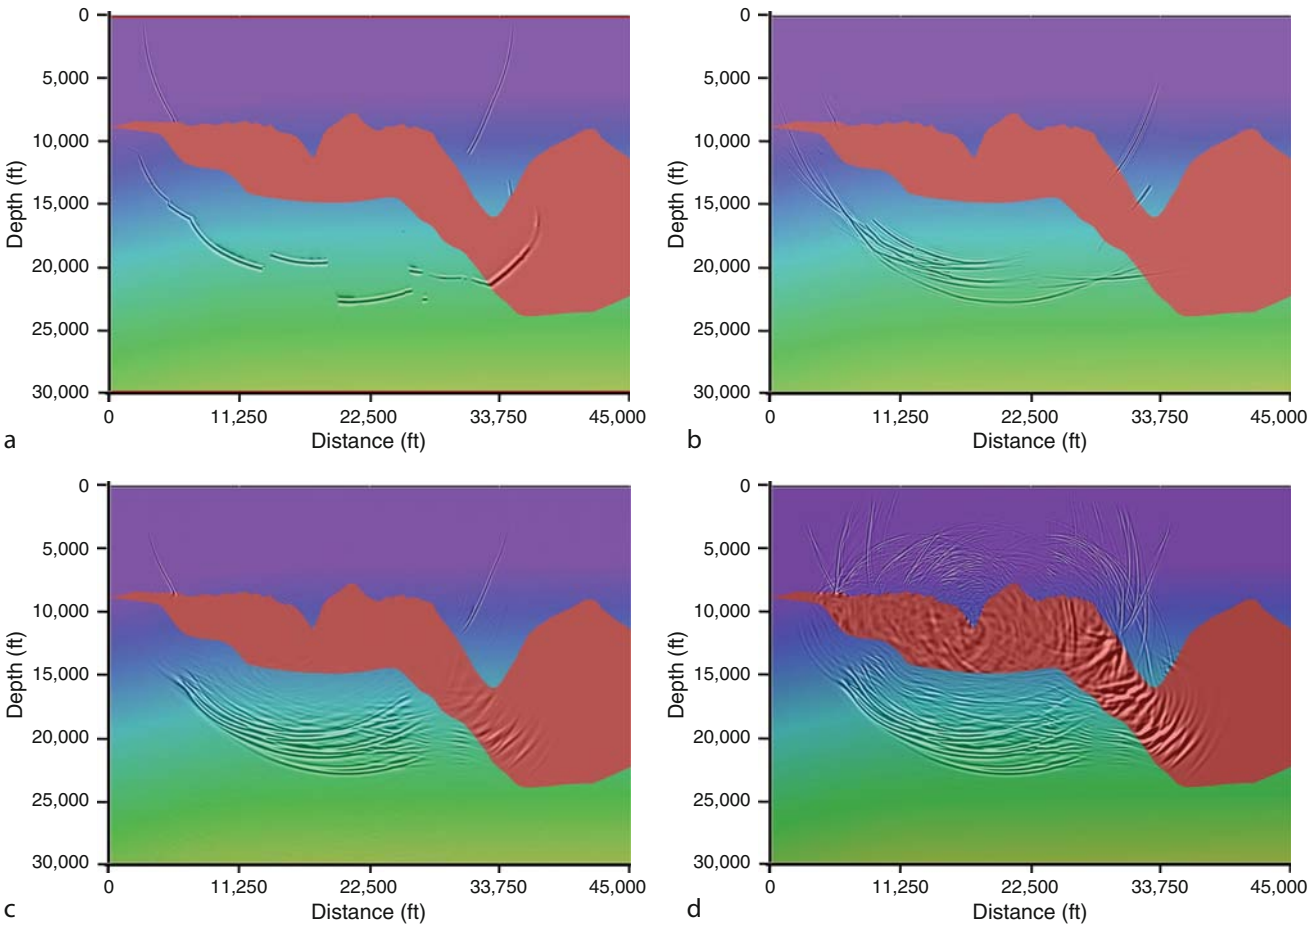
Seismic, Migration, Figure 4 Prestack depth migrated images from a synthetic thrust model data set. In (**a**), the anisotropy in the dipping thrust sheet is ignored by the migration, leading to inaccurate imaging below the thrust sheet. In (**b**), the migration has accounted for the anisotropy, leading to correct structural imaging.

entire section at shallow depths is a shear-wave artifact that has been mis-migrated by the P-wave migration program.

The second example illustrates the action of various migration methods: Kirchhoff, beam, OWEM, and RTM. Figure 5 shows four images overlaid on a geologic cross section, each obtained by migrating a single event on a single zero-offset trace through the complicated geology/velocity model shown (called Sigsbee2a). A high-velocity salt body of complex shape has been inserted into a set of lower-velocity sedimentary layers, and we note the effect of the geometry and velocity on the migration algorithms. The migrated images are, in effect, wavefronts modeled by the migration methods; full migrated images are formed by adding together such partial images from all samples on all traces. The Kirchhoff migrated image (Figure 5a) shows the effect of the assumption, made by most Kirchhoff migration programs, that at most one travel path for seismic energy connects a given upper-surface location with each subsurface location. The wavefield discontinuities in the subsalt area are physically impossible, and will cause inaccurate, noisy images in areas of structural complexity. The remaining images show wavefields of greater continuity and complexity in the subsalt area. The most complicated wavefield, produced by RTM, should produce the most accurate image. This happens in practice when the velocity field is accurate and the input traces are free from unwanted noise such as elastic-wave mode-converted events.

The evolving role of migration in seismic data processing

Before seismic processing became digital, migration was a standalone process. Pencil-and-paper or mechanical migration provided a cross section that showed where to drill. Later, poststack migration was the final seismic processing step; all other processing was intended to prepare a stacked data set for migration. With prestack migration, migration has moved to a central location in the processing flow. In tomography, it is common to process the signals on a migrated stack or in a set of CIG's. In postmigration amplitude analysis, it is common to analyze and alter the migrated waveforms. In the future, when the



Seismic, Migration, Figure 5 The action of migration, illustrated on four different migration methods: (**a**) Kirchhoff; (**b**) beam; (**c**) one-way wave-equation; (**d**) reverse-time. In each, a single event from a single zero-offset trace was migrated. The migration methods have interacted differently with the velocity model, producing different wavefronts. (From Etgen et al., 2009).

wave equation used for migration can model earth effects more completely than at present, seismic data will undergo less processing before migration, and the migrated data will predict rock properties directly.

Summary

Seismic migration has been used in prospecting for oil and natural gas since the 1920s. Since the 1970s, migration has been applied as a wave-equation process, explicitly recognizing that reflections recorded at the earth's surface are the result of wavefields propagating and reflecting inside the earth. Wavefield migration has taken several forms (time-domain, frequency-domain; finite-difference, integral) because of the variety of ways for expressing the propagation of wavefields. All these different forms of migration are still in use because each of them has features that the others lack: flexibility, steep-dip capability, etc. When computer power was limited, migration was usually performed after NMO/stack, allowing a reduction of the size of the data volume input to migration. Nowadays most migrations are performed before stack in 3-D. Another shift has been from time to depth, bringing migration closer to the problem of estimating seismic velocities inside the earth. A separate development has been the capability of migration to preserve amplitudes for estimating rock properties near reflector locations. With migration velocity estimation and amplitude analysis, migration has moved from the final step of the seismic processing flow to a more central role. This means that an increasing amount of processing and analysis is performed on migrated gathers before they are stacked to form the final structural image.

Seismic ray theory. High-frequency asymptotic method of study of seismic wavefields in complex inhomogeneous isotropic or anisotropic media with curved structural interfaces.

Introduction

The ray theory belongs to the methods most frequently used in seismology and seismic exploration for forward and inverse modeling of high-frequency seismic body waves. In smoothly varying media with smooth interfaces, it can provide useful approximate solutions of the elastodynamic equation of satisfactory accuracy. Starting from an intuitive description of the propagation of seismic waves along special trajectories - rays, it has developed into a highly sophisticated method, described briefly in this review paper.

The ray method has its advantages and disadvantages. The basic advantages are its applicability to complex,

isotropic and anisotropic, laterally varying layered media and its numerical efficiency in such computations. It provides a physical insight into the wave propagation process by separating the wavefield into individual elementary waves and by allowing their identification. In addition, it makes possible to track the paths in the medium along which energy of individual waves propagates, an aspect very important in tomography. The ray method also represents an important basis for other related, more sophisticated methods, such as the paraxial ray method, the Gaussian beam summation method, the Maslov method, the asymptotic diffraction theory, etc. The ray method also has some limitations. As mentioned above, it is approximate. It is applicable only to smooth media with smooth interfaces, in which the characteristic dimensions of inhomogeneities are considerably larger than the prevailing wavelength of the considered waves. The ray method can yield distorted results and may even fail in some special regions called *singular regions*.

The seismic ray method owes a lot to optics and radiophysics. Although the techniques used in different branches of physics are very similar, there are some substantial differences. The ray method in seismology is usually applied to more complicated structures than in optics or radiophysics. There are also different numbers and types of waves considered in different branches of physics.

The first seismological applications of ray concepts date back to the end of the 19th century. Then, only *kinematics*, specifically travel times, were used. Probably the first attempts to use also *dynamics* (amplitudes and waveforms) were made by Sir H. Jeffreys. The ray series solutions of elastodynamic equation with variable coefficients were first suggested by Babich (1956) and Karal and Keller (1959) for inhomogeneous isotropic media, and by Babich (1961) for inhomogeneous anisotropic media.

The Earth's interior is anisotropic or weakly anisotropic in some of its parts. Seismic anisotropy and its effects on wave propagation play an important role in contemporary seismology and seismic exploration. Consequently, it has also been necessary to develop the ray theory for elastic anisotropic media. It is important to emphasize that, for S waves, the ray theory for anisotropic media does not yield the ray theory for isotropic media in the zero anisotropy limit. For this reason, we describe systematically the ray theory for anisotropic media and also present corresponding formulae for isotropic media, and explain the differences between both of them.

S waves require generally a special attention. Well understood phenomenon is propagation of two separate shear waves in anisotropic media. Less understood and an underestimated phenomenon is shear-wave coupling, which occurs in weakly anisotropic media or in vicinities of shear-wave singularities. In such regions, standard ray theories for anisotropic as well as isotropic media do not work properly. Therefore, we also briefly describe the coupling ray theory for S waves, which fills the gap between ray theories for isotropic and anisotropic media.

We give here neither a detailed derivation of ray-theoretical expressions nor a relevant systematic bibliography. This would extend the text considerably. We refer, however, to several textbooks, in which the ray theory is treated in a considerably greater detail (Červený et al., 1977; Kravtsov and Orlov, 1990; Červený, 2001; Chapman, 2004). The reader may also find useful information in several review papers devoted to seismic ray theory and its various aspects (Červený et al., 1988; Virieux, 1996; Chapman, 2002; Červený et al., 2007). Examples of computations based on the ray theory can be found, for example, in Červený et al. (1977) and Gjøystdal et al. (2002). Here we refer only to papers, in which the relevant methods and procedures were first proposed, and/or which give a useful more recent treatment of the subject.

We use the following notation. We denote Cartesian coordinates x_i and time t. The dots above letters denote partial derivatives with respect to time ($\ddot{u}_i = \partial^2 u_i/\partial t^2$) and the index following the comma in the subscript indicates the partial derivative with respect to the relevant Cartesian coordinate ($u_{i,j} = \partial u_i/\partial x_j$). We consider high-frequency time-harmonic seismic body waves, with the exponential factor $\exp(-\mathrm{i}\omega t)$, where ω is fixed, positive, real-valued circular frequency. The lower-case Roman indices take the values 1, 2, 3, the upper-case indices 1, 2. Hats over bold symbols indicate 3×3 matrices, bold symbols without hats denote 2×2 matrices. The Einstein summation convention over repeating Roman indices is used, with exception of indices in parentheses.

Basic equations of the seismic ray method

For smoothly varying elastic media, the source-free *equation of motion* reads

$$\tau_{ij,j} - \rho\,\ddot{u}_i = 0. \tag{1}$$

Here $\tau_{ij}(x_n, t)$, and $u_i(x_n, t)$ are Cartesian components of stress tensor and displacement vector, respectively, and ρ is the density. In anisotropic media, the stress tensor τ_{ij} and the infinitesimal strain tensor $e_{ij} = \frac{1}{2}(u_{i,j} + u_{j,i})$ are related by Hooke's law:

$$\tau_{ij} = c_{ijkl} e_{kl} = c_{ijkl} u_{k,l}. \tag{2}$$

$c_{ijkl}(x_n)$ is a tensor of elastic moduli (stiffness tensor), satisfying symmetry relations $c_{ijkl} = c_{jikl} = c_{ijlk} = c_{klij}$. There are, at the most, 21 independent elastic moduli. Inserting Equation 2 into Equation 1, we get the *elastodynamic equation*

$$(c_{ijkl} u_{k,l})_{,j} - \rho\,\ddot{u}_i = 0. \tag{3}$$

In the seismic ray method, high-frequency seismic body waves propagating in smoothly varying, isotropic or anisotropic, media are studied. The formal ray series solution of the elastodynamic equation (3) for the displacement vector

$\mathbf{u}(x_n,t)$ is sought in the form of an asymptotic series in inverse powers of circular frequency ω,

$$\mathbf{u}(x_n,t) = \exp[-\mathrm{i}\omega(t-T(x_n))] \left[\mathbf{U}^{(0)}(x_n) + \frac{\mathbf{U}^{(1)}(x_n)}{(-\mathrm{i}\omega)} + \frac{\mathbf{U}^{(2)}(x_n)}{(-\mathrm{i}\omega)^2} + \ldots\right]. \quad (4)$$

Here $T(x_n)$ is the real-valued travel time, $\mathbf{U}^{(k)}$, $k = 0,1,2,\ldots$ are complex-valued *vectorial amplitude coefficients*. Surfaces $T(x_i) = const.$ are called *wavefronts* (or phase fronts). In perfectly elastic media, functions $T(x_n)$, and $\mathbf{U}^{(k)}(x_n)$ are frequency independent.

Also other forms of the ray series have been used in the seismic ray method. For example, Chapman (2004) developed the seismic ray method using the ray series for particle velocity and traction. Such a formal ray series has certain advantages with respect to Equation 4. Here, however, we consider systematically the traditional ray series (4) for the displacement vector.

Inserting Equation 4 into elastodynamic equation (3), we obtain a series in inverse powers of ω, which equals zero. Consequently, the coefficients of the individual powers of ω must also equal zero. This yields a system of equations called the basic recurrence system of equations of the ray method. This system can be used to determine the eikonal equations for travel times $T(x_n)$ and, successively the equations for the amplitude coefficients $\mathbf{U}^{(0)}(x_n)$, $\mathbf{U}^{(1)}(x_n)$, $\mathbf{U}^{(2)}(x_n)$,.... The equations for $\mathbf{U}^{(k)}(x_n)$ yield, among others, transport equations. For a detailed derivation of the basic system of equations of the ray method see Červený (2001, sect. 5.7).

The vectorial amplitude coefficients $\mathbf{U}^{(k)}(x_n)$, $k = 1,2,\ldots$, can be expressed as a sum of the *principal component* and *additional component*. The principal component of $\mathbf{U}^{(k)}(x_n)$ is the projection of $\mathbf{U}^{(k)}(x_n)$ into the unit vector parallel to the zero-order amplitude coefficient $\mathbf{U}^{(0)}(x_n)$, the additional component of $\mathbf{U}^{(k)}(x_n)$ is the remaining part of $\mathbf{U}^{(k)}(x_n)$. In this way, the additional component of the zero-order amplitude coefficient $\mathbf{U}^{(0)}(x_n)$ is zero. The complexity of the equations for higher-order amplitude coefficients $\mathbf{U}^{(k)}$ increases rapidly with increasing k. Moreover, the higher-order amplitude coefficients are inaccurate and unstable, as they are very sensitive to fine details of the medium. The instability of the amplitude coefficients increases with increasing k. For these reasons, only the zero-order coefficient $\mathbf{U}^{(0)}(x_n)$, at the most with the additional component of $\mathbf{U}^{(1)}(x_n)$, has been used in seismological applications. In the following, we shall concentrate on the zero-order ray approximation only.

The zero-order approximation of the ray method reads:

$$\mathbf{u}(x_n,t) = \mathbf{U}(x_n)\exp[-\mathrm{i}\omega(t-T(x_n))]. \quad (5)$$

In Equation 5, we have dropped the superscript (0) of $\mathbf{U}(x_n)$. We call $\mathbf{U}(x_n)$ the complex-valued *vectorial amplitude*. In smooth, laterally varying media, containing smooth structural interfaces, the zero-order approximation (5) of the ray method usually offers sufficiently accurate results, particularly for travel time $T(x_n)$. Its great advantage is that it allows one to work with frequency-independent travel time and amplitude. However, if the medium under consideration becomes more and more complex (less smooth), vectorial amplitude $\mathbf{U}(x_n)$ becomes less accurate. In structures exceeding a certain degree of complexity, the ray method may yield inaccurate results or even fail.

The first equation of the basic system of equations of the ray method reads:

$$(\Gamma_{ik} - \delta_{ik})U_k = 0, \quad i = 1,2,3. \quad (6)$$

Here $\mathbf{\Gamma}$ is the 3×3 *generalized Christoffel matrix* with elements given by the relation:

$$\Gamma_{ik} = a_{ijkl}p_j p_l. \quad (7)$$

In Equation 7, p_i are the Cartesian components of the slowness vector $\mathbf{p}$,

$$p_i = \partial T/\partial x_i \quad (8)$$

and $a_{ijkl} = c_{ijkl}/\rho$ are density-normalized elastic moduli. Note that the classical Christoffel matrix, with elements $a_{ijkl}n_j n_l$, contains components of the real-valued unit vector $\mathbf{n}$ (perpendicular to the wavefront) instead of $\mathbf{p}$. For this reason, we call $\mathbf{\Gamma}$the "generalized" Christoffel matrix. The relation between p_i and n_i is $p_i = n_i/\mathcal{C}$, where $\mathcal{C}$ is the phase velocity.

The generalized 3×3 Christoffel matrix in solid media is symmetric ($\Gamma_{ik} = \Gamma_{ki}$), positive definite ($\Gamma_{ik}a_i a_k > 0$, where a_i are components of any non-vanishing real-valued vector) and homogeneous function of the second degree in p_i ($\Gamma_{ik}(x_n, ap_j) = a^2\Gamma_{ik}(x_n,p_j)$ for any non-vanishing constant a). It has three real-valued positive eigenvalues $G_m(x_n,p_j)$, and three corresponding real-valued unit eigenvectors $\mathbf{g}^{(m)}(x_n,p_j)$, $m = 1,2,3$. G_m and $\mathbf{g}^{(m)}$ are solutions of the eigenvalue equation

$$(\Gamma_{ik} - \delta_{ik}G_m)g_k^{(m)} = 0, \quad i = 1,2,3. \quad (9)$$

Eigenvectors $\mathbf{g}^{(1)}, \mathbf{g}^{(2)}, \mathbf{g}^{(3)}$ are mutually perpendicular. Eigenvalue G_m and the relevant eigenvector $\mathbf{g}^{(m)}$ are mutually related as follows:

$$G_m = \Gamma_{ik}g_i^{(m)}g_k^{(m)} = a_{ijkl}p_j p_l g_i^{(m)}g_k^{(m)}. \quad (10)$$

For isotropic media, it is sufficient to specify elastic moduli $c_{ijkl}(x_n)$ in terms of Lamé's elastic moduli $\lambda(x_n)$ and $\mu(x_n)$, describing isotropic media, as follows:

$$c_{ijkl} = \lambda\delta_{ij}\delta_{kl} + \mu(\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}). \quad (11)$$

Elements of the generalized Christoffel matrix are then given by the relation:

$$\Gamma_{ik} = \frac{\lambda+\mu}{\rho}p_i p_k + \frac{\mu}{\rho}\delta_{ik}p_n p_n. \quad (12)$$

In isotropic media, the expressions for eigenvalues and eigenvectors of the generalized Christoffel matrix can be determined analytically:

$$G_1 = G_2 = \beta^2 p_k p_k, \qquad G_3 = \alpha^2 p_k p_k. \tag{13}$$

Here

$$\alpha^2 = (\lambda + 2\mu)/\rho, \qquad \beta^2 = \mu/\rho. \tag{14}$$

The eigenvector relevant to the eigenvalue G_3 equals $\mathbf{n}$, the unit vector perpendicular to the wavefront. The eigenvectors relevant to coinciding eigenvalues G_1 and G_2 are mutually perpendicular unit vectors situated arbitrarily in the plane perpendicular to $\mathbf{n}$.

Eikonal equation. Polarization vector

The comparison of the basic equation of the ray method (6) with the eigenvalue equation (9) for the 3×3 generalized Christoffel matrix shows that Equation 6 is satisfied, if the eigenvalue G_m of the generalized Christoffel matrix satisfies the relation

$$G_m(x_i, p_j) = 1, \tag{15}$$

and if the complex-valued vectorial amplitude $\mathbf{U}$ of the wave under consideration is related to eigenvector $\mathbf{g}^{(m)}$ as follows:

$$\mathbf{U} = A\mathbf{g}^{(m)}. \tag{16}$$

Equation 15 is the important *eikonal equation*. It is a nonlinear, first-order partial differential equation for travel time $T(x_n)$. Equation 16 shows that displacement vector $\mathbf{U}$ is parallel to the appropriate eigenvector $\mathbf{g}^{(m)}$. For this reason, we call $\mathbf{g}^{(m)}$ the *polarization vector*. Symbol $A(x_n)$ denotes the complex-valued, frequency-independent, *scalar amplitude*.

Taking into account that G_m is a homogeneous function of the second degree in p_i, where $\mathbf{p} = \mathcal{C}^{-1}\mathbf{n}$, we obtain $G_m(x_i, p_j) = \mathcal{C}^{-2} G_m(x_i, n_j)$. This, Equations 15 and 10 yield

$$\mathcal{C}^2(x_i, n_j) = G_m(x_i, n_j) = a_{ijkl} n_j n_l g_i^{(m)} g_k^{(m)}. \tag{17}$$

Phase velocity $\mathcal{C}$ is the velocity of the wavefront in direction $\mathbf{n}$. The phase-velocity vector $\boldsymbol{\mathcal{C}} = \mathcal{C}(x_i, n_j)\mathbf{n}$ has the direction of $\mathbf{n}$, i.e., it is perpendicular to the wavefront. It follows from Equation 17 that the squares of phase velocity $\mathcal{C}$ are eigenvalues $G_m(x_i, n_j)$ of the classical Christoffel matrix with elements $a_{ijkl} n_j n_l$.

Generally, eigenvalues G_m, $m = 1, 2, 3$, of the generalized Christoffel matrix are mutually different. They correspond to three high-frequency body waves propagating in inhomogeneous anisotropic media. We assign G_1 and G_2 to S1 and S2 waves and G_3 to P wave. If the eigenvalues are different, their polarization vectors can be determined uniquely.

If two eigenvalues coincide, we speak of the *degenerate case* of the eigenvalue problem. The corresponding eigenvectors can then be chosen as mutually perpendicular vectors situated arbitrarily in the plane perpendicular to the third eigenvector. Eigenvalues G_m may coincide *locally*, along certain lines or at certain points, which correspond to the so-called *S-wave singular directions*, or may be close to one another *globally* in a vicinity of singular directions or in *weakly anisotropic media*. The approximate but unique determination of polarization vectors in the latter situations is possible using perturbation approach (Jech and Pšenčík, 1989).

In isotropic media, the S-wave eigenvalues G_1 and G_2 coincide *globally*, see Equation 13. Consequently, in isotropic media, the S waves are controlled by a single eikonal equation and we have thus only two different eikonal equations corresponding to P and S waves. As the equations for the eigenvalues in isotropic media can be determined analytically, we can express the eikonal equations for P and S waves explicitly:

$$\alpha^2 p_k p_k = 1 \quad \text{for P waves}, \tag{18}$$

$$\beta^2 p_k p_k = 1 \quad \text{for S waves}. \tag{19}$$

In isotropic media, the generally complex-valued amplitude vector $\mathbf{U}$ can be expressed in the simple form (16) only for P waves. In this case the polarization vector $\mathbf{g}^{(3)} = \mathbf{n}$, i.e., it is perpendicular to the wavefront. For S waves, $\mathbf{U}$ must be considered in the following form:

$$\mathbf{U} = B\mathbf{g}^{(1)} + C\mathbf{g}^{(2)}. \tag{20}$$

Here $\mathbf{g}^{(1)}$ and $\mathbf{g}^{(2)}$ are two mutually perpendicular unit vectors in the plane tangent to the wavefront, i.e., perpendicular to the vector $\mathbf{n}$. The computation of $\mathbf{g}^{(1)}$ and $\mathbf{g}^{(2)}$ along the ray is explained later, see Equation 37. Symbols $B(x_n)$ and $C(x_n)$ are the corresponding, generally complex-valued scalar amplitudes.

In the seismic ray method, it is common to express the eikonal equation (15) in Hamiltonian form. Hamiltonian $\mathcal{H}(x_i, p_j)$ may be introduced in various ways. We shall consider the Hamiltonian, which is a homogeneous function of the second degree in p_i. For inhomogeneous anisotropic media, we can introduce the Hamiltonian expressed in terms of $G_m(x_i, p_j)$, see Equation 10:

$$\mathcal{H}(x_i, p_j) = \frac{1}{2} G_m(x_i, p_j) = \frac{1}{2} a_{ijkl} p_j p_l g_i^{(m)} g_k^{(m)}. \tag{21}$$

The eikonal equation (15) then yields:

$$\mathcal{H}(x_i, p_j) = \frac{1}{2}. \tag{22}$$

It holds for anisotropic as well as isotropic media.

From Equations 13 and 21, we get for isotropic inhomogeneous media:

$$\mathcal{H}(x_i, p_j) = \frac{1}{2} V^2(x_i) p_k p_k, \tag{23}$$

where $V = \alpha$ for P waves and $V = \beta$ for S waves.

Ray tracing and travel-time computation

The eikonal equation in Hamiltonian form (22), with $p_j = \partial T/\partial x_j$, is a non-linear partial differential equation of the first order for travel time $T(x_i)$. It can be solved by the method of characteristics. The characteristics of eikonal equation (22) are spatial trajectories, along which Equation 22 is satisfied, and along which travel time T can be computed by quadratures. The characteristics of the eikonal equation represent *rays*.

The characteristics of the eikonal equation expressed in general Hamiltonian form are described by a system of non-linear, ordinary differential equations of the first order:

$$\frac{\mathrm{d}x_i}{\mathrm{d}u} = \frac{\partial \mathcal{H}}{\partial p_i}, \quad \frac{\mathrm{d}p_i}{\mathrm{d}u} = -\frac{\partial \mathcal{H}}{\partial x_i}, \quad \frac{\mathrm{d}T}{\mathrm{d}u} = p_k \frac{\partial \mathcal{H}}{\partial p_k}. \tag{24}$$

Here u is a real-valued parameter along the ray. The relation between parameter u and the travel time along the ray depends on the form of the Hamiltonian used, see the last equation in Equations 24. For Hamiltonians, which are homogeneous functions of the second degree in p_i, the Euler equation for homogeneous functions yields $p_k \partial \mathcal{H}/\partial p_k = 2\mathcal{H}$. If we consider Hamiltonian (21), we get $\mathrm{d}T/\mathrm{d}u = 1$ from Equations 24. For travel time T along the ray, denoted $\tau = T$, Equations 24 simplify to:

$$\frac{\mathrm{d}x_i}{\mathrm{d}\tau} = \frac{\partial \mathcal{H}}{\partial p_i}, \quad \frac{\mathrm{d}p_i}{\mathrm{d}\tau} = -\frac{\partial \mathcal{H}}{\partial x_i}. \tag{25}$$

This system of equations is usually called the *ray tracing system*. Solution of the ray tracing system (25) with appropriate initial conditions yields $x_i(\tau)$, the coordinates of points along the ray trajectory, and $p_i(\tau)$, the Cartesian components of the slowness vectors along the ray. The travel time T along the ray is obtained automatically, $T = \tau$.

Inserting Equation 21 in Equations 25, we obtain the ray tracing system for m-th wave in inhomogeneous anisotropic media:

$$\begin{aligned} \frac{\mathrm{d}x_i}{\mathrm{d}\tau} &= a_{ijkl} p_l g_j^{(m)} g_k^{(m)}, \\ \frac{\mathrm{d}p_i}{\mathrm{d}\tau} &= -\frac{1}{2} \frac{\partial a_{jkln}}{\partial x_i} p_k p_n g_j^{(m)} g_l^{(m)}. \end{aligned} \tag{26}$$

In the derivation of the first set of Equations 26 for $\partial \mathcal{H}/\partial p_i$, we took into account that $\Gamma_{ik} \partial (g_i^{(m)} g_k^{(m)})/\partial p_n = 0$. An alternative version of ray tracing equation (26) was derived by Červený (1972), in which the eigenvectors $\mathbf{g}^{(m)}$ are not used.

The initial conditions for the ray tracing system (26) are $x_i = x_{0i}$, $p_i = p_{0i}$, where x_{0i} and p_{0i} satisfy the eikonal equation (22), corresponding to the wave we wish to compute (P, S1 or S2). Components p_{0i} of the initial slowness vector $\mathbf{p}_0$ can be then expressed as $p_{0i} = n_{0i}/\mathcal{C}(x_{0i})$, where $\mathcal{C}$ is the relevant phase velocity. The eikonal equation (22) is then satisfied along the whole ray.

In inhomogeneous isotropic media, the ray tracing system (25) with Equation 23 yields

$$\frac{\mathrm{d}x_i}{\mathrm{d}\tau} = V^2 p_i, \quad \frac{\mathrm{d}p_i}{\mathrm{d}\tau} = -\frac{\partial \ln V}{\partial x_i}. \tag{27}$$

The initial conditions for the ray tracing system (27) are again $x_i = x_{0i}$, $p_i = p_{0i}$, where $p_{0i} = n_{0i}/V(x_{0i})$. Here $V = \alpha$ for P waves, and $V = \beta$ for S waves.

As τ is the travel time along the ray, $\mathrm{d}x_i/\mathrm{d}\tau$ represent the Cartesian components $\mathcal{U}_i$ of the *ray-velocity vector* $\boldsymbol{\mathcal{U}}$ of the m-th wave:

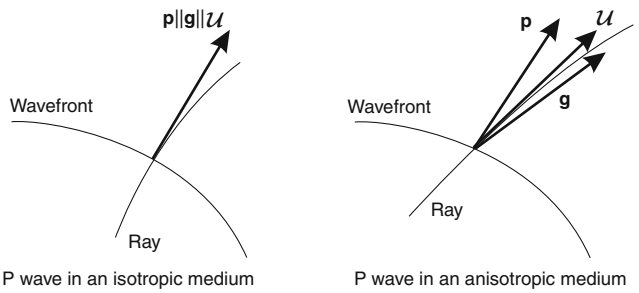
$$\mathcal{U}_i = a_{ijkl} p_l g_j^{(m)} g_k^{(m)}. \tag{28}$$

In non-dissipative anisotropic media, the ray-velocity vector $\boldsymbol{\mathcal{U}}$ is also called the group-velocity vector or the energy-velocity vector. As indicated by the name, the energy velocity vector $\boldsymbol{\mathcal{U}}$ represents the velocity of the energy propagation.

In anisotropic media, the ray-velocity vector $\boldsymbol{\mathcal{U}}$ must be strictly distinguished from the phase-velocity vector $\boldsymbol{\mathcal{C}}$. In inhomogeneous anisotropic media, the ray-velocity and phase-velocity vectors $\boldsymbol{\mathcal{U}}$ and $\boldsymbol{\mathcal{C}}$ are generally different, both in size and direction. Vector $\boldsymbol{\mathcal{U}}$ is always greater than $\boldsymbol{\mathcal{C}}$. The two vectors are equal (in size and direction) only in special directions, called *longitudinal directions*.

In inhomogeneous isotropic media, Equation 28 for the ray-velocity vector yields $\boldsymbol{\mathcal{U}} = V^2 \mathbf{p}$. For the phase-velocity vector, using Equation 17, we get $\boldsymbol{\mathcal{C}} = V^2 \mathbf{p}$. In both cases, $V = \alpha$ for P waves, and $V = \beta$ for S waves. Thus, the ray-velocity and phase-velocity vectors are identical in isotropic media.

Figure 1 shows mutual orientation of ray-velocity vector $\boldsymbol{\mathcal{U}}$, phase-velocity vector $\boldsymbol{\mathcal{C}}$ (parallel to slowness vector $\mathbf{p}$) and polarization vector $\mathbf{g}$ of a P wave propagating in an isotropic (left) and anisotropic (right) medium. While $\boldsymbol{\mathcal{U}}$, $\boldsymbol{\mathcal{C}}$ and $\mathbf{g}$ are parallel in isotropic media, they generally differ in anisotropic media. For S waves, the vectors $\boldsymbol{\mathcal{U}}$ and $\boldsymbol{\mathcal{C}}$ have similar orientation as in the case of P waves. The polarization vectors $\mathbf{g}$ are, however, perpendicular



Seismic, Ray Theory, Figure 1 Slowness vector $\mathbf{p}$ (perpendicular to the wavefront), ray-velocity vector $\boldsymbol{\mathcal{U}}$ (tangent to the ray) and polarization vector $\mathbf{g}$ of a P wave propagating in an isotropic (*left*) and anisotropic (*right*) medium. For simplicity, the three vectors in the right-hand plot are shown in one plane. In general, this is not the case in anisotropic media.

(isotropic medium) or nearly perpendicular (anisotropic medium) to the ray.

Ray tracing systems (26) and (27) can be simply solved if the initial values x_{0i} and p_{0i} are specified at some point S. We then speak of *initial-value ray tracing*. The standard numerical procedures of solving the system of ordinary differential equations of the first order with specified initial conditions can then be used (Runge-Kutta, etc.). A very important role in seismology is played by *boundary-value ray tracing*, in which we seek the ray, satisfying some boundary conditions. The typical boundary-value problem is *two-point ray tracing*, in which we seek the ray connecting two specified points. Mostly, the controlled initial-value ray tracing (controlled shooting method) is used to solve this problem (Červený et al., 2007). Boundary-value ray tracing is considerably more complicated than initial-value ray tracing.

There are four important differences between initial-value ray tracing in isotropic and anisotropic media. First: In anisotropic media, we deal with three waves, P, S1 and S2, in isotropic media with two waves, P and S, only. Second: In inhomogeneous anisotropic media, ray tracing system (26) is the same for all three waves. The wave under consideration is specified by the initial conditions, which must satisfy the eikonal equation of the considered wave. In isotropic inhomogeneous media, the ray tracing systems are different for P and S waves, see Equations 27 with $V = \alpha$ and $V = \beta$, respectively. Third: In isotropic media, the initial direction of the slowness vector specifies directly the initial direction of the ray (as the tangent to the ray and the slowness vector have the same directions). In anisotropic media, the direction of the ray is, generally, different from the direction of the slowness vector. Nevertheless, we have to use p_{0i} as the initial values for the ray tracing system. The ray-velocity vector $\boldsymbol{\mathcal{U}}$ can be simply calculated from slowness vector $\mathbf{p}$ at any point of the ray, including the initial point. Fourth: Ray tracing for P and S waves is regular everywhere in inhomogeneous isotropic media. In anisotropic media, problems arise with tracing S-wave rays in vicinities of singular directions, or if medium is nearly isotropic (quasi-isotropic).

The problem of ray tracing and travel-time computation in inhomogeneous media has been broadly discussed in the seismological literature; particularly for inhomogeneous isotropic media. Many ray tracing systems and many suitable numerical procedures for performing ray tracing have been proposed. For 1-D isotropic media (vertically inhomogeneous, radially symmetric), the ray tracing systems may be simplified so that they reduce to simple quadratures, well known from classical seismological textbooks (Aki and Richards, 1980). Standard programs for ray tracing and travel-time computations in laterally varying isotropic and anisotropic structures are available, see, for example, program packages SEIS (2D isotropic models), CRT and ANRAY (3D isotropic/anisotropic models) at http://sw3d.cz/. Programs for anisotropic media have, however, problems with S-wave computations in quasi-isotropic media and in the vicinities of shear-wave singularities. In such cases, the standard ray theory should be replaced by the coupling ray theory. Numerical procedures based on the coupling ray theory are, unfortunately, rare.

Ray tracing may also serve as a basis for the so-called *wavefront construction method* (Gjøystdal et al., 2002). In this case, for a selected wave, wavefronts with travel times $T = T_0 + k\Delta T$ are computed successively from the previous wavefronts with travel times $T = T_0 + (k-1)\Delta T$. The wavefront construction method has found broad applications in seismic exploration.

Let us consider a two-parametric system of rays, call it the *ray field*, and specify the individual rays in the ray field by *ray parameters* γ_1, γ_2. Ray parameters γ_1, γ_2 may represent, e.g., the take-off angles at a point source, or the curvilinear Gaussian coordinates of initial ray points along the initial surface. The family of rays with ray parameters within the limit $[\gamma_1, \gamma_1 + \mathrm{d}\gamma_1]$, $[\gamma_2, \gamma_2 + \mathrm{d}\gamma_2]$, is called the *elementary ray tube* or briefly the ray tube. We further introduce *ray coordinates* $\gamma_1, \gamma_2, \gamma_3$ in such a way that γ_1, γ_2 are ray parameters, and γ_3 is some monotonic parameter along a ray (arclength s, travel time τ, etc.). Here we consider $\gamma_3 = \tau$, but our results may be simply modified for any other monotonic parameter γ_3. We further introduce the 3×3 transformation matrix $\hat{\mathbf{Q}}$ from ray to Cartesian coordinates with elements $Q_{ij} = \partial x_i / \partial \gamma_j$. The Jacobian of transformation from ray to Cartesian coordinates, $\det \hat{\mathbf{Q}}$, can be expressed as follows:

$$\det \hat{\mathbf{Q}}(\tau) = (\partial \mathbf{x}(\tau)/\partial \gamma_1 \times \partial \mathbf{x}(\tau)/\partial \gamma_2)^T \boldsymbol{\mathcal{U}}(\tau). \qquad (29)$$

The vectorial product in Equation 29 has the direction of the normal to the wavefront, specified by $\mathbf{n} = \mathcal{C}\,\mathbf{p}$. As $\mathbf{p}(\tau) \cdot \boldsymbol{\mathcal{U}}(\tau) = 1$, see Equations 28, 10, and 15, we also obtain

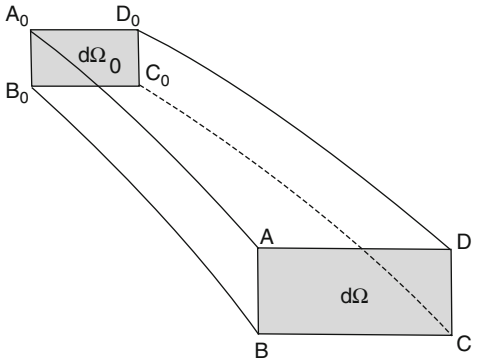
$$\det \hat{\mathbf{Q}}(\tau) = \pm \mathcal{C}(\tau) |(\partial \mathbf{x}(\tau)/\partial \gamma_1 \times \partial \mathbf{x}(\tau)/\partial \gamma_2)|. \qquad (30)$$

Thus Jacobian $\det \hat{\mathbf{Q}}(\tau)$ equals $\pm \mathcal{C}(\tau) \mathrm{d}\Omega(\tau)$, where $\mathrm{d}\Omega(\tau) = |(\partial \mathbf{x}(\tau)/\partial \gamma_1 \times \partial \mathbf{x}(\tau)/\partial \gamma_2)|$ is the scalar surface element cut out of the wavefront by the ray tube. It measures the expansion or contraction of the ray tube, see Figure 2. For this reason, the 3×3 matrix $\hat{\mathbf{Q}}(\tau)$ is also often called the *geometrical spreading matrix* and various quantities related to $\det \hat{\mathbf{Q}}(\tau)$ are called *geometrical spreading*. It plays an important role in the computation of the ray-theory amplitudes.

Transport equation. Computation of ray-theory amplitudes

The second equation of the basic system of equations of the ray method yields the transport equation for the scalar ray-theory amplitude $A(x_i)$. The transport equation is a partial differential equation of the first order. It can be expressed in several forms. One of them, valid both for isotropic and anisotropic media, reads

$$\nabla \cdot (\rho A^2 \boldsymbol{\mathcal{U}}) = 0. \qquad (31)$$



Seismic, Ray Theory, Figure 2 Elementary ray tube. $d\Omega_0$ and $d\Omega$ are scalar surface elements cut out of the wavefront by the ray tube. This means that in isotropic media, the normals to $d\Omega_0$ and $d\Omega$ are parallel to rays. In anisotropic media, they are not.

It is common to solve the transport equation along the ray. $\nabla \cdot \boldsymbol{\mathcal{U}}$ can then be expressed as follows:

$$\nabla \cdot \boldsymbol{\mathcal{U}} = \mathrm{d}[\ln(\det \hat{\mathbf{Q}})]/\mathrm{d}\tau \tag{32}$$

(Červený, 2001, Equation 3.10.24). Inserting Equation 32 into Equation 31 yields the transport equation in the form of the first-order ordinary differential equation along the ray:

$$\mathrm{d}\big(\rho(\tau)A^2(\tau)\det \hat{\mathbf{Q}}(\tau)\big)/\mathrm{d}\tau = 0. \tag{33}$$

This yields a simple form of the continuation relation for $A(\tau)$ along the ray:

$$A(\tau) = \left[\frac{\rho(\tau_0)\det \hat{\mathbf{Q}}(\tau_0)}{\rho(\tau)\det \hat{\mathbf{Q}}(\tau)}\right]^{1/2} A(\tau_0). \tag{34}$$

We obtain another suitable continuation relation for amplitudes along the ray by introducing a special local Cartesian coordinate system y_1, y_2, y_3, varying along the ray. We call it the *wavefront orthonormal coordinate system*. At any point of the ray specified by $\gamma_3 = \tau$, the y_3 axis is parallel to slowness vector $\mathbf{p}$, and the y_1, y_2 axes are confined to the plane tangential to the wavefront at $\gamma_3 = \tau$. Axes y_1 and y_2 are mutually perpendicular. If we denote the 3×3 transformation matrix from ray coordinates to wavefront orthonormal coordinates by $\hat{\mathbf{Q}}^{(y)}$, then

$$\det \hat{\mathbf{Q}}(\tau) = \det \hat{\mathbf{Q}}^{(y)}(\tau) = \mathcal{C}(\tau)\det \mathbf{Q}^{(y)}(\tau). \tag{35}$$

Here $\mathcal{C}(\tau)$ is the phase velocity, and $\mathbf{Q}^{(y)}(\tau)$ is the 2×2 upper-left submatrix of $\hat{\mathbf{Q}}^{(y)}(\tau)$. Using Equation 35 in Equation 34, we obtain the continuation relation in an alternative form:

$$A(\tau) = \left[\frac{\rho(\tau_0)\mathcal{C}(\tau_0)\det \mathbf{Q}^{(y)}(\tau_0)}{\rho(\tau)\mathcal{C}(\tau)\det \mathbf{Q}^{(y)}(\tau)}\right]^{1/2} A(\tau_0). \tag{36}$$

An important property of continuation relation (36) is that $\det \mathbf{Q}^{(y)}(\tau)$ is uniquely determined by coordinates y_1 and y_2, confined to the plane tangential to the wavefront at τ. Thus, Equation 36 remains valid for any coordinate systems q_i (even nonorthogonal), in which mutually perpendicular coordinate axes q_1 and q_2 are confined to the plane tangential to the wavefront, but the axis q_3 is taken in a different way than y_3, for example along the ray. This is, e.g., the case of the well-known *ray-centered coordinate system* q_1, q_2, q_3. We have $\det \mathbf{Q}^{(q)}(\tau) = \det \mathbf{Q}^{(y)}(\tau)$.

Transport equations for P and S waves in isotropic media may be also expressed in the form of Equation 31. The expression is straightforward for P waves. For S waves, transport equations for scalar amplitudes B and C in Equation 20 are generally coupled. They decouple only if the unit vectors $\mathbf{g}^{(1)}$ and $\mathbf{g}^{(2)}$ in Equation 20 satisfy the following relation along the ray:

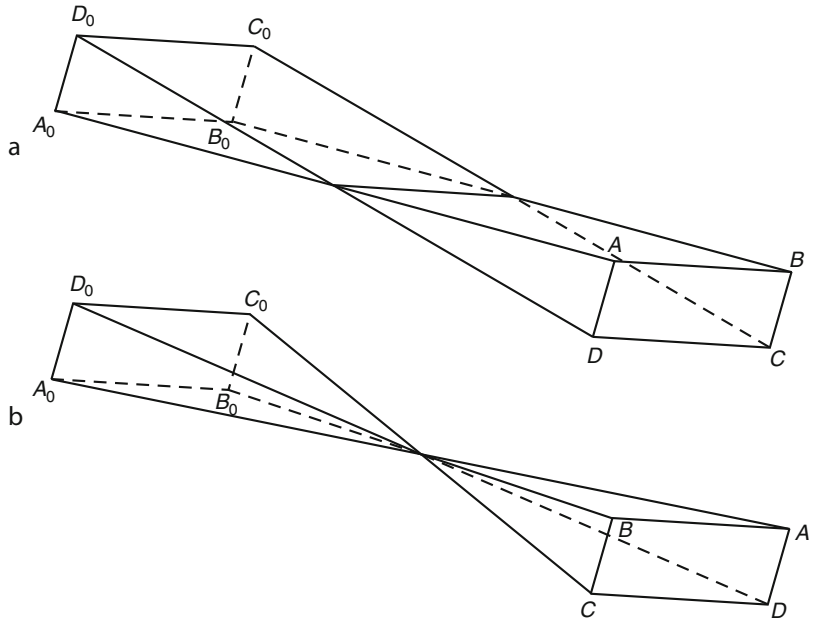
$$\mathrm{d}\mathbf{g}^{(M)}/\mathrm{d}\tau = (\mathbf{g}^{(M)} \cdot \nabla\beta)\mathbf{n}, \quad M = 1, 2. \tag{37}$$

In the terminology of the Riemanian geometry, vector $\mathbf{g}^{(M)}$ satisfying Equation 37 is transported parallelly along the ray. If $\mathbf{g}^{(1)}$ and $\mathbf{g}^{(2)}$ are chosen as mutually perpendicular and perpendicular to $\mathbf{n}$ at one point of the ray, Equation 37 guarantees that they have these properties at any point of the ray. Consequently, $\mathbf{g}^{(1)}$ and $\mathbf{g}^{(2)}$ are always perpendicular to the ray and do not rotate around it as the S wave progresses. As $\mathbf{g}^{(1)}$, $\mathbf{g}^{(2)}$ and $\mathbf{n}$ are always orthonormal, and $\mathbf{n}$ is known at any point of the ray, it is not necessary to use Equation 37 to compute both vectors $\mathbf{g}^{(M)}$. One of them can be determined from the orthonormality condition, once the other has been computed using Equation 37.

Quantity $\det \hat{\mathbf{Q}}(\tau)$ in Equation 34 may be zero at some point $\tau = \tau^C$. This means that the cross-sectional area of the ray tube shrinks to zero at $\tau = \tau^C$. The relevant point $\tau = \tau^C$ of the ray is called the *caustic point*. At the caustic point, the ray solution is singular and yields an infinite amplitude there. In passing through the caustic point τ^C along the ray, the argument of $[\det \hat{\mathbf{Q}}(\tau)]^{1/2}$ may change by $\pm\pi/2$ or $\pm\pi$ (Kravtsov and Orlov, 1999). The former case corresponds to the caustic point of the first order, see Figure 3a, during which the ray tube shrinks to an elementary arc, the latter case corresponds to the caustic point of the second order, see Figure 3b, during which the ray tube shrinks to a point. It is common to introduce the *phase shift due to caustic* $T^C(\tau, \tau_0)$ using the relation

$$\left[\frac{\det \hat{\mathbf{Q}}(\tau_0)}{\det \hat{\mathbf{Q}}(\tau)}\right]^{1/2} = \left|\frac{\det \hat{\mathbf{Q}}(\tau_0)}{\det \hat{\mathbf{Q}}(\tau)}\right|^{1/2} \exp[\mathrm{i}T^C(\tau, \tau_0)] \tag{38}$$

if caustic point τ^C is situated between τ_0 and τ. The phase shift due to the caustic is cumulative. If the ray passes through several caustic points along the ray between τ_0 and τ, the phase shift due to caustics is the sum of the individual phase shifts. It is often expressed in the form $T^C(\tau, \tau_0) = -\frac{1}{2}\pi k(\tau, \tau_0)$, where $k(\tau, \tau_0)$ is an integer,



Seismic, Ray Theory, Figure 3 Caustic points of (**a**) the first order and (**b**) second order. (Figure 3.13 of Červený, 2001.)

called the KMAH index (to acknowledge the work by - Keller, Maslov, Arnold and Hörmander in this field). The continuation relation for ray-theory amplitudes (34) can then be modified to read:

$$A(\tau) = \left(\frac{\rho(\tau_0)|\det \hat{\mathbf{Q}}(\tau_0)|}{\rho(\tau)|\det \hat{\mathbf{Q}}(\tau)|} \right)^{1/2} \exp[\mathrm{i}T^C(\tau, \tau_0)] A(\tau_0). \tag{39}$$

Equation 36 can be transformed to the analogous form as Equation 39 as the zeros of $\det \mathbf{Q}^{(\gamma)}(\tau)$ are situated at the same points τ^C on the ray as the zeros of $\det \hat{\mathbf{Q}}(\tau)$.

The KMAH index can be calculated along the ray as a byproduct of dynamic ray tracing. For detailed derivations and discussion see Bakker (1998) and Klimeš (2010).

There are some differences between the KMAH indices along the rays in isotropic and anisotropic media. In isotropic media, the KMAH index always increases when the ray passes through a new caustic point, either by one or two. In anisotropic media, however, it may also decrease by one or two at some caustic points. This happens only for S waves as a consequence of the concave form of the slowness surface of the corresponding S wave.

Dynamic ray tracing. Paraxial approximations

As we can see in Equation 34, the computation of the ray-theory amplitudes requires knowledge of $\det \hat{\mathbf{Q}}$, where $\hat{\mathbf{Q}}(\tau)$ characterizes the properties of the ray field in the vicinity of the ray under consideration. $\hat{\mathbf{Q}}(\tau)$ can be computed by the procedure called *dynamic* (or paraxial) *ray tracing*. In addition to $\hat{\mathbf{Q}}(\tau)$ with elements $Q_{ij}(\tau) = \partial x_i / \partial \gamma_j$, we also have to introduce a new 3×3 matrix $\hat{\mathbf{P}}(\tau)$ with elements $P_{ij}(\tau) = \partial p_i / \partial \gamma_j$. The equation for P_{ij} must be included to obtain the linear dynamic ray tracing system. Differentiating ray tracing equations (25) with respect to γ_j, we can easily obtain a system of linear ordinary differential equations of the first order for Q_{ij} and P_{ij},

$$\begin{aligned} \frac{\mathrm{d}Q_{ij}}{\mathrm{d}\tau} &= \frac{\partial^2 \mathcal{H}}{\partial p_i \partial x_k} Q_{kj} + \frac{\partial^2 \mathcal{H}}{\partial p_i \partial p_k} P_{kj}, \\ \frac{\mathrm{d}P_{ij}}{\mathrm{d}\tau} &= -\frac{\partial^2 \mathcal{H}}{\partial x_i \partial x_k} Q_{kj} - \frac{\partial^2 \mathcal{H}}{\partial x_i \partial p_k} P_{kj}, \end{aligned} \tag{40}$$

see Červený (1972). This system is usually called the *dynamic ray tracing system*, and the relevant procedure dynamic ray tracing. It can be solved along a given ray Ω, or together with it.

The dynamic ray tracing system (40) may be expressed in various forms. Instead of Cartesian coordinates x_i, we can use the wavefront orthonormal coordinates y_i, or the ray-centered coordinates q_i. Then, instead of the 3×3 matrices $\hat{\mathbf{Q}}$ and $\hat{\mathbf{P}}$, it is sufficient to seek the 2×2 matrices $\mathbf{Q}^{(y)}$, $\mathbf{P}^{(y)}$ or $\mathbf{Q}^{(q)}$, $\mathbf{P}^{(q)}$. This reduces the number of DRT equations, but complicates their right-hand sides (Červený 2001, sect. 4.2).

As the dynamic ray tracing system (40) is of the first order and linear, we can compute its fundamental matrix consisting of six linearly independent solutions. The 6×6 fundamental matrix of system (40) specified by the 6×6 identity matrix at an arbitrary point $\tau = \tau_0$ of the ray is called the *ray propagator matrix* and denoted by $\mathbf{\Pi}(\tau, \tau_0)$.

The 6×6 ray propagator matrix $\mathbf{\Pi}(\tau, \tau_0)$ is symplectic:

$$\mathbf{\Pi}^T(\tau, \tau_0)\mathbf{J}\mathbf{\Pi}(\tau, \tau_0) = \mathbf{J}, \quad \text{with } \mathbf{J} = \begin{pmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{I} & \mathbf{0} \end{pmatrix} \tag{41}$$

If we know the matrices $\hat{\mathbf{Q}}(\tau_0)$, $\hat{\mathbf{P}}(\tau_0)$, we can compute $\hat{\mathbf{Q}}(\tau)$, $\hat{\mathbf{P}}(\tau)$ at any point τ of the ray by a simple matrix multiplication

$$\begin{pmatrix} \hat{\mathbf{Q}}(\tau) \\ \hat{\mathbf{P}}(\tau) \end{pmatrix} = \mathbf{\Pi}(\tau, \tau_0) \begin{pmatrix} \hat{\mathbf{Q}}(\tau_0) \\ \hat{\mathbf{P}}(\tau_0) \end{pmatrix}. \tag{42}$$

The ray propagator matrix $\mathbf{\Pi}(\tau, \tau_0)$ satisfies the chain rule, $\mathbf{\Pi}(\tau, \tau_0) = \mathbf{\Pi}(\tau, \tau_1)\mathbf{\Pi}(\tau_1, \tau_0)$, where point τ_1 is situated arbitrarily on the ray. It is simple to compute the inverse of $\mathbf{\Pi}(\tau, \tau_0)$: $\mathbf{\Pi}^{-1}(\tau, \tau_0) = \mathbf{\Pi}(\tau_0, \tau)$. We can express $\mathbf{\Pi}(\tau, \tau_0)$ in the following way:

$$\mathbf{\Pi}(\tau, \tau_0) = \begin{pmatrix} \hat{\mathbf{Q}}_1(\tau, \tau_0) & \hat{\mathbf{Q}}_2(\tau, \tau_0) \\ \hat{\mathbf{P}}_1(\tau, \tau_0) & \hat{\mathbf{P}}_2(\tau, \tau_0) \end{pmatrix}, \tag{43}$$

where $\hat{\mathbf{Q}}_1(\tau, \tau_0), \hat{\mathbf{Q}}_2(\tau, \tau_0), \hat{\mathbf{P}}_1(\tau, \tau_0)$ and $\hat{\mathbf{P}}_2(\tau, \tau_0)$ are 3×3 matrices.

Equation 42 can be used to obtain a very important quantity – the 3×3 matrix $\hat{\mathbf{M}}(\tau)$ of second derivatives of the travel-time field with respect to Cartesian coordinates, with elements $M_{ij} = \partial^2 T / \partial x_i \partial x_j$:

$$\hat{\mathbf{M}}(\tau) = \hat{\mathbf{P}}(\tau)(\hat{\mathbf{Q}}(\tau))^{-1}. \tag{44}$$

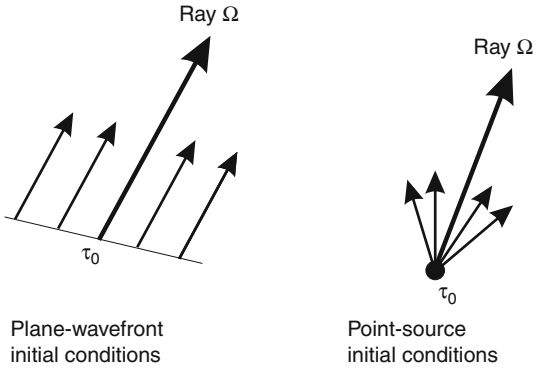
Matrix $\hat{\mathbf{M}}(\tau)$ plays an important role in the computation of travel time not only along the ray Ω, but also in its "quadratic" paraxial vicinity:

$$T(\mathbf{x}) = T(\mathbf{x}^\Omega) + (\mathbf{x} - \mathbf{x}^\Omega)^T \mathbf{p}(\tau) + \frac{1}{2}(\mathbf{x} - \mathbf{x}^\Omega)^T \hat{\mathbf{M}}(\tau)(\mathbf{x} - \mathbf{x}^\Omega). \tag{45}$$

In Equation 45, $\mathbf{x}$ denotes an arbitrary point in the paraxial vicinity of the ray Ω, close to point $\mathbf{x}^\Omega = \mathbf{x}^\Omega(\tau)$ on the ray Ω; slowness vector $\mathbf{p}(\tau)$ and the matrix $\hat{\mathbf{M}}(\tau)$ are given at $\mathbf{x}^\Omega$. The possibility of computing the travel time in the paraxial vicinity of the ray has many important applications.

The properties of the 6×6 ray propagator matrix $\mathbf{\Pi}(\tau, \tau_0)$ described above remain valid even for the 4×4 ray propagator matrices $\mathbf{\Pi}^{(y)}(\tau, \tau_0)$ or $\mathbf{\Pi}^{(q)}(\tau, \tau_0)$ expressed in wavefront orthonormal coordinates y_i or ray-centered coordinates q_i. The ray propagator matrices $\mathbf{\Pi}^{(y)}(\tau, \tau_0)$ and $\mathbf{\Pi}^{(q)}(\tau, \tau_0)$ are identical, therefore, they can be expressed in terms of the same 2×2 matrices $\mathbf{Q}_1(\tau, \tau_0)$, $\mathbf{Q}_2(\tau, \tau_0)$, $\mathbf{P}_1(\tau, \tau_0)$ and $\mathbf{P}_2(\tau, \tau_0)$. Matrices $\mathbf{Q}_1(\tau, \tau_0), \mathbf{P}_1(\tau, \tau_0)$ correspond to the plane-wavefront initial conditions at τ_0, and matrices $\mathbf{Q}_2(\tau, \tau_0), \mathbf{P}_2(\tau, \tau_0)$ to the point-source initial conditions at τ_0, see Figure 4. The 2×2 matrix $\mathbf{Q}_2(\tau, \tau_0)$ plays an important role in computing the ray-theory Green function. The quantity

$$\mathcal{L}(\tau, \tau_0) = |\det \mathbf{Q}_2(\tau, \tau_0)|^{1/2} \tag{46}$$



Seismic, Ray Theory, Figure 4 Plane-wavefront and point-source initial conditions for dynamic ray tracing. In anisotropic media, rays are not perpendicular to the wavefront.

is called the *relative geometrical spreading*. It corresponds to a point source.

As in Equation 44, we can define the 2×2 matrix of the second derivatives of the travel-time field with respect to y_1, y_2 or q_1, q_2 as follows:

$$\mathbf{M}(\tau) = \mathbf{P}(\tau)(\mathbf{Q}(\tau))^{-1}. \tag{47}$$

We will now briefly summarize several useful ray-theory quantities and applications, which rely fully or partly on dynamic ray tracing. For derivations and more detailed explanations, see Červený (2001, Chap. 4), where also many other applications and references can be found: (1) Paraxial travel times. (2) Paraxial slowness vectors. (3) Paraxial rays. (4) Curvature of the wavefront. (5) Matrix of geometrical spreading $\hat{\mathbf{Q}}$ and the relevant matrix $\hat{\mathbf{P}}$. (6) Continuation relations for ray-theory amplitudes along the ray. (7) Relative geometrical spreading. (8) Phase shift due to caustics. (9) Ray-theory elastodynamic Green function. (10) Higher-order spatial derivatives of the travel-time field. (11) Fresnel volumes and Fresnel zones. (12) Surface-to-surface propagator matrix. (13) Boundary-value problems in four-parametric system of paraxial rays, including two-point ray tracing. (14) Factorization of the geometrical spreading.

Dynamic ray tracing is also needed in the investigation of ray chaos and in computations of Lyapunov exponents, in the ray-perturbation methods and in modifications and extensions of the ray method such as Maslov method, Gaussian beam and Gaussian packet summation methods, in Kirchhoff-Helmholtz method and in various diffraction methods.

Coupling ray theory for S waves in anisotropic media

In inhomogeneous weakly anisotropic media, the standard ray theory described above yields distorted results since it is unable to describe the coupling of S1 and S2 waves propagating with approximately equal phase velocities. This problem can be removed by using the coupling ray

theory. In the coupling ray theory, the amplitudes of the two S waves can be computed along a trajectory called the *common ray* (Bakker, 2002; Klimeš, 2006). The closer the common ray approximates actual S-wave rays, the more accurate results the coupling ray theory yields. The common rays can be constructed in a reference isotropic medium or in the actual anisotropic medium. A convenient option is to compute common rays using ray tracing equations (25) with the Hamiltonian given as

$$\mathcal{H}(x_i, p_j) = \frac{1}{4}[G_1(x_i, p_j) + G_2(x_i, p_j)]. \tag{48}$$

In Equation 48, G_1 and G_2 are eigenvalues of the Christoffel matrix $\mathbf{\Gamma}$, see equation (7), corresponding to S1 and S2 waves.

The coupling ray theory solution is sought in the form (Coates and Chapman, 1990; Bulant and Klimeš, 2002):

$$\begin{aligned}\mathbf{u}(\tau, t) = A(\tau)[r_1(\tau)\mathbf{g}^{(1)}(\tau)\exp(\mathrm{i}\omega\tau_1) \\ + r_2(\tau)\mathbf{g}^{(2)}(\tau)exp(\mathrm{i}\omega\tau_2)]\exp(-\mathrm{i}\omega t).\end{aligned} \tag{49}$$

Here, $A(\tau)$ is the scalar amplitude (34) or (36) calculated along the common ray. The symbols $\mathbf{g}^{(1)}$ and $\mathbf{g}^{(2)}$ denote the S-wave eigenvectors of the generalized Christoffel matrix $\Gamma(x_i, p_j)$ calculated along the common ray. The travel times τ_1 and τ_2 are travel times corresponding to the above vectors $\mathbf{g}^{(1)}$ and $\mathbf{g}^{(2)}$. They can be obtained by quadratures along the common ray:

$$\begin{aligned}\mathrm{d}\tau_1/\mathrm{d}\tau &= [\Gamma_{ik} g_i^{(1)} g_k^{(1)}]^{-1/2}, \\ \mathrm{d}\tau_2/\mathrm{d}\tau &= [\Gamma_{ik} g_i^{(2)} g_k^{(2)}]^{-1/2}.\end{aligned} \tag{50}$$

The amplitude factors r_1 and r_2 are solutions of two coupled ordinary differential equations (Coates and Chapman, 1990):

$$\begin{pmatrix}\mathrm{d}r_1/\mathrm{d}\tau \\ \mathrm{d}r_2/\mathrm{d}\tau\end{pmatrix} = \frac{\mathrm{d}\varphi}{\mathrm{d}\tau}\begin{pmatrix}0 & \exp(\mathrm{i}\omega[\tau_2(\tau)-\tau_1(\tau)]) \\ -\exp(\mathrm{i}\omega[\tau_1(\tau)-\tau_2(\tau)]) & 0\end{pmatrix}\begin{pmatrix}r_1 \\ r_2\end{pmatrix}, \tag{51}$$

where the angular velocity $\mathrm{d}\varphi/\mathrm{d}\tau$ of the rotation of the eigenvectors $\mathbf{g}^{(1)}$ and $\mathbf{g}^{(2)}$ is given by

$$\frac{\mathrm{d}\varphi}{\mathrm{d}\tau} = \mathbf{g}^{(2)}\frac{\mathrm{d}\mathbf{g}^{(1)}}{\mathrm{d}\tau} = -\mathbf{g}^{(1)}\frac{\mathrm{d}\mathbf{g}^{(2)}}{\mathrm{d}\tau}. \tag{52}$$

For detailed description of the algorithm, see Bulant and Klimeš (2002).

There are many possible modifications and approximations of the coupling ray theory. In some of them, the amplitude vector $\mathbf{U}$ of coupled S waves is sought along the common ray in the form of Equation 20, in which the amplitude factors B and C can be expressed as

$$B(\tau) = A(\tau)\mathcal{B}(\tau) \qquad C(\tau) = A(\tau)\mathcal{C}(\tau). \tag{53}$$

In Equations 53, $A(\tau)$ is again the scalar ray amplitude, see equation (34) or (36), calculated along the common S-wave ray. There are many ways how to evaluate factors $\mathcal{B}$ and $\mathcal{C}$ (Kravtsov, 1968; Pšenčík, 1998; Červený et al., 2007). Here we present a combination of coupling ray theory and of the first-order ray tracing (Farra and Pšenčík, 2010). In the approximation of Farra and Pšenčík (2010), the common ray is obtained as the first-order ray, see section on ray perturbation methods. The vectors $\mathbf{g}^{(K)}$, appearing in Equation 20, specify the first-order approximation of the S-wave polarization plane. The factors $\mathcal{B}$ and $\mathcal{C}$ in Equations 53 are then obtained as a solution of two coupled ordinary differential equations, which result from the corresponding two coupled transport equations:

$$\begin{pmatrix}\mathrm{d}\mathcal{B}/\mathrm{d}\tau \\ \mathrm{d}\mathcal{C}/\mathrm{d}\tau\end{pmatrix} = -\frac{\mathrm{i}\omega}{2}\begin{pmatrix}\mathcal{M}_{11}-1 & \mathcal{M}_{12} \\ \mathcal{M}_{12} & \mathcal{M}_{22}-1\end{pmatrix}\begin{pmatrix}\mathcal{B} \\ \mathcal{C}\end{pmatrix}. \tag{54}$$

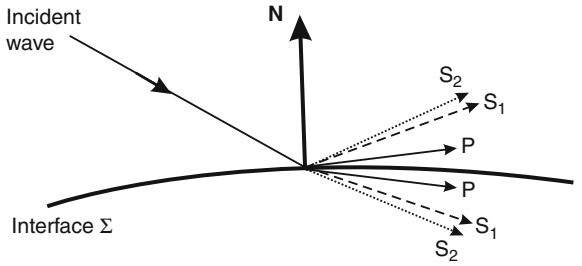
Evaluation of the matrix $\boldsymbol{\mathcal{M}}$ with elements $\mathcal{M}_{IJ}$ is simple (see Farra and Pšenčík (2010); Equations 20 and 7).

The resulting equations reduce to standard ray-theory equations in inhomogeneous isotropic media, they describe properly S-wave coupling in inhomogeneous weakly anisotropic media and even yield separate S waves when anisotropy is stronger. Common S-wave rays are regular everywhere. They do not suffer from problems well known from tracing rays of individual S waves in anisotropic media and are suitable for investigating shear-wave splitting.

Effects of structural interfaces

Assume that the ray is incident on a curved structural interface. If we wish to continue the ray computations for the reflected, transmitted, monotypic or converted waves, see Figure 5, we have to use relevant transformation relations for the ray tracing system, dynamic ray tracing system and for the ray theory amplitudes at the interface.

The transformation relations for ray tracing and dynamic ray tracing systems at interfaces are well known (Červený, 2001). For the sake of brevity, we do not present them here. We shall, however, discuss the transformation of amplitudes. In the zero-order ray approximation, the transformation of ray-theory amplitudes across an interface is described by plane-wave reflection/transmission coefficients. In other words, amplitudes of generated waves do not depend on the curvature of the wavefront of the incident wave and the curvature of the interface at the point of incidence Q. Neither do they depend on the gradients of the density and on gradients of the density-normalized elastic moduli at Q, on both sides of the interface. They depend only on the local values of the density and density-normalized elastic moduli at Q (on both sides of the interface) and on the angle of incidence (the acute angle between the slowness vector of the incident wave and the normal to the interface $\mathbf{N}$ at the point of incidence Q).



Seismic, Ray Theory, Figure 5 Slowness vectors of P, S1 and S2 waves generated at the point of incidence Q of a curved interface separating two inhomogeneous anisotropic media. All slowness vectors at Q are situated in the plane of incidence specified by the slowness vector of the incident wave and the normal to the interface **N** at Q. Ray-velocity vectors (tangent to rays) of individual waves at Q are, in general, not confined to the plane of incidence. In isotropic media, instead of reflected and transmitted S1 and S2 waves, single reflected and transmitted S waves are generated. In inhomogeneous weakly anisotropic media, single coupled S waves are generated. Ray-velocity vectors of individual waves at Q are situated in the plane of incidence in isotropic media.

Various types of R/T coefficients may be used. The displacement R/T coefficients are used most frequently (Aki and Richards, 1980; Červený et al., 1977 for isotropic media; Fedorov, 1968 for anisotropic media). Very useful are the energy R/T coefficients, as they are reciprocal. The relation between the energy R/T coefficient $\mathcal{R}(Q)$ and the displacement R/T coefficient $R(Q)$ is as follows:

$$\mathcal{R}(Q) = R(Q)\left[\frac{\rho(\tilde{Q})\mathcal{U}_n(\tilde{Q})}{\rho(Q)\mathcal{U}_n(Q)}\right]^{1/2} \tag{55}$$

(Červený 2001, sect. 5.4.3). Here Q is the point of incidence, and $\tilde{Q}$ the relevant initial point of the R/T wave, both points being, of course, identical. $\mathcal{U}_n$ is the normal component (perpendicular to the interface) of the ray-velocity vector. We further introduce the complete energy R/T coefficients $\mathcal{R}^C$ along the ray using the relation

$$\mathcal{R}^C = \prod_{k=1}^{N} \mathcal{R}(Q_k). \tag{56}$$

The complete energy R/T coefficient $\mathcal{R}^C$ corresponds to the ray which interacts N-times with interfaces (at points of incidence $Q_1, Q_2, ..., Q_N$) between the initial and end point of the ray.

Generalization of the continuation relation (36) for the ray-theory amplitudes along the ray situated in a laterally varying anisotropic medium containing curved interfaces then reads:

$$A(\tau) = \left(\frac{\rho(\tau_0)\mathcal{C}(\tau_0)|\det \mathbf{Q}^{(y)}(\tau_0)|}{\rho(\tau)\mathcal{C}(\tau)|\det \mathbf{Q}^{(y)}(\tau)|}\right)^{1/2} \mathcal{R}^C \exp[\mathrm{i}T^C(\tau,\tau_0)]A(\tau_0). \tag{57}$$

In seismic prospecting, in the technique called *amplitude variation with offset* (AVO), it is common to work with the so-called *weak-contrast R/T coefficients*. They are linearized versions of exact R/T displacement coefficients. Linearization is mostly made with respect to the contrasts of the density and elastic moduli across the interface. There is a great variety of linearized formulae depending on the type of media surrounding the interface (isotropic, anisotropic), strength of anisotropy (weak, strong), etc. The coefficients yield reasonable approximation in the vicinity of normal incidence. For increasing incidence angles, their accuracy decreases. The advantage of the weak-contrast coefficients is their simplicity and the possibility of expressing them in explicit form. The effects of the individual medium parameters on the coefficients can than be easily evaluated.

Ray-theory elastodynamic Green function

The elastodynamic Green function $G_{in}(R,t,S,t_0)$ represents the i-th Cartesian component of the displacement vector at location R and time t, due to a single-force point source situated at location S and oriented along the n-th Cartesian axis, with the time dependence $\delta(t-t_0)$. We introduce quite analogously the ray-theory elastodynamic Green function, with only two differences. The first difference is that ray-theory Green function is defined as a sum of *elementary ray-theory Green functions* computed along rays of selected elementary waves (direct, multiply reflected/transmitted, etc.). The second difference is that the elementary ray-theory Green functions are not exact, but only zero-order ray approximations.

In the frequency domain the elementary ray-theory elastodynamic Green function $G_{in}(R,S,\omega)$ for $t_0 = 0$ reads:

$$G_{in}(R,S,\omega) = \frac{g_n(S)g_i(R)\exp[\mathrm{i}T^G(R,S) + \mathrm{i}\omega T(R,S)]}{4\pi[\rho(S)\rho(R)\mathcal{C}(S)\mathcal{C}(R)]^{1/2}\mathcal{L}(R,S)}\,\mathcal{R}^C. \tag{58}$$

Here $\mathcal{L}(R,S)$ is the relative geometrical spreading, given by Equation 46, $g_i(R)$ and $g_n(S)$ are the eigenvectors of the generalized Christoffel matrix at R and S (polarization vectors corresponding to the considered elementary wave), T is the travel time along the ray from S to R, $\mathcal{R}^C$ the complete energy R/T coefficient resulting from interactions of the ray under consideration with interfaces between S and R, and $T^G(R,S)$ the complete phase shift due to caustics along the ray between S and R. The relevant KMAH index in anisotropic media may also include a contribution at a point source S (if the slowness surface of the considered wave is concave at S). In isotropic media, this contribution is always zero.

The complete energy R/T coefficient $\mathcal{R}^C$, the travel time $T(R,S)$, the relative geometrical spreading $\mathcal{L}(R,S)$ and the complete phase shift due to caustics are always reciprocal. Consequently, the elementary ray-theory

elastodynamic Green function satisfies a very important property of reciprocity:

$$G_{in}(R,S,\omega) = G_{ni}(S,R,\omega). \tag{59}$$

This relation is valid for any elementary seismic body wave generated by a point source.

For elementary ray-theory Green functions in inhomogeneous weakly anisotropic media see Pšenčík (1998).

Chaotic rays. Lyapunov exponents

In homogeneous media, geometrical spreading increases linearly with increasing length of the ray. In heterogeneous media, behavior of geometrical spreading is more complicated, and depends considerably on the degree of heterogeneity of the medium. In models, in which the heterogeneity exceeds certain degree, average geometrical spreading increases exponentially with increasing length of the ray. Rays in such a medium often exhibit chaotic behavior, which is characterized by a strong sensitivity of rays to the initial ray data (for example, to ray parameters). The rays with only slightly differing ray data at an initial point tend to diverge *exponentially* at large distances from the initial point. Consequently, the rays intersect many times and many rays pass through the same point. With such *chaotic rays*, two-point ray tracing is practically impossible, and the ray tubes are not narrow enough for travel time interpolation. The chaotic behavior of rays increases with increasing length of rays and prevents applicability of the ray theory.

The exponential divergence of chaotic rays in the phase space (the space formed by spatial coordinates x_i and slowness-vector components p_j) can be quantified by the so-called *Lyapunov exponents*. They may be introduced in several ways. It is common to express them in terms of characteristic values of the ray propagator matrix. The relevant expressions for the Lyapunov exponents and several numerical examples for 2D models without interfaces can be found in Klimeš (2002a). See also Červený et al. (2007), where other references can be found.

The estimate of the Lyapunov exponent of a single finite ray depends on its position and direction. The Lyapunov exponents associated with rays of different positions and directions can be used to calculate *average Lyapunov exponents* for the model. The average Lyapunov exponents play a very important role in smoothing the models so that they are suitable for ray tracing (Červený et al., 2007).

Ray perturbation methods

Ray perturbation methods represent an important part of the ray theory. They can be used for approximate but fast and transparent solutions of forward problems in complicated models. They play even more important role in the inverse problems.

Ray perturbation methods are useful everywhere, where we wish to compute the wavefield or its constituents (travel times, amplitudes, polarization) in complicated models, which deviate only little from simple, *reference models*, for which computations are simpler. The solutions for complicated models are then sought as perturbations of simpler solutions for the reference models. Examples are computations in weakly anisotropic media, which use an isotropic medium as reference, or in weakly dissipative media, which use a perfectly elastic medium as reference. Basic role in these approaches is played by *reference rays* traced in reference media. Solutions in perturbed media can be given in the form of a power series in the deviations of the perturbed and reference models. Mostly, the *first-order approximation*, i.e. the first term of the power series, is used.

The most frequent application of ray perturbation methods is in travel-time computations. First-order travel-time perturbation formulae for isotropic media are known and have been used (mostly in tomography) for several decades. Well known and broadly applied are also first-order travel-time formulae for anisotropic media (Červený and Jech, 1982; Hanyga, 1982; Červený, 2001, sect. 3.9). Travel-time perturbations are obtained by quadratures along reference rays. As integration parameters, the parameters along reference rays are used.

Recently, several procedures for computation of higher-order travel-time perturbations for weakly anisotropic media (note that anisotropy of the Earth is mostly weak) were proposed. The procedure based on the so-called perturbation Hamiltonians (Klimeš, 2002b; Červený et al., 2007) allows computation of highly accurate travel times along a fixed reference ray in a reference medium. Another procedure is based on the so-called first-order ray tracing described briefly below. In the latter method, second-order travel-time perturbations can be calculated along first-order rays.

Relatively recent is the use of ray perturbation methods in *first-order ray tracing* and *first-order dynamic ray tracing* (Pšenčík and Farra, 2007; Farra and Pšenčík, 2010). It allows to compute, approximately, not only rays and travel times, but whole wavefields. To derive first-order ray tracing and dynamic ray tracing, the perturbation approach is used in which deviations of anisotropy from isotropy are considered to be of the first order. Then it is just sufficient to use Equations 25 and 40 with Equation 21, in which the exact eigenvalue G_m is replaced by its first-order approximation. The resulting ray tracing provides first-order rays, first-order travel times and the first-order geometrical spreading. By simple quadratures along first-order rays, second-order travel-time corrections can be computed. This approach is applicable to P and S waves. In case of S waves, it can include the computation of coupling effects. First-order ray tracing and dynamic ray tracing are used in this case for computing common rays, first-order travel times and geometrical spreading along them, using the Hamiltonian (48). The wavefield of S waves is obtained by solving second-order coupling equations along the common rays. The procedure yields standard ray-theory results for S waves propagating in isotropic

media, and approximate results in anisotropic media when the S waves are coupled or even decoupled.

Ray perturbation method for weakly dissipative media

In viscoelastic media, the density-normalized stiffness tensor a_{ijkl} is complex valued:

$$a_{ijkl}(x_n) = a^R_{ijkl}(x_n) - \mathrm{i}a^I_{ijkl}(x_n). \tag{60}$$

If a^I_{ijkl} is small, the viscoelastic medium can be considered as a perturbation of a perfectly elastic medium (Červený, 2001, sect. 5.5.3) which has a form of the imaginary-valued term $-\mathrm{i}a^I_{ijkl}$. Reference ray in the reference perfectly elastic medium and corresponding real-valued travel time T along the reference ray between points S and R can be obtained by standard ray tracing in perfectly elastic media. The imaginary travel time T^I (travel-time perturbation due to $-\mathrm{i}a^I_{ijkl}$) can be then obtained by quadratures along the reference ray:

$$T^I = \frac{1}{2}\int_S^R Q^{-1}(\tau)\mathrm{d}\tau. \tag{61}$$

The quantity Q in Equation 61 is a direction-dependent *quality factor* for anisotropic media, corresponding to the Hamiltonian (21):

$$Q^{-1} = a^I_{ijkl}p_j p_l g_i g_k. \tag{62}$$

For general Hamiltonians, the quality factor Q is given by the relation $Q^{-1} = -\mathrm{Im}\mathcal{H}(x_i, p_j)$.

The imaginary travel time T^I in Equation 61 is responsible for the exponential amplitude decay along the reference ray. For causal dissipation, the stiffness tensor (60) is frequency dependent. The above described perturbation approach is then equivalent to the perturbation scheme, in which $a^I_{ijkl}(x_n, \omega)$ is considered to be of the order of ω^{-1} for $\omega \to \infty$ (Kravtsov and Orlov, 1990; Gajewski and Pšenčík, 1992).

In an inhomogeneous isotropic, weakly dissipative medium, the expression (62) reduces to the well-known formula

$$Q^{-1} = -\mathrm{Im}V^2/\mathrm{Re}V^2 \doteq -2\mathrm{Im}V/\mathrm{Re}V, \tag{63}$$

in which V is the complex-valued velocity, $V = \alpha$ for P waves and $V = \beta$ for S waves. Complex-valued quantities α and β are generalizations (to the complex space) of real-valued α and β from Equation 14.

Concluding remarks. Applications, modifications, and extensions of the ray method

Seismic ray method has found broad applications both in global seismology and in seismic exploration. The advantages of the seismic ray method consist in its numerical efficiency, universality, conceptual clarity, and in its ability to investigate various seismic body waves independently of other waves. Although its accuracy is only limited, the seismic ray method is the only method which is able to give an approximate answer to many problems of high-frequency seismic body wave propagation in laterally varying, isotropic or anisotropic, perfectly elastic or dissipative, layered and block structures.

In classical global seismology, the seismic ray method has been traditionally used to study the internal structure of the whole Earth, assuming that the Earth is radially symmetric. The standard Earth's model, obtained in this way, is expressed in terms of distribution of elastic velocities as a function of depth.

At present, the applications of the seismic ray method are considerably broader. It is broadly used to study the 3-D local lateral inhomogeneities in the structure, the form and physical properties of structural interfaces, the local anisotropy, attenuation, etc. In addition to forward modeling, the ray perturbation methods are also broadly used for inversions based on measured travel times or whole waveforms. In lithospheric structural studies, particularly in crustal seismology, the ray-synthetic seismograms have been also often used for ultimate comparison with observed seismograms. The computation of ray-synthetic seismograms requires determination of not only travel times, but also ray-theory amplitudes and polarization of individual waves. Seismic ray method has also found broad applications in other branches of seismology. Very important examples are the localization of seismic sources and the simultaneous localization with structural inversion.

In most applications of the ray method in seismic exploration for oil, the use of local 3-D structures with structural curved interfaces is a necessity. Sophisticated algorithms have been developed and used to image the structures under consideration. At present, the most important role is played by migration algorithms. Seismic ray theory and its extensions have found important applications in these algorithms.

The ray method is not valid universally. We have briefly described three serious limitations of the ray method: (a) The ray method can be used only for high-frequency signals. (b) In models, in which heterogeneity of the medium exceeds certain degree, the ray field has chaotic character, particularly at large distances from the source. (c) The standard ray method cannot be used for computing S waves propagating in inhomogeneous, weakly anisotropic media. It must be replaced by the coupling ray theory. The coupling ray theory must be used even in moderately or strongly anisotropic media, in the vicinity of shear-wave singular directions.

The ray method fails, however, even in other singular situations. In smooth isotropic media, the most important type of singularity are *caustics*. Caustics may attain various forms. Various extensions of the ray method can be used to compute wavefields in caustic regions. These extensions are frequency dependent. See a detailed treatment of wavefields in caustic regions in Kravtsov and Orlov (1999), and also in Stamnes (1986). In models with

smooth structural interfaces, other singularities often appear. For edge and vertex points, see Ayzenberg et al. (2007). For critical singular regions, at which head waves separate from reflected waves, see Červený and Ravindra (1971). For the waves, whose rays are tangential to interfaces, see Thomson (1989).

Specific methods, designed for different types of singularities may be used for computing wavefields in singular regions. Disadvantage of these methods is that they are different for different singularities. Morever, singular regions often overlap, and the wavefield in the overlaping region requires again different treatment. It is desirable to have available a more general extension of the ray method, applicable uniformly in any of the mentioned singular regions, or, at least, in most of them. Such an extension would simplify ray computations considerably and could even lead to more accurate results.

Several such extensions of the ray method have been proposed. We do not describe them here in detail. Instead, we merely present references, in which more details and further references can be found. Let us mention the Maslov asymptotic ray theory introduced to seismology by Chapman and Drummond (1982), see also Thomson and Chapman (1985), Chapman (2004). Another extension of the ray method is based on the summation of Gaussian beams (Popov, 1982; Červený et al., 1982). For the relation of this method with the Maslov method see Klimeš (1984). The Gaussian beam summation method has found applications both in the forward modeling of seismic wavefields and in migrations in seismic exploration. It is closely related to the method of summation of Gaussian packets (Červený et al., 2007). Ray theory can be also used in the Born scattering theory (Chapman and Coates, 1994; Chapman, 2004). For waves reflected from a smooth structural interface separating two heterogeneous, isotropic or anisotropic media, the Kirchhoff surface integral method can be used. For details and many references see Chapman (2004, sect. 10.4). Another useful extension of the ray method is the one-way wave equation approach (Thomson, 1999).

Acknowledgments

The authors are very grateful to Luděk Klimeš and Ravi Kumar for valuable comments and recommendations. The research was supported by the consortium project Seismic Waves in Complex 3-D Structures, by research projects 205/07/0032 and 205/08/0332 of the Grant Agency of the Czech Republic; and by research project MSM0021620860 of the Ministry of Education of the Czech Republic.

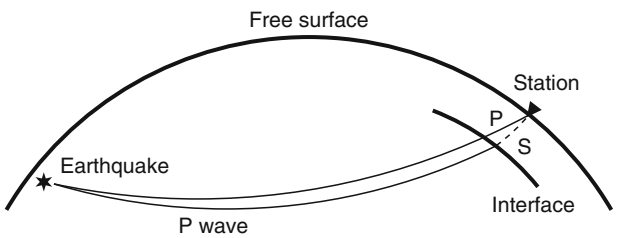
Receiver functions; Scattered teleseismic waves

Definition

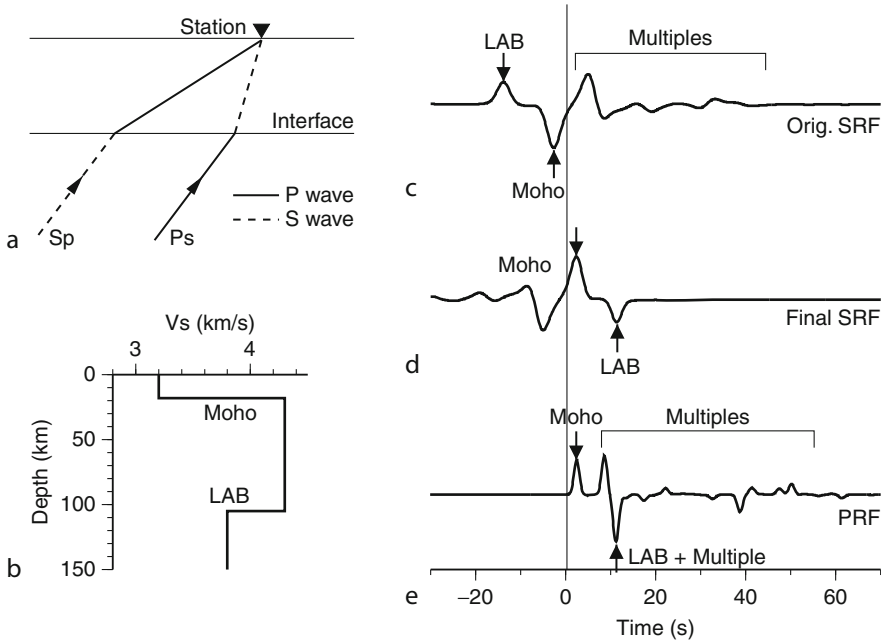
Receiver function. Response of the Earth's structure below seismic stations to incident teleseismic waves. Seismic discontinuities in the Earth's crust or upper mantle cause waves from distant earthquakes to be converted from P to S waves or vice versa, or to be multiply reflected between discontinuities before arriving the stations. Such scattered waves carry information about the seismic structure of the lithosphere and upper mantle. Scattered waves are weak signals and summation of many records is usually required to visualize the useful information.

Receiver function technique

If a seismic wave hits a discontinuity between two solid materials with different physical parameters, a part of the wave will be reflected and another part will be transmitted. There is also mode conversion between compressional (P) waves and shear (S) waves (see *Energy Partitioning of Seismic Waves*). Therefore, a P wave crossing a discontinuity will generate an S wave (called Ps), which will follow the P wave with a slower speed; and an S wave will produce a P wave (called Sp), which will run ahead of the S wave with a faster speed. If these wave types are recorded at the surface and their incidence angles and the material velocities are known, the depth of the discontinuity, where they are generated can be determined from the differential times of the two seismic phases, mother phase



Seismic, Receiver Function Technique, Figure 1 P receiver function geometry. The target zone below the three-component receiver is illuminated from below. The source is an earthquake at a large epicentral distance. When a plane P wave encounters interfaces below the receiver, Ps waves are generated. The incidence angle of the P wave is always bigger than that of the Ps waves. The travel path of S receiver functions (SRFs) is very similar, except that the incidence angle of the S wave is smaller than that of the Sp wave.

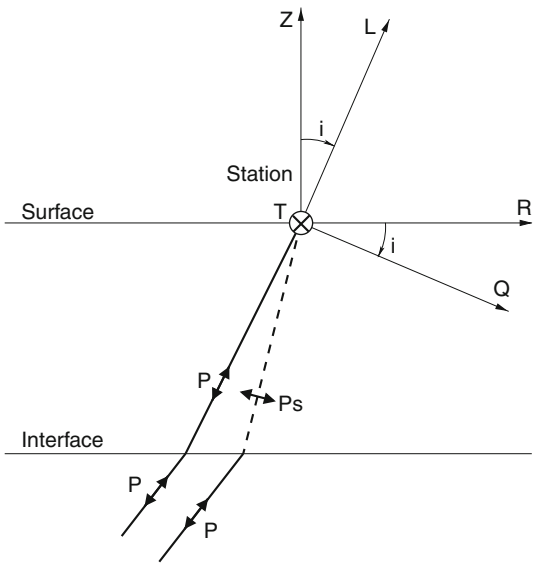


Seismic, Receiver Function Technique, Figure 2 (**a**) Sketch showing ray paths of teleseismic Ps and Sp converted waves below a station. Note that the piercing point of Sp is offset farther away from the station than that of Ps. (**b**) Velocity model for the calculation of P and S receiver functions. (**c**) Theoretical S receiver function (SRF), primary conversions arrive prior to S (which arrives at zero time and is omitted here), crustal multiples arrive after S. (**d**) S receiver function (trace **c**) after reversal of timescale and amplitude for better comparison with P receiver functions (PRFs). (**e**) P receiver functions (PRFs) of model in (**b**). The main difference of P and S receiver functions is that S receiver functions are free of crustal multiples at the time of the lithosphere–asthenosphere boundary (LAB) arrivals. Note that in the case of a homogeneous halfspace, no signal would be contained in the above traces (Yuan et al., 2007).

and daughter phase. The waveforms of both phases carry information about the structure of the discontinuity, which can be isolated by the receiver function technique. The ray path of such waves is shown in Figure 1. Figure 2 compares incident P and S phases for a simple model with two discontinuities (Moho and lithosphere–asthenosphere boundary, LAB, see *Earth's Structure, Continental Crust*; *Lithosphere, Continental*; *Lithosphere, Oceanic*), which cause converted and multiply reflected phases that lead finally to the receiver functions. There are a number of processing steps required in the receiver function technique, which will be considered in the following.

Separation of P and S waves

Since the converted daughter phase is a different wave type with different particle motion, it can be separated from the mother phase. The usual vertical, north–south and east–west (ZNE) components of a seismic record should be rotated, for better identification of signals, into a coordinate system where P, SV, and SH wave types are on different components. Due to heterogeneities close to the station, such a coordinate system (frequently called LQT or P-SV-SH system, see Figure 3) depends on the local angle of incidence and back azimuth. In many cases, only the horizontal components N and E are rotated into the radial (R) and transverse (T) components. Frequently

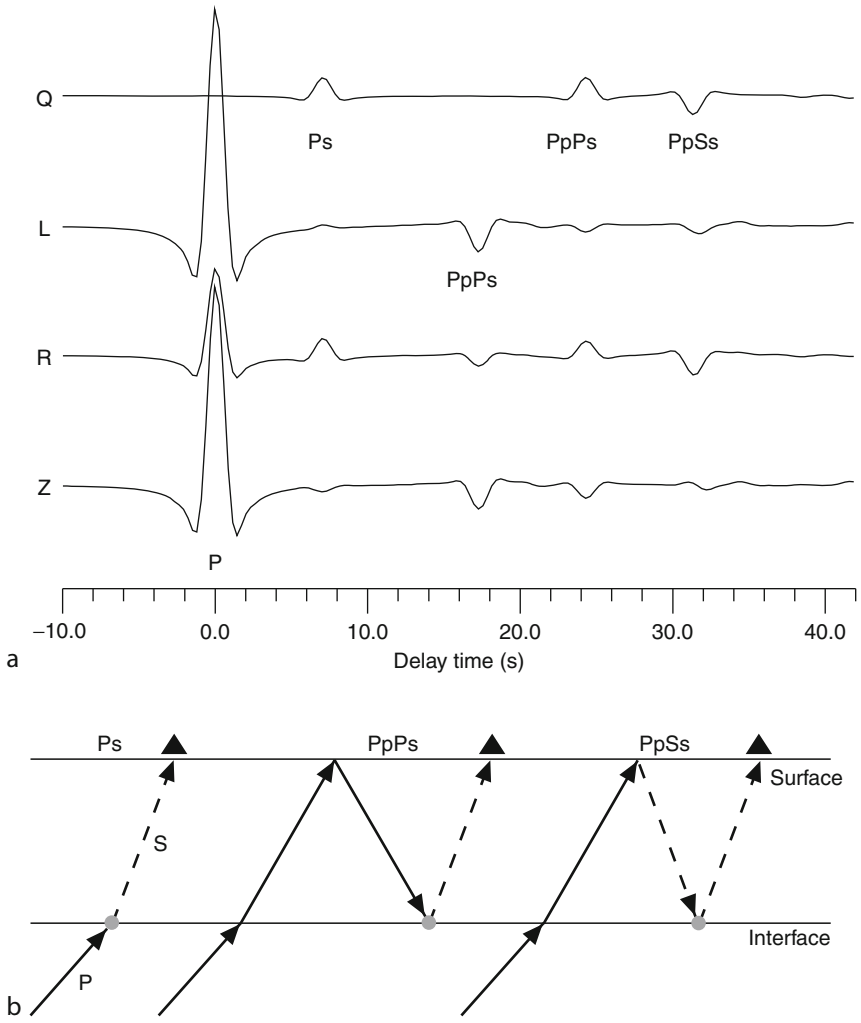


Seismic, Receiver Function Technique, Figure 3 Rotation of the radial (R) and vertical (Z) components around the angle of incidence into the L and Q system (Vinnik, 1977). The P wave is in this case only on the L component and the SV wave is only on the Q component. The SH wave remains on the T component.

the rotation is done according to the theoretical back azimuth between receiver and source and the theoretical angle of incidence according to epicentral distance. A local ray coordinate system may be determined from the diagonalization of the covariance matrix of the ZNE recordings within a certain time window (Montalbetti and Kanasewich, 1970; Kind and Vinnik, 1988). The length of the time window used plays an important role for determination of rotation angles with this technique. The influence of the free surface of the Earth is small and in most cases not considered. In Figure 4, theoretical seismograms in the ZR and LQ coordinate system are shown, along with ray diagrams for direct Ps phase and multiple phases PpPs and PpSs.

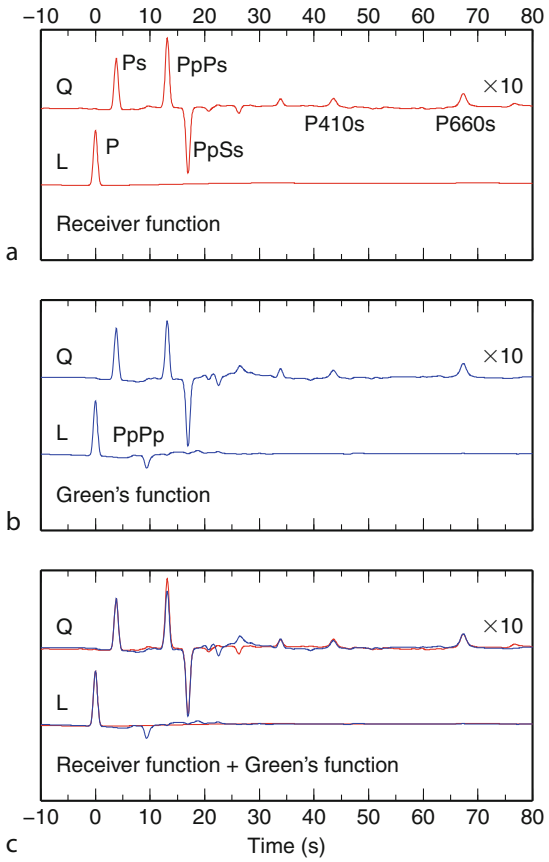
Deconvolution

After separation of P and SV wave types on separate components, it is much easier to identify and interpret the small converted signals. In earlier times when only analog data records were available, only a few records could be searched for converted phases. With the large amount of digital data now available (see *Seismological Networks*), weak signals can be enlarged relatively easily by summation of many records. A number of problems need to be considered before seismic records can be summed. Different waveforms and amplitudes generated by different earthquakes are another problem, which needs to be taken into account before summation of many traces can be applied. After rotation, records of one source and many distributed stations may be summed because all records are caused by a single event with the same source-time function. This is the well-known delay and sum technique. However the results of such a summation will be the response function at the source region (including, e.g., depth phases) and not the "receiver function." If we are interested in the structure beneath a seismic receiver,



Seismic, Receiver Function Technique, Figure 4 (**a**) Effects of rotation of theoretical Z and R coordinates into the LQ system. Phases arriving as S wave (Ps, PpPs, PpSs) at the station remain on the Q component only. Phases that arrive as P waves remain on the L component (P, PpPp). (**b**) Ray paths of crustal multiples.

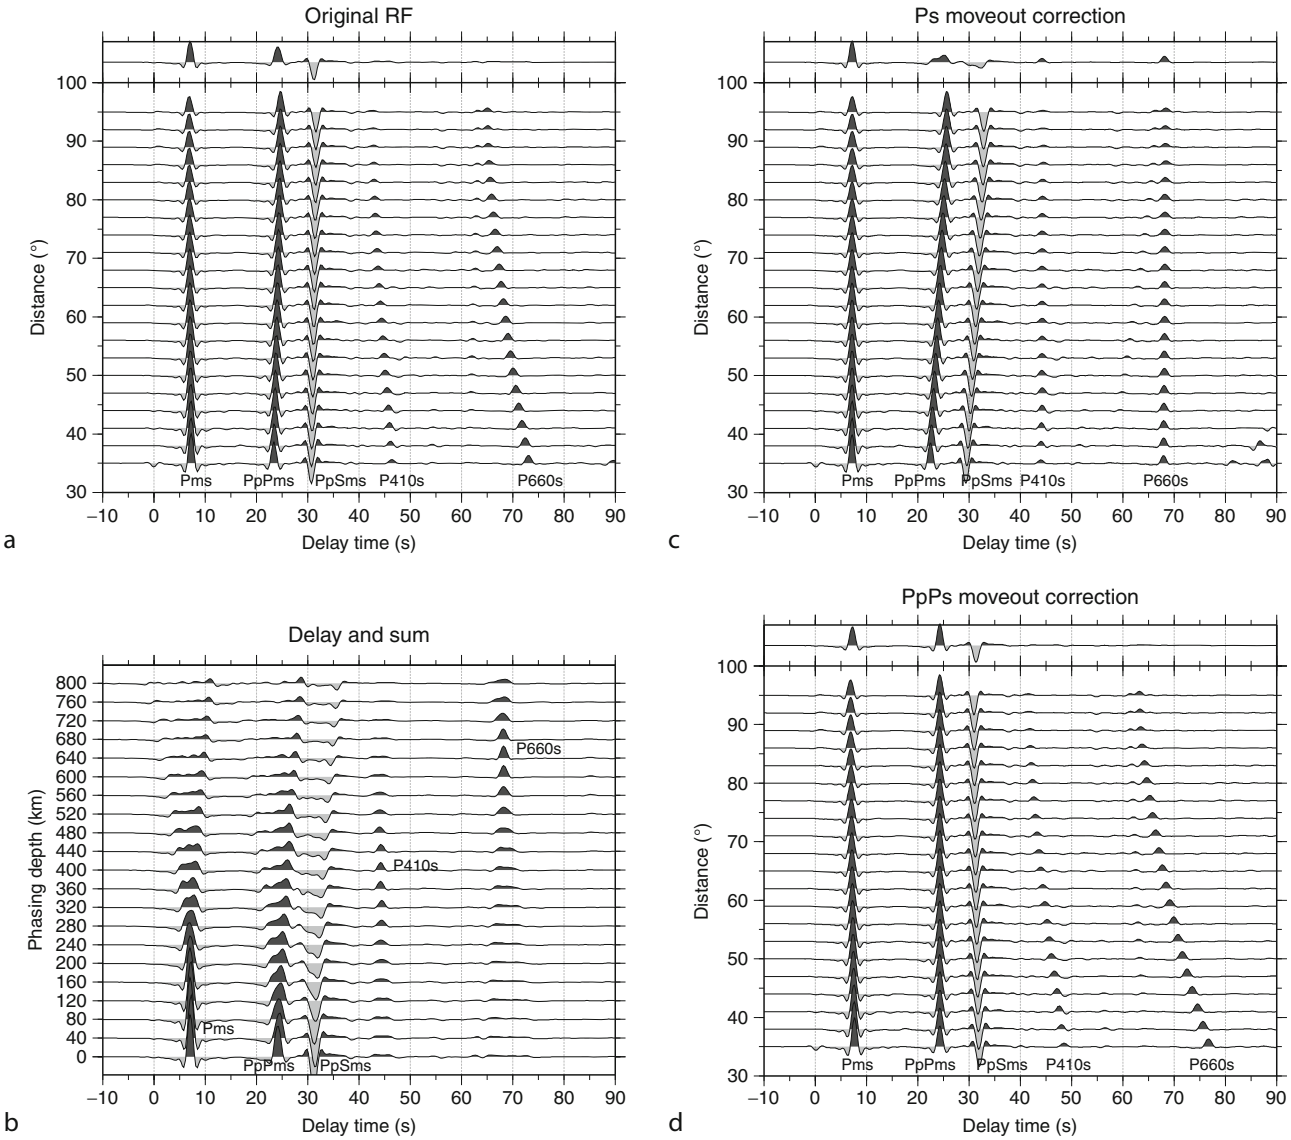
records from many earthquakes at this receiver with very different source-time functions and magnitudes must be summed. Only in this case we will obtain as the result of the summation the response of the structure beneath a receiver. Influences of the receiver structure are common to all records and will be enhanced by summation. In contrast, influences of the source or the source structure (depth phases, conversions near the source) will be reduced. Obtaining the structure beneath a receiver is especially interesting because in contrast to sources we can move the receivers where we need them and record teleseismic events to study the structure at nearly any location (with many problems at ocean bottom stations). The procedure used for source equalization is usually deconvolution. In the frequency domain, deconvolution of P receiver functions (PRFs) means division of the SV component by the P component and in S receiver functions (SRFs) it means division of the P component by the SV component (Langston, 1979; Gurrola et al., 1995). In time domain, a Wiener filtering approach (Kind et al., 1995) can be applied. For P receiver functions, an inverse filter can be generated by minimizing the least-square difference between the observed P waveform on the vertical component and the desired delta-like spike function. The inverse filter is then convolved with other components to obtain receiver functions. Ligorria and Ammon (1999) proposed an alternative approach to iteratively remove the source and propagation effects. The question which type of deconvolution is carried out does not seem to be very significant. After deconvolution, amplitude normalization is applied, resulting in amplitude values of the converted phase in percent of the incident phase. Deconvolution, however, has one principal disadvantage. One entire component is considered as the source-time function. For example, the entire P component over duration of perhaps 100 s is deconvolved from the SV component. This means all signals within this window on the P component are considered source. For example, P multiples within the crust at the receiver site will also be eliminated by this kind of deconvolution. In this sense, deconvolution prevents computation of the complete Green's function (impulse response) at the receiver site (Kumar et al., 2010; Baig et al., 2005; Bostock, 2004; Langston and Hammer, 2001). The modification of seismic records caused by deconvolution is demonstrated in Figure 5. Kumar et al. (2010) have shown that plain summation of many records of a seismic station results in SV component traces, which are nearly identical with deconvolved traces and P component traces are preserved. They only applied amplitude and sign equalization and summed all traces aligned along the maximum of the P signal (see Kumar et al., 2010). The only disadvantage of the new technique is that more traces are needed to obtain the same signal-to-noise ratio.



Seismic, Receiver Function Technique, Figure 5
(**a**) Deconvolved, (**b**) original theoretical seismograms (Kind, 1985) and (**c**) the overlay of both for a simple crust-mantle model. All phases except P are eliminated on the deconvolved P component. The deconvolved SV (Q) component differs significantly from the theoretical SV component. The P_MP phase has disappeared on the deconvolved SV component, as expected. However, the PpPs Moho multiple reflection has a significantly distorted amplitude (Kumar et al., 2010).

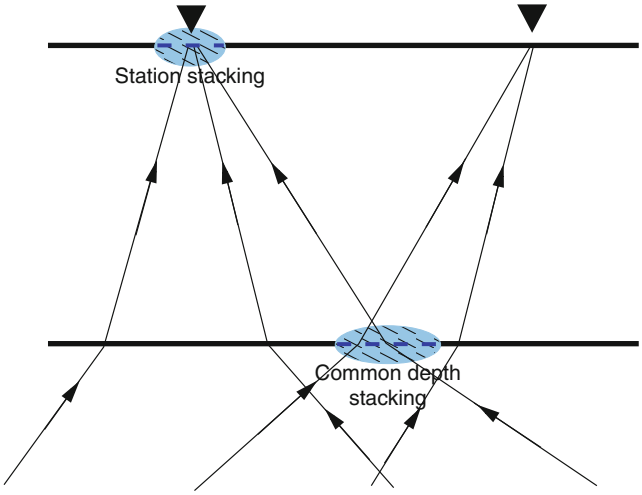
Moveout correction and summation

An important problem is that seismic phases travel with different velocities. This means that the differential times of seismic phases in one record depend on epicentral distances. Therefore, only records from similar epicentral distances can be summed. Traces from different distances may also be summed if the conversions arrive very closely in time to their mother phase (perhaps still possible for crustal conversions). For converted phases arriving later from greater depths, it is necessary to consider effects of their different slowness. Vinnik (1977) has solved this problem by using a delay and sum technique known from array processing and applying it to the upper mantle discontinuities. Results are displayed in a slowness-time plot (or conversion-depth-time plot, see Figure 6). Another solution is that the distance moveout correction procedure could be applied before summation, which is very well known in applied seismics (see *Deep Seismic Reflection and Refraction Profiling*). In moveout correction, the timescale is stretched or compressed in order to parallelize the same type of traveltime curves. A fixed reference



Seismic, Receiver Function Technique, Figure 6 Theoretical P receiver functions in original form and moveout corrected. A velocity model is needed to apply the moveout correction. (*Bottom left*) Delay and sum technique developed by Vinnik (1977). Delays are computed for a number of assumed depths of conversion.

slowness of 6.4 s/degree (or 67° epicentral distance) is frequently used at which the timescale remains unchanged. At smaller distances the timescale is compressed, and expanded at larger distances, in order to transform the traveltime curve of the converted phase under investigation into one parallel to the mother signal. After moveout correction, a number of traces may be lined up and summed into a single trace. A group of traces used for summation could be all records from either one station or records with piercing points in a certain geographical region (box) at a certain depth (common conversion point technique, Dueker and Sheehan, 1997, see Figure 7). The advantage of the moveout correction and summation technique is that single traces representing groups of traces can be easily compared. After moveout correction for direct conversions, the summation traces contain only such phases. Surface multiples are destructively superimposed because of their different slowness. Moveout corrections cannot only be applied to Ps or Sp conversions, but also to other phases like multiples. In this case, the summation trace contains only a certain type of multiples (see Figure 6). Moveout correction and summation also solves a special problem in S receiver functions. Not every precursor of S on the P component is an S-to-P



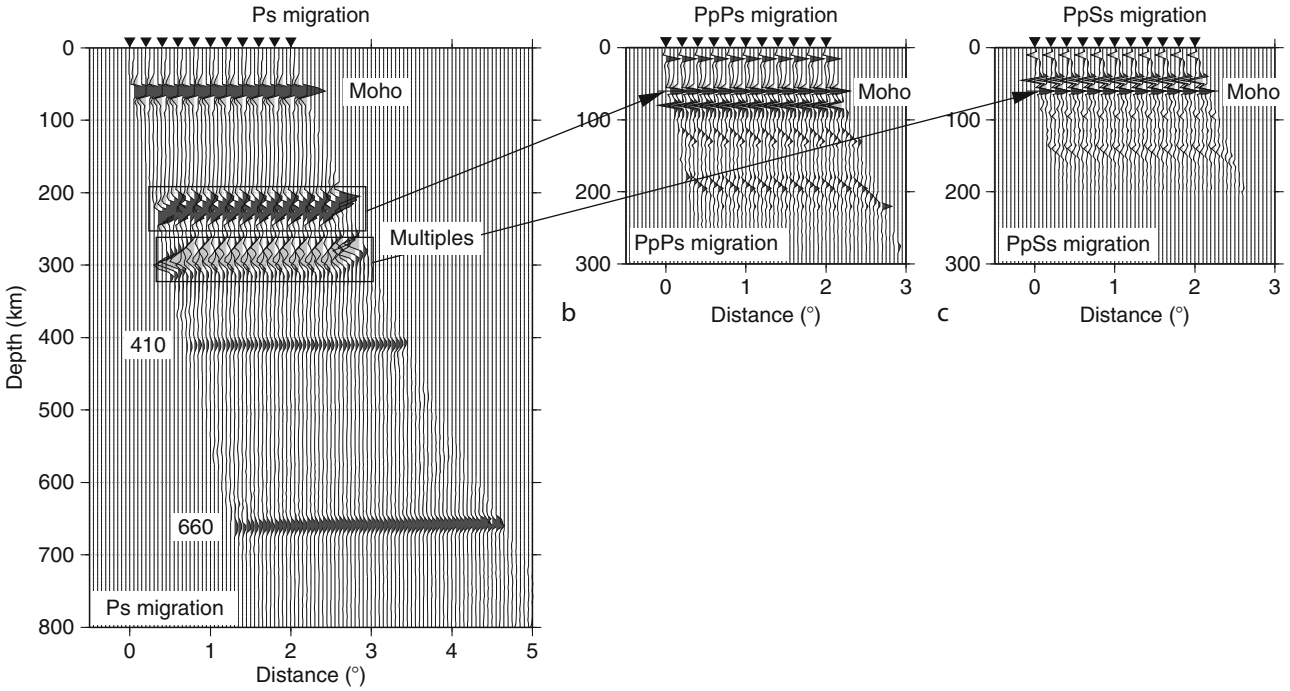
Seismic, Receiver Function Technique, Figure 7 Cartoon showing receiver function rays in a simple Earth model. Single station summation is useful for shallower studies or for averages over larger regions in greater depths. In case of dense deployments of several stations, common depth summation, (CCP) may be used.

conversion. Surface multiples of the P phase can also arrive on the vertical component as precursors of S (Bock, 1994). These phases have, fortunately, a different slowness and are suppressed in the delay and sum technique or the moveout correction and sum technique.

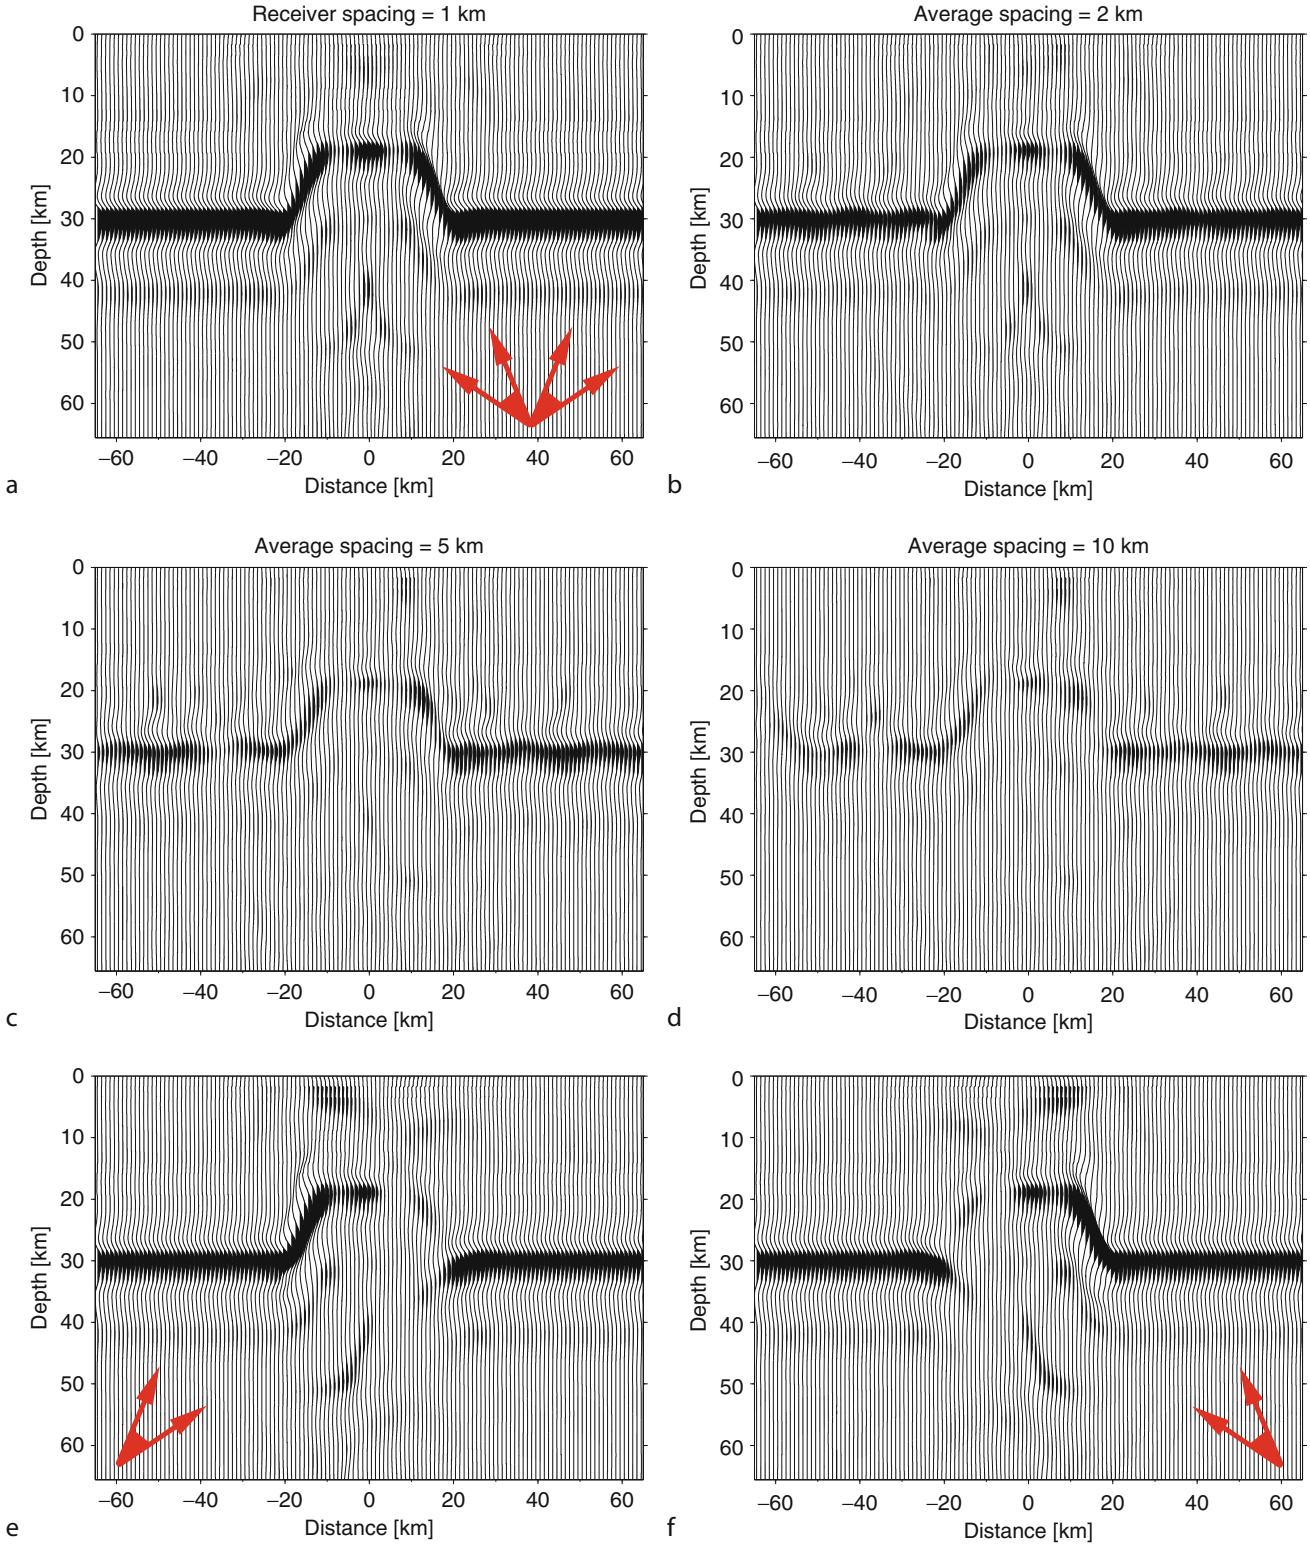
CCP stack and migration

Stacking by single stations is meaningful if piercing points from different stations are not overlapping in the depth range studied. If several stations are closely spaced and piercing points are overlapping at the study depth, summation by common regions of piercing points at that depth may be more meaningful (common conversion point stacking, CCP). In this case, piercing point locations for conversions at a defined depth are computed and all traces with piercing points inside a defined area are summed (see Figure 7).

Stacked time domain receiver functions are not yet the goal of the processing, even if clear converted phases can be recognized. We need to know where in the three-dimensional Earth the conversion occurs. Therefore, the final goal is the migration from the time series into



Seismic, Receiver Function Technique, Figure 8 Principle of depth migration of seismic records (theoretical seismograms in this case). Each ray from each station is back projected into an assumed model of the Earth. The amplitudes of the seismogram are distributed along this ray path. In the left figure it is assumed that all energy in the seismogram originates from direct conversions; in the other figures it is assumed that all energy is caused by multiples. Migration can, like moveout correction, only be done for one wave type at a time. The energy of the other phase type is migrated to the wrong depth and not focused.



Seismic, Receiver Function Technique, Figure 9 (**a**–**d**) Migrated theoretical 1-Hz receiver functions of a dome structure with different receiver spacing. A spacing of 5 or less kilometers is required to obtain a good image of the structure. (**e**–**f**) Effects of illuminating the structure from limited back azimuths (see *arrows*, Ryberg and Weber, 2000). Station spacing is 1 km.

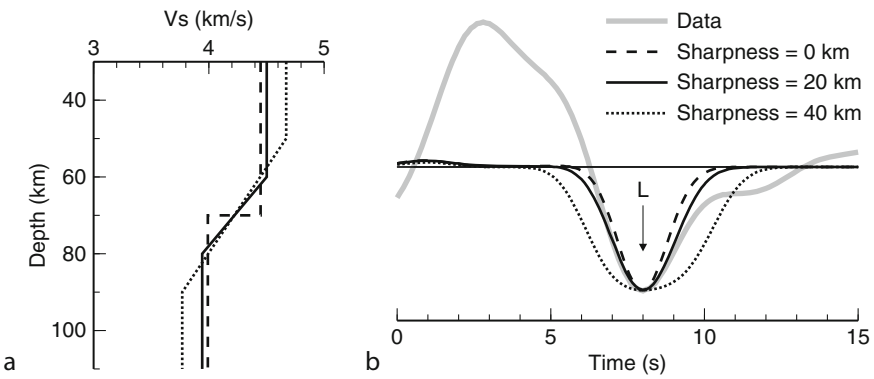
a depth model (see *Seismic, Migration*). Depth migration with a known velocity depth model is necessary for this purpose. Migration is a very well-known technique in controlled source seismics. In earthquake seismology with relatively sparse station distribution more simple versions of migration with one-dimensional models are often used. The amplitudes of the receiver function traces are distributed along the ray path of a known velocity depth model. The Earth model is divided in boxes and amplitudes of all rays in one box are summed. The result is an approximate two-dimensional (or three-dimensional) distribution of seismic energy in space where hopefully seismic discontinuities can be identified (see Figure 8). In the case of P receiver functions, such images are blurred with multiples from the surface, which produce apparent discontinuities. One of the first examples of receiver function depth migration is given by Kosarev et al. (1999). A more sophisticated development is given, e.g., by Bostock (2002).

The results of the processing steps described so far indicate the great similarity with steep angle–controlled source techniques. The topography of seismic discontinuities in the interior of the Earth is displayed either in the time or space domain. Distance moveout corrections and depth migration are the most important common steps. The main differences are the frequency content (which determines the resolution) and depth penetration. Steep angle seismics uses frequencies of many Hertz, whereas the teleseismic signals have periods from one to many seconds. Steep angle seismics does not always reach the Moho, whereas receiver functions have practically unlimited depth penetration since the signals are incident from below. Ryberg and Weber (2000) conclude from computations of theoretical seismograms of two-dimensional models that a station spacing of a few kilometers is required if structures with a few kilometers scale length need to be resolved (see Figure 9). A station density of a few kilometers has so far been achieved only in very few deployments (e.g., Hansen and Dueker, 2009).

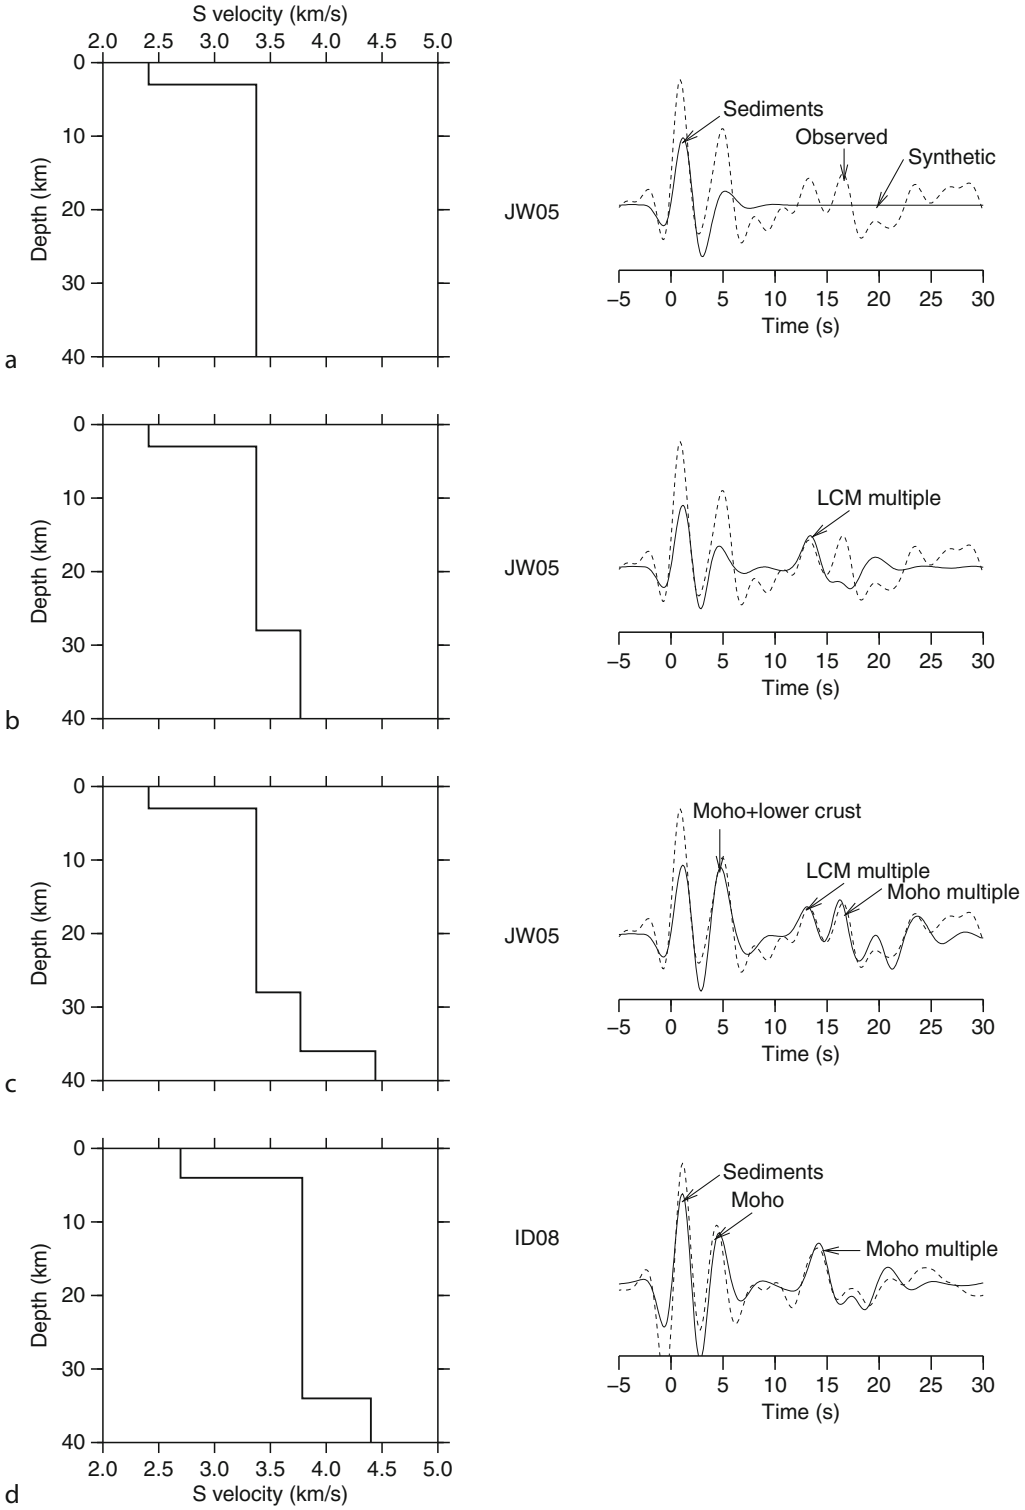
Waveform modeling

The above described processing steps for receiver functions lead to the detection and location of discontinuities in the interior of the Earth and their topography, ranging from the base of the sedimentary layers to the upper mantle transition zone between 410- and 660-km depth. A frequently applied additional step in receiver functions is the inversion of the waveforms over the entire length of the receiver function at a station into a one-dimensional velocity depth model (e.g., Ammon et al., 1990; Kind et al., 1995). Such an inversion technique has the capability of fitting the data nearly perfectly. However, problems involved are the nonuniqueness of the inversion and the assumption that seismic phases, which have been generated by a three-dimensional Earth, can be transformed into a one-dimensional model (Ammon et al., 1990). Although the nonuniqueness problem has been improved recently by using long-period signals (Jacobsen and Svenningsen, 2008), even a perfect fit of the observed waveforms with theoretical waveforms encounters the problem of fitting three-dimensional effects and possible noise into a one-dimensional model.

Somewhat closer to reality seems to be the inversion of isolated waveforms of conversions from individual discontinuities in P or S receiver functions (e.g., Moho or LAB). An example is given by Li et al. (2007), see Figure10. They summed about 8,000 S-to-P converted signals from the LAB (S receiver functions) in the western US and inverted the width of the summed signal in terms of thickness of the LAB gradient. They obtained a transition zone of not more than 20 km. However, determinations of the size of the velocity jump and of the thickness of the LAB from summation traces may depend on



Seismic, Receiver Function Technique, Figure 10 Modeling of the LAB summation phase in the western US (Li et al., 2007, Figure 8). (**a**) Models with different sharpness and velocity contrast of the LAB. Dashed line: LAB as a first-order discontinuity; solid line: LAB as a 20-km thick gradient transition zone and dotted line: LAB as a 40-km thick gradient transition zone. (**b**) Waveforms of data and synthetic S receiver functions. The thick gray line is the summation of all the S receiver function stacks for each station after an alignment of the LAB phase. A 3–20 s bandpass filter is applied prior to alignment and summation for a better phase correlation. Synthetic S receiver functions correspond to the models shown in (**a**). The large positive swing in the data at less than 5 s is the averaged Moho signal, which is not computed in the synthetic seismograms.



Seismic, Receiver Function Technique, Figure 11 Forward waveform modeling of P receiver functions with relatively simple models (Mohsen et al., 2005).

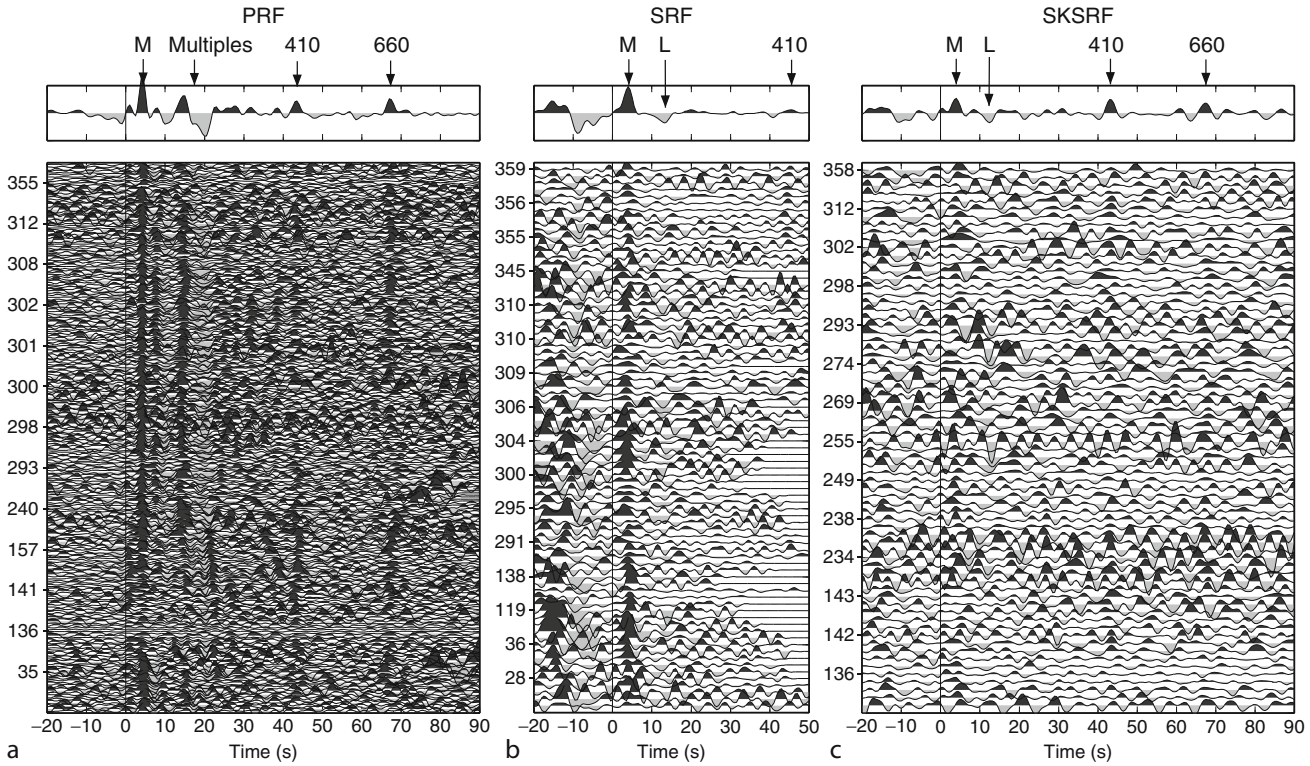
focusing and defocusing effects of the topography within the region of piercing points and erroneous transform topography into the vertical velocity structure. Therefore, this 20-km gradient must be considered as an upper limit in this case. Another example is given by Mohsen et al. (2005) in Figure 11. They show how each one of the observed seismic phases may be modeled with good accuracy with a relatively simple model.

Two data examples

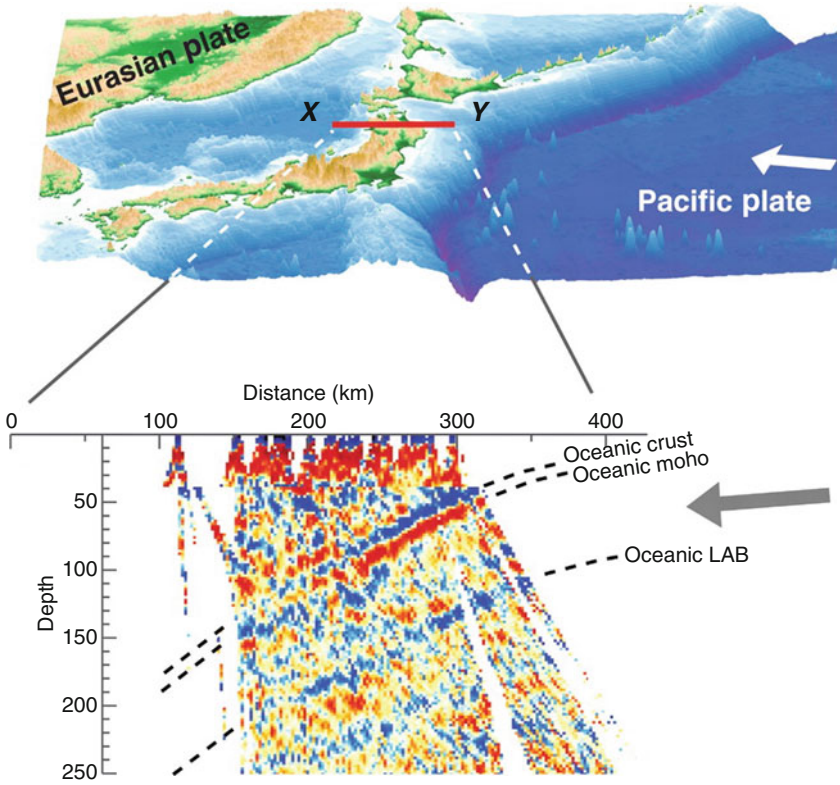
In Figure 12 are shown P, S, and SKS receiver functions in time domain from a seismically quiet station in northern Canada. The interesting point in these data is that in S and SKS receiver function (SKSRF), a clear negative phase is observed at 12–13 s, which corresponds to a depth of about 110 km. A negative signal indicates a low velocity zone. Such a zone in that depth may be caused by the LAB. However, from surface wave studies a much larger depth of the LAB is expected in this region. These contradicting results pose very interesting questions about the structure of the upper mantle beneath old cratons. In Figure 13 is shown an excellent example of depth migrated P receiver functions beneath a subduction zone (Kawakatsu et al., 2009). The subducting oceanic lithosphere is completely visible, including upper and lower boundary of the oceanic crust and the lower boundary of the oceanic lithosphere (see *Lithosphere, Oceanic*).

Summary

Receiver functions or converted waves belong to a class of small secondary scattered waves generated by a relatively strong main phase like P or S. Similar scattered phases are precursors of other main phases like PP, SS, or P′P′, which have the great advantage to cover areas that are difficult to access, like oceans (see *Body Waves*; *Seismic Phase Names: IASPEI Standard*). These techniques are since about 30 years the main tools to study discontinuities of material properties in the Earth. The other main seismic tool is tomography, which is sensitive to smooth changes of material properties. The success of the scattered wave techniques was made possible by the great extension of high quality seismic networks in the last decades. Permanent and mobile networks supplement each other. Especially studies of the lithospheric plates and the mantle transition zone have gained much from the new techniques. Many more detailed results can be expected when much denser networks will be used in future.



Seismic, Receiver Function Technique, Figure 12 PRFs, SRFs, and SKSRFs of station YKW3 (Yellow Knife, Canada). The receiver functions are corrected for moveout with a reference slowness of 6.4 s/degree and a reference model of the IASP91 (Kennett and Engdahl, 1991). The number of the PRFs is more than 200, the numbers of the SRFs and SKSRFs are ~80 each. A three-pole low-pass filter with corner frequency of 3 S is applied to all the data. Back azimuth values for some sample traces are labeled to the left of each trace. The summation trace is plotted above each receiver function section. Main conversion phases are labeled on the summation traces.



Seismic, Receiver Function Technique, Figure 13 P receiver functions for ocean bottom station WP2 and receiver function image of subducting Pacific plate beneath northeast Japan. In the topographic map, the inverted red triangle indicates the location of WP2, which is deployed at a depth of 460 m below the seafloor with a water column of 5,566-m thick. (**a**) P receiver function image along the profile XY using dense land seismic data of Hi-net from Japan. *Red* and *blue* colors indicate velocity increase (from shallow to deep) and decrease at the point, respectively. The top surface of the slab and the oceanic Moho are clearly imaged, as well as the bottom surface of the slab (i.e., subducting LAB). (**b**) P receiver function and S receiver function for WP2. Negative phases associated with a shear wave velocity drop marked as LAB appear to correspond to the strong negative (*blue*) signature of the subducting slab below Japan. (After Kawakatsu et al., 2009.)

A recent review of the receiver function technique has been given by Rondenay (2009). A number of additional processing steps are the use of multiples to determine average crustal properties (e.g., Zhu and Kanamori, 2000), the role of anisotropy (e.g., Levin and Park, 1997; Schulte-Pelkum et al., 2005), or three-dimensional inversion (e.g., Bostock, 2002).

Reflection matrix method

Definition

Reflectivity method is a semi-analytic method for computing synthetic seismograms in layered elastic media. The method has now been extended to anisotropic and laterally varying media.

The reflectivity method

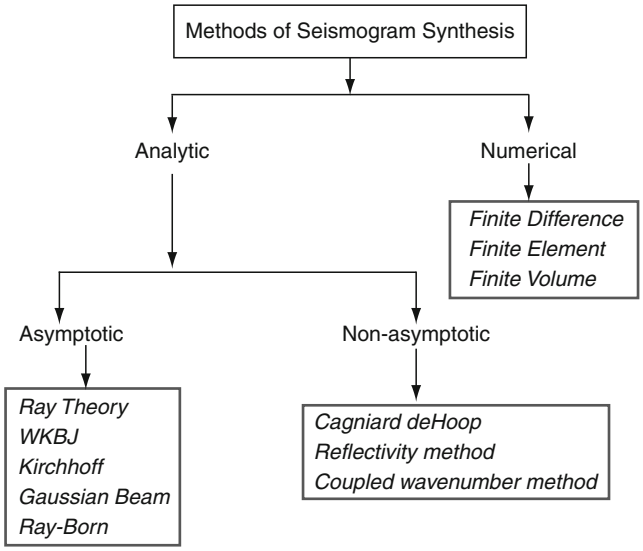
Introduction

Synthetic seismograms are now used routinely for interpretation of field seismic data and evaluating the performance of seismic processing algorithms. Generation of synthetic seismograms essentially involves solution of the partial differential equation (PDE) for seismic wave propagation. Different forms of the PDE are available for different earth models (e.g., acoustic, isotropic, elastic, anisotropic, homogeneous, and laterally inhomogeneous). Brute force numerical methods such as finite differences and finite elements can, in principle, handle models of any complexity. However, they are limited by the speed of computation and computer memory. Even with our latest computer technology, generation of realistic 3D synthetic seismograms is not possible within reasonable clock time.

Much effort has been spent over the years in developing methods that are fast and accurate. We are left with three choices:

- Approximate the earth model and generate analytic or semi-analytic solutions.
- Derive approximate (asymptotic) solution for realistic heterogeneous models.
- Derive pure numerical solution for general heterogeneous models.

Figure 1 provides a fairly complete list of the methods currently available for seismic modeling. Pure numerical methods based on finite-difference (Virieux, 1984) and finite-element (Marfurt, 1984; Komatitsch and Tromp, 1999; DeBasabe and Sen, 2007) approaches generate complete solutions but these methods become prohibitively expensive at high frequencies. The ray-based methods generate asymptotic solutions at infinite frequency and can be applied to models of general complexity as long as rays can be traced through the medium (Cerveny, 2001). Although the original WKBJ method is valid for layered media, its extension to laterally varying media is the Maslov method (Chapman and Drummond, 1982).



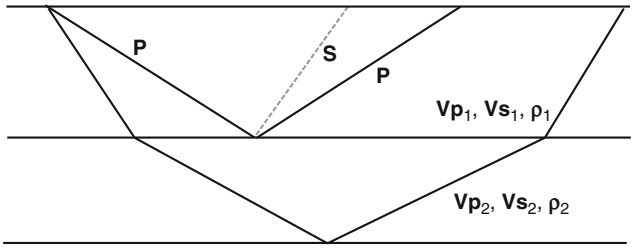
Seismic, Reflectivity Method, Figure 1 Different methods for computing synthetic seismograms: the reflectivity method is a semi-analytic method that is generally valid for layered earth models.

The methods such as the reflectivity (Fuchs and Muller, 1971) or Cagniard-deHoop method (e.g., Aki and Richards, 2000) are included in the category of non-asymptotic analytic method. They were originally proposed for layered (1D) isotropic media and are still commonly used in such media although some extensions of these methods to anisotropy and lateral heterogeneity have indeed been reported. Although I included these methods in the category of "analytic method," their final evaluation is done numerically. Thus strictly speaking, they should be included in the category of "semi-analytic" methods. The speed of computation of these methods can be improved by using asymptotic approximation at the final stage of evaluation of an oscillatory integral.

The primary goal of this entry is to provide an overview of the reflectivity method – perhaps the most popular method of seismogram synthesis. In the following sections, I will summarize the theory and numerical methods pertaining to reflectivity and provide some numerical examples. Finally, I will discuss an extension of the reflectivity method to laterally inhomogeneous media.

Plane waves

The plane waves are fundamental to understanding wave propagation. It has been demonstrated that a point source response can be generated by a weighted sum of individual plane wave responses (e.g., Aki and Richards, 2000). In a homogeneous medium, plane waves propagate without spreading. In a stratified medium, plane waves remain planar during their propagation. However, as they propagate through a stack of flat layers (Figure 2), they undergo changes in amplitude and phase.



Seismic, Reflectivity Method, Figure 2 A stack of layers in which each layer is characterized by its elastic parameters and layer thickness: as an incident plane wave propagates through the stack of layer, it undergoes mode conversion and changes in amplitude due to reflection and transmission.

- The amplitude changes can be accounted for by imposing boundary conditions of continuity of displacement and stress resulting in expressions for the so-called plane wave reflection and transmission coefficients.
- Travel time changes can be computed using individual layer velocities for locally linear ray-paths.
- Changes in propagation angle can be computed by imposing Snell's law of preservation of horizontal slowness.
- In a stratified medium, an incident plane wave generates converted waves and internal multiples with appropriate amplitudes given by reflection and transmission coefficients.

Figure 2 displays a stack of layers in which each layer is characterized by its elastic parameters (densities and, P- and S-wave velocities) and thicknesses in an elastic isotropic medium. An incident plane P-wave characterized by a ray (normal to the plane) given by the angle it makes with the vertical axis is shown in the top layer. At the first layer boundary, it generates a reflected P-wave and a reflected SV-wave (converted). It also generates several reverberations with the top free surface (not shown in the figure). As the plane wave enters the second layer, it changes its propagation direction and similarly generates several converted waves and multiples. The primary task in generating synthetic seismograms is to keep track of all of these paths and account for all these amplitude and phase changes. The reflectivity method does exactly that. However, before we look into the details of the reflectivity method, let us first examine some simple cases with a few rays.

Simple plane wave synthetics

It is fairly straightforward to generate plane wave synthetic seismograms for a layered medium for a few rays or plane waves. Two fundamental parameters involving plane wave seismograms are the ray parameter or horizontal slowness denoted by p and vertical delay time denoted by τ. They are defined as follows

$$p = \frac{\sin\theta}{v}, \quad q = \frac{\cos\theta}{v}, \tag{1}$$

where, θ is the vertical angle of the ray, q is called the vertical slowness and

$$\tau = 2hq, \tag{2}$$

where, h is the layer thickness.

Now referring to Figure 2, the *PP* reflection delay time for layer 1 is

$$\tau_1^{PP} = 2h_1 q_1^P, \tag{3}$$

and the *PS* reflection delay time is

$$\tau_1^{PS} = h_1\left(q_1^P + q_1^s\right). \tag{4}$$

In the above equations, the subscript represents the layer and the superscript represents the wavemode under consideration. The plane wave response of the primary *PP* mode from the interface between layer 1 and layer 2 can be written down in the frequency-slowness domain as

$$R(\omega, p) = R_1^{PP} \exp\left(i\omega 2h_1 q_1^{PP}\right), \tag{5}$$

where, R_1^{PP} is the *PP* plane wave reflection coefficient for interface 1. Similar expression can be written down for the *PS* mode primary reflection.

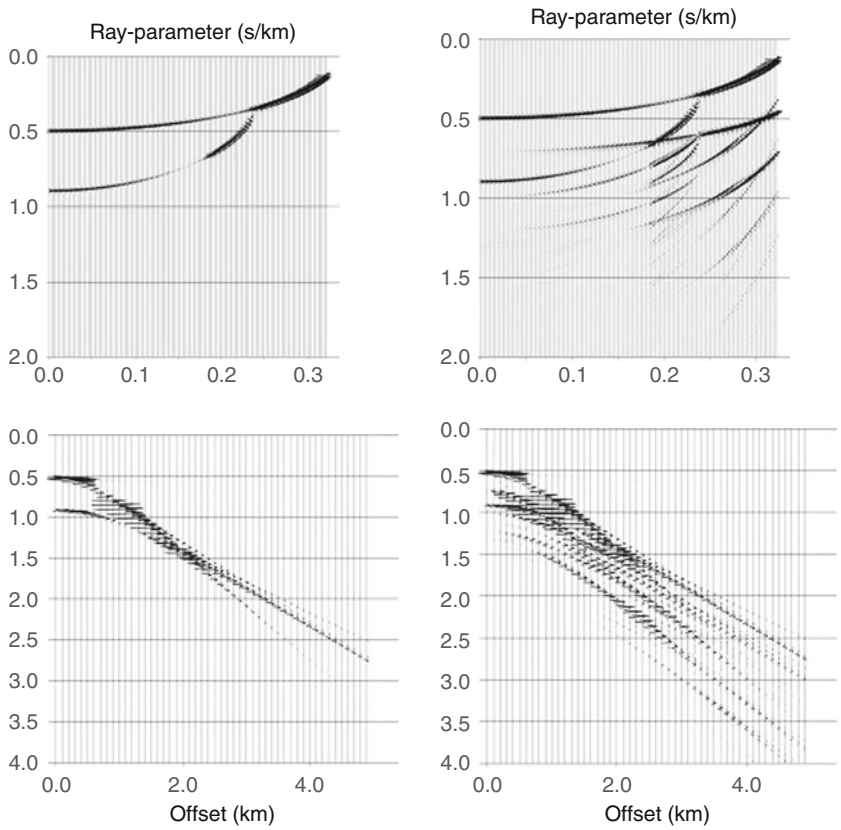
$$R(\omega, p) = R_1^{PS} \exp\left(i\omega h_1\left(q_1^P + q_1^S\right)\right). \tag{6}$$

To include the reflection from the second layer, we simply need to add a term appropriate for the second layer (similar to Equation 3) resulting in the following expression

$$R(\omega, p) = T_{1D}^{PP} R_2^{PP} T_{1U}^{PP} \exp\left(i\omega\left(2h_1 q_1^{PP} + 2h_2 q_2^{PP}\right)\right), \tag{7}$$

where we include the effects of transmission using downgoing (with subscript D) and upgoing (with subscript U) transmission coefficients. Expressions similar to Equation 7 can also be written down for mode-converted waves.

Examples of plane wave and point source synthetic seismograms are shown in Figure 3; these are generated for a vertical point force and only the traces of vertical component of displacement are shown. The upper panel



Seismic, Reflectivity Method, Figure 3 Examples of plane wave and point source synthetic seismograms for a model comprising two elastic layers over a half space: these were generated for a vertical point force and only the traces of vertical component of displacement are shown. The upper panel shows the plane wave seismograms in τ-p domain while the lower panel shows the corresponding x-t domain synthetic seismograms. The left panel shows seismograms for primary *PP* reflections only. The right panel shows the seismograms that include primary *PP*, *PS* and internal multiples from the second layer.

shows the plane wave seismograms in τ-*p* domain while the lower panel shows the corresponding *x*-*t* domain synthetic seismograms. The left panel shows seismograms for primary *PP* reflections only. Note two distinct reflections from the two layer boundaries. The right panel shows seismograms that include primary *PP*, *PS,* and internal multiples from the second layer.

It is fairly straightforward to compute seismograms for a few selected phases for a few layers. In reality, we have many layers and an infinite number of ray-paths – these are not easy to count. The reflectivity method offers an elegant algorithm for computing full response without having to count rays. Of course, we may choose to compute a few selected phases under reflectivity formulation as well, if desired.

Theory

Detailed developments of the theory of the reflectivity method for isotropic media can be found in Fuchs and Muller (1971) and Kennett (1983). Derivations for an anisotropic layered medium can be found in Booth and Crampin (1983) and Fryer and Frazer (1984). We start with the two fundamental equations in seismology, namely, the constitutive relation and the equation of motion given by,

$$\tau = \mathbf{C} : \nabla \mathbf{u} \tag{8}$$

$$\rho\omega^2 \mathbf{u} = \nabla \cdot \tau + \mathbf{f}, \tag{9}$$

where, τ is a second rank stress tensor, **C** is the fourth rank elastic stiffness tensor, **u** is the displacement vector, ω is the angular frequency, and **f** is a body force term. Note that the above equations are in frequency domain.

The fundamental assumption in reflectivity is that the medium is layered and therefore, we can apply transformations over *x* and *y* coordinates to horizontal wave numbers K_x and K_y or horizontal slowness p_x and p_y. For isotropic and layered transversely isotropic media, we can make use of cylindrical symmetry and transform to radial ray parameter *p* and azimuth ϕ. For a general anisotropic medium, we simply apply Fourier transforms over *x* and *y* coordinates to transform Equations 8 and 9 into horizontal wave numbers or ray-parameter domain. Once that is achieved, all the analytic developments are done in the frequency ray-parameter domain.

The equation of motion and the constitutive relation are thus transformed into the following system of ordinary differential equations in depth *z*, by applying a Fourier transform in *x* and *y*

$$\mathbf{b} = i\omega\, \mathbf{A}\mathbf{b} + \mathbf{f}, \tag{10}$$

where, $\mathbf{b} = \left[u_x\, u_z\, u_y\, \tau_{xz}\, \tau_{zz}\, \tau_{yz}\right]^T = \mathbf{b}(\omega, \mathbf{p})$is the stress-displacement vector which is a function of frequency ω and horizontal slowness *p*, **A**(ω, **p**) is the system matrix that is a function of elastic coefficients, and **f** is a body force term. For isotropic and transversely isotropic media, the Equation 10 decouples into two systems, namely a P-SV (4 × 4) system and an SH (2 × 2) system. The solution of the ODE (Equation 10) can be carried out by a propagator matrix method (Gilbert and Backus, 1966). It is well known that the propagator matrix is generally unstable due to growing exponentials (e.g., Jensen et al., 1993). Stable solutions can be obtained by one of the three methods:

- A global matrix approach (Schmidt and Tango, 1986).
- Compound matrix approach where we define a new system of ODE in which the elements of the new system matrix are the minors of the original system matrix. The original 4 × 4 P-SV system maps into a 6 × 6 system (Dunkin, 1965; Phinney et al., 1987).
- An invariant imbedding or a reflection matrix approach (Kennett, 1983).

Of the three methods listed above, the compound matrix and the reflectivity methods have been widely used in seismology. Table 1 summarizes the two methods. The reflectivity method has been very popular because of its ray-interpretation and easy generalization to azimuthally anisotropic media. In the unconditionally stable reflection matrix approach (Kennett, 1983), the propagation uses the eigenvalues and eigenvectors of the system matrix **A**; the eigenvalues are the vertical phase functions. These

Seismic, Reflectivity Method, Table 1 Reflection matrices or compound matrices?

Reflectivity approach	Compound matrix approach
Unconditionally stable	**Unconditionally stable**
For the P-SV case, the algorithm evaluates four 2 × 2 complex reflection/transmission matrices and iteration equations for each frequency and ray-parameter.	For the P-SV case, the algorithm has fewer floating-point operations than the reflectivity method. The method is computationally faster than the reflectivity method.
Derivatives or differential seismograms can be computed analytically for isotropic and vertically transversely isotropic (VTI) media	Derivatives or differential seismograms can be computed analytically for isotropic and VTI media
Derivatives can be computed by semi-analytic approach for general anisotropic media	–
Requires VERY CAREFUL coding	**Coding is very EASY**
Most efficient for general anisotropic media	• Very slow for general anisotropy
Ray-interpretation is possible. Selected rays and selected number of multiples can be included. The algorithm is VERY FLEXIBLE	Complete solution is derived

eigenvalues and eigenvectors are used to define four upgoing and downgoing reflection and transmission coefficient matrices, $\mathbf{R}_D$, $\mathbf{T}_D$, $\mathbf{R}_U$, and $\mathbf{T}_U$. These are propagated through the stack of layers to obtain a composite reflection matrix that includes the effects of reflection, transmission, mode conversion, and internal multiples. Kennett (1983) derived the following iteration equation (Kennett, 1983; p.127), which can be used to compute the R/T matrices of a zone AC when those of zones AB and BC are known:

$$\begin{aligned}
\mathbf{R}_D^{AC} &= \mathbf{R}_D^{AB} + \mathbf{T}_U^{AB}\mathbf{R}_D^{BC}\left[\mathbf{I} - \mathbf{R}_U^{AB}\,\mathbf{R}_D^{BC}\right]^{-1}\mathbf{T}_D^{AB} \\
\mathbf{T}_D^{AC} &= \mathbf{T}_D^{BC}\left[\mathbf{I} - \mathbf{R}_U^{AB}\,\mathbf{R}_D^{BC}\right]^{-1}\mathbf{T}_D^{AB} \\
\mathbf{R}_U^{AC} &= \mathbf{R}_U^{BC} + \mathbf{T}_D^{BC}\mathbf{R}_U^{AB}\left[\mathbf{I} - \mathbf{R}_D^{BC}\,\mathbf{R}_U^{AB}\right]^{-1}\mathbf{T}_U^{BC} \\
\mathbf{T}_U^{AC} &= \mathbf{T}_U^{AB}\left[\mathbf{I} - \mathbf{R}_D^{BC}\,\mathbf{R}_U^{AB}\right]^{-1}\mathbf{T}_U^{BC}.
\end{aligned} \tag{11}$$

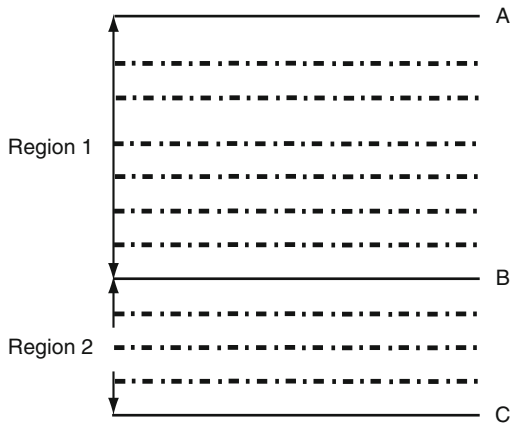
Equation 11 is the most fundamental development of the reflectivity formulation. Given the R/T matrices (which include layer propagation and interaction terms) of two consecutive regions AB and AC (Figure 4), we can compute the response of region AC using Equation 11. Thus, we can propagate through the stack of layers resulting in an unconditionally stable algorithm.

Let us examine the downward reflection matrix in Equation 11 in slightly more detail. Using the matrix identity

$$(\mathbf{I} - \mathbf{A})^{-1} = I + \mathbf{A}\mathbf{A} + \mathbf{A}\mathbf{A}\mathbf{A} + \ldots, \tag{12}$$

we can write

$$\begin{aligned}
\mathbf{R}_D^{AC} &= \mathbf{R}_D^{AB} + \mathbf{T}_U^{AB}\mathbf{R}_D^{BC}\left[\mathbf{I} - \mathbf{R}_U^{AB}\,\mathbf{R}_D^{BC}\right]^{-1}\mathbf{T}_D^{AB} \\
&= \mathbf{R}_D^{AB} + \mathbf{T}_U^{AB}\mathbf{R}_D^{BC}\mathbf{T}_D^{AB} + \mathbf{T}_U^{AB}\mathbf{R}_D^{BC}\mathbf{R}_U^{AB}\,\mathbf{R}_D^{BC}\mathbf{T}_D^{AB} + \ldots
\end{aligned} \tag{13}$$



Seismic, Reflectivity Method, Figure 4 Zones AB and BC from a stack of layers; if the upgoing and downgoing reflection/transmission matrices for these two zones are known, those for the entire stack *AC* can be generated using the iteration equations.

Figure 5 clearly shows that Equation 13 includes all the internal multiples and mode-converted waves. We may also choose to retain a few terms in the expansion and thus compute exact response of a few rays.

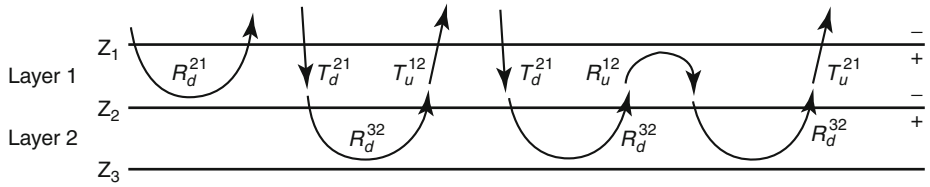
While computing the up/downgoing reflection/transmission matrices through the stack of layers, we need to save the appropriate matrices through the source, receiver layers, and the free surface. Finally, one can compute the entire stress/displacement vector comprising the components of displacement and traction at any receiver location.

Note that we obtain our solution in the frequency ray-parameter domain. An inverse temporal Fourier transforms results in (τ-p) seismograms. Synthetics in the offset-time domain can be obtained by plane wave synthesis of the (ω, p) or (τ-p) seismograms. A general flow chart for computing synthetic seismograms by the reflectivity method is shown in Figure 6. Note that the ray-parameter, layer and frequency loops can be interchanged depending on the application. As stated earlier, intermediate results in (τ-p) domain are very useful for understanding wave propagation and amplitude effects since they are devoid of spherical spreading loss (Fryer, 1980).

Computational issues

It has been demonstrated that the reflectivity algorithm reviewed in this entry is unconditionally stable (Kennett, 1983). However, one must incorporate some practical strategies in computing noise-free synthetic seismograms (e.g., Mallick and Frazer, 1987).

- *Spatial aliasing*: Generation of offset synthetics from plane wave seismograms requires evaluation of an oscillatory integral. The integrand becomes more and more oscillatory with increase in offset and frequency. Thus a practical strategy would be to use a frequency dependent sampling interval in ray-parameters. Alternatively, one can use the minimum ray-parameter increment appropriate for the highest frequency and the largest offset of interest. We also need to use smooth tapers at the high and low ends of the ray-parameter window to avoid truncation phases.
- *Temporal aliasing*: It can be avoided either by using a very large time window or adding a small imaginary part in the frequency following a method outlined in Phinney (1965).
- *Parallelization*: For high frequency and large offset calculation, the reflectivity calculation may be computationally intensive especially for azimuthally anisotropic media, where reflectivity calculation needs to be performed for a large number of ray parameters. Note that (Figure 6) almost the entire reflectivity computation can be done in parallel resulting in an algorithm that may be termed "embarrassingly parallel." One of the simplest ways to parallelize is to distribute the computation of ray-parameter traces equally to the available nodes of a computer (e.g., Roy et al., 2005). The master node collects all the ray parameter traces (note that there is no communication in between the



Seismic, Reflectivity Method, Figure 5 A demonstration of how the iteration equation includes all the reflection and transmission effects.

General Flow chart

- Loop over ray-parameter
  - Loop overe layer
    - Compute R/T (up going and downgoing) for all the interfaces
    - loop over frequency
      - evaluate iteration equation
    - end loop over frequency
  - end loop over layer
  - inverse FFT for (tau-p) seismograms
- End loop over ray-parameter
- Sum the plane wave responses to compute point source synthetics

Seismic, Reflectivity Method, Figure 6 A general flow chart for developing a reflectivity code.

nodes required for the calculation of ray parameter trace). This results in an almost linear speedup as a function of the number of nodes. MPI (message passing interface) can be used for parallelization; the reflectivity code can also be parallelized using simple compiler directives, if coded carefully.

- *Attenuation*: In order to include attenuation, we need to specify Q values for P- and S- waves for each layer. For frequency dependent attenuation, the velocities are complex and dependent on frequency. In such cases, the layer loop (Figure 6) becomes the deepest loop.

Applications

Exploration scale modeling: Numerous applications of reflectivity synthetic seismograms for exploration can be found in literature. This algorithm is often used to generate synthetic seismograms from well logs and then used in calibrating a seismic gather at the well location and well tie (e.g., Sen, 2006). Figure 7a shows α_0, β_0, density, and VTI anisotropy parameters ε and δ derived from a well log as a function of two way time. The plane wave synthetics for an isotropic and VTI model and their differences are shown in Figure 7b. Note that for isotropic calculations, ε and δ values were set equal to zero; for VTI calculations, P- and S-wave velocities from well logs were treated as vertical P and S velocities respectively. Offset synthetics for isotropic and VTI models and their differences are shown in Figure 7c. As expected, the effect of anisotropy is more pronounced at large offsets or ray-parameters.

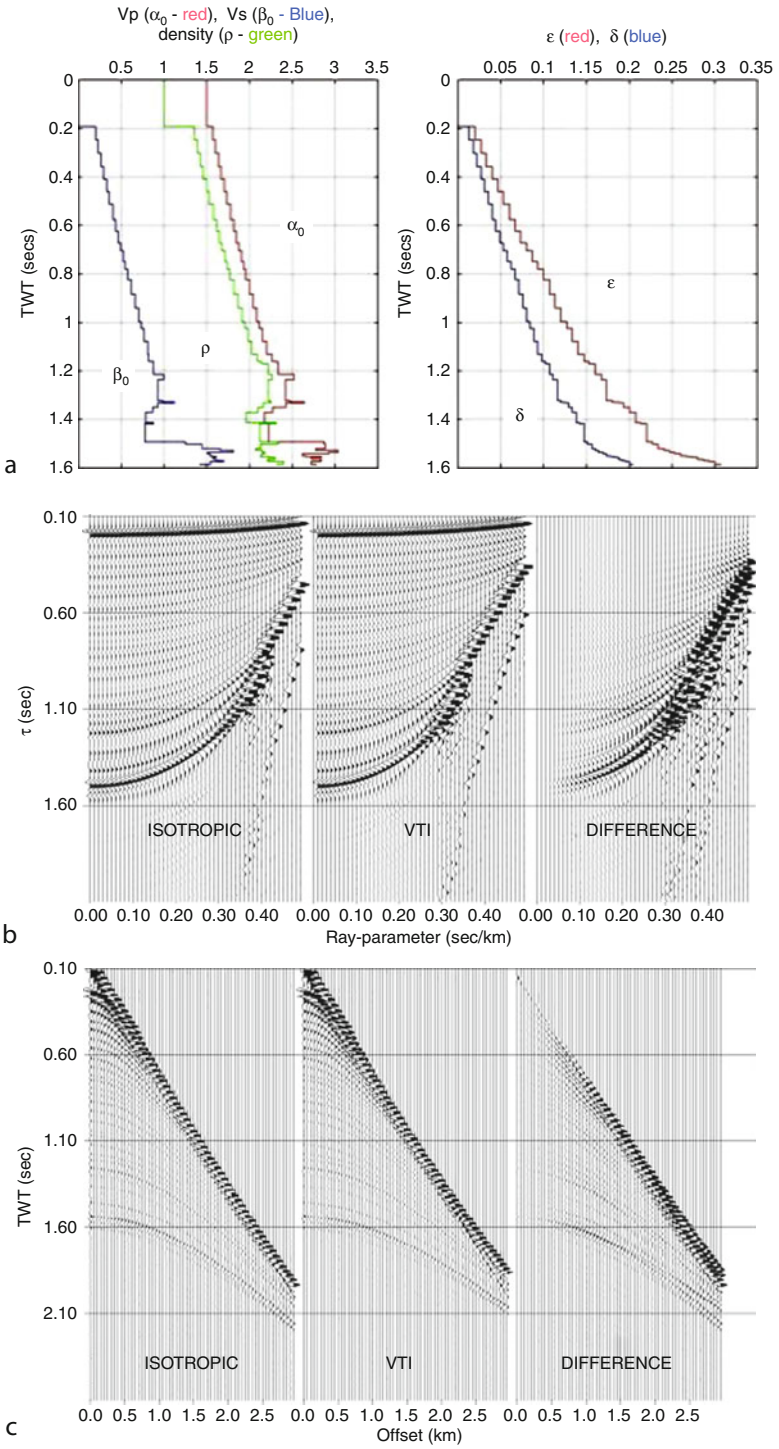
Modeling anisotropy in the core–mantle transition zone (D″): For modeling at regional and teleseismic distances, we need to apply earth-flattening transformation to the models prior to computing synthetic seismograms using a reflectivity code. An example of such modeling is given in Pulliam and Sen (1998) in which attempts were made to model shear wave splitting observations of S-wave phases that propagate nearly horizontally through the core–mantle transition zone. Figure 8 shows the data and the corresponding synthetic seismograms for a station at Hockley from earthquakes from Tonga-Fiji. The model used for reflectivity calculation includes transversely isotropic layers with a horizontal axis of symmetry within the D″ zone.

Modeling in azimuthally anisotropic media (comparison with FD): An example of comparison of azimuthally anisotropic reflectivity synthetic seismograms with those computed by a 3D azimuthally anisotropic finite-difference code is shown in Figure 9 (Bansal and Sen, 2008). The synthetics computed by the two methods are in excellent agreement.

Extension to laterally heterogeneous media

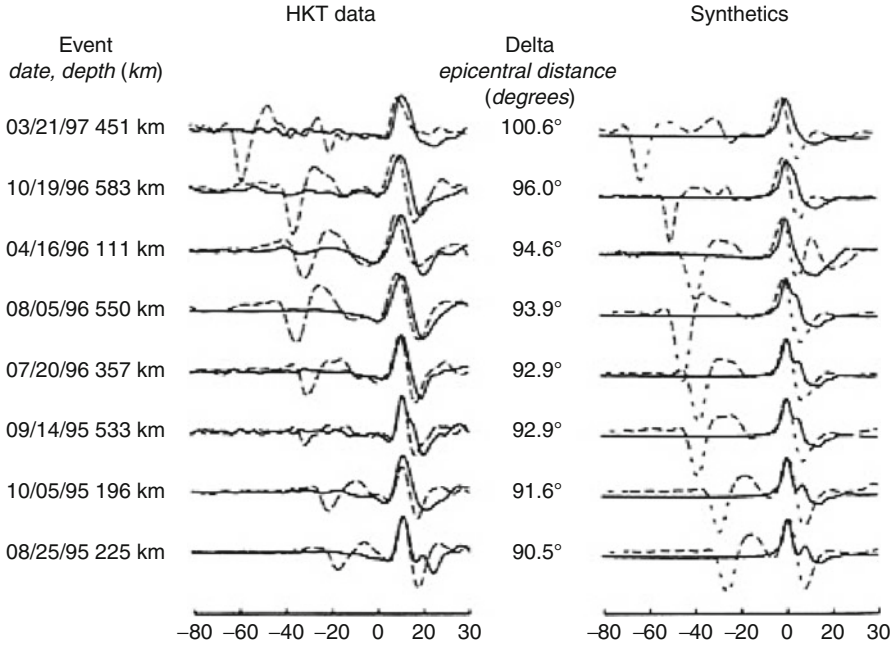
Extension of the reflectivity method to two dimensions, where the velocities and densities are allowed to vary laterally as well, is nontrivial. Koketsu et al. (1991) and Sen and Pal (2009) developed extended reflectivity methods for the case of homogeneous layers separated by irregular or curved interfaces which do not cross each other. Lateral media variations within a layer cannot be easily taken into account in a reflectivity-type formalism because the concept of an interface is inherent in it except using the concepts of pseudo-differential operators and Fourier Integral operators (McCoy et al., 1986).

Across a flat surface, the horizontal slowness p is conserved according to Snell's law. However, across an irregular interface, an incident ray with a particular p is scattered into different plane waves with slownesses p'. This is mathematically equivalent to Fourier transforming the dependence of z on x to the scattered set of p' or k' (wave number). Now the coefficients $\mathbf{R_D}(p)$, $\mathbf{R_U}(p)$, $\mathbf{T_D}(p)$, and $\mathbf{T_U}(p)$ become functions of both p and p'. The 2D extension of the method as proposed by Koketsu et al. (1991) involves explicit evaluation of boundary conditions that results in a matrix formulation involving several matrix inversions in the coupled ray-parameter domain; numerous numerical artifacts are caused by such matrix operations. An alternate asymptotic approach was



Seismic, Reflectivity Method, Figure 7 (**a**) *Vp*, *Vs*, density, *e* and *d* for a well log model; (**b**) plane wave synthetic seismograms for an isotropic model (*left*), VTI model (*middle*), and the difference (*right*); (**c**) offset synthetic seismograms for an isotropic model (*left*), VTI model (*middle*), and the difference (*right*).

proposed by Sen and Pal (2009) by examining a tangent-plane or Kirchhoff formulation in the plane wave domain to replace the exact boundary condition evaluation (Sen and Frazer, 1991). All other reflectivity operations such as the invariant imbedding or iterative computation of reflection, transmission, multiple, and mode conversions can be readily applied even under this approximation. This new algorithm computes noise-free seismograms even



Seismic, Reflectivity Method, Figure 8 Comparison of S-wave arrivals from Tonga-Fiji events recorded at Hockley station. Synthetic seismograms (*right panel*) were computed using a reflectivity code for a model containing transversely isotropic layers with a horizontal axis of symmetry within the core–mantle transition zone. with coarse sampling of the interfaces and ray-parameters. Approximate calculation of reflection/transmission coefficients, however, does not include multiple interaction of a plane wave with an interface.

Sen and pal (2009) performed computations in the coupled slowness domain and thus, multiple shot-receiver data can be synthesized rapidly. Intermediate results in the coupled slowness space provide important insight into understanding wave propagation in heterogeneous media. Figure 10 shows synthetic seismograms for a model with two homogeneous layers over a half space (Figure 10a) such that the top interface is flat and the second interface is dipping with a constant dip. Figure 10b shows synthetic seismograms in (τ-p-p') domain; note that for the flat layer, the scattered p is the same as the incident ray-parameter and the same for the dipping reflector is different from the incident ray-parameter. Synthetic shot gathers for three shot locations shown in Figure 10a are displayed in Figure 10c. These were all computed using a 2D reflectivity code in which internal multiples were not included. Similarly, Figure 11 shows the synthetic seismograms for a 2 layer over half space model where both the interfaces are curved. Note the triplicated arrivals in the seismograms in both τ-p-p' domain (Figure 11b) and shot gathers (Figure 11c). Note the triplicated arrivals in the seismograms due to curved interfaces.

Summary

Seismic modeling is crucial to understanding seismic wave propagation and interpreting field seismic records. Several methods for seismic modeling are available; they vary in accuracy, model assumptions, and computational speed. Of these, the reflectivity method is perhaps the most popular. The original reflectivity formulation is valid for 1D elastic media. It is capable of computing a complete response of a layered earth model. If needed, this can also be designed to compute responses of a few selected phases. The cost of computation grows with the number of layers, increase in frequency, and offset. Most isotropic models can now be computed fairly rapidly on standard desktop workstations or personal computers. Azimuthally anisotropic models require computations in two wave numbers and therefore can be computationally demanding. Parallel algorithms can be easily developed for rapid computation of reflectivity synthetic seismograms for large models. For 1D full waveform inversion, the reflectivity forward modeling is invoked a large number of times where a parallel reflectivity algorithm is also essential. The reflectivity algorithm has been used in a wide variety of applications including seismic modeling in exploration and whole earth scales. Full waveform inversion methods based on reflectivity forward modeling are becoming increasingly popular (e.g., Sen and Roy, 2003). The method has also been extended to modeling in laterally heterogeneous media and to electromagnetic modeling in layered media (Sena et al., 2008).

Seismic intrinsic attenuation

Definition

Linear viscoelastic attenuation. The fractional loss of seismic energy in a material in which elastic deformation (strain) induced by one cycle of a seismic wave or mode lags in time the applied stress associated with the wave or mode.

Apparent seismic attenuation. The loss of energy in a propagating seismic wave or standing mode due to viscoelasticity combined with the loss of scattered energy redistributed in time and space by heterogeneity.

Introduction

The amplitude of seismic waves decreases with increasing distance from earthquake, explosion, and impact sources. How this amplitude decreases, how rapidly it occurs, and how it depends on frequency of the seismic waves is fundamentally important to the efforts to describe Earth structure and seismic sources. The decay of amplitude of seismic waves with increasing distance of propagation through earth is known as seismic wave attenuation. The attenuation occurring under high-temperature rheological

conditions in the earth's interior can be called seismic viscoelastic attenuation.

Seismic attenuation and its variation with location within the Earth are useful for determining the anelastic properties of the earth as a function of depth. Seismic attenuation also shows large lateral variations that can be related to lateral variations in geological and geophysical properties not as easily detected by measurement of seismic velocities. In addition to providing information on a physical property, research in seismic attenuation has also been strongly motivated by more practical problems. One problem has been the prediction of ground motion due to probable earthquakes in different regions. The frequency content and decay with distance of this strong ground motion is an important input to the design of earthquake resistant structures and to disaster forecasting (see *Earthquakes, Strong-Ground Motion*). Another problem has been to estimate the size and detectability of underground nuclear tests (see *Seismic Monitoring of Nuclear Explosions*).

How do seismic waves attenuate?

The attenuation of seismic waves is due to three effects: geometric spreading, intrinsic attenuation, and scattering.

Geometric spreading

Geometric spreading leads to an energy density decrease that occurs as an elastic wave front expands with increasing distance from its source. In a homogeneous Earth of constant velocity and density, the geometric spreading of a seismic body wave is proportional to the reciprocal of the distance between source and receiver. In the real Earth, velocity and density vary strongly with depth and less so laterally. Given a model of this variation, however, the geometric spreading of a body wave can be easily calculated (see *Seismic, Ray Theory*).

Intrinsic viscoelastic attenuation

Intrinsic (viscoelastic) attenuation occurs at high temperatures due to internal friction during the passage of an elastic wave. It is controlled by the thermal and defect properties of the medium in which the wave is propagating. It can result in a phase lag between strain and stress giving rise to strain energy dissipation and associated frequency dependence (dispersion) of the relevant modulus or speed of the propagating elastic wave. The microscopic mechanisms of intrinsic attenuation have been described in several different ways, including the resistive and viscous properties of oscillator models of the atoms in crystalline lattices, the movement of interstitial fluids between grain boundaries and cracks (O'Connell and Budiansky, 1977), and the frictional sliding of cracks. Jackson (1993, 2007) reviews laboratory experiments that investigate microscopic mechanisms of intrinsic attenuation. This article concentrates on the measurement of intrinsic attenuation from recordings of seismic waves at great distance.

Scattering attenuation

Scattering attenuation occurs when elastic energy is scattered and redistributed into directions away from the receiver or into waves arriving in later time windows at the receiver (see *Seismic Waves, Scattering*). Scattering takes place by reflection, refraction, and mode conversion of elastic energy by wavelength-scale irregularities in the medium. These irregularities are discontinuous or rapid variations in the velocity and/or density of the medium. In the crust and uppermost mantle, variations in velocity and density can be particularly strong in the lateral as well as the vertical direction.

Linear viscoelasticity

Rheology

A stress is a vector force per unit area applied to a solid. A strain is non-dimensional measure of the deformation of the solid due to the applied stress, such as the change in a length element divided by the original length. The equation that relates stress and strain is sometimes termed the *rheology* or the *constitutive* relation (see *Mantle Viscosity*). A linear viscoelastic rheology can be described by a linear differential equation:

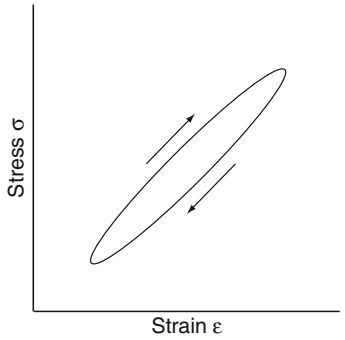
$$L_1\sigma(t) = L_2\varepsilon(t) \tag{1}$$

Where L_1 and L_2 are any linear combinations of operators of the time $\frac{d^n}{dt^n}$ or $\int dt^n$. This type of equation can describe both the elastic strain of a material over a short time interval of applied stress as well as its viscous behavior and flow over a longer time interval (Gross, 1953; Nowick and Berry, 1972; Jackson et al., 2005; Kohistedt, 2007).

Anelastic hysteresis

Seismic oscillations at distances beyond several fault lengths from an earthquake excite small strains less than 10^{-6}. These strains are recoverable during a cycle of seismic oscillation and lag the applied stress of the oscillation in time. Because of the time lag, a cycle of increasing and decreasing stress does not produce a perfectly proportional increase and decrease in strain. Instead a hysteresis loop occurs (Figure 1). The area enclosed by the hysteresis loop is a measure of the energy lost due to heat and internal friction. During the stress cycle associated with the passage of a seismic wave, the energy lost to this internal friction is not available to deform the adjacent regions of the solid ahead of the wave front and therefore the amplitude of the wave decreases.

From the hysteresis curve, one can see that the stress–strain relation cannot be described by a simple constant of proportionality in the time domain. A more complicated relation involving an integral over time is required to describe strain at any instant of time as a function of the prior time history of the applied stress. By Fourier transforming the rheologic equation, however, and keeping only terms describing the short-term anelastic behavior, the stress–strain relation can be simply expressed



Seismic, Viscoelastic Attenuation, Figure 1 Stress–strain hysteresis curve showing the behavior of strain during a cycle of applied stress induced by a propagating seismic wave.

by means of either a complex elastic modulus $\hat{G}(\omega)$ or by its reciprocal, the complex elastic compliance, $\hat{J}(\omega)$:

$$\hat{\sigma}(\omega) = \hat{G}(\omega)\varepsilon(\omega) \tag{2a}$$

$$\hat{\varepsilon}(\omega) = \hat{J}(\omega)\hat{\sigma}(\omega) \tag{2b}$$

The elastic modulus $\hat{G}$ and compliance $\hat{J}$ must be a complex numbers to describe the phase lag of strain. $\hat{G}$ and $\hat{J}$ must also be frequency dependent because the phase lag of strain depends on the time history of stress, the shape of the hysteresis curve changing with different load histories. All the usual measures of anelasticity, including the frequency-dependent quality factor $Q(\omega)$ and the dispersion of the complex phase velocity $\hat{v}(\omega)$ can be expressed in terms of the complex compliance $\hat{J}(\omega)$ (Jackson and Anderson, 1970).The trend of the frequency dependencies can be inferred from the time lag of strain from applied stress.

A feature of the complex modulus is that its real part will be smaller at zero or very low frequency and larger at infinite or very high frequency. That is, there will be an instantaneous response of strain to the applied stress, which is smaller than the eventual equilibrium response after longer time. The difference between the modulus at infinite frequency $G(\infty)$, representing the instantaneous or *unrelaxed* response, and the low-frequency limit of the modulus $G(0)$, for the equilibrium or *relaxed* response, is called the *modulus defec*t ΔG, with

$$\Delta G = G(\infty) - G(0) \tag{3}$$

The relaxed and unrelaxed moduli are pure real numbers that can be determined by observing a sequence of hysteresis curves for increasing frequencies of monochromatic loads. The frequency dependence of the real part of the modulus G at frequencies between 0 and ∞ implies that the propagation of a stress pulse will be dispersive, with higher frequencies traveling faster than lower frequencies.

Q and complex velocity

Since simple mechanical systems, composed of springs and dashpots and simple electric circuits also obey linear equations of the form of Equations 2a, b, there are analogies between the quantities describing these systems and quantities in the stress–strain relation. For example, strain behaves like voltage, stress like current, and the complex compliance $\hat{J}$ like the complex impedance of an electric circuit. Similar to the resonance phenomenon in circuits and mechanical systems, a Q can be defined by the average energy W per cycle divided by the energy lost or work done per cycle, ΔW:

$$Q = \frac{W}{\Delta W} \tag{4}$$

Large Q's imply small energy loss; small Q's imply large loss. Q is a measure of the area contained in the hysteresis loop of a stress–strain cycle. The inverse of (Equation 4), Q^{-1}, is sometimes simply termed the *attenuation or internal friction* (Knopoff, 1964*)*.

Plane waves of frequency ω and propagating in the + or − direction can be defined by the phasor $\exp(i\omega t - \hat{k}t)$ where $\hat{k}$ is a complex wave number $\frac{\omega}{\hat{c}}$ and $\hat{c}$ is a complex velocity defined from the local density ρ and complex modulus $\hat{G}$, with

$$\hat{c} = \sqrt{\frac{\hat{G}}{\rho}} \tag{5}$$

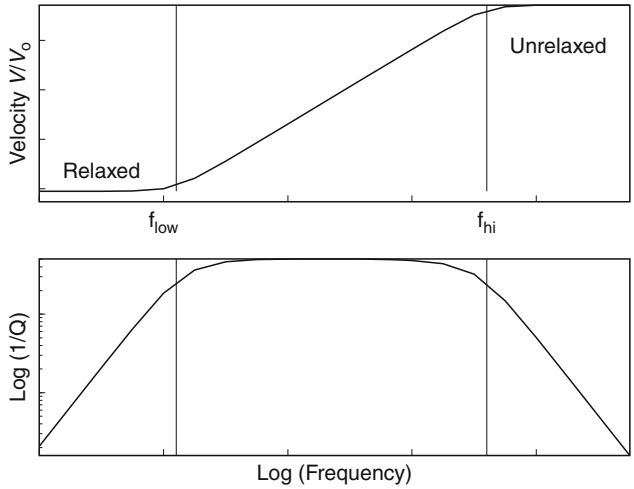
From the average energy density and loss per cycle of a complex plane wave, it can be shown that $Q = \frac{\mathrm{Re}(\hat{G})}{\mathrm{Im}(\hat{G})}$. It is often less confusing to report the reciprocal parameter Q^{-1}, which represents the usually small perturbations to perfect elasticity.

The $Q^{-1}(\omega)$ relaxation spectrum

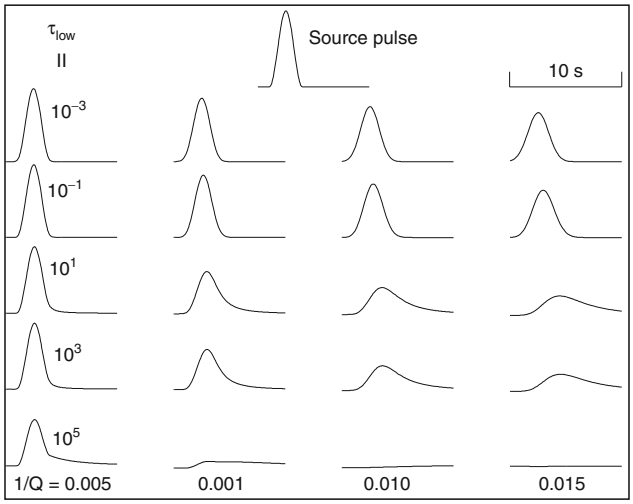
Since $\hat{G}$ depends on frequency, Q also depends on frequency. Zener (1960) described the frequency-dependent effects on an elastic modulus of a solid having a single characteristic time τ for the relaxation of stress. A distribution of relaxation times can be constructed to give a Q^{-1} having a general dependence on frequency. The function $Q^{-1}(\omega)$ is called the *relaxation spectrum*. In the Earth and in many solid materials, the relaxation spectrum is observed to be slowly varying and nearly constant over a broadband of frequencies. A theoretical requirement is that the attenuation Q^{-1} cannot increase faster than ω^1 or decrease faster than ω^{-1}. Figure 2 shows how a continuous distribution of relaxations can produce a Q^{-1} that is nearly constant with a frequency over a broadband. Once the limits of an absorption band are specified, however, it is not possible to have an arbitrarily high Q^{-1} (low viscoelastic Q) over an arbitrarily broad-frequency band without making an unrealistically large modulus defect ΔG. Measured modulus defects in shear are typically less than 25%.

Velocity dispersion

Although the dispersion in elastic moduli had long been known and predicted from the theories of viscoelasticity,



Seismic, Viscoelastic Attenuation, Figure 2 Viscoelastic dispersion of seismic velocity (*top*) and attenuation (*bottom*) showing a relaxation spectrum constant with frequency between two corner frequencies.



Seismic, Viscoelastic Attenuation, Figure 3 Pulse distortion showing the effects of viscoelastic dispersion for variable low-frequency corner and peak attenuation.

it was only widely recognized in seismology when velocity models determined in the low-frequency band from the normal modes of the earth (0.0001–0.01 Hz) were compared with velocity models determined in a high-frequency band (0.1–10 Hz) of body waves (Dziewonski and Anderson, 1981). The models were found to differ and the difference was found to agree with the amount of dispersion predicted from average Q models of the Earth. For example, since the preliminary reference Earth model (PREM), was derived from observations of both the travel times of body waves as well as the eigen frequencies of free oscillations, it reports velocities referenced at both 0.001 Hz and at 1 Hz.

Another more subtle effect of this velocity dispersion can be seen in the propagation of pulses as body waves. A stress disturbance that propagates from its point of initiation as a symmetric narrow Gaussian or triangle-shaped function in time gradually evolves into an asymmetric pulse (Figure 3). High frequencies traveling faster than low frequencies are preferentially loaded into the front of the pulse (Futterman, 1962; Carpenter, 1967). Common theories for the physical mechanism of earthquakes as either frictional slip on a plane or a propagating crack triggered by tectonic stress often predict a far-field displacement pulse that has either a different or opposite form of asymmetry than that predicted for the effect of viscoelastic attenuation. These differences can assist in separating the effects of the source-time history from the effects of viscoelastic attenuation.

Effects of scattering

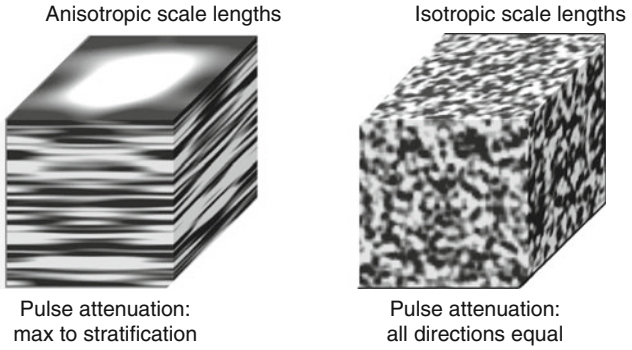
Equivalent medium

At frequencies that are so low that wavelengths are much larger than the characteristic scales of heterogeneity, the attenuative effects of scattering can usually be neglected. At sufficiently low frequency, little energy is lost to scattering, and the medium behaves like an equivalent medium, having properties that are an average of small-scale heterogeneities.

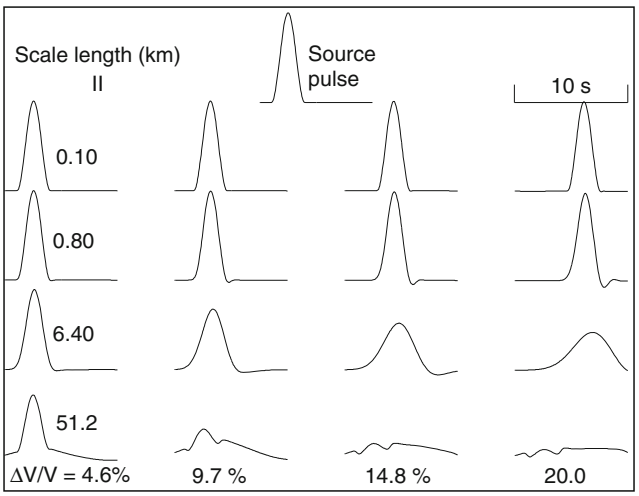
Stochastic dispersion

The most complicated domain in which to perform calculations is where the wavelength is of the order of the scale length of the heterogeneity (Figure 4). In this domain, the presence of heterogeneities can profoundly alter the propagation of the wavefield, both the initial cycle of a body wave pulse as well as the motion immediately following the initial cycle or *coda*. The effects of scattering can be calculated in a one-dimensional medium consisting of thin planar layers in which the velocity in each layer is assigned randomly (O'Doherty and Anstey, 1971; Richards and Menke, 1983). A prediction of such experiments is that body waves will exhibit a stochastic dispersion in which high-frequency energy is transferred into the coda following the first several cycles. This stochastic dispersion may have some biasing effects on measures of intrinsic attenuation. In measures of the spectrum taken over a narrow time window, different results can be obtained, depending on the length of window analyzed, with less attenuation of higher frequencies estimated from longer time windows.

Pulse measurements such as width and rise time may also be biased because higher-frequency energy has been transferred out of the pulse into the later coda. This behavior is opposite to the effects of intrinsic attenuation on a propagating pulse, in which higher frequencies arrive at the beginning of the pulse. A symmetrically shaped displacement source pulse loses less of its symmetry as it propagates through the heterogeneous medium (Figure 5). Anisotropy of the scale lengths of heterogeneity can also be important factor (Hong and Wu, 2005), attenuation being strongest for paths for which the



Seismic, Viscoelastic Attenuation, Figure 4 Example heterogeneity in the Earth and the directional dependence of attenuation of a body wave pulse for wavelengths that are approximately equal to either the dominant scale length (isotropic heterogeneity) or the dominant scale length in the direction of propagation (anisotropic heterogeneity).



Seismic, Viscoelastic Attenuation, Figure 5 Pulse distortion showing the effects of scattering attenuation for variable scale lengths and velocity perturbation calculated by Cormier and Li (2002) using the Dynamic Composite Elastic Modulus (DYCEM) theory of Kaelin and Johnson (1998).

wavelength is of the order of the characteristic scale length in the medium in that direction.

Effects of anisotropy

The existence of general anisotropy in the real part of the elastic modulus has the potential to bias some estimates of anelastic attenuation from either shear wave pulses or surface waves. In a medium having general anisotropy, the decompositions of shear wave motion into SH and SV motion will each contain the interference of two orthogonal shear wave polarizations that are neither SH nor SV (see *Shear-Wave Splitting: New Geophysics and Earthquake Stress-Forecasting*). The broadening of the SH component due to the interference of two quasi-S waves arriving close in time can be mistaken for the broadening due to anelastic attenuation. The regions of the deep Earth characterized by the strongest elastic anisotropy are the upper 400 km of the mantle (Silver, 1996) and the lowermost 400 km of the mantle near the core-mantle boundary (Panning and Romanowiz, 2006). The effects of elastic anisotropy must be removed by combined analysis of SV and SH components of motion, resolving the polarizations of two quasi-S waves, before viscoelastic attenuation can be properly measured.

Measurement and modeling attenuation

Measurements of amplitude of seismic waves may be taken directly from seismograms or from their frequency spectra. To measure the attenuation, we must predict its effects from a model and vary the parameters of the model to fit the observed amplitude, amplitude ratio, or waveform. The effects of intrinsic attenuation in any modeling algorithm operating in the frequency domain can be simply obtained by allowing elastic moduli and/propagation velocities to become complex. Elastic boundary conditions, reflection and transmission at boundaries, travel times, and amplitudes are calculated exactly as in a non-attenuating solid but with elastic moduli and associated velocities analytically continued to complex values. This step of analytic continuation of real moduli to complex moduli is the same whether one wishes to predict the waveform of a body wave or surface wave or spectrum of free oscillations. The size of the imaginary part of the elastic moduli, parameterized by the value of Q^{-1}as a function of depth and frequency, is chosen to match an observed waveform, spectrum, amplitude ratio, or spectral ratio.

The attenuation operator for body waves

As an example of these procedures, consider an experiment with body waves. The effects on a body wave of source radiation, geometric spreading, reflection-transmission, and intrinsic attenuation are most conveniently expressed in the frequency domain by a product of complex functions. The complex $\hat{\Omega}(\vec{x},\omega)$ spectrum of a body wave propagation from a point $\vec{x}_o$ to a receiver at $\vec{x}$ is

$$\hat{\Omega}(\vec{x},\omega) = \hat{B}(\vec{x}_o,\vec{x},\omega)\,\hat{S}(\omega)\,\hat{A}(\omega) \tag{6}$$

The function $\hat{S}(\omega)$ is the Fourier transform of the source-time function. $\hat{B}(\vec{x}_o,\vec{x},\omega)$ incorporates a product of reflection-transmission coefficients, reverberations at source and receiver, geometric spreading, and source radiation pattern. $\hat{A}(\omega)$ is defined by

$$\hat{A}(\omega) = \exp[i\omega\,\hat{T}(\omega)] \tag{7}$$

where $\hat{T}(\omega)$ is the complex travel time obtained by integrating the reciprocal of complex velocity along a ray or normal to the wave front of the body wave:

$$\hat{T}(\omega) = \int_{\text{ray}} \hat{c}(\omega)\mathrm{d}s \tag{8}$$

For body waves, the dominant effect of attenuation on amplitude and phase is given by $\hat{A}(\omega)$. The effects of attenuation on reflection-transmission coefficients and geometric spreading, which have been lumped into $\hat{B}$ are much smaller and can be neglected unless the attenuation is very large (Q is very small). For $Q >> 1$, $\hat{A}(\omega)$ can be rewritten as

$$\hat{A}(\omega) = \exp\left[\frac{-\omega t*(\omega)}{2}\right] \exp\left\{i\omega\left[\mathrm{Re}\ \hat{T}(\infty) - \frac{H[t*(\omega)]}{2}\right]\right\} \tag{9}$$

where

$$t*(\omega) = \int_{\text{ray}} \frac{Q^{-1}}{\hat{c}(\omega)} ds \tag{10}$$

In Equation 9, the attenuation effect is contained in the factor $\exp\left[\frac{-\omega t*(\omega)}{2}\right]$, and the dispersive effect is in the factor $\exp\left\{i\omega\left[\mathrm{Re}\ \hat{T}(\infty) - \frac{H[t*(\omega)]}{2}\right]\right\}$. The operator H is a Hilbert transform. In a band of frequencies in which Q and t^* are nearly constant

$$H[t*(\omega)]/2 = \frac{\ln(\omega/\omega_0)}{\pi}\ t* \tag{11}$$

where ω_0 is a reference frequency contained in the band (Liu et al., 1976). The value of $T(\infty)$ need not be known and can be replaced by some reference time or predicted from an Earth model for the phase being analyzed. The Hilbert transform relation in Equation 11 for the dispersive phase of $\hat{A}(\omega)$ says that $\hat{A}(\omega)$ must be a minimum phase filter in the frequency domain. In general, the Fourier transform of the source-time function, $\hat{S}(\omega)$, is not a minimum phase filter, which can help in the separation and discrimination of the source spectrum from the effects of $\hat{A}(\omega)$ in the total expression for the far-field spectrum $\Omega(\vec{x}, \omega)$.

The phase given by Equation 11 will be accurate only between and far from the low- and high-frequency corners of the relaxation spectrum. Accurate representations of $\hat{A}(\omega)$ across a broad-frequency band can be obtained for general relaxation spectra by substituting expressions for complex velocity $\hat{c}(\omega)$ in Equation 8 obtained by superposing multiple Zener relaxations centered on single relaxation times whose strength is varied to achieve a desired shape for the relaxation spectrum. A useful expression for $\hat{c}(\omega)$ that is accurate for all frequencies across a relaxation spectrum, which is flat between two corner frequencies, can be derived from formulae for complex modulus given by Minster (1978), and is

$$\hat{c}(\omega) = c_{\text{ref}}(\omega_0)\frac{\sqrt{1 + 2\pi Q^{-1}\ln[\psi(\omega)]}}{\mathrm{Re}\sqrt{1 + 2\pi Q^{-1}\ln[\psi(\omega_0)]}} \tag{12a}$$

where

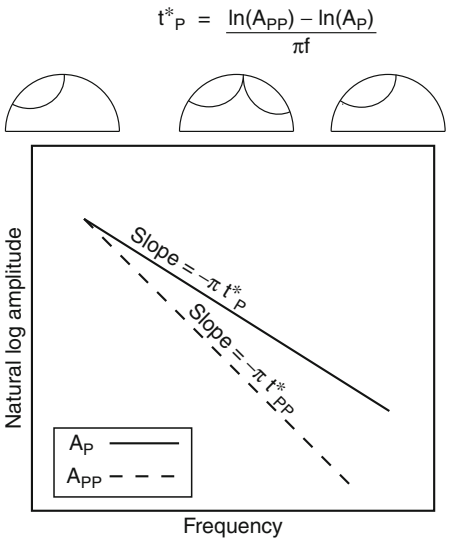
$$\psi(\omega) = \frac{i\omega + 1/\tau_1}{i\omega + 1/\tau_2} \tag{12b}$$

with τ_1 and τ_2 the relaxation times corresponding to the low and high frequency corners respectively. $c_{ref}(\omega_0)$ is a real velocity at the reference frequency ω_0.

Most measurements of attenuation attempt to measure only the amplitude effect of attenuation through the term $\exp[-\omega t*(\omega)/2]$ from the spectral shape of body waves. There are basically two types of experiments commonly reported: matching of (1) spectral decay rates and (2) spectral ratios. In experiment (1) a shape for the displacement source spectrum $S(\omega)$ is assumed usually to be a flat level followed by a decay of ω^{-2} above a corner frequency. The additional decay observed at high frequencies in data spectra is taken as a measure of $t*$ in $\exp[-\omega t*(\omega)/2]$. In experiment (2), a ratio of two different seismic phases from the same source is observed in which the source spectrum is assumed to approximately cancel and the factor related to ratios of geometric spreading and near source and receiver crustal reverberations can be assumed to contribute a simple constant scalar factor. If the phases analyzed are recorded at the same receiver and are incident at nearly the same angles, then crustal reverberations at the source and receiver will approximately cancel. Both types of experiments usually apply some type of smoothing to the spectra to remove biasing effects of spectral holes caused by interfering crustal multiples, source complexities, scattering, and multipathing that are not included in the simple propagation model. Figure 6 illustrates an attenuation experiment of this type.

Since t^* measures only the path-integrated effect of attenuation, many such experiments for different ray paths, bottoming at a range of different depths, are needed to construct a model of Q as a function of depth. Serious breakdowns in this approach, however, exist for cases in which the factorization of the observed spectrum into a product of a geometric spreading, source spectrum, and crustal effects is no longer accurate. One such case is when the body waves in question experience frequency-dependent effects of diffraction near caustics or grazing incidence to discontinuities. The spectral ratios of PKnKP waves, for example, are dominated by the effects of frequency-dependent reflection and transmission coefficients at grazing incidence to the core-mantle boundary. Instead of decreasing linearly with increasing frequency, an observed spectral ratio increases with frequency and exhibits a curvature in a log-log plot, which is consistent with a Q near infinity ($Q^{-1} = 0$) in the other core (Cormier and Richards, 1976).

It is becoming more common to model and invert for viscoelastic attenuation parameters in the time domain, including not only the magnitude of the viscoelastic attenuation parameter Q^{-1}, but also its frequency dependence. Examples of such a study are the inversions for Q^{-1} in the inner core assuming either a viscoelastic



Seismic, Viscoelastic Attenuation, Figure 6 The steps (*top*) to measure the path-integrated attenuation t^* of P waves in the mantle from a log-log plot (*bottom*) of stacked PP and P spectra (A_{PP} and A_P). The distances of observed P and PP spectra are chosen such that each turning ray path of PP is identical in shape and length to that of the single turning ray path of P in the mantle (Adapted from figures in Warren and Shearer, 2000).

(Li and Cormier, 2002) or a scattering origin of attenuation (Cormier and Li, 2002). In these studies, the combined effects of mantle attenuation and source-time function were first modeled by fitting P waves observed in the great circle range 30–90°. Attenuation in the liquid outer core was assumed to be zero. Parameters defining a viscoelastic relaxation spectrum in the inner core were then varied to match the observed PKIKP waveforms. Care must be taken to examine a broad range of attenuation parameters because waveform inversions of this type are very non-linear.

Free oscillations and surface waves

Measurements of attenuation in the low-frequency band of the free oscillations of the Earth are conducted in the frequency domain by observing the width of the individual resonance peaks associated with each mode. These measurements face special problems associated with the broadening produced by lateral heterogeneity of elastic Earth structure. This heterogeneity splits the degenerate modes of a radially symmetric Earth, making a set of modes that would have the same frequency have slightly different frequencies. The slightly different frequencies of the split modes may not be easily resolved in the data spectra and can be confused with the broadening of a single resonance peak of a mode caused by attenuation.

Lateral heterogeneity also complicates the measurement of viscoelastic attenuation of surface waves. Heterogeneity introduces focusing, defocusing, and multipathing, all of which must be accurately modeled to understand the separate attenuative effects of viscoelasticity.

The frequency band of free-oscillation and surface waves (0.001–0.1 Hz), however, offers the best hope of obtaining radially symmetric whole-Earth models of viscoelastic attenuation in this frequency band. This is because lateral variations in attenuation structure are averaged by the gravest modes of oscillation and surface waves that make multiple circuits around the Earth. Computational advances have made the division between free-oscillation and surface wave studies fuzzier, with common approaches now amounting to time-domain modeling of complete low-frequency (<0.1 Hz) seismograms for combined three-dimensional models of viscoelasticity and heterogeneity.

Numerical modeling

Fully numerical modeling of the seismic wavefield allows the combined effects of heterogeneity and viscoelasticity in three-dimensions to be predicted. If the numerical technique is formulated in the frequency domain, substituting a complex velocity for an assumed relaxation spectrum can incorporate viscoelastic attenuation.

If the technique is formulated in the time domain by a finite difference approach, it is neither simple nor efficient to incorporate attenuation by convolution of the wavefield calculated in a non-attenuating medium with an attenuation operator $A(t)$ for individual waves propagating in the attenuating medium, where $A(t)$ is the Fourier transform of $\widehat{A}(\omega)$ defined in Equation 9. Instead, time-domain *memory functions* can be defined to describe a viscoelastic relaxation (Robertsson et al., 1994; Blanch et al., 1995) that can be integrated over time simultaneously with the equations describing particle velocity or displacement and stress. In practice, only three-memory functions, distributed evenly over the logarithm of their characteristic times, are required to simulate a broad frequency band in which Q^{-1} varies slowly.

Interpretation of attenuation measurements in the earth

Shear versus bulk attenuation

In the most general theory of viscoleasticity, it is possible to have with energy loss to occur during both a cycle of volumetric strain as well as shear strain. Since the velocity of a P wave depends on both the bulk and shear moduli, the attenuation Q_P^{-1} of a P wave can be written as a linear combination of the attenuations Q_K^{-1} and Q_S^{-1} defined from complex shear and bulk moduli:

$$Q_P^{-1} = L\,Q_S^{-1} + (1 - L)\,Q_K^{-1} \tag{13}$$

where $(4/3)(V_S/V_P)^2$ and V_P and V_S are the compressional and shear velocities respectively (Anderson, 1989). Although plausible mechanisms for defects in bulk moduli have been found in both laboratory measurements and analytic models of specific attenuation mechanisms, measurements on real data find that bulk dissipation in

the earth is small and, in most cases, can be neglected. One exception may occur when the pressure and temperature state in a narrow depth regions of the earth are close to those near a phase transition, either solid–liquid (Stevenson, 1983) or solid–solid (Ricard and Chambat, 2009). Except for these regions, intrinsic attenuation occurs almost entirely in shear, associated with lateral movement of lattice defects, grain boundaries and/or fluids rather than with changes in material volume. Hence, for viscoelastic attenuation purely in shear in a Poisson solid, for which $V_P = \sqrt{3}\, V_S$,

$$Q_P^{-1} = \frac{4}{9}\, Q_s^{-1} \tag{14}$$

and the parameter for path-integrated attenuation of S waves or $t*_S$ is approximately $4\, t*_P$. Most experiments confirm these values. There is a suggestion, however, that the apparent Q_P^{-1} tends to approach Q_S^{-1} and $t*_S < 4\, t*_P$ at frequencies higher than 1 Hz. These observations are likely evidence of scattering rather than of bulk attenuation because the effects of scattering increase at higher frequencies. With scattering, the apparent Q_S^{-1} tends to approach the apparent Q_P^{-1}, especially when they are measured from pulse widths or spectra taken in a frequency band and medium for which wavelengths are of the order of richest heterogeneity scale lengths of the medium. Thus, the assumption of viscoelastic attenuation occurring mainly in shear can aid in separating the effects of scattering from intrinsic attenuation in body wave pulses.

Frequency dependence

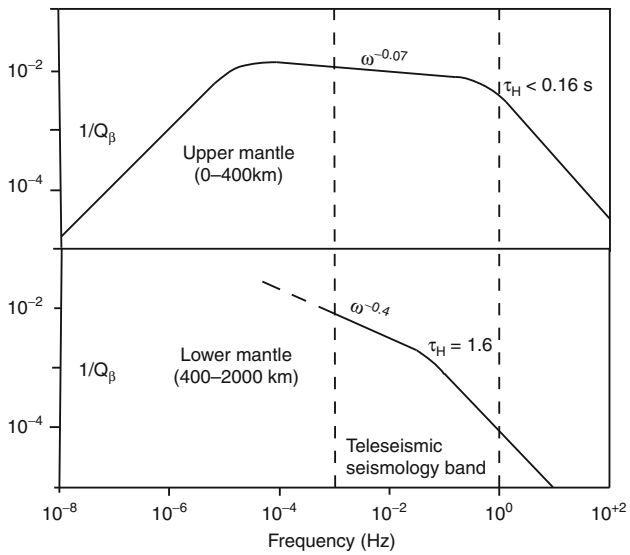
When the results of attenuation measurements determined from free-oscillations and body waves in the 0.0001–0.1 Hz band began to be compared with observations of body wave spectra in the 1–10 Hz band, it became apparent that even under the assumption of a white source spectrum that an increase in Q with frequency was necessary to explain the amplitude of spectra in the 1–10 Hz band.

Thermal activation

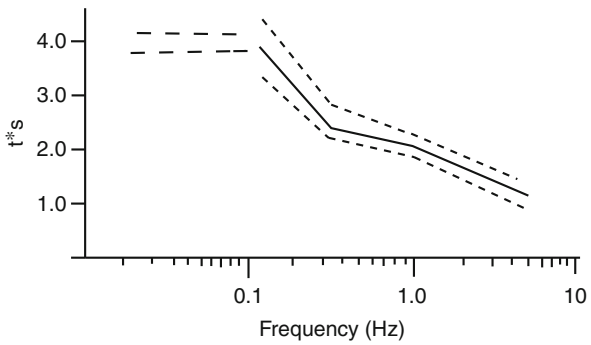
Frequency dependence of viscoelastic attenuation has been interpreted in terms of physical mechanisms of attenuation that are thermally activated. In these mechanisms, the low-frequency corner f_L is tied to a relaxation time τ_L, where $f_L = 1/(2\,\pi\,\tau_L)$. The time τ_L depends on temperature T and pressure P as follows:

$$\tau_L = \tau_0 \exp\left(\frac{E* + PV*}{RT}\right) \tag{15}$$

where $E*$ and $V*$ are the activation energy and volume, respectively. Both the low- and high-frequency corners (f_L, f_H) of an absorption band are assumed to be similarly affected, temperature and pressure acting to slide the absorption band through a band of frequencies. A typical width to expect for the relaxation spectrum of the mantle is about 5 orders of magnitude in frequency, $\tau_L/\tau_H = 10^5$ (Minster and Anderson, 1981; Anderson and Given, 1982). A simplified model of an absorption band with depth in the earth's mantle is shown in Figure 7. The movement of the absorption band toward lower frequencies longer periods in the mantle below 400 km depth is consistent with the type of behavior shown in Figure 8 for the $t*_S$ measured from shear waves of an earthquake. The difference in the location of the absorption band with respect to the band of seismic frequencies is consistent with models of the temperature and pressure profiles of



Seismic, Viscoelastic Attenuation, Figure 7 A frequency and depth-dependent model of shear attenuation in the Earth's mantle derived from modeling broadband shear waves. This model has been used by the National Earthquake Information Center (NEIC) to correct for viscoelastic attenuation in the reported radiated elastic energy from earthquakes (Boatwright and Choy, 1986; Choy and Boatwright, 1995).



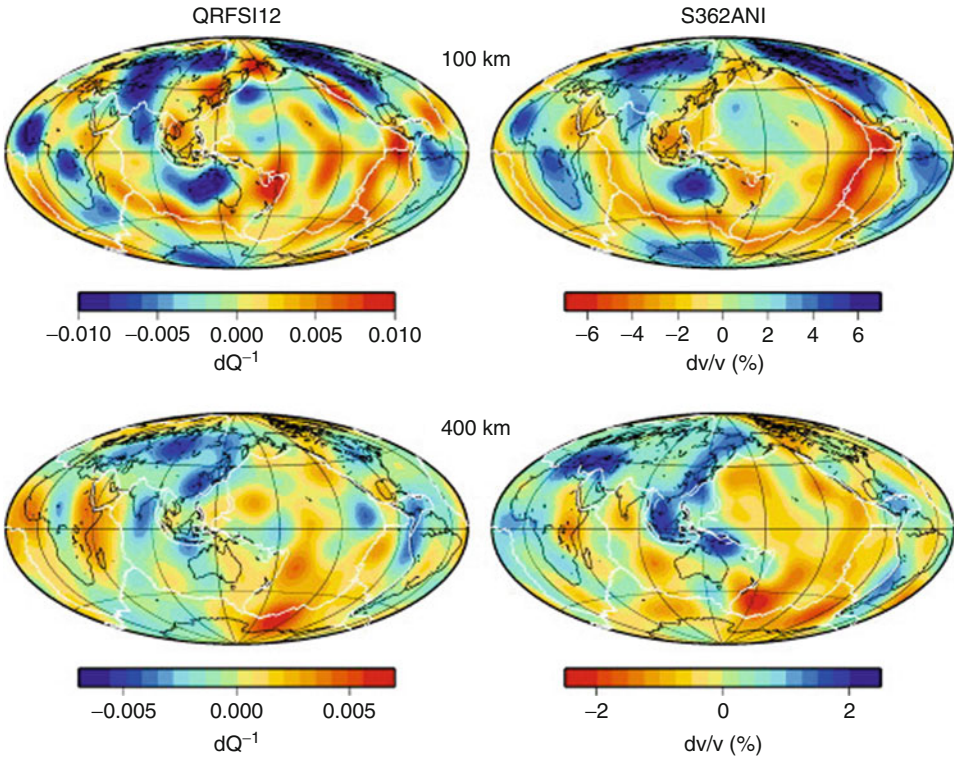
Seismic, Viscoelastic Attenuation, Figure 8 Path-integrated attenuation $t*$ of S waves in the mantle as a function of frequency determined from modeling broadband shear waves predicted from the frequency and depth-dependent attenuation model shown in Figure 7 (Choy and Cormier, 1986).

the Earth's mantle for specific values of E^* and V^*. Relaxation times are also affected by the grain size of minerals, which may increase from millimeter to centimeter in the upper 400 km of the mantle (Faul and Jackson, 2005). A rapid increase in temperature with depth can rapidly change the location of the absorption band with respect to the seismic band. Given a specific temperature profile, estimated values of the activation energy and volume, and grain size, a combined shear velocity and Q_S profile can be predicted and modified to fit an observed shear velocity profile.

Regional variations

Romanowicz and Mitchell (2007) review and interpret both global and many regional variations in intrinsic attenuation, including correlations with velocity perturbations. Tomographic images of perturbations to seismic velocities and attenuations in the mantle can qualitatively be interpreted as images of lateral temperature variations, leaving open the possibility of additional contributions to the observed heterogeneity from chemical variations. In the upper mantle, tectonically active regions overlain by radiogenically younger crust are more attenuating than the mantle underlying inactive regions such as continental shields (Figure 9). The shape of the frequency dependence across the seismic band seems to remain similar in different regions, although the Q at a given frequency is lower for a tectonically young region than for an older shield region. Although motion of interstitial water and partial melt can produce high attenuation, grain boundary and defect mechanisms in a dry mantle have been shown to be equally effective in explaining regions of high attenuation in the upper mantle, except possibly behind island arcs and directly beneath active spreading ridges (Karato and Jung, 1998; Faul and Jackson, 2005).

Generally, perturbations in attenuation Q^{-1} inversely correlate with those in shear wave velocity (Roth et al., 2000). The correlations between shear velocity and shear attenuation appear to be consistent with thermal activation, in which the dispersive effect of attenuation acts jointly with variations in the high-frequency corner of the mantle relaxation spectrum to produce the observed variations in travel time and frequency content. Deep chemical differences between the upper mantle beneath shields and that beneath young continents and oceans as well as in the deep mantle, however, have been suggested by comparing anomalies in shear velocity versus bulk velocity V_K, where $V_K = \sqrt{V_P^2 - (4/3)V_S^2}$. Milder lateral temperature differences in the mid- and lower mantle tend to make the relaxation spectrum more laterally stable in height, width, and location within a frequency band, reducing the observed lateral heterogeneity in velocity and attenuation in these regions.



Seismic, Viscoelastic Attenuation, Figure 9 Inverted upper mantle shear velocity perturbations and shear attenuation. (From Dalton et al., 2009).

Global models of attenuation (e.g., Gung and Romanowicz, 2004) often do not have the resolving power to detect spatially concentrated regions of high attenuation and sharp spatial gradients found in regional studies beneath and near island arcs, mid-ocean spreading ridges, and hot mantle plumes. The dense path coverage required of higher-frequency (0.1–2 Hz) body waves to resolve smaller spatial scales usually is lacking, except in regions containing dense seismic networks. Even larger scale, long-established lateral variations, such as high attenuation west of the Rocky Mountains in North America and low-attenuation east (Der et al., 1982), are not very apparent in some global studies (Warren and Shearer, 2002).

Strain dependence

Laboratory measurements of Q in rocks find dependence in strain beginning at strains of about 10^{-6}. The strain dependence decreases with increasing confining pressure. The Q is also strongly dependent on moisture and interstitial fluids between cracks in rocks and grain boundaries and soils. These observations are consistent with a physical mechanism of frictional sliding across cracks. Unlike viscoelastic relaxations, which are representative of all linear mechanisms, frictional sliding is an inherently non-linear mechanism, depending on strain amplitude.

Estimates, when non-linear effects occur, may be made by calculating the strain associated with the seismic wave being analyzed. A rough estimate can be obtained by assuming that the wave front is a plane wave and dividing the particle velocity by the propagation velocity. For example, the particle velocities of body waves observed in strong ground motion recordings from 0 km to 10 km from the hypocenter of a magnitude 6 earthquake are typically 0.01 m/s. If the body wave propagates at 3 km/s, the strain observed at the strong ground motion site is roughly 0.01 m/s divided by 3×10^3 m/s or strain = 3.3×10^{-5}. This value is likely to be in the non-linear regime of surficial rocks having open cracks or pores. In this strain regime, it becomes important to solve the elastic equation of motion with non-linear terms in its rheology (Bonilla et al., 2005), including terms proportional to the square of strain.

Summary

The intrinsic attenuation of seismic waves in the earth has been found to be consistent with loss mechanisms that are thermally activated. The observed regional and frequency dependences of seismic Q agree with the expected lateral variations in a geotherm having a rapid temperature increase in the upper 400 km of the mantle, followed by a slower vertical and lateral variation in the mid- and lower mantle. High velocities correlate with regions of low attenuation; low seismic velocities correlate with regions of high attenuation. Measurements are consistent with losses primarily in shear rather than bulk deformations.

The existence of lateral heterogeneity in the elastic properties of the Earth complicates the measurement of viscoelastic properties. The longer scale lengths of heterogeneity can split modes of free oscillation and focus and defocus body waves and surface waves. Shorter scale lengths scatter seismic energy, broaden the waveforms of body waves, and redistribute energy into different time and angular windows. Observations that are useful for discriminating between the effects of scattering attenuation versus viscoelastic attenuation include the ratio of apparent P wave attenuation to apparent S wave attenuation, the rate of velocity dispersion within a frequency band, and the apparent viscoelastic modulus defect. The intensity of heterogeneity in percent fluctuation of velocities and densities is higher at shorter scale lengths at shallower depths in the Earth's crust and upper mantle. There is still a need for experiments that determine finer details of how the distribution of heterogeneity changes with depth and lateral location in the Earth and its anisotropy of scale lengths. Many, if not most experiments, have not completely removed the effects of heterogeneity on the apparent attenuation, making their results an upper bound on the viscoelastic Q^{-1}.

Laboratory experiments find a transition from linear to non-linear rheology at strains of the order of 10^{-6}. The observed strain dependence of Q and its dependence on pressure in the shallow crust agree with a mechanism of frictional sliding of cracks. It is still unknown how and at what strain levels linear superposition begins to break down close to a seismic source.

Although a consensus has been reached on the major features and thermal activation of intrinsic attenuation in most of the Earth's upper mantle, this is less true of other deep regions of the Earth. Definitive experiments are still needed for the determination of Q^{-1} in the lowermost 400 km of the mantle, where increased lateral heterogeneity exists across a broad spatial spectrum, complicating the separation of its effects from those of viscoelasticity. A concept unifying lateral variations in velocity, elastic anisotropy, scattering, and apparent attenuation in the uppermost inner core is needed (e.g., Calvet and Margerin, 2008).

Waveform inversion

Definition

Tomography. An inversion method to produce slicing image of the internal structures of an object, by recording wavefield propagating through and scattered/refracted/reflected back from the object, and observing the difference in the effects on the wave energy impinging on those structures.

Introduction

Waveform tomography is an imaging technology using seismic data to reconstruct the Earth subsurface physical properties, represented by seismic velocity, attenuation coefficient, etc. It is usually formulated as an inverse problem. Many seismic tomography methods use the arrival time information extracted from the waveform recordings as the input data to an inversion process. These methods are generically referred to as travel time tomography. Comparing to travel time tomography, waveform tomography has at least two major features. First, the input data consist of the seismic waveforms themselves, as opposed to travel times, amplitudes, or some other secondary attributes of the recorded data. This makes waveform tomography have a better resolution than travel time tomography. Secondly, the underlying numerical method is based on the full wave equation, as opposed to a ray approximation or a Born approximation. This makes waveform tomography more accurate than the travel time counterpart. These two features also make the inverse problem of waveform tomography more difficult to solve.

However, as field seismic data usually lack low-frequency information, travel time tomography may provide a reliable starting model for the iterative waveform inversion (Pratt et al., 2002). If waveform tomography is implemented in the frequency domain, the inversion process proceeds from low to high-frequency components. In the time domain, a band-pass filter can be applied to the seismic data, and inversion uses band-pass filtered data with low frequencies first and proceeds to higher frequencies. Even for the frequency-domain implementation, in order to suppress the low signal-to-noise ratio effect of frequency data and to make the inversion procedure robust, waveform tomography usually uses a group of frequencies simultaneously in an iterative inversion, and proceeds from low to high-frequency groups, generating a high-resolution image of the subsurface model.

Waveform tomography has been used successfully on transmission data, such as crosshole seismic data, and to wide-angle reflection/refraction seismic data with a certain degree of success. It has also been used for regional-scale studies on the crustal and upper mantle velocity structure, using scattering waves, surface waves and SH-waves from either exploration seismics or broad-band teleseismograms. In addition, there is a good progress on its application to reflection-seismic data with limited source-receiver offsets (Wang and Rao, 2009). The seismic reflection method is a routine practice in the hydrocarbon exploration, and the data dominated by the pre-critical reflection energy, reflected back from subsurface contrasts in physical parameters, are well suited for seismic migration for the structural image. Applying the waveform tomography technique to these reflection data can quantitatively extract the geophysical parameters, for identifying different lithologies and different fracture characteristics and even for indicating the hydrocarbon distribution directly.

Waveform modeling

Seismic wave propagation satisfies both Newton's second law and Hook's law, and can be expressed by the following five simultaneous first-order differential equations in two-dimensional case:

$$
\begin{aligned}
\rho \frac{\partial u}{\partial t} &= \frac{\partial \tau_{xx}}{\partial x} + \frac{\partial \tau_{xz}}{\partial z}, \\
\rho \frac{\partial w}{\partial t} &= \frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{zz}}{\partial z}, \\
\frac{\partial \tau_{xx}}{\partial t} &= c_{11} \frac{\partial u}{\partial x} + c_{13} \frac{\partial w}{\partial z} + c_{15} \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right), \\
\frac{\partial \tau_{zz}}{\partial t} &= c_{31} \frac{\partial u}{\partial x} + c_{33} \frac{\partial w}{\partial z} + c_{35} \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right), \\
\frac{\partial \tau_{xz}}{\partial t} &= c_{51} \frac{\partial u}{\partial x} + c_{53} \frac{\partial w}{\partial z} + c_{55} \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right),
\end{aligned}
\tag{1}
$$

where u and w are the particle-velocity components in the horizontal and vertical directions, respectively, τ_{xx}, τ_{xz} and τ_{zz} are stress components, ρ is density, and

$$\begin{bmatrix} c_{11} & c_{13} & c_{15} \\ c_{31} & c_{33} & c_{35} \\ c_{51} & c_{53} & c_{55} \end{bmatrix} \tag{2}$$

are the elastic constants in Hook's law relating stress to strain in the two-dimensional case. The first two equations are derived from Newton's second law, and the last three from Hooke's law for an elastic medium. Eliminating stress components, these five simultaneous equations can be coupled into two equations,

$$\begin{aligned} &-\rho\frac{\partial^2 u}{\partial t^2}+\frac{\partial}{\partial x}\left(c_{11}\frac{\partial u}{\partial x}+c_{15}\frac{\partial w}{\partial x}\right)+\frac{\partial}{\partial x}\left(c_{15}\frac{\partial u}{\partial z}+c_{13}\frac{\partial w}{\partial z}\right)\\ &+\frac{\partial}{\partial z}\left(c_{51}\frac{\partial u}{\partial x}+c_{55}\frac{\partial w}{\partial x}\right)+\frac{\partial}{\partial z}\left(c_{55}\frac{\partial u}{\partial z}+c_{53}\frac{\partial w}{\partial z}\right)=0,\\ &-\rho\frac{\partial^2 w}{\partial t^2}+\frac{\partial}{\partial x}\left(c_{51}\frac{\partial u}{\partial x}+c_{55}\frac{\partial w}{\partial x}\right)+\frac{\partial}{\partial x}\left(c_{55}\frac{\partial u}{\partial z}+c_{53}\frac{\partial w}{\partial z}\right)\\ &+\frac{\partial}{\partial z}\left(c_{31}\frac{\partial u}{\partial x}+c_{35}\frac{\partial w}{\partial x}\right)+\frac{\partial}{\partial z}\left(c_{35}\frac{\partial u}{\partial z}+c_{33}\frac{\partial w}{\partial z}\right)=0, \end{aligned} \tag{3}$$

defined in terms of horizontal and vertical wave components u and w. These equations are valid for the Earth media with arbitrary anisotropy and heterogeneity.

In the forward modeling of seismic wave propagation based upon either five or two simultaneous equations, there has been steady development in the finite-difference implementations. As the time derivatives are approximated by $\partial u/\partial t \approx (u_{i+1}-u_i)/\Delta t$ and $\partial^2 u/\partial t^2 \approx (u_{i+1}-2u_i+u_{i-1})/\Delta t^2$, where i is the time index, $t_i = i\Delta t$, and Δt is the step size in time, the wavefield at the current time can be calculated based on the previous wavefield: $u_{i+1} = f(u_i)$ or $u_{i+1} = f(u_i, u_{i-1})$; it is therefore an explicit finite-difference scheme (Alford et al., 1974; Kelly et al., 1976). For the spatial derivatives, a second-order staggered grid scheme for numerical stability was proposed by Virieux (1986), and was extended to a fourth-order scheme for greater accuracy by Levander (1988).

In the frequency domain, the two simultaneous equations become

$$\begin{aligned} &\omega^2\rho u+\frac{\partial}{\partial x}\left(c_{11}\frac{\partial u}{\partial x}+c_{15}\frac{\partial w}{\partial x}\right)+\frac{\partial}{\partial x}\left(c_{15}\frac{\partial u}{\partial z}+c_{13}\frac{\partial w}{\partial z}\right)\\ &+\frac{\partial}{\partial z}\left(c_{51}\frac{\partial u}{\partial x}+c_{55}\frac{\partial w}{\partial x}\right)+\frac{\partial}{\partial z}\left(c_{55}\frac{\partial u}{\partial z}+c_{53}\frac{\partial w}{\partial z}\right)=0,\\ &\omega^2\rho w+\frac{\partial}{\partial x}\left(c_{51}\frac{\partial u}{\partial x}+c_{55}\frac{\partial w}{\partial x}\right)+\frac{\partial}{\partial x}\left(c_{55}\frac{\partial u}{\partial z}+c_{53}\frac{\partial w}{\partial z}\right)\\ &+\frac{\partial}{\partial z}\left(c_{31}\frac{\partial u}{\partial x}+c_{35}\frac{\partial w}{\partial x}\right)+\frac{\partial}{\partial z}\left(c_{35}\frac{\partial u}{\partial z}+c_{33}\frac{\partial w}{\partial z}\right)=0. \end{aligned} \tag{4}$$

where ω is the angular frequency. This system of wave equations can be solved in parallel for individual frequencies, using also a finite-difference method. Once all frequency components of the wavefield at any spatial position are obtained, performing inverse Fourier transform with respect to the frequency variable will produce the time-domain seismic trace at this location.

However, the frequency-domain implementation is much more time consuming, compared to its counterpart in the time domain. This is because the frequency-domain calculation involves the solution of linear algebraic equations as the follows. With a finite-differencing scheme, Equation 4 may be presented in a matrix form as

$$\mathbf{Mu} = \mathbf{s}, \tag{5}$$

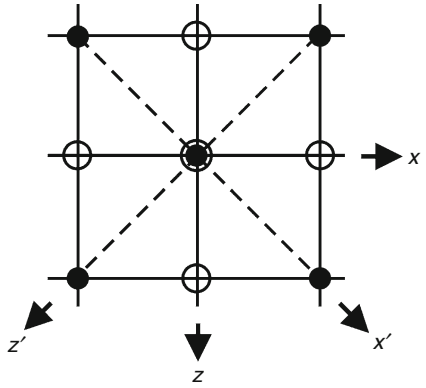
where $\mathbf{M}$ is a matrix approximating the partial differential operators, $\mathbf{u}$ is a vector representing the two components of the wavefield at all grids, and $\mathbf{s}$ is a vector representing the source term, which is zero everywhere except at the location of the source (added to the right-hand side of the wave equations). To obtain wavefield $\mathbf{u}$, one needs to solve the linear algebraic equation system 5, that is, to solve the inverse matrix, $\mathbf{M}^{-1}$. It is therefore an implicit finite-difference scheme.

The matrix $\mathbf{M}$ represents a significant storage requirement, which is largely determined by the numerical bandwidth of $\mathbf{M}$ and by the manner in which the structural sparsity of the matrix is maintained in any solution method. The bandwidth of the differencing matrix is determined by the number of nodes needed for a spatial derivative. For example, for a second-order finite-differencing, a first derivative needs 3×3 nodes, and for a fourth-order 5×5 nodes. A minimal, rotated computational star is a scheme that can minimize the bandwidth of the matrix and meanwhile improve the accuracy for finite-difference modeling. It does not require any new grid points as used in a second-order finite-differencing but can produce an equivalent of fourth-order accuracy in finite-differencing (Štekl and Pratt, 1998). As shown in Figure 1, the ○ symbol represents the five nodes needed in second-order finite-differencing of a first derivative, and the • symbol represents the five nodes in a 45° rotated finite-differencing star. Coupling these two second-order finite-differencing stars does not use additional points outside the 3×3 nodes, and there will be no increase in the numerical bandwidth of the differencing matrix. Therefore, the increment in computational cost and storage requirement over the ordinary second-order scheme is negligible.

In a rotated coordinate system, the elastic constants (2) become

$$\begin{bmatrix} c_{11}' & c_{13}' & c_{15}' \\ c_{31}' & c_{33}' & c_{35}' \\ c_{51}' & c_{53}' & c_{55}' \end{bmatrix} = \mathbf{B}\begin{bmatrix} c_{11} & c_{13} & c_{15} \\ c_{31} & c_{33} & c_{35} \\ c_{51} & c_{53} & c_{55} \end{bmatrix}\mathbf{B}^T, \tag{6}$$

where the rotation operator is



Seismic, Waveform Modeling and Tomography, Figure 1 The minimal, rotated computational star for finite-difference modeling. The symbol ○ represents the only five nodes required in the ordinary, second-order finite-differencing star. The symbol • represents the five nodes in a rotated computational star. The combination of these two stars indicates the coupling of the central node to the nearest neighbors on the grid. The final star does not use additional points outside the 3×3 nodes, but coupling includes those nodes not presented in the original star.

$$\mathbf{B} = \begin{bmatrix} \cos^2\theta & \sin^2\theta & 2\sin\theta\cos\theta \\ \sin^2\theta & \cos^2\theta & 2\sin\theta\cos\theta \\ -\sin\theta\cos\theta & \sin\theta\cos\theta & \cos^2\theta - \sin^2\theta \end{bmatrix}, \tag{7}$$

and θ is rotated angle of new coordinate. Considering a special case of 45° rotation, where the rotated coordinate system is (x', z') and displacements are (u', w') in the rotated coordinate system, Equation 4 becomes

$$\begin{aligned} &\omega^2\rho u' + \frac{\partial}{\partial x'}\left(c_{11}'\frac{\partial u'}{\partial x'} + c_{15}'\frac{\partial w'}{\partial x'}\right) + \frac{\partial}{\partial x'}\left(c_{15}'\frac{\partial u'}{\partial z'} + c_{13}'\frac{\partial w'}{\partial z'}\right) \\ &+ \frac{\partial}{\partial z'}\left(c_{51}'\frac{\partial u'}{\partial x'} + c_{55}'\frac{\partial w'}{\partial x'}\right) + \frac{\partial}{\partial z'}\left(c_{55}'\frac{\partial u'}{\partial z'} + c_{53}'\frac{\partial w'}{\partial z'}\right) = 0, \\ &\omega^2\rho w' + \frac{\partial}{\partial x'}\left(c_{51}'\frac{\partial u'}{\partial x'} + c_{55}'\frac{\partial w'}{\partial x'}\right) + \frac{\partial}{\partial x'}\left(c_{55}'\frac{\partial u'}{\partial z'} + c_{53}'\frac{\partial w'}{\partial z'}\right) \\ &+ \frac{\partial}{\partial z'}\left(c_{31}'\frac{\partial u'}{\partial x'} + c_{35}'\frac{\partial w'}{\partial x'}\right) + \frac{\partial}{\partial z'}\left(c_{35}'\frac{\partial u'}{\partial z'} + c_{33}'\frac{\partial w'}{\partial z'}\right) = 0. \end{aligned} \tag{8}$$

The relationship between displacements (u', w') in the rotated coordinate system and (u, w) in the original coordinate system is given by

$$u = \frac{1}{\sqrt{2}}(u' - w'),\ w = \frac{1}{\sqrt{2}}(u' + w'). \tag{9}$$

By subtracting and adding two equations in Equation 8 and then using relations in Equation 9, one can obtain

$$\begin{aligned} &\omega^2\rho u + \frac{1}{2}\frac{\partial}{\partial x'}\left((c_{11}' - c_{51}' - c_{15}' + c_{55}')\frac{\partial u}{\partial x'}\right. \\ &\quad\left. + (c_{11}' - c_{51}' + c_{15}' - c_{55}')\frac{\partial w}{\partial x'}\right) \\ &\quad + \frac{1}{2}\frac{\partial}{\partial x'}\left((c_{15}' - c_{55}' - c_{13}' + c_{53}')\frac{\partial u}{\partial z'}\right. \\ &\quad\left. + (c_{15}' - c_{55}' + c_{13}' - c_{53}')\frac{\partial w}{\partial z'}\right) \\ &\quad + \frac{1}{2}\frac{\partial}{\partial z'}\left((c_{51}' - c_{31}' - c_{55}' + c_{35}')\frac{\partial u}{\partial x'}\right. \\ &\quad\left. + (c_{51}' - c_{31}' + c_{55}' - c_{35}')\frac{\partial w}{\partial x'}\right) \\ &\quad + \frac{1}{2}\frac{\partial}{\partial z'}\left((c_{55}' - c_{35}' - c_{53}' + c_{33}')\frac{\partial u}{\partial z'}\right. \\ &\quad\left. + (c_{55}' - c_{35}' + c_{53}' - c_{33}')\frac{\partial w}{\partial z'}\right) = 0, \\ &\omega^2\rho w + \frac{1}{2}\frac{\partial}{\partial x'}\left((c_{11}' + c_{51}' - c_{15}' - c_{55}')\frac{\partial u}{\partial x'}\right. \\ &\quad\left. + (c_{11}' + c_{51}' + c_{15}' + c_{55}')\frac{\partial w}{\partial x'}\right) \\ &\quad + \frac{1}{2}\frac{\partial}{\partial x'}\left((c_{15}' + c_{55}' - c_{13}' - c_{53}')\frac{\partial u}{\partial z'}\right. \\ &\quad\left. + (c_{15}' + c_{55}' + c_{13}' + c_{53}')\frac{\partial w}{\partial z'}\right) \\ &\quad + \frac{1}{2}\frac{\partial}{\partial z'}\left((c_{51}' + c_{31}' - c_{55}' - c_{35}')\frac{\partial u}{\partial x'}\right. \\ &\quad\left. + (c_{51}' + c_{31}' + c_{55}' + c_{35}')\frac{\partial w}{\partial x'}\right) \\ &\quad + \frac{1}{2}\frac{\partial}{\partial z'}\left((c_{55}' + c_{35}' - c_{53}' - c_{33}')\frac{\partial u}{\partial z'}\right. \\ &\quad\left. + (c_{55}' + c_{35}' + c_{53}' + c_{33}')\frac{\partial w}{\partial z'}\right) = 0. \end{aligned} \tag{10}$$

Now there are two systems of partial differential equations:

$$\begin{aligned} &\rho\omega^2 u + A_1 = 0, \\ &\rho\omega^2 w + B_1 = 0, \end{aligned} \quad \text{and} \quad \begin{aligned} &\rho\omega^2 u + A_2 = 0, \\ &\rho\omega^2 w + B_2 = 0, \end{aligned} \tag{11}$$

where A_1 and B_1 are the partial differential parts of Equation 4 in the original coordinate system, and A_2 and B_2 are the partial differential parts of equation system 10 in the rotated coordinate system. The two systems can be combined to as

$$\begin{aligned} &\rho\omega^2 u + aA_1 + (1-a)A_2 = 0, \\ &\rho\omega^2 w + aB_1 + (1-a)B_2 = 0, \end{aligned} \tag{12}$$

where a is an optimal real-valued coefficient that must be sought to maximize the accuracy of the solution for all propagation directions.

While it is feasible to calculate the inverse matrix $\mathbf{M}^{-1}$ for a small, 2D model, in many practical problems such as 3D seismic modeling, the system $\mathbf{Mu} = \mathbf{s}$ with a large, sparse matrix is solved iteratively rather than directly. An approximate solution $\tilde{\mathbf{u}}$ is first obtained by solving using a related, preconditioning matrix. This preconditioner is chosen such that it is related to the true matrix, but is much faster to invert. The approximate solution $\tilde{\mathbf{u}}$ from the preconditioner is then substituted into the true matrix equation to discover the effective source, $\tilde{\mathbf{s}} = \mathbf{M}\tilde{\mathbf{u}}$. The difference $\mathbf{s} - \tilde{\mathbf{s}}$ between this effective source and the true source can then be treated as an actual source for the next iteration. The final solution $\mathbf{u}$ to the original matrix equation is found if the difference is sufficiently small (Warner et al., 2008).

Figure 2 shows the snapshot of wave propagation through an anisotropic medium. The elastic coefficients are summarized as

$$c_{11} = 29.26, \quad c_{33} = 23.98, \quad c_{55} = 4.29,$$
$$c_{13} = c_{31} = 17.27, \quad c_{15} = c_{51} = 1.98,$$
$$c_{35} = c_{53} = 2.53(\text{Gpa}),$$

and the density of the medium is a constant of 2.5 g/cm^3. The source is a Ricker wavelet with dominate frequency of 10 Hz. The snapshot shows clearly qP-wave front propagating in difference directions with different velocities. S-wave front can also been observed in these figures.

Waveform modeling uses an elastic wave equation, for the generality, and produces a wavefield presented as particle-velocity components. In a homogeneous, isotropic media, $c_{11} = c_{33} = \lambda + 2\mu$, $c_{13} = c_{31} = \lambda$ and $c_{55} = \mu$, where λ and μ are Lamé parameters, and $c_{15} = c_{51} = c_{35} = c_{53} = 0$. In an acoustic assumption, $c_{11} = c_{33} = c_{13} = \lambda$ and $c_{55} = c_{15} = c_{35} = 0$. With the acoustic assumption, most field seismic records are pressure data. According to Newton's second law, the relationship between particle velocity (u, w) and pressure P is

$$\rho \frac{\partial u}{\partial t} = -\frac{\partial P}{\partial x}, \rho \frac{\partial w}{\partial t} = -\frac{\partial P}{\partial z}. \tag{13}$$

Inverse method

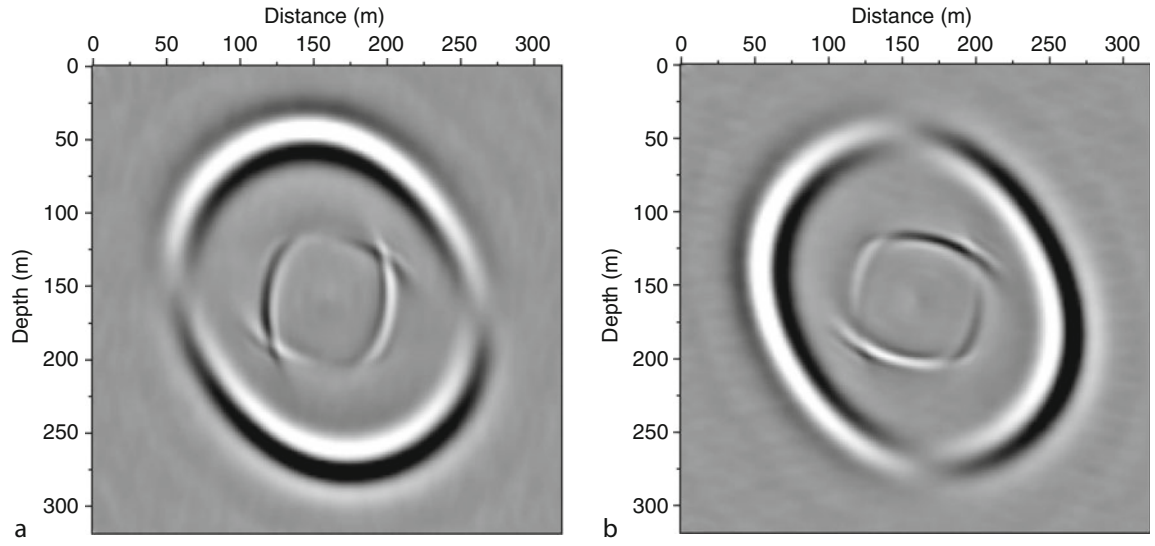
Seismic waveform tomography is an inverse problem with an objective function defined by

$$\varphi(\mathbf{m}) = [\mathbf{P}(\mathbf{m}) - \mathbf{P}_{\text{obs}}]^{\text{H}} \mathbf{C}_{\text{D}}^{-1} [\mathbf{P}(\mathbf{m}) - \mathbf{P}_{\text{obs}}] + \mu[\mathbf{m} - \mathbf{m}_0]^{\text{H}} \mathbf{C}_{\text{M}}^{-1} [\mathbf{m} - \mathbf{m}_0], \tag{14}$$

where $\mathbf{m}_0$ is a reference model, $\mathbf{m}$ is the model to invert for, $\mathbf{P}(\mathbf{m})$ is a modeled data set based on model $\mathbf{m}$, $\mathbf{P}_{\text{obs}}$ is an observed data set, $\mathbf{C}_{\text{D}}$ is the data covariance matrix with units of $(data)^2$, defining the uncertainties in the data set, $\mathbf{C}_{\text{M}}$ is the model covariance matrix with units of $(model\ parameter)^2$, and μ is a scalar that controls the relative weights of the data fitting term and the model constraint in the objective function. In Equation 14, the superscript $^{\text{H}}$ denotes the complex conjugate transpose.

For minimizing the objective function, a gradient method can be used. It starts with the differentiation of the objective function with respect to the model parameters:

$$\frac{\partial \varphi}{\partial \mathbf{m}} = 2(\mathbf{F}^{\text{H}} \mathbf{C}_{\text{D}}^{-1} \delta\mathbf{P} + \mu \mathbf{C}_{\text{M}}^{-1} \delta\mathbf{m}), \tag{15}$$



Seismic, Waveform Modeling and Tomography, Figure 2 Snap shot of wave propagation in an anisotropic medium: (**a**) horizontal component and (**b**) vertical component.

where $\delta\mathbf{m} = \mathbf{m} - \mathbf{m}_0$ is the model perturbation, $\delta\mathbf{P} = \mathbf{P}(\mathbf{m}) - \mathbf{P}_{\text{obs}}$ is the data residual, and $\mathbf{F}$ is a matrix of the Fréchet derivative of $\mathbf{P}(\mathbf{m})$ with respect to the model $\mathbf{m}$. The first term in Equation 15 is the gradient direction of the data misfit:

$$\hat{\boldsymbol{\gamma}} = \mathbf{F}^{\mathrm{H}}\mathbf{C}_{\mathrm{D}}^{-1}\delta\mathbf{P} = \mathbf{F}^{\mathrm{H}}\delta\hat{\mathbf{P}}, \tag{16}$$

where $\delta\hat{\mathbf{P}} = \mathbf{C}_{\mathrm{D}}^{-1}\delta\mathbf{P}$ is a weighted data residual. Set $\partial\varphi/\partial\mathbf{m} = 0$ in Equation 15, one obtains the following equation

$$\delta\mathbf{m} = -\alpha\mathbf{C}_{\mathrm{M}}\hat{\boldsymbol{\gamma}}, \tag{17}$$

where α is a update step length that needs to be determined.

In order to evaluate the gradient $\hat{\boldsymbol{\gamma}}$ using Equation 16, one needs to know the Fréchet matrix $\mathbf{F}$, which is obtained from the following linear formula,

$$\delta\mathbf{P} = \mathbf{F}\delta\mathbf{m}. \tag{18}$$

This is the first term in a Taylor's series for $\delta\mathbf{P}$ and relates the data perturbation $\delta\mathbf{P}$ to the model perturbation $\delta\mathbf{m}$. However, a direct computation of $[\mathbf{F}]_{ij} = \partial P_i/\partial m_j$ is a formidable task when P_i are seismic waveforms. The action of matrix $\mathbf{F}^{\mathrm{H}}$ on the weighted data residual vector $\delta\hat{\mathbf{P}}$ (Equation 16) can be computed by a series of forward modeling steps, summarized as follows (Lailly, 1984; Tarantola, 1984, 1987).

The frequency-domain acoustic wave equation for a constant density medium with velocity $c_0(\mathbf{r})$ is

$$\left(\nabla^2 + \frac{\omega^2}{c_0^2(\mathbf{r})}\right)P_0(\mathbf{r},\omega) = -S(\omega)\delta(\mathbf{r}-\mathbf{r}_0), \tag{19}$$

where $\mathbf{r}$ is the position vector, $\mathbf{r}_0$ locates the source position, $S(\omega)$ is the source signature of frequency ω, and $P_0(\mathbf{r},\omega)$ is the (pressure) wavefield of this frequency and we drop off the frequency reference in the following discussion. If the velocity is perturbed by a small amount, $\delta c(\mathbf{r}) << c_0(\mathbf{r})$, that is, $c_0(\mathbf{r}) \to c(\mathbf{r}) = c_0(\mathbf{r}) + \delta c(\mathbf{r})$, then the total wavefield is correspondingly perturbed to $P_0(\mathbf{r}) \to P(\mathbf{r}) = P_0(\mathbf{r}) + \delta P(\mathbf{r})$. Following wave Equation 19, δP approximately satisfies

$$\left(\nabla^2 + \frac{\omega^2}{c_0^2(\mathbf{r})}\right)\delta P(\mathbf{r}) = 2\omega^2 P_0(\mathbf{r})\frac{\delta c(\mathbf{r})}{c_0^3(\mathbf{r})}. \tag{20}$$

Considering $2\omega^2 P_0(\mathbf{r})\delta c(\mathbf{r})/c_0^3(\mathbf{r})$, the term on the right-hand side, as a series of "virtual sources" over $\mathbf{r}$, the integral solution for $\delta P(\mathbf{r})$ can be expressed as

$$\delta P(\mathbf{r}) = -\int_{\Omega} \delta c(\mathbf{r}')\frac{2\omega^2}{c_0^3(\mathbf{r}')}P_0(\mathbf{r}')G(\mathbf{r},\mathbf{r}')\mathrm{d}\mathbf{r}', \tag{21}$$

where $G(\mathbf{r},\mathbf{r}')$ is the Green's function for the response at $\mathbf{r}$ to a point source at $\mathbf{r}'$ for the original velocity field. Note that in the acoustic case where one assumes density to be constant, and defines the model by the velocity field only, $\mathbf{m} \equiv \mathbf{c}$. Then comparing Equation 21 against the matrix-vector form of Equation 18, we see that the Fréchet matrix is defined with element, $F(\mathbf{r},\mathbf{r}') = -[2\omega^2/c_0^3(\mathbf{r}')]P_0(\mathbf{r}')G(\mathbf{r},\mathbf{r}')$. Substituting this Fréchet kernel into Equation 16, one obtains

$$\hat{\boldsymbol{\gamma}}(\mathbf{r}) = \left(\frac{2\omega^2}{c_0^3(\mathbf{r})}\right)^* \int_D P_0^*(\mathbf{r}')G^*(\mathbf{r},\mathbf{r}')\delta\hat{P}(\mathbf{r}'). \tag{22}$$

Replacing the integral over the data space with a summation over source and receiver pairs, denoted by s and g respectively, as the source and receiver position are inherently discrete and finite in number, one can obtain

$$\begin{aligned}\hat{\boldsymbol{\gamma}}(\mathbf{r}) &= \left(\frac{2\omega^2}{c_0^3(\mathbf{r})}\right)^* \sum_s \left(P_0^*(\mathbf{r};\mathbf{r}_s)\sum_g G^*(\mathbf{r},\mathbf{r}_g)\delta\hat{P}(\mathbf{r}_g;\mathbf{r}_s)\right)\\ &= \left(\frac{2\omega^2}{c_0^3(\mathbf{r})}\right)^* \sum_s \left(P_0^*(\mathbf{r};\mathbf{r}_s)P_b^*(\mathbf{r};\mathbf{r}_s)\right),\end{aligned} \tag{23}$$

where

$$P_b(\mathbf{r};\mathbf{r}_s) = \sum_g G(\mathbf{r},\mathbf{r}_g)\delta\hat{P}^*(\mathbf{r}_g;\mathbf{r}_s) \tag{24}$$

representing the wavefield generated by a series of virtual sources $\delta\hat{P}^*(\mathbf{r}_g)$, corresponding to a single source $\mathbf{r}_s$. Note that wavefield $P_b(\mathbf{r};\mathbf{r}_s)$ is not calculated directly from Equation 24, but is computed using the same forward modeling scheme as used for the wave Equation 19 with the virtual sources $\delta\hat{P}^*(\mathbf{r}_g)$, a procedure often referred to as data residual back-propagation.

In summary, waveform tomography is performed iteratively. For each iteration, the inversion procedure may be divided into four steps:

1. For a given model estimate, calculating the synthetic wavefield $P_0(\mathbf{r};\mathbf{r}_s)$ at space position $\mathbf{r}$ corresponding to a source point at $\mathbf{r}_s$
2. Using the weighted data residual $\delta\hat{\mathbf{P}} = \mathbf{C}_{\mathrm{D}}^{-1}\delta\mathbf{P}$ as virtual sources to generate a so-called back-propagation wavefield $P_{\mathrm{b}}(\mathbf{r};\mathbf{r}_s)$
3. Crosscorrelation of the original wavefield $P_0(\mathbf{r};\mathbf{r}_s)$ and the back-propagation wavefield $P_{\mathrm{b}}(\mathbf{r};\mathbf{r}_s)$ to get the gradient direction $\boldsymbol{\gamma} = \mathbf{C}_{\mathrm{M}}\hat{\boldsymbol{\gamma}}$, where $\mathbf{C}_{\mathrm{M}}$ is the model covariance matrix with units of $(\textit{model parameter})^2$
4. Estimating the model update $\delta\mathbf{m} = -\alpha\boldsymbol{\gamma}$, where α is the optimal step length that can be found by using the linear approximation or simply line search for a minimum of the objective function.

In a time-domain implementation of waveform inversion, the gradient direction is calculated by

$$\hat{\boldsymbol{\gamma}}(\mathbf{r}) = \frac{2}{c_0^3(\mathbf{r})}\sum_s \int \left(\frac{\partial}{\partial t}p_0(\mathbf{r};\mathbf{r}_s)\frac{\partial}{\partial t}p_b(\mathbf{r};\mathbf{r}_s)\right)\mathrm{d}t, \tag{25}$$

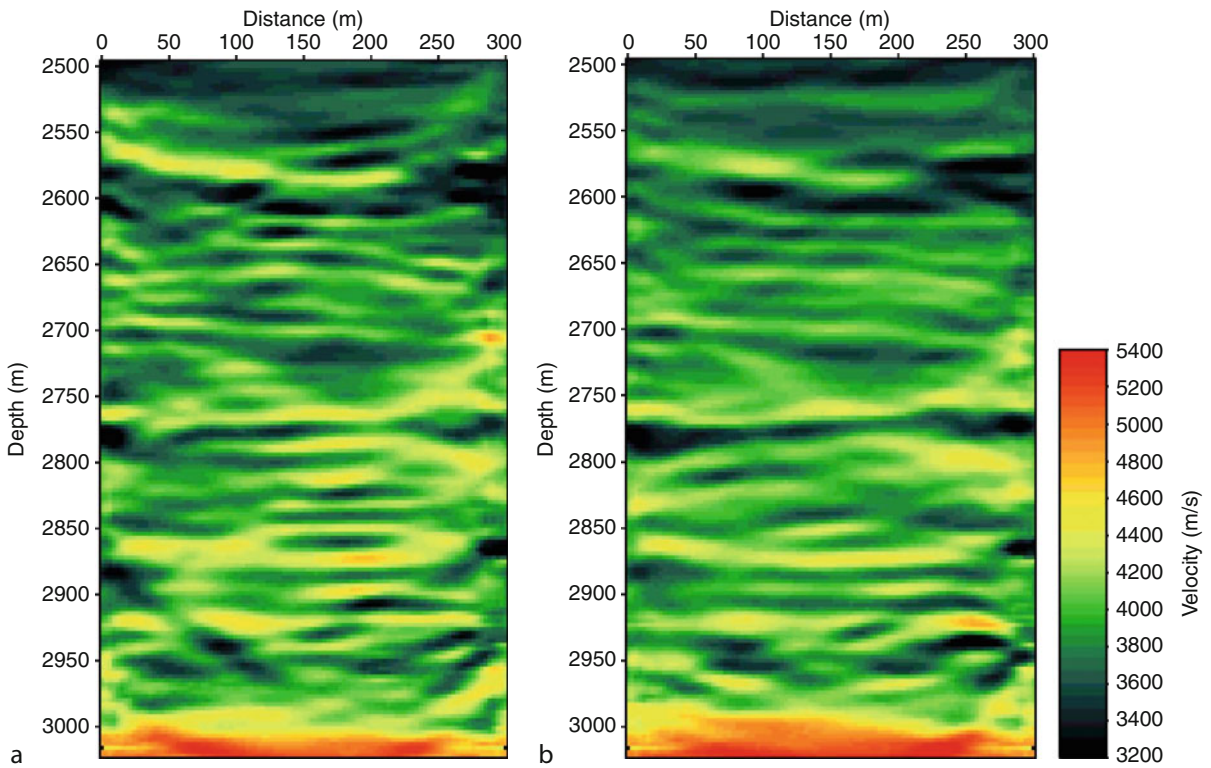
where $\partial p_0(\mathbf{r};\mathbf{r}_s)/\partial t$ denotes the time derivative of the time-domain forward propagated wavefields, and $\partial p_b(\mathbf{r};\mathbf{r}_s)/\partial t$ is the time derivative of the back-projected residual waveforms in the time domain. Zero-leg correlation of these two wavefields provides us the gradient direction for model updating.

Strategies for choosing frequencies

When dealing with real seismic data, poor signal-to-noise ratio of data slices in the frequency domain is a problem at least that affects waveform tomography. For real data application, a group of frequencies is necessarily used simultaneously for each individual iteration in the inversion procedure (Pratt and Shipp, 1999; Wang and Rao, 2006). Simultaneously using neighboring frequencies from the same spatial imaging position may have an averaging effect that suppresses the data noise to the input of the inversion. For a fixed number of model parameters to invert for, using many more data samples in the inversion means that the inverse problem becomes much better determined.

Here is a real data example of crosshole geometry, with two experiments to combat the noise in real data. In the first experiment, we use all selected frequencies consecutively (190, 195, 200, 205, . . . , 485 Hz). We start with the initial model generated from travel time inversion, and invert the 190 Hz data component first. Then, we switch to a higher frequency component (195 Hz) of the data as the inversion progresses. The result from each lower frequency is used as the starting model for the next higher frequency inversion. At each frequency stage, three iterations are carried out. Figure 3a shows the reconstructed image after using all 60 selected frequencies between 190 and 480 Hz with 5 Hz interval.

In the second experiment, we use a group of five neighboring frequencies simultaneously in the inversion. The 60 selected frequencies are assigned into 12 groups with increasing frequency contents. The result from each lower frequency group is used as the starting model for the inversion of the next higher frequency group. This strategy might mitigate the nonlinearity of the problem: For lower frequencies, the method is more tolerant of velocity errors, as these are less likely to lead to errors of more than a half-cycle in the waveforms (Pratt and Shipp, 1999). For each group, three iterations are carried out, proceeding through all groups. For each iteration, the gradient of each frequency group is computed using all five frequencies simultaneously. Figure 3b shows the tomographic image after using all of 12 frequency groups consecutively.



Seismic, Waveform Modeling and Tomography, Figure 3 Waveform tomography with a single frequency at a time or a group of frequencies simultaneously. (**a**) The inversion is executed by each frequency consecutively. The velocity image after using all 60 selected frequencies between 190 and 480 Hz (with 5 Hz interval). The image has strong X-shaped artifacts. (**b**) The inversion is executed one group by one group in sequence. The image after using all 12 frequency groups, each has five frequency components.

Comparing the images of those two experiments, one can observe that Figure 3a is marked by the presence of some X-shaped artifacts that cross the image. Such artifacts are quite often obtained in crosshole tomography, especially when waveform inversion is attempted. It is due to the non-uniform coverage of the object spectrum and the lack of information about the object spectrum in certain directions (Wu and Toksöz, 1987). When using multiple frequencies simultaneously, the inherent filtering (smoothing) effect might have an extrapolation effect of the object spectrum to the blind area. The second experiment has much fewer artifacts, and the image is smoother and more continuous than that of experiment one, especially at the 2,800–2,950 m portions. We recommend using the strategy of the second experiment in practice so that we can also mitigate the data noise effectively in the input of waveform tomography.

The computation time of the frequency-domain waveform tomography is linearly proportional to the total number of temporal frequencies used in the inversion. In reflection geometry, source-receiver pairs vary with different offsets and move along the surface. One may explore this coverage of a variety of plane-wave imaging directions, to reduce the number of frequencies needed in waveform tomography (Sirgue and Pratt, 2004). The frequency selection strategy is

$$f_{n+1} = \frac{f_n}{\cos\phi}, \tag{26}$$

where f_n is the frequency previously used, f_{n+1} is a new frequency for inversion, and $\cos\phi = z/\sqrt{h_{\max}^2 + z^2}$ is the cosine of the reflection angle, corresponding to the maximum value of the half source-receiver offset $h_{\max}$ and the target depth z. This strategy eliminates some frequencies but has a continuous coverage on vertical wave number k_z, as

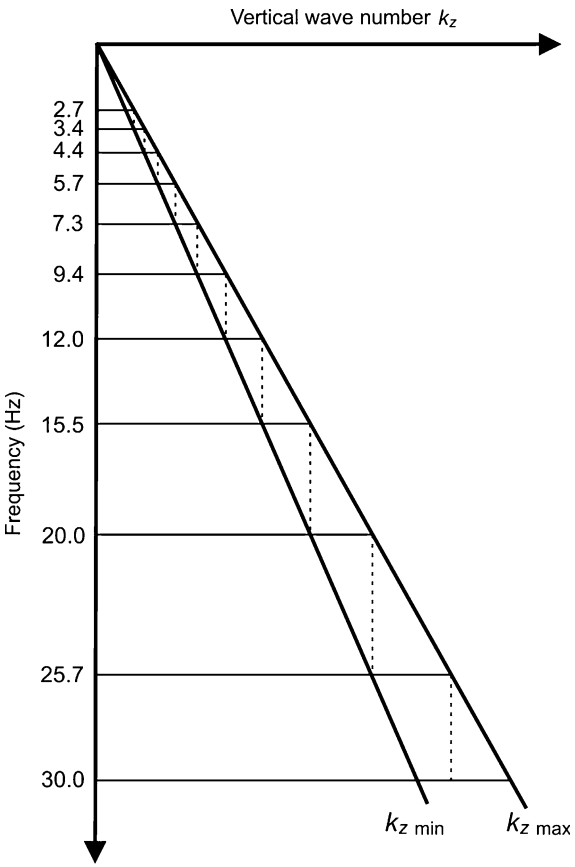
$$k_{z\min}(f_{n+1}) = k_{z\max}(f_n), \tag{27}$$

where

$$k_{z\max} = \frac{2f}{c_0}, \quad k_{z\min} = \frac{2f}{c_0}\cos\phi, \tag{28}$$

and $c_0/2$ are half of the background velocity. Figure 4 illustrates the wave number coverage corresponding to the selected frequencies in a waveform tomography example (Wang and Rao, 2009). For a model with $h_{\max} = 2,275\,\text{m}$, $z = 2,800\,\text{m}$ and $\cos\phi \approx 0.776$, the following 11 frequencies, 2.7, 3.4, 4.4, 5.7, 7.3, 9.4, 12.0, 15.5, 20.0, 25.7, and 30.0 Hz, may be selected. In this list, the dominant frequency 20 Hz is included in the inversion, and the last frequency is $f_{\max} = 30\,\text{Hz}$, due to the limitation of finite-difference modeling, which is less than the predicted value of 33.1 Hz.

On the other hand, if assuming there is no source-receiver offset coverage to be exploited, adequate wave number samples are needed in order to obtain a sufficiently good image in the model space. In this case,



Seismic, Waveform Modeling and Tomography, Figure 4 The coverage of the vertical wave numbers corresponding to 11 selected frequencies for an example waveform tomography.

the sampling rate should satisfy the anti-aliasing condition, $\Delta k_z \le 1/z_{\max}$, where $z_{\max}$ is the maximum depth to be imaged, and Δk_z is the sampling rate of the vertical wave number. Given the minimum value of the vertical wave number at frequency f by Equation 28, the difference between two neighboring wave number samples is

$$\Delta k_z \equiv k_{z\min}(f + \Delta f) - k_{z\min}(f) = 2\cos\phi\frac{\Delta f}{c_0} \le \frac{1}{z_{\max}}. \tag{29}$$

Finally, the following anti-aliasing condition for frequency sampling is obtained:

$$\Delta f \le \frac{c_0}{2z_{\max}\cos\phi}. \tag{30}$$

In this example, $\Delta f = 0.3\,\text{Hz}$.

Waveform tomography proceeds sequentially from low to high frequencies (Sirgue and Pratt, 2004; Pratt, 2008). This is because the nonlinearity of the inverse problem depends on the frequency of the data. As the misfit function at low frequencies is more linear than at high frequencies, the low-frequency inversion will have a better chance to

be successful and can accurately recover the low wave number components of the velocity model. The velocity model with accurate low wave number components is a good initial model for higher frequency inversions. At low frequencies, coarser grids can be used for computing numerical solutions of the wave equation than at high frequencies, resulting in a computational efficiency. This is a so-called multiscale approach (Bunks et al., 1995).

The multiscale approach can also be implemented in the time-domain waveform tomography (Boonyasiriwat et al., 2009). In the frequency domain, it is straightforward to apply the multiscale method, as a single frequency component is used at a time in the inversion. In the time-domain inversion, a frequency band is used instead of single frequency. For each band-passed filtered data set, the finite-difference grid size is determined by the maximum frequency of the band. Assuming a square grid, $\Delta x = \Delta z$, the grid size allowed to use in the forward modeling is determined by

$$\Delta x \le \frac{\lambda_{\min}}{N} = \frac{c_{\min}}{N f_{\max}}, \tag{31}$$

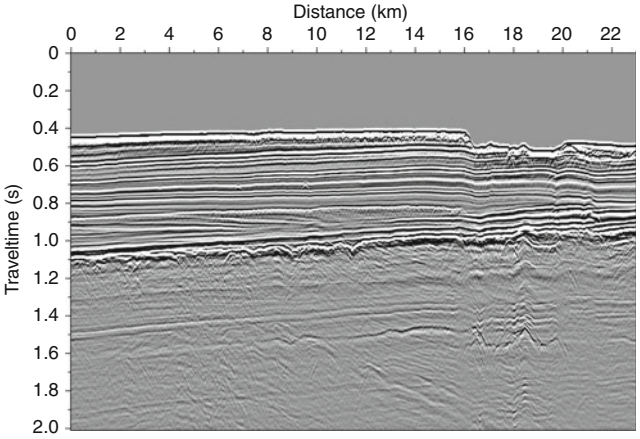
where $\lambda_{\min}$ is the minimum wavelength, $c_{\min}$ is the minimum velocity, $f_{\max}$ is the maximum frequency of the band, and N is the number of grid points at least per minimum wavelength, required by the numerical dispersion condition for the finite-difference scheme (Levander, 1988). At low frequencies, coarser grids can be used than at high frequencies. Therefore, low-frequency inversions will be considerably fast and efficient compared to high-frequency inversions, and can afford to take a large number of iterations in order to obtain an accurate estimate of low wave number components of the velocity model. Higher wave number components are progressively recovered through the sequential uses of higher frequency-band data in the inversions. Therefore, the multiscale approach should have a steady convergence than a single-scale method that tends to recover both low and high wave numbers simultaneously.

Preprocessing for field data waveform tomography

Let us demonstrate the application of waveform tomography to a real, marine seismic data set, as shown in Figure 5. This example profile shows the structure along the section. However, the input to waveform tomography is a series of shot records, which should be subject to some necessary processing, such as multiple attenuation and transformation of the original point sources to equivalent line sources, before they are used in tomography.

Figure 6a is a sample shot record, consisting of 120 traces with a minimum source-receiver offset of 337.5 m and a maximum source-receiver offset of 1,825 m. We investigate the feasibility of reflection-seismic tomography within such a narrow source-receiver offset range.

Waveform tomography usually does not include free-surface multiples. Otherwise including seismic multiples



Seismic, Waveform Modeling and Tomography, Figure 5 An example profile of marine seismic data, which shows the structure along a section. However, the input to waveform tomography is a series of shot records, which should be subject to some necessary processing.

bouncing back and forward within the water layer in the tomographic inversion will increase the nonlinearity of the problem. As the number of multiples increases, the errors in model (and in turn in synthetics) will also increase. We use a narrow-offset shot record in multiple attenuation, also to avoid the wide-angle refraction of the water bottom and their multiples, as the current methodology for free-surface multiple prediction cannot properly model the refraction multiples. As marked in Figure 6a, the most difficult part of multiple attenuation is where the refraction wave just starts appearing. Figure 6b displays a shot record and the one after free-surface multiple attenuation, using a multiple prediction through inversion (MPI) method (Wang, 2004, 2007). The real shot record is generated by a point source, but Figure 6c is an equivalent line-source shot gather, after partial compensation as follows.

Before input to waveform tomography, a shot record of real seismic data needs to be partially compensated, to become a gather generated from a line source. For a two-dimensional (2-D) case, the 2-D Green's function is

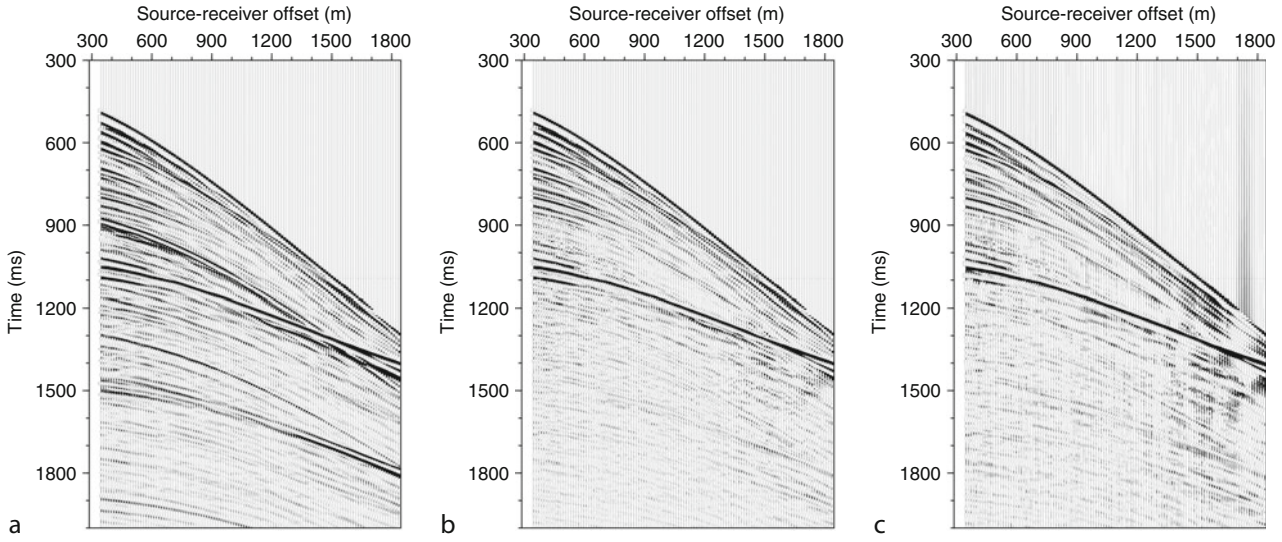
$$G_{2D}(\mathbf{r}, \mathbf{r}_s, \omega) = \left(\frac{c}{i8\pi\omega R}\right)^{1/2} \exp\left(-i\omega\frac{R}{c}\right), \tag{32}$$

where $R = |\mathbf{r} - \mathbf{r}_s|$ is the distance from the source, and c is the acoustic velocity of the medium. For a three-dimensional (3-D) case, Green's function is

$$G_{3D}(\mathbf{r}, \mathbf{r}_s, \omega) = \frac{1}{4\pi R} \exp\left(-i\omega\frac{R}{c}\right). \tag{33}$$

Comparing the 2-D and 3-D Green's functions produces a partial compensation operator as

$$W = \sqrt{\frac{2\pi R c}{i\omega}}. \tag{34}$$



Seismic, Waveform Modeling and Tomography, Figure 6 A marine seismic data example. (**a**) A sample shot record with 120 traces. (**b**) The shot record after multiple attenuation. (**c**) The same shot record after partial compensation.

In the time domain, the operator W shows the following behavior (in the far-field),

$$W(t) = D_{-1/2}(t)\sqrt{2\pi Rc}, \tag{35}$$

where $D_{-1/2}(t)$ is a half-integrator, defined as the inverse Fourier transform of $(i\omega)^{-1/2}$ (Deregowski and Brown, 1983). For a narrow-offset, reflection geometry, one can assume $2R \propto ct$ and obtain

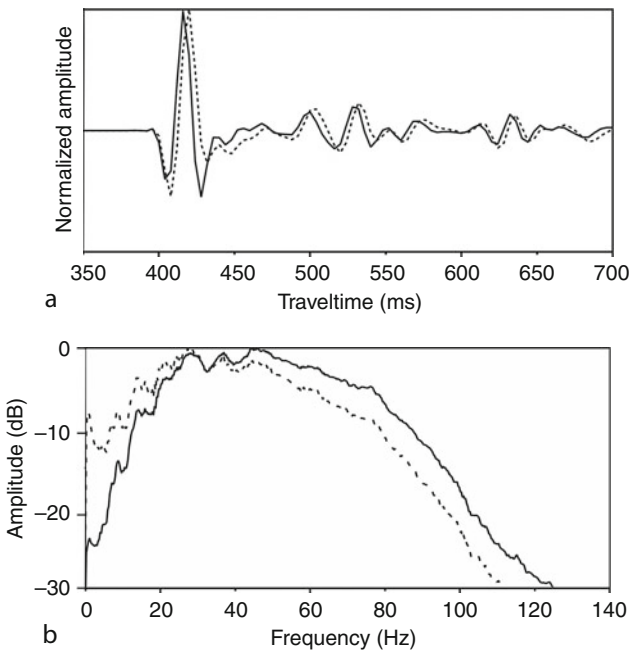
$$W(t) \propto D_{-1/2}(t)c(t)\sqrt{t}. \tag{36}$$

Therefore, this partial compensation may be implemented in two steps: scaling $c(t)\sqrt{t}$ in the time domain, and multiplication $(i\omega)^{-1/2}$ in the frequency domain.

Figure 7 closely compares a seismic trace from a point source (solid curve) and a trace after partial compensation (dash curve). With the application of the operator $(i\omega)^{-1/2}$, wavelets in the trace from an equivalent line source are broader than those actually generated from a point source.

Alternatively, one could use a 2.5-D wave modeling and inversion scheme for waveform tomography. But as it involves integration along the infinite line-source direction that is perpendicular to the source-receiver profile, a 2.5-D scheme would take a much longer running time, compared to the 2-D wave modeling and inversion (Song and Williamson, 1995).

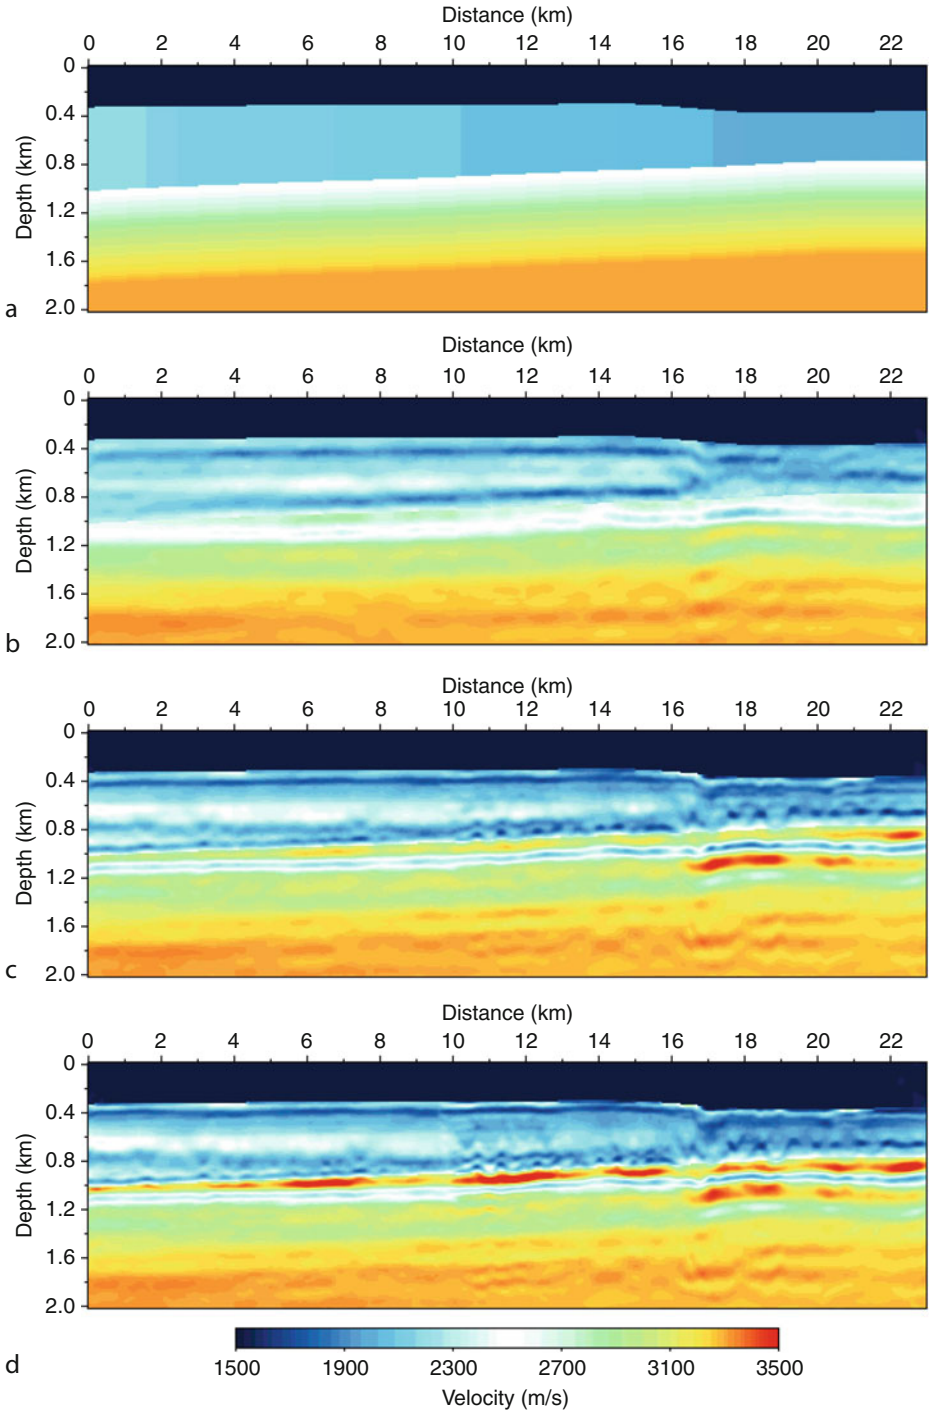
The frequency ω can also be complex-valued, to include an exponential function either for the amplitude attenuation or compensation. The attenuation used in wavefield $P(t)$ is for suppressing the wrap-around effect in the Fourier transform domain. An opposite sign with an exponential increase in $P(t)$ could also be used to boost the energy of deep reflections. In the latter case, the real data should be balanced with an automatic gain control.



Seismic, Waveform Modeling and Tomography, Figure 7 (**a**) Comparison between a seismic trace from an actual point source (*solid*) and the trace after partial compensation (*dash curve*). Wavelets in a trace from a line source (i.e., after partial compensation) are broader than those from a point source. (**b**) Comparison of amplitude spectra of seismic traces from a point source and a line source.

Reflection-seismic waveform tomography

In the reflection-seismic data, there is no significant energy recorded at low frequencies less than 6 Hz. A travel time inversion is often performed to generate the initial velocity model for the iterative waveform tomography (Pratt et al., 2002). Referring to the stack section (Figure 5), we pick the travel times of two reflections from the pre-stack seismic data, and run a travel time



Seismic, Waveform Modeling and Tomography, Figure 8 Waveform tomography. (**a**) The initial velocity model built from travel time tomography. (**b**) The velocity model of waveform tomography using frequencies in the range of 6.9–7.5 Hz. (**c**) The velocity model of waveform tomography using frequencies in the range of 6.9–13.8 Hz. (**d**) The final velocity model obtained from the waveform tomography using all frequencies in the range of 6.9–30 Hz.

inversion to generate a layered velocity model with two interfaces (Figure 8a). The first layer is a water layer with velocity 1,500 m/s. The second layer has a linear velocity of 2,200 m/s at one end and 2,000 m/s at distance 23 km.

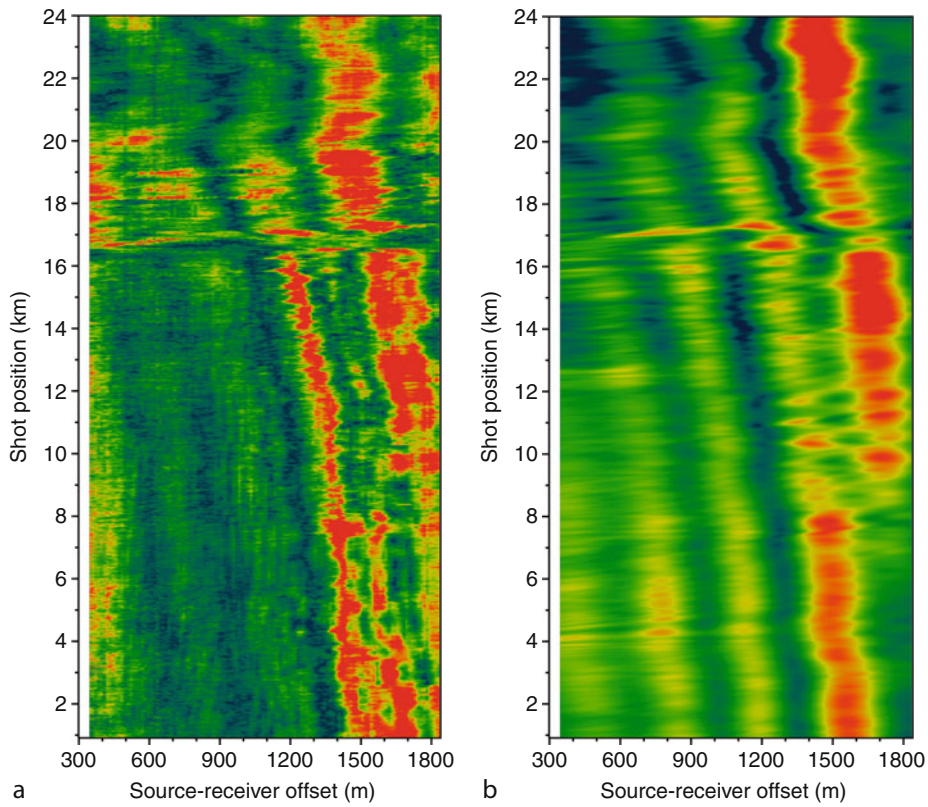
In the frequency-domain waveform tomography, we use a group of three frequencies simultaneously in each iterative inversion. Using a group of neighboring frequencies in the input can suppress the noise effect in the real data, and also more data samples used in an inversion means a much better determined inverse problem. In this example, there are 26 groups of frequencies in total in the range of 6.9–30 Hz with an interval of 0.3 Hz. The first group includes frequencies 6.9, 7.2, and 7.5 Hz, and the last group includes frequencies 29.4, 29.7, and 30 Hz. Figures 8b and 8c are the velocity models from waveform tomography using frequencies in ranges of 6.9–7.5 Hz and 6.9–13.8 Hz, respectively, where Figure 8d is the final velocity model obtained from waveform tomography using all frequencies in the range.

Although the starting model generated by travel time tomography generates a smooth boundary for the water bottom, waveform tomography produces a sharp geometry with a spatial variation close to that shown in seismic sections (Figure 5). The tomography image shows clearly a stratified structure underneath the water layer. In the second layer, at the distance between 0 and 10 km, there is a high-low-high vertical velocity variation immediately underneath the water bottom, between depth of 350 and 700 m at the left end of the profile, and a high-low-high-low vertical variation above the second interface. At the distance between 17 and 23 km, there is also a low-high-low vertical velocity variation within the second layer.

Most significantly, in the third layer, high-low-high velocity channels appear immediately underneath the second interface and cross the entire section. These thin-layers separation could not be generated by any conventional travel time tomography. Beneath that, the velocity pattern in the depth between 1.2 and 1.6 km varies laterally between 0–5, 5–17, and 17–23 km in distance.

Seismic reflection is generated due to the contrast in impedance, which is the product of density and velocity. In the inversion example here however, the density is assumed to be constant. Therefore, for a more accurate quantitative interpretation of the high velocity variation within the topmost thin layer immediately underneath the water layer, a density contrast between the water and water-bottom sediment needs be compensated.

Figure 9 compares a sample frequency slice (at 9.3 Hz) of real data input to waveform tomography and synthetic data generated from the inversion result. The vertical axis is the shot position in the surface, and the horizontal axis is the source-receiver offset. The data displayed are the



Seismic, Waveform Modeling and Tomography, Figure 9 (**a**) A sample amplitude slice of real seismic data at frequency 9.3 Hz. (**b**) The amplitude slice of synthetics at the same frequency, obtained from the waveform tomography result.

amplitudes of complex-valued samples in the frequency domain, and are normalized based on their RMS values. For the far-offset seismic traces, there are strong amplitudes for post-critical angle reflections, which play an important role in the inversion for the shallow part of model. There is also a good fit at near-offset traces, which influence the high wave number perturbations of the velocity field.

Summary

Waveform tomography uses the original waveform recordings and wave equation modeling to extract high-resolution tomographic images from seismic data. Travel time inversion may be used first to provide a reliable initial model for the waveform inversion. The latter uses a group of frequencies simultaneously in an iterative inversion, and proceeds from low to high frequencies. Even for reflection-seismic data with limited source-receiver offset, the waveform tomography also can potentially image subsurface features with detailed spatial variation at sub-wavelength scales.

SEISMICITY, INTRAPLATE

Paul Bodin
Pacific Northwest Seismic Network (PNSN), University of Washington, Seattle, WA, USA

Definition

Intraplate Seismicity refers to earthquakes that take place on faults other than those that form the boundaries between Earth's tectonic plates.

Historical context

From the inception of plate tectonics as a simple set of unifying concepts, Earth scientists recognized that the notion of completely rigid plates should not be taken to be rigorous or complete. Deformations of Earth's crust and upper mantle, and the earthquakes that generally accompany them, must take place off of recognized plate interfaces. This fact was evident theoretically because in order for

plate tectonics to operate on timescales greater than one Wilson cycle, new plate boundaries must form within plates, so deformation must take place off of existing plate boundaries. In addition, it was unassailable observationally because seismicity off of recognized plate boundaries clearly *does* take place, albeit at a relatively trivial pace compared to Earth's total earthquake production.

Two generations later, despite the fact that they obviously exist, intraplate earthquakes remain enigmatic and challenging; fitting subjects for special study. The dominant questions about these earthquakes not only reveals our incomplete understanding of earthquake physics in general, but also highlights a number of issues specific to active tectonics and seismic hazard in intraplate settings.

Definitions and classification

We may define interplate earthquakes as being those that rupture parts of faults that connect directly mechanically to the globe-girdling system of recognized boundaries between tectonic plates. Intraplate earthquakes break faults that do not so connect. The difference is one of ultimate slip. Because interplate faults form a network within which new plates may be created and old plates consumed, slip on them is unbounded. On the other hand, the total slip on intraplate faults must terminate at the ends of the fault. So increasing slip comes at the cost of increasing strain in the surrounding rocks which, itself being presumably limited, caps how much any given fault can slip. Therefore, intraplate faults may be expected to slip generally more slowly, and less far, than interplate faults, and this possibly to have some consequence on the characteristics of earthquakes on the two types of faults.

It is customary for Earth scientists to distinguish further between intraplate earthquakes that break faults within *mobile zones* and those that take place within *stable zones*. Mobile zones are regions that, although not directly on recognized plate boundary fault, have been experiencing regional deformation distributed over a broad area near a plate boundary. An example is the active faulting across China, Tibet, and Mongolia, the deformations of which may be clearly related to three-dimensional complexities in the plate boundary framework. Stable zones are not only sufficiently remote from plate boundaries to be insensitive to their geometric complexities, but also are stable in the sense that significant tectonic events have not affected them during the Cenozoic Era ($\sim$66 million years). They are generally expected to be areas of cold, thick continental lithosphere. Earthquakes in stable continental regions, often designated SCR earthquakes, are particularly enigmatic.

Reasons to distinguish intraplate earthquakes

One reason to study intraplate earthquakes (and particularly SCR earthquakes) as a class involves a practical consequence: they strike the most unwary victims. Because of the long recurrence intervals between intraplate earthquakes, the threatened populace is generally unprepared and the structures they build are particularly vulnerable. It has recently been noted that this argument is becoming less restrictive to intraplate earthquakes as population growth within plate boundary regions has taken place so quickly of late that even these regions are becoming less prepared as a whole (Bilham, 2009). Nevertheless, the argument remains applicable in plate interiors where the building stock may be not only not up to modern seismic codes, but is generally older.

In part, SCR earthquakes remain especially enigmatic not merely because they are rare, but also because their recurrence may be so long that (1) the sizes and sometimes locations of previous earthquakes are not well known, even for those that have occurred in historical times, and (2) it is usually not possible to ascertain what their recurrence is with certainty. This leads to great uncertainty about the seismic hazards in intraplate regions. Is damaging earthquake shaking possible anywhere (albeit with small probability within any 50-year time period)? Or are even SCR earthquakes restricted to occur in places with discernible (and hence predictable) characteristics? This is tantamount to a question of whether the entirety of Earth's crust at critical stress levels such that only small fluctuations or differences in fault strength control the occurrence of earthquakes.

With such long recurrence intervals, seismological observations are sparse and we rely on the paleoseismic evidence contained within the geological record to try to understand them. It is clear that plate tectonics is accurate to first order and that intraplate deformation takes place very slowly, which makes them a challenge for even modern high-precision geodetic techniques. It seems likely that progress in understanding intraplate earthquakes will remain slow for the time being.

Another reason they are of special interest is that they may reveal clues about elusive earthquake physics. While Earth scientists believe that nearly all tectonic earthquakes are caused by sudden slip on a fault driven by stresses in the surrounding rock (the elastic rebound theory), the specific mechanisms that localize rupture initiation and growth of a rupture remain obscure. Systematic differences between fault, stress, and geological characteristics of intraplate faults discussed below may be exploited to test hypotheses of the important controls of earthquake fault rupture.

Do intraplate and interplate earthquakes scale differently?

Because intraplate earthquakes, and particularly those in stable zones, have longer recurrence intervals, it is often hypothesized that their host faults will have longer time to "heal" between earthquakes (e.g., Scholz, 2002). Fault healing here refers to a set of hypothesized fault processes such as the formation of minerals that bind the sides of the

fault together making them stronger over time. Thus, intraplate earthquakes may be expected to break under higher loads – at higher stress levels – than their cousins that break more active plate boundary faults. The anticipated result is that they "scale" differently: that is, big earthquakes differ from small earthquakes in systematically different ways in interplate as opposed to intraplate regions. Specifically, intraplate earthquake ruptures will slip more in an earthquake per unit of fault area, relieve more stress (have a larger "stress drop") and produce more seismic energy for their size, than the earthquakes we are more familiar with at plate boundaries. Thus seismologists expect, and arguably observe, that intraplate earthquakes tend to have higher stress drops than interplate earthquakes. Seismological evidence suggests that as a class their stress drops may be a factor of 2–5 higher than plate boundary earthquakes (Kanamori and Allen, 1986). But because observations are so few, much uncertainty remains about this issue.

Source scaling studies are further hindered by systematic differences between seismic wave propagation in intraplate regions and that in more mobile or active zones. Because rock surrounding plate boundaries is often less intact and hotter than in plate interiors, seismic wave energy is more strongly absorbed, or attenuated, than in the cold hard hearts of plates. So, per unit of energy released at their source, the effects of intraplate earthquakes are more widely distributed – they have a longer reach.

What drives intraplate earthquakes?

Probably the most critical enigma of intraplate seismicity concerns the source of driving stresses. It is easy to invoke "left over" or residual stresses originating from geometric irregularities or variations in frictional properties on the master plate boundary faults to explain the origin of mobile zone intraplate earthquakes. Remote from plate boundaries, occasionally sources of localized stresses may be recognized. One clear example is from intraplate regions experiencing uplift from glacial rebound, as ice sheets retreat with global warming. This mechanism well explains the seismicity pattern of Sweden, for example (e.g., Mörner, 2009). Swarms of seismicity often accompany geothermal activity, even at sites in the remote interior of tectonic plates (e.g., Ibs-von Seht et al., 2008). Where such sources of localized stress are not evident, however, it is more problematic to assign the provenance of seismic stress. Modeling studies suggest that stresses within plates may be best explained as a combination of resolved stresses originating at plate boundaries (although they may be thousands of kilometers distant) plate bending due to a plate's travel over a non-spherical Earth, or forces arising from convective patterns in Earth's mantle.

Many scientists presume that intraplate earthquakes take place at sites where crustal rocks have been significantly weakened compared to those in surrounding rocks. In this model, seismicity should be associated with reactivated fault zones. Big intraplate earthquakes are thought to be restricted to areas that have previously been faulted, say within failed continental rift systems (e.g., Johnson, 1996).

One intriguing idea is that the strength of faults could be reduced by high pore-fluid pressure. Fluids (which could include water or even carbon dioxide or hydrocarbons) that occupied the internal portion of a fault could become pressurized and reduce the frictional resistance of the fault to slipping. That would imply that seismically active faults in intraplate regions are those that contain significant quantities of fluids at high confining stress. Sufficient stress to drive earthquakes could indeed be present everywhere within plate interiors, and the conditions to release the stress controlled by something external.

Examples

The moment magnitude (Mw) = 6.8 "Nisqually" earthquake of January 23, 2001 in Washington state, USA, provides an example of an intraplate earthquakes breaking a fault within the crust of the subducting ocean plate (Ichinose et al., 2006). The earthquake resulted from slip on a normal fault driven by bending stresses as the downgoing slab flexes in its descent. On a larger scale, the Cascadia subduction zone provides an interesting example of the interplay between inter- and intraplate earthquakes in that while the master plate boundary megathrust fault is broken about every 500 years with large subduction thrust events (e.g., Satake and Atwater, 2007), there appears to be no current seismicity on the plate boundary fault. Rather all earthquakes either historical or instrumentally recorded are either intra-slab events or crustal earthquakes within the overriding North America plate. These events are interplate by our definition. However, they are clearly associated with a nearby subduction interface and are driven by residual stresses that the plate boundary is unable to completely relieve.

The May 13, 2008 Mw = 7.9 Wenchuan earthquake in the Szechuan Province of China is an earthquake in the tectonically mobile zone of Asia, and is part of the escape of material from Asia and the uplifting of the Himalaya due to the collision of the Indian subcontinent with Asia. About 300 km of a fault on the boundary between the Longmenshan orogenic belt and the Szechuan basin broke in the earthquake (Burchfiel et al., 2008). With a high overall stress drop of 17 MPa and localized patches of up to 53 MPa (Zhang et al., 2009), the Wenchuan earthquake had large slip and disastrous effects on a populace that was largely unaware of the potential for, and unprepared for, this long-recurrence-interval (2,000–10,000 years) intraplate earthquake.

The January 26, 2001 Mw = 7.6 Bhuj earthquake took place ~400 km? from the rather diffuse onshore portion of the left-lateral strike-slip Makran boundary between India and the Arabian and Eurasian plates, but within the

western part of the peninsular Indian shield. It broke the deeper part (~5 to ~40 km) of a previously unknown reverse fault. It was located within ~100 km of a similar-sized (though shallower) earthquake in 1835 that generated a surface rupture – the Allah Bundh in the Great Rann of Kachchh. The stress drop was a high, but not extreme ~16–20 MPa, but the earthquake was very powerful, with the source lasting only about 7 s. Widespread liquefaction and secondary effects were observed, but the large death toll (~30,000) was apparently not the result of extreme ground motions, which could have been engineered for, but rather of poor construction and preparation.

Controversy

One particularly illustrative and significant example of SCR interplate seismicity concerns the New Madrid Seismic Zone that threatens a 7-state region surrounding the lower Mississippi River valley in the south central USA (e.g., Johnson and Schweig, 1996). The region was the site of at least three major earthquakes during the winter of 1811–1812. While at the time thinly populated and rural, a return of these earthquakes today would affect ten million people and put at risk numerous cities, commerce, and transportation and communication infrastructure. The 1811–1812 earthquakes were accompanied by a host of surface effects (liquefaction, landslides, surface deformation) that remain visible in the landscape today. Ground motions from the earthquakes were also reported to be felt as far away as Charleston, South Carolina (~950 km) and even Boston, Massachusetts (~1,600 km). There is a complex zone of active microearthquakes producing several $M < 3$ earthquakes each week. Early research based on ground-shaking intensities derived from historical reports proposed that the three largest earthquakes in the series exceeded M8. The ~100-km long zone of active microseismicity, which many presume to represent the active faults, seems much too small to host even a single M8 earthquake, let alone three, unless stress drops, and therefore slip per unit length, were extremely large. The earthquakes occupy a shallow basin formed atop a failed continental rift, formed in latest Precambrian time and briefly reactivated (but once again failed) in the Cretaceous. The faults are oriented such that they are nearly optimally oriented to be reactivated as thrust and strike-slip fault in the current compressional mid-plate stress regime.

Subsequent reexamination of the historic intensity data, and taking into account the feeble attenuation of Seismic waves within rocks in the plate interior, have yielded generally smaller estimates of magnitudes, as low as M7 for the three largest 1811–1812 earthquakes. In the absence of new information, however, it might be best to admit that while these earthquakes were undoubtedly large, their magnitudes will remain forever moot. Paleoseismic studies of earthquake-induced liquefaction features in surface deposits reveal at least four repeated episodes of strong shaking (as strong as what took place in the early nineteenth century), often in clusters like the 1811–1812 events, with an average recurrence interval of ~500 years. The geological evidence for recurrent large earthquakes is balanced by the lack of primary surface faulting, or even the prominent topographic relief one would expect if much slip had taken place at the rates paleoseismic evidence infers for the past several thousand years. So either the big events are really a good deal smaller than the largest estimates of their size or seismic activity in the zone was initiated only a few thousand years ago.

Geodetic evidence, from repeated campaign surveys and continuous GPS studies show that deformation surrounding the active seismic zone (Smalley et al., 2005) is very slow, with some (e.g., Newman et al., 1999) arguing that it is not different from zero. However, given the lack of a mid-plate fault model it is not clear what deformation pattern one should expect. So there is no general agreement about what the lack of observed active deformation means, and the interpretations remain contentious. Some suggest that either the largest earthquakes to be expected from the seismic zone are not so terrifyingly large as previously thought, or perhaps that, however large they were, they are not being recharged with stress and are not to be feared. Others hold that the paleoseismic, historical, and microseismic evidence point to the likelihood of future damaging earthquakes just like the historical ones, albeit driven by processes that are still beyond our ken.

Summary or conclusions

Intraplate seismicity is a catchall phrase that encompasses a wide variety of seismogenic phenomena; essentially all earthquakes that do not occur on plate bounding faults. Locales hosting intraplate earthquakes range from broad deformation zones that surround some plate boundaries to areas that lie within the cores of continents. Larger earthquakes – especially those in what are otherwise tectonically stable cold continental crust – appear to be associated with faults that formed in an earlier tectonic setting but are reactivated by the stress field applied currently. Not all faults are so reactivated, so it is likely that some as-yet-unclear weakening mechanism causes only certain faults to fail. Localized deformation, say glacial rebound or geothermal stresses can be responsible for interplate earthquakes, but does not explain all of them. As a class of faults, intraplate faults usually slip more slowly and less far than interplate faults, and this leads to longer intraplate earthquake recurrence intervals. Also, and probably related to this, intraplate earthquakes may generally be expected to have larger stress drops. Although less frequent than plate boundary earthquakes, intaplate seismicity is very dangerous because the population and infrastructure at risk from them is less prepared than in more seismically active areas. The study of intraplate seismicity is an endeavor that, because of its low rate is best done by integrating across different source regions and combining different Earth science disciplines.

Definition

Subduction zone. Consuming plate boundary where the oceanic plate subducts into the mantle beneath the continental plate.

Interplate earthquakes. Earthquakes that occur along the plate boundary. In case of the subduction zone, they occur at the shallow portion of the boundary between the subducting plate and the overriding plate.

Intraslab earthquakes. Earthquakes that occur within the subducted plate, that is, within the slab.

Shallow earthquakes. Earthquakes that occur at depths shallower than 60 km. Focal depths of interplate earthquakes in subduction zones are usually shallower than 60 km, and so they are shallow earthquakes.

Intermediate-depth earthquakes. Earthquakes that occur at depths of 60–300 km.

Deep earthquakes. Earthquakes that occur at depths deeper than 300 km. Both intermediate-depth and deep earthquakes occur only within the subducted plate, and so they are intraslab earthquakes.

Introduction

There are seismically active and inactive areas on the Earth. Most of Earth's seismic activity is concentrated in narrow continuous belts that wrap around it. Plate tectonics proposes that the Earth's entire surface is comprised of somewhat more than ten large, rigid, mosaic-like plates, and that the relative movement of these plates causes tectonic activity at their boundaries. Consequently, most earthquakes are concentrated at plate boundaries, forming narrow, belt-shaped seismic zones.

Oceanic plates are generated at mid-ocean ridges by the upwelling of mantle material. Since the Earth's surface area is constant, the surface area does not expand with the generation of the oceanic plate. Instead, the same amount of material moves back down into the mantle. The generation of plates is balanced by the consumption of other plates elsewhere at consuming plate boundaries. *Subduction zones* are where oceanic plates plunge downward into the mantle. At subduction zones, two plates collide with each other; the heavier plate is overridden by the lighter one and sinks down into the mantle. Thus, the heavier oceanic plate subducts beneath the lighter continental plate. The subduction of the oceanic plate causes high seismic activity. In fact, it is in these subduction zones that most of the world's large earthquakes occur.

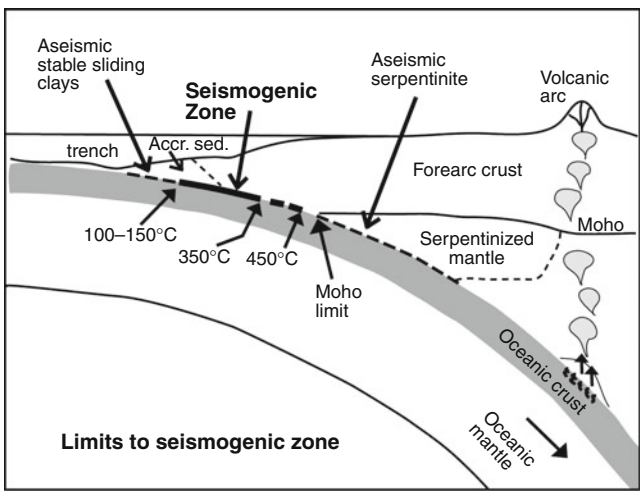
Interplate earthquakes

In subduction zones, the denser oceanic plate sinks down into the mantle underneath the lighter continental plate.

The shallow portion of the plate boundary is locked by friction, and in order to release accumulated stress, occasional slips at the plate boundary occur and cause earthquakes. Most of the world's large, shallow earthquakes are interplate earthquakes caused in this way. Interplate coupling occurs only within a specific range of depths, which seems to be primarily determined by the temperature of the plate interface.

Oleskevich et al. (1999) estimated the thermal structures of plate interfaces in several subduction zones, and compared them with the updip and downdip depth limits of source areas of large interplate earthquakes. The results show: (1) the updip limit of the depth of interplate earthquakes corresponds with the depth at which the temperature of the plate boundary reaches 100–150°C and (2) the downdip limit approximately matches the depth at which the temperature reaches 350°C (Figure 1). In the shallowest part of plate interfaces, smectite clays, which are clay minerals distributed in the sediments there, prevent interplate coupling by producing stable sliding. The temperature rises with increasing depth and when it reaches 100–150°C, dehydration decomposition occurs and the smectite clay turns into illite and chlorite. This transformation is considered the onset of interplate coupling.

Then, deeper, where the temperature exceeds 350°C, interplate coupling ceases and stable sliding takes place again. Figure 1 shows that the transition zone from unstable sliding to stable sliding occurs at depths where the temperature ranges from 350°C to 450°C. In the case where the depth at which the temperature of the plate interface reaches 350°C is deeper than the depth at which it contacts the Moho of the upper plate, the contact zone with the Moho is considered to be the downdip limit. The reason the downdip is limited to the Moho contact zone is that stable sliding prevails where the mantle of the upper plate contacts the oceanic plate because the mantle may be serpentinized by water supplied by the dehydration of the subducting oceanic plate. It is considered that interplate earthquakes do not occur any more under those conditions (Hyndman et al., 1995). In some subduction zones, such as in northeast Japan, the upper plate's mantle is not serpentinized, since the seismic wave velocities there show normal values of non-serpentinized mantle materials. In such cases, the downdip limit is once again determined by temperature, although the specific temperature at which the transition occurs is not yet known.

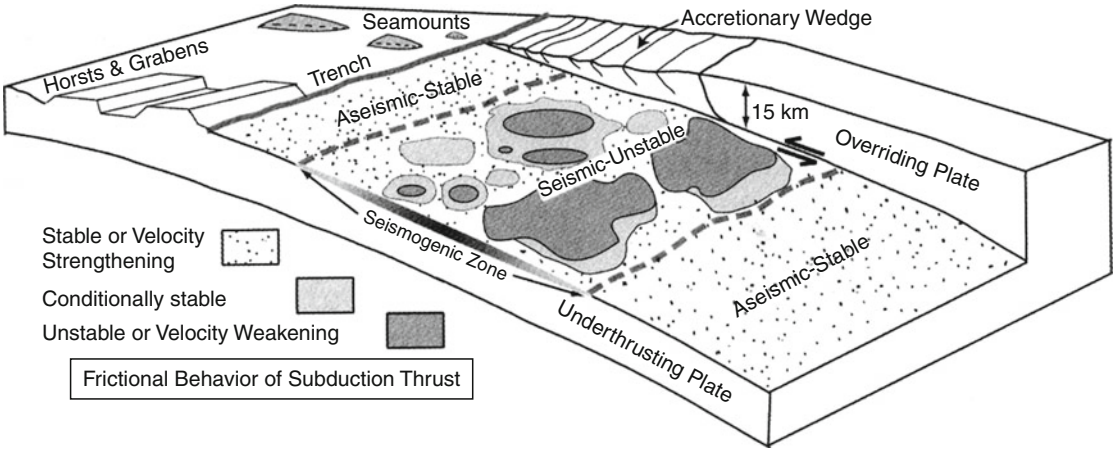


Seismicity, Subduction Zone, Figure 1 Sketch of the subduction plate boundary seismogenic zone (Oleskevich et al., 1999, copyright by the American Geophysical Union).

The degree of interplate coupling can be indicated by how much interplate slip is accounted for by earthquakes. This index is called "seismic coupling" and denotes the percentage of the seismic slip among all slip amounts occurring at the "seismogenic zone" in Figure 1. If seismic coupling is 1, all slip occurring in that area is caused by earthquakes. In contrast, if it is 0, it means that all slip occurring in that area is aseismic stable sliding. Seismic coupling differs from one subduction zone to another, and the larger the maximum magnitude of interplate earthquakes is in a subduction zone, the larger is its seismic coupling (Lay and Kanamori, 1981).

The younger the age of the subducting plate and the faster the plates are converging, the larger the maximum earthquake magnitude (Ruff and Kanamori, 1980) and so the stronger is the interplate coupling. A faster convergence velocity results in a higher rate of stress accumulation, which would accompany a higher rate of earthquake activity. Young plates are generally less dense than older plates, and being relatively light, the gravitational force pulling them downward is weaker and their subduction angle is lower than with older, denser plates. When the subduction angle is low, the contact area between the subducting plate and the upper plate is large. The large contact area and relatively weak downward force produce strong interplate coupling between the plates. Moreover, younger plates have relatively smoother plate surfaces because they do not have long alteration histories after their generation at the midoceanic ridge, which probably allow the formation of larger focal areas of large maximum earthquakes. For these reasons, if two plates have the same subduction velocity, the younger plate will have stronger interplate coupling and larger maximum earthquake magnitude (Kanamori, 1977).

Interplate coupling along the seismogenic zone is heterogeneous both in space and time; the seismogenic zone is not fully locked, as mentioned above, and some portions of it will slide stably during interseismic periods. Seismic waveform inversions of large interplate earthquakes have revealed spatially heterogeneous seismic slip along the seismogenic zone, and backslip inversions of geodetic data, which estimate spatial distribution of interplate coupling, have confirmed spatially heterogeneous strain accumulation along the zone during the interseismic period. A conceptual model of frictional properties on the fault surface based on laboratory-derived fault constitutive laws



Seismicity, Subduction Zone, Figure 2 A conceptual model of frictional properties on the subduction plate boundary (originally from Bilek et al. (2002) and modified by Dixon and Moore (2007), copyright by the Columbia University Press).

(Figure 2) explains the observed heterogeneous interplate coupling along the seismogenic zone. It involves patches of frictionally unstable fault surface surrounded by stable and conditionally stable fault surfaces. Frictionally stable portions of the fault are subject to steady aseismic sliding, whereas unstable patches (asperities) remain locked during the interseismic period. Then they finally fail, as evidenced by the occurrence of earthquakes. Conditionally stable portions typically slide stably, but may fail and slide dynamically if loaded at high strain rates by the seismic slip of a neighboring asperity. Earthquakes nucleate only in the unstable patches, and once an earthquake occurs in an unstable patch its seismic slip propagates throughout the patch, with some penetration into the neighboring conditionally stable areas. This conceptual model indicates that the larger the area occupied by the frictionally unstable patches in the seismogenic zone, the larger the seismic coupling of that subduction zone is.

Shallow inland intraplate earthquakes

Convergence of two plates at subduction zones causes stress accumulation also in the overriding continental plate, producing deformation in it well beyond the trench axis. Usually, this deformation is compressional crustal shortening, which partially accommodates the plate convergence. Shallow earthquakes occur in the crust of the overriding plate, reflecting this ongoing compression. Focal mechanisms of these earthquakes are thrust fault or strike-slip fault with compressional axis oriented nearly in the plate convergence direction. Recurrence intervals of these types of earthquakes are much longer than those of interplate thrust earthquakes. However, once they occur, it often causes serious damages in lives and societies due to the shallow hypocenter and proximity to inhabited areas.

In most cases, these shallow inland earthquakes occur in the depth range between 1–3 and 10–20 km, forming the seismogenic zone mainly in the upper crust of the overriding plate. Deformation is made by aseismic ductile flow at shallow depths above the upper bound because of the presence of unconsolidated granular material, and at large depths below the lower bound because of the onset of plasticity at a critical temperature (Scholz, 1998). This critical temperature is considered to be about 300–400°C, and so the lower bound of the seismogenic zone varies depending on the local thermal gradient.

Active faults, which are surface traces of repeated fault movements by earthquakes, show locations where in the seismogenic zone of the overriding plate large shallow earthquakes have occurred in the recent past, the Quaternary Period. Surveys of active faults further provide information on history of earthquakes, including their magnitudes and the time of the last event, which is basic and important for long-term earthquake forecast of shallow inland intraplate earthquakes.

Although we can learn from active faults where large earthquakes have occurred, it is difficult to understand why earthquakes occur in those locations. Recent investigations based on dense GPS and seismic observation network data in Japan have provided some information on this problem. Analyses of GPS data showed the existence of belt-like zones with concentrated crustal shortening in the overriding plate, along which many large shallow earthquakes have occurred or active faults are distributed (Sagiya et al., 2000; Miura et al., 2004). Seismic tomography studies revealed prominent low seismic velocity zones in the lower crust to the uppermost mantle right beneath these concentrated deformation zones (Nakajima et al., 2001; Nakajima and Hasegawa, 2007). The low seismic velocities are inferred to reflect the existence of aqueous fluids, which are perhaps supplied from the subducted slabs. These observations suggest that the fluids weaken the surrounding crustal materials and cause the concentrated deformation there, leading to large shallow inland earthquakes (Iio et al., 2004; Hasegawa et al., 2005). If this is the case, places to which aqueous fluids

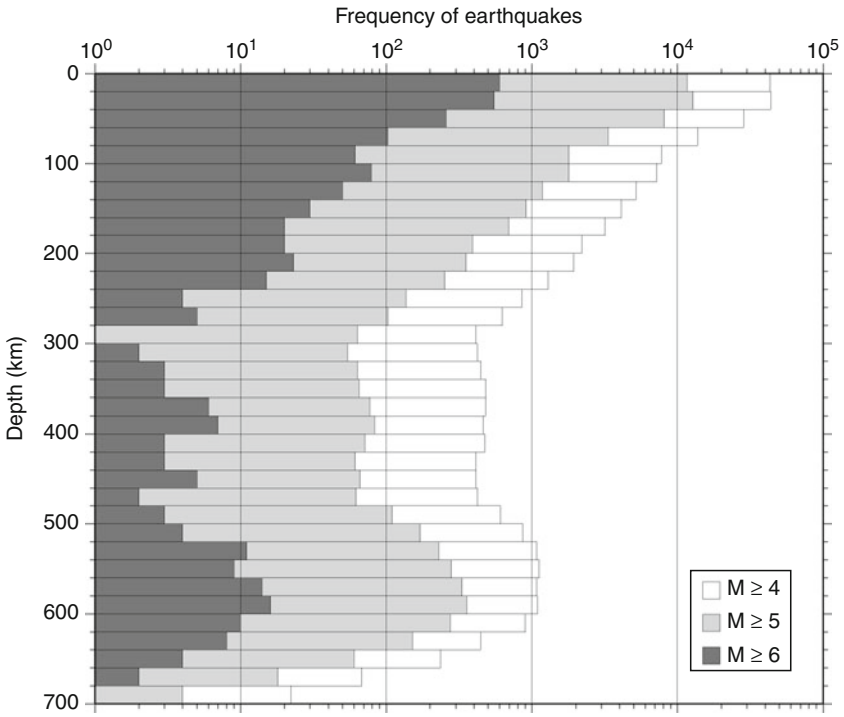
are supplied intensively from the mantle wedge below are considered to be locations where large shallow earthquakes occur.

Intraslab earthquakes

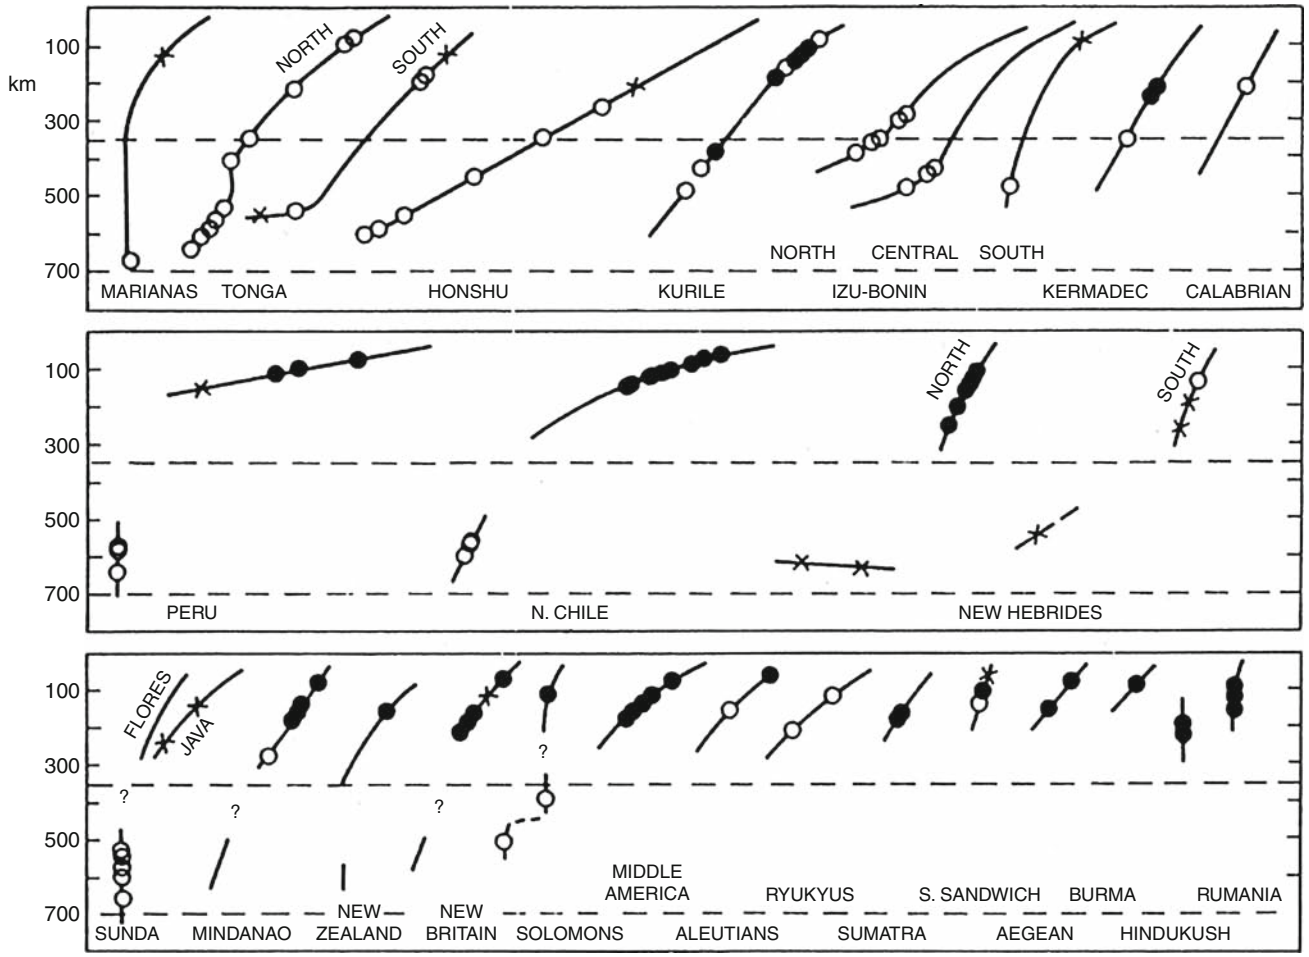
Earthquakes that occur at depths of more than about 60 km are found only in subduction zones. That is because these earthquakes occur in subducting oceanic plates or slabs. They are distributed in an inclined plane in the mantle, which is called "deep seismic zone" or "Wadati–Benioff zone," after its discoverers. The frequency distribution of earthquakes for each depth range throughout the world (Figure 3) shows that depths from 0 to 50–60 km have the greatest occurrence frequency. Proceeding deeper, the frequency decreases nearly monotonically until a depth of about 300 km, then starts to increase with depth from that point, reaching a local maximum at 500–600 km deep. The earthquake depth range can be divided into three zones: shallow (0–60 km), intermediate depth (60–300 km), and deep (deeper than 300 km). Of these, intermediate-depth earthquakes and deep earthquakes occur within the slab so they are called intraslab earthquakes (or slab earthquakes).

In many cases, the focal mechanisms of intraslab earthquakes are classified as either downdip compression (DC) earthquakes, in which the compressional axis is oriented in the dip direction of the slab, or downdip extension (DE) earthquakes, in which, on the contrary, the tensional axis is oriented in the dip direction of the slab. There is a systematic tendency in the depth distribution of focal mechanisms that depends on the age of the subducting plate. That is, as indicated in Figure 4: (1) DE-type earthquakes dominate in young plate subduction zones such as in Central America, in which intraslab earthquakes occur only to a depth of about 250 km. (2) Intraslab earthquakes occur to a depth of about 650 km in old plate subduction zones such as Tonga and the Izu-Bonin arc, and the DC-type focal mechanism dominates at all depths in those areas. (3) Subduction zones such as the Kermadec and Kuriles areas have characteristics intermediate between (1) and (2); DE-type earthquakes dominate in shallow reaches while DC-type earthquakes dominate deeper. (4) In subduction zones like Chile and the New Hebrides areas, in which intraslab earthquakes do not occur at depths between 300 and 500 km, the DE-type dominates at shallow depths while the DC-type dominates deeper.

Isacks and Molnar (1971) explain the formation of these earthquake-generating stress fields in the slab as follows. The depths to which the downdip ends of slabs reach constitute four different conditions (Figure 5). In one configuration, the end of the slab reaches the top of the high strength lower mantle (Figure 5c), which corresponds to the conditions described in (2) above. In two other configurations, it ends within the upper mantle (Figures 5a and b) corresponding to (1) and (3) above. In the fourth case, the slab is not continuous, but is divided into upper and lower segments (Figure 5d) corresponding to (4) above. When slabs subduct into the mantle, the resistive force becomes



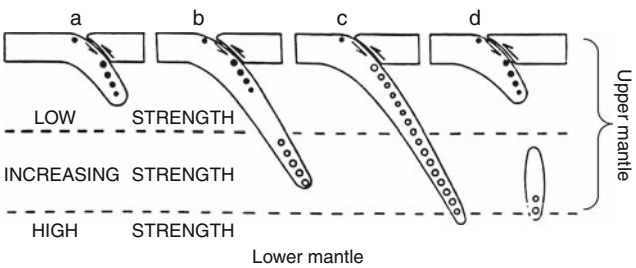
Seismicity, Subduction Zone, Figure 3 Focal depth distribution of global seismicity. Earthquakes with magnitudes greater than 4, 5, and 6 in the EHB catalog (Engdahl et al., 1998) for the period from 1964 to 2004 are plotted.



Seismicity, Subduction Zone, Figure 4 Global summary of stress states within subducting slabs (Isacks and Molnar, 1971, copyright by the American Geophysical Union). Open and solid circles show downdip compression and downdip extension, respectively. Crosses indicate that neither the compression nor tension axis is approximately parallel to the slab dip.

stronger with increasing depth, and the earthquake-generating stress fields discussed above are formed. Although the above explanation by Isacks and Molnar seems plausible at first glance, recent seismic tomographic studies are now revealing that the end of the slabs reach the top of the lower mantle in most subduction zones. Therefore, the interpretation provided in Figure 5 is not always correct.

Slab mineralogy studies have shown that depth perturbations of phase transformation boundaries resulting from thermal anomalies within the slabs also generate positive and negative buoyancy forces depending on depth, and so are major contributors to stress fields in the slabs (e.g., Bina et al, 2001). Figure 6 shows a diagram of the mineralogy in a subducting slab. Since the slab is colder than the surrounding mantle, the α-olivine to β-spinel phase transformation at 410 km depth and the β-spinel to γ-spinel phase transformation at 550 km depth become shallower, whereas decomposition of γ-spinel to perovskite + magnesiowustite at 660 km depth becomes deeper

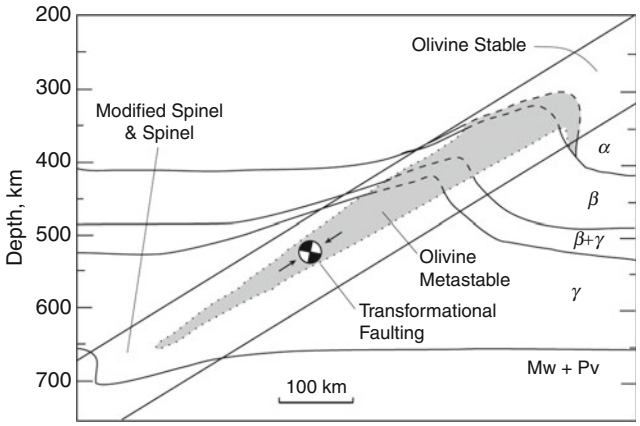


Seismicity, Subduction Zone, Figure 5 Sketch of a model explaining the stress state within the subducting slab where gravitational forces act on excess mass within the slab (Isacks and Molnar, 1971, copyright by the American Geophysical Union).

than in the ambient mantle. Moreover, the olivine to β-spinel transition must be kinetically hindered within the cold slab, since the relatively colder temperatures in the slab inhibit reaction rates. A wedge-shaped zone of

metastable peridotite thus formed in the cold core of the slab persists to the depth shown by the shaded area in Figure 6 (Kirby, 1995).

Upward deflections of the olivine to β-spinel transition at 410 km and the β-spinel to γ-spinel transition at 550 km yield negative buoyancy forces by stabilizing the dense higher pressure phases in the slab surrounded by the less dense lower pressure phases in the ambient mantle. On the contrary, the downward deflection of the γ-spinel to perovskite + magnesiowustite transition at about 660 km yields positive buoyancy forces. Moreover, the metastable olivine wedge yields positive buoyancy forces. Downdip compression at depths deeper than about 300 km, observed for all the subduction zones (Figure 4), can be well explained by the compressional stress generated by the combination of the buoyancy forces produced by the metastable olivine wedge, the downward deflection of the perovskite-forming transition, and the force resisting slab penetration into the lower mantle (Chen et al., 2004). It is expected that the downdip compressional stress caused by the metastable olivine wedge is smaller for warm (young) and slow slabs. Chen et al. (2004) found a good correlation between the thermal parameter of the slab and the nature of the downdip stress at depths shallower than about 300 km in accordance with this expectation: warm, slow slabs tend to have tensional stress; and cold, fast slabs tend to have compressional stress.

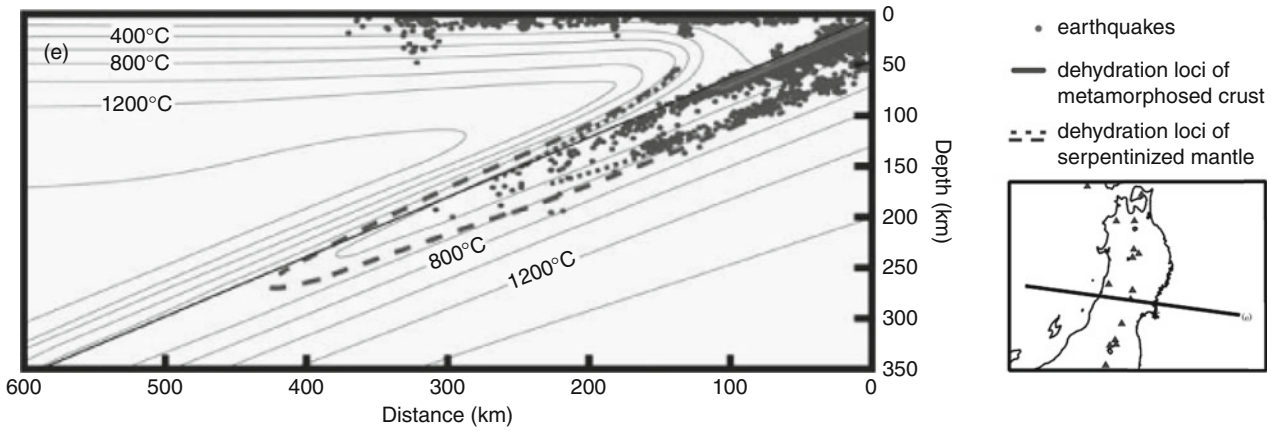


Seismicity, Subduction Zone, Figure 6 Schematic diagram of the mineralogy within a subducting slab (Kirby, 1995, copyright by the American Geophysical Union).

Intermediate-depth earthquakes: double seismic zone

It is known that intermediate-depth intraslab earthquakes form a double seismic zone in several subduction zones. This was first clearly found beneath northern Honshu, in northeast Japan (Figure 7), where the deep seismic zone is composed of two planes at depths of 70–150 km that are parallel to each other and separated by about 30 km (Hasegawa et al., 1978). Upper-plane earthquakes, most of which occur in the crust of the slab, have DC-type focal mechanisms, while lower-plane ones, occurring in the mantle of the slab, are characterized as DE-type earthquakes. Engdahl and Scholz (1977) explained the formation of such a double-planed deep seismic zone by the unbending of the subducting oceanic plate at this depth range. Later studies showed, however, that DC-type upper-plane and DE-type lower-plane events are not always seen and that in some subduction zones both the upper and lower planes have DC stress. These observations indicate that the unbending force may not be the main cause of the formation of the double seismic zone, although it must be acting on the plate.

Similar to ordinary shallow earthquakes, most intermediate-depth and deep earthquakes have double-couple radiation patterns and little or no isotropic



Seismicity, Subduction Zone, Figure 7 Double seismic zone and dehydration loci of oceanic crust and mantle for central Tohoku, northeast Japan, projected on an across-arc vertical cross section (Yamasaki and Seno, 2003, copyright by the American Geophysical Union). The solid line and broken and dotted lines show the dehydration loci of the crust and mantle, respectively. Dots denote earthquake hypocenters. Medium thick and thin lines are the upper plate interface and isotherm contours, respectively.

component (Frohlich, 2006). However, it has been thought that intermediate-depth and deep earthquakes are mechanically different from shallow earthquakes that are generated by brittle fracture. This is because normal stress on the fault becomes too high to cause ordinary brittle shear faulting. At depths of 60–650 km, the overburden produces confining pressures of 2–23 GPa, yielding the strength of the fault of about the same order of magnitude. Earthquake occurrence requires a shear stress exceeding that strength, but it is unlikely that such a high shear stress is actually produced at such depths in the slab. Even if some process in the slab can produce such a high shear stress, it cannot be maintained because ductile flow will occur. Therefore, some special mechanism is necessary to generate earthquakes at such great depths.

One possible mechanism that decreases the strength of the fault for intermediate-depth earthquakes is dehydration embrittlement (Raleigh and Paterson, 1965; Green and Houston, 1995). Before its subduction, the oceanic plate contains a considerable amount of water as hydrated minerals. The temperature and pressure of the plate rise as it subducts and decompose the hydrated minerals and discharge water. The water reduces the effective normal stress and enables brittle fracture. Dehydration embrittlement also seems to explain the formation of the double seismic zone as discussed below.

If dehydration embrittlement is the mechanism generating intermediate-depth intraslab earthquakes, intraslab earthquakes should not be expected to occur everywhere in the slab, but only where hydrated minerals exist, particularly at facies boundaries where the water content changes. It has become increasingly clear that intermediate-depth intraslab earthquakes do seem to occur in such areas.

In order to examine whether or not dehydration embrittlement is the cause of intraslab earthquakes, we need to know the location within the slab where the hydrated minerals are decomposed and the water is discharged. Yamasaki and Seno (2003) determined the locations in the slab where the dehydration decompositions of serpentinized slab mantle and metamorphosed slab crust occur based on experimentally obtained phase diagrams of rocks. They compared these locations with the spatial distribution of intraslab earthquakes. The result for the Pacific slab under northeast Japan is shown in Figure 7. The estimated dehydration loci of the crust and mantle roughly correspond to the location of the upper and lower planes of the double seismic zone. They obtained the same results for the other five subduction zones. This explains well why double seismic zones are formed and why earthquakes in the lower plane have a planar distribution near the center of the slab mantle.

The above results support the dehydration embrittlement model of intraslab earthquakes. However, whether hydrated minerals actually exist at depths where lower-plane earthquakes occur (the deeper part of the mantle that lies at a maximum of about 40 km below the upper slab boundary) is still a point of contention. In this regard, further validation is necessary for the generation of lower-plane events.

Formation of a belt of intraslab seismicity in the slab crust beneath northeast Japan

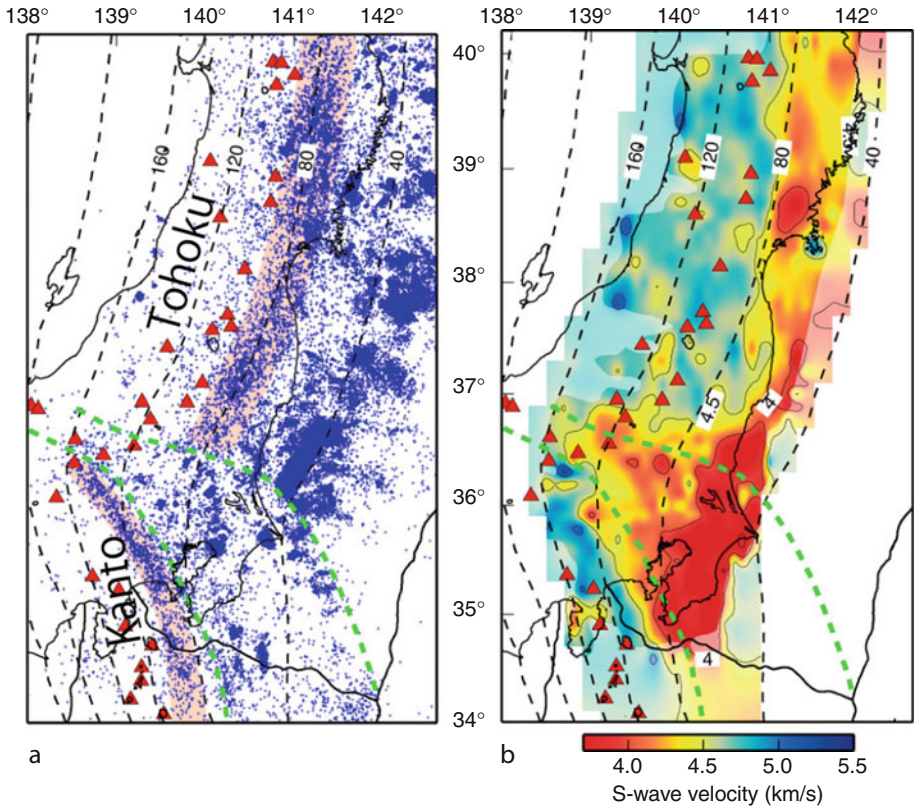
Recent studies have shown a more detailed spatial distribution of upper-plane earthquakes and revealed its clear relationship with the slab structure. This, as described below, can be explained well if the cause of intraslab earthquakes is dehydration embrittlement.

As indicated by the pale-pinked zones in Figure 8a, earthquakes in the upper plane of the double seismic zone beneath northeast Japan form a remarkable belt-like seismic zone at depths between 70 and 90 km, parallel to iso-depth contours of the upper surface of the Pacific slab. The across-arc vertical cross section of earthquakes in Figure 9 also shows that there is a concentration of earthquakes at depths of 70–90 km, which corresponds to the belt-like seismicity indicated in Figure 8a. If the cause of intraslab earthquakes is dehydration embrittlement, this concentration of seismicity is expected to correspond to the location in the slab crust where hydrated minerals are present, particularly around the facies boundary where dehydration occurs.

This belt-like seismicity indicated by the pale-pinked zones is not parallel to iso-depth contours, but is oblique to them and deepens locally in Kanto (Figure 8a). This local deepening is thought to be caused by the shield effect of the Philippine Sea slab, which is located immediately above the Pacific slab. The two slabs are in direct contact under Kanto, and the contact zone between the two is indicated as an area enclosed by two broken lines in the figure. The downdip end of the contact zone is parallel to the belt-like seismicity beneath Kanto, which is oblique to the iso-depth contours of the upper plate interface. Such a clear correspondence indicates that under Kanto, the Philippine Sea slab prevents the Pacific slab from being heated up by the mantle wedge and delays the phase transformation in the slab crust, resulting in the locally deepened belt-like seismicity in that area (Hasegawa et al., 2007).

Phase transformation of the slab crust causes an increase in seismic wave velocity. Therefore, we can verify from seismic tomography whether the phase transformation is the cause of the belt-like seismicity. Distribution of S-wave velocity in the slab crust (Figure 8b) shows that the low-velocity layer persists down to about 80 km depth in Tohoku; deeper than that, S-wave velocity becomes high. On the other hand, in Kanto, the depth range of the low-velocity layer deepens locally in the zone of contact with the Philippine Sea slab. This means the distribution of S-wave velocity also confirms the prediction that the phase transformation is delayed.

Direct comparison with mineralogical research results does not allow us to verify whether the phase transformation accompanying dehydration actually occurs at the depth of this belt-like seismicity. Though accurate



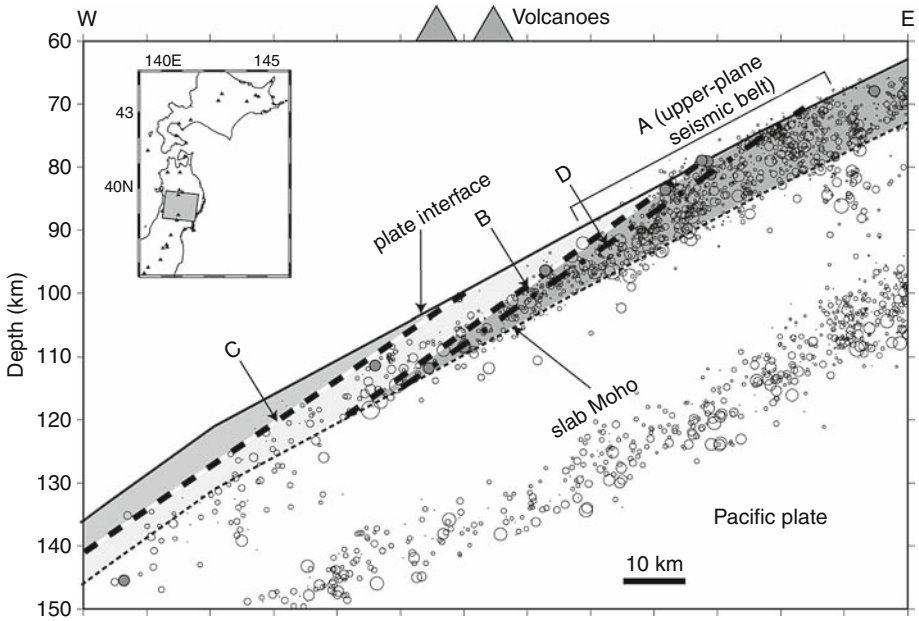
Seismicity, Subduction Zone, Figure 8 (**a**) Earthquake epicenter distribution and (**b**) S-wave velocity distribution in the subducting Pacific slab crust beneath northeast Japan (Nakajima et al., 2009, copyright by the American Geophysical Union). Pale-pinked zones in (**a**) show the belt-like seismic zone. S-wave velocity perturbations on a curved plane 5 km below the upper surface of the slab are shown in (**b**) by the color scale at the bottom. Iso-depth contours of the upper surface of the slab are shown by broken curves. The zone of contact with the overlying Philippine Sea slab is enclosed by green broken lines.

temperature distribution in the slab is necessary for such a detailed examination, unfortunately, many uncertainties remain regarding the estimation of the temperature in the slab. However, it is possible to make at least a rough estimate. In the vertical cross section in Figure 9, the facies boundaries estimated based on the phase diagram of midoceanic ridge basalt (MORB) by Hacker et al. (2003) and the geotherm by Peacock and Wang (1999) are shown as broken lines. The concentration of earthquakes forming the belt-like seismicity is found around the facies boundary in the shallower areas (B in the figure). That approximately agrees with the prediction based on the dehydration embrittlement model. As another example, the facies boundary determined by using the MORB phase diagram by Omori et al. (2009) and the subducted slab geotherm by van Keken et al. (2002) are indicated as a dashed-dotted line (D) in the figure. In this case also, the facies boundary approximately agrees with the location of the belt-like seismicity. Since many uncertainties remain in the estimation of the slab temperature, we need further validation for the location of the facies boundary. At any rate, the facies boundary must be strongly dependent not on pressure but on temperature.

Deep earthquakes

As described in previous sections, seismic observations seem to support the dehydration embrittlement hypothesis for the generation of intermediate-depth earthquakes, at least those in the crust of the slab. Focal depth distribution of global seismicity (Figure 3) shows that the frequency of earthquakes, after a nearly monotonic decrease from shallow depths, recovers at a depth of about 300 km and gradually increases until the local maximum at 500–600 km. This may suggest that a different mechanism is working for the generation of deep earthquakes.

Several hypotheses have been proposed for the generation of deep earthquakes. There exists the difficulty in generating deep earthquakes as already described in section "Intermediate-depth earthquakes: double seismic zone." Three mechanisms out of those proposed so far seem to overcome the difficulty. One is the shear heating



Seismicity, Subduction Zone, Figure 9 Across-arc vertical cross section of intraslab earthquakes in central Tohoku, northeast Japan (Kita et al., 2006, copyright by the American Geophysical Union). Earthquakes are shown by open circles. The estimated jadeite lawsonite blueschist–lawsonite amphibole eclogite facies boundary (B) and the lawsonite amphibole eclogite–eclogite facies boundary (C) of the MORB (Hacker et al., 2003) are denoted by thick broken lines. The facies boundary (D) based on Omori et al. (2009) is also shown by a dashed-dotted line.

instability of creep (Griggs and Handin, 1960; Ogawa, 1987). Plastic creep of minerals produces heat, while high temperatures promote creep. Therefore, positive feedback promoting creep would arise if the creep of a thin layer occurs at a higher rate than the heat produced by the creep diffuses into the surrounding area. Thus, the creep accelerates, and finally the thin layer of material begins to melt, producing dynamic slip on the layer, that is, occurrence of an earthquake.

The second hypothesis is the transformational faulting (Kirby et al., 1987; Green and Burnley, 1989). Olivine in the mantle of the slab transforms to β-spinel associated with the subduction of the slab. The phase transformation does not occur simultaneously but originates sporadically here and there, forming small lens-shaped spinel phases. The phase transformation proceeds as these spinel lenses expand. The spinel lenses will be formed in a direction perpendicular to the maximum compressive stress axis due to volume reduction occurring in the phase transformation. At the same time, compressive stress will arise at the tip of each spinel lens due to volume reduction as the phase transformation proceeds. This compressive stress promotes the phase transformation. In this way, the spinel lens expands as if it were a crack. Green and Burnley called this spinel lens anticrack. At some critical anticrack density, those anticracks that are aligned on a plane directed obliquely to the maximum compressive axis at an acute angle are connected with each other and become unified, producing a dynamic slip on the plane, that is, the occurrence of an earthquake.

The last one is the dehydration embrittlement. Although this hypothesis seems to work for the generation of intermediate-depth earthquakes as already explained, some researchers argue that the dehydration reaction continues to occur in the mantle of the slab at greater depths and that dehydration embrittlement is responsible also for deep earthquakes (Omori et al., 2004).

It is not clear which of the three mechanisms is actually working, or if another completely different mechanism is responsible for generating deep earthquakes. More investigations are required for an exact understanding of the mechanism by which deep earthquakes are generated.

Summary

Recent investigations have significantly developed our understanding of generation mechanism for earthquakes in subduction zones. Asperity model seems to be applicable to interplate earthquakes. This gives us a theoretical background for long-term earthquake forecast: Place and magnitude of future earthquakes can be estimated from information on locations and sizes of asperities on the plate boundary. Dehydration embrittlement model seems to work as the generation mechanism for intraslab intermediate-depth earthquakes, particularly for earthquakes in the slab crust. Aqueous fluids expelled by the

dehydration reaction in the subducted plate migrate upward, finally reaching the arc crust. Recent investigations have shown that the fluids thus supplied originally from the subducting plate play an important role in generating shallow inland intraplate earthquakes. Generation mechanism for deep earthquakes is still an open question. More systematic and intensified studies are expected to resolve it.

Definition

Seismogram interpretation. Identification of various phases appearing on seismograms (measurable changes in frequency and/or amplitude), including the recognition of the waves with respect to possible travel paths through the Earth.

Introduction

A seismogram is the recording of earth motion (displacement, velocity, or acceleration) as a function of time. Its appearance reflects the combined effects of the source, the propagation path, the characteristics of the recording instrument (see *Seismic Instrumentation*), and the ambient noise due to the specific conditions at the particular recording site. To decipher the often complicated form of seismogram traces requires an extensive knowledge of source physics, structure of the Earth, wave propagation, and earthquake geography. In the early years of observational seismology, say, prior to 1960, the analyst was essentially reading short- and long-period analog seismograms made on smoked, photographic, or heat-sensitive paper or by ink-pen recorders. Approximately, in the middle of the 1980s, the situation changed dramatically. The advent and extensive deployment of broadband digital seismometers with large dynamic ranges complemented with an access to fast, powerful computers opened for seismogram interpreters new possibilities never expected before. Today, the interpreter performs easily a set of operations that significantly improve and accelerate the process of phase identification on digital seismic records. These include, for example, rotation of seismogram components and particle motion techniques. Digital multichannel data serve as input for frequency-wave number analysis and polarization filtering. Synthetic seismograms model observations and phase onsets revealed on seismograms can be associated within narrow time windows with theoretically predicted onset arrival times.

Velocity models for radially stratified Earth have been developed to provide travel times for major seismic waves for the purpose of earthquake location and phase identification. In 1987, IASPEI initiated an effort to update the JB Tables (Jeffreys and Bullen, 1940), which have served for 50 years, by constructing new global travel-time tables. With access to an extensive ISC data set (1964–1987) this effort resulted in two velocity models: *iasp91* (Kennett and Engdahl, 1991) and *sp6* (Morelli and Dziewonski, 1993) deduced from empirical smoothed travel-time curves of the main phases. The two models reveal only small differences in predicted travel times. With respect to the older JB Tables, the most significant differences were found in the upper mantle and core (see *Earth's Structure, Global*). New, *iasp91*, travel-time tables, which include also the ancillary phases, were calculated from the velocity model (Kennett, 1991). For teleseismic *P* waves, the new tables are in average 1.8–1.9 s faster than the JB Tables. The *iasp91* model was slightly modified in 1995 and a new model *ak135* was proposed (Kennett et al., 1995). The model is suited for predicting the arrival times of a wide variety of seismic phases. It is routinely used by major agencies (ISC, NEIC) in event locations and phase identifications.

At first sight, it seems that there is a contradiction between the duration of the rupture at the source, which takes between a fraction of a second and a few minutes (depending on magnitude), and the length of the observed seismogram, which for large and distant shocks can extend over several hours. The length of the seismogram depends primarily on various wave propagation effects such as reflection, refraction, mode conversion, dispersion, etc., and has little to do with the duration of the quake. A seismogram, especially from a distant earthquake, will often show a number of more or less distinct waves, commonly called phases, distributed in time, which have traveled along different propagation paths and, which were subjected to different mode conversions. Numerous manuals for seismogram interpretation have been available since the early 1950s. Some of them have been of local/regional importance, but some have gained worldwide recognition. The latter include works of Neumann (1951), Simon (1968), Willmore (1979), Payo (1986), and Kulhanek (1990). The most recent is the manual edited by Borman (2002).

Essentially, there are two types of seismic waves, *P* and *S* body waves (see *Body Waves*) and Love (*LQ*) and Rayleigh (*LR*) surface waves (see *Surface Waves*). The most important characteristics of body and surface waves, which are invaluable in any seismogram interpretation, are the following:

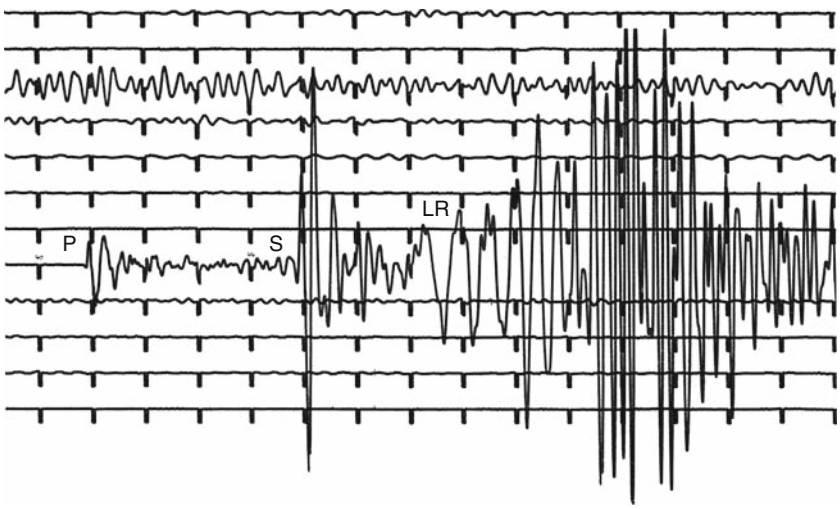
- Different waves travel with different velocities. At any epicentral distance, *P* is recorded first, followed by *S*, *LQ*, and *LR*.
- Body waves produce records in the high-frequency range, from 0.1 to 10 Hz, while surface waves occupy low frequencies of about 0.1 Hz and lower. Exceptions will be described later.
- Due to different polarization, *P*-waves are usually better displayed on vertical-component seismograms while *S*-waves are often best on horizontal-component records. Fluids do not sustain shear strain and therefore *S*-waves do not travel through liquid parts of Earth's interior. *LQ*-waves are exhibited only on horizontal-component records, while *LR*-waves are received by both the vertical and horizontal seismometers. For shallow shocks, surface waves usually dominate the seismogram.
- Surface waves exhibit an important property called velocity dispersion (see *Surface Waves*). In practice, this means that the long period surface waves approach the station first and are recorded ahead of the "slower" shorter waves. Ideally, the seismogram of *LQ*- or *LR*-waves will start with long-period motion, which gradually, as time increases, will turn into shorter and shorter periods.

Some of these features are demonstrated on the seismogram displayed in Figure 1. There is a sharp *P* onset followed after approximately 4 min by a clear *S*. About 2 min after *S* we observe the arriving *LR* (vertical-component seismogram). The clearly dispersive character of the recorded *LR* in this case manifests a continental propagation path signature. The large *LR* amplitudes indicate a shallow-focus depth. Except for the first *P* onset, all later arrivals are contaminated by codas of preceding phases so that, on the records, there is virtually no interval of quiescence between individual phases.

In the following description, we introduce several categories of seismic events. The classification is based on the distance between the event and the recording site, that is, on the epicentral distance, which in turn governs propagation paths along which seismic waves travel through the Earth's interior. Events recorded at distances shorter than about 1° will be called local events. Regional earthquakes are shocks recorded at distances between approximately 1° and 10°. For epicentral distances 0–10°, seismic waves propagate through the crust and/or along Moho. Accordingly, we call these waves, crustal waves. At recording distances 10–103°, the waves travel mainly through the mantle. For distances larger than about 103°, seismic waves enter the core or are diffracted along the core-mantle boundary (so-called core waves). Events observed at distances larger than 20° (or 30°) are collectively called teleseisms.

Crustal waves; recording distances 0–10°

In a one-layer continental crust, a source located within the crust radiates both *P* and *S* waves, which will be recorded along the Earth's surface. These waves are encoded as *Pg* and *Sg*. The subscript *g* refers to granitic layer. In continental earthquakes it has been often observed that *Sg* has the largest amplitude. The nomenclature of seismic phases used in the present article is that of the IASPEI Standard (Storchak et al., 2003 or *Seismic*

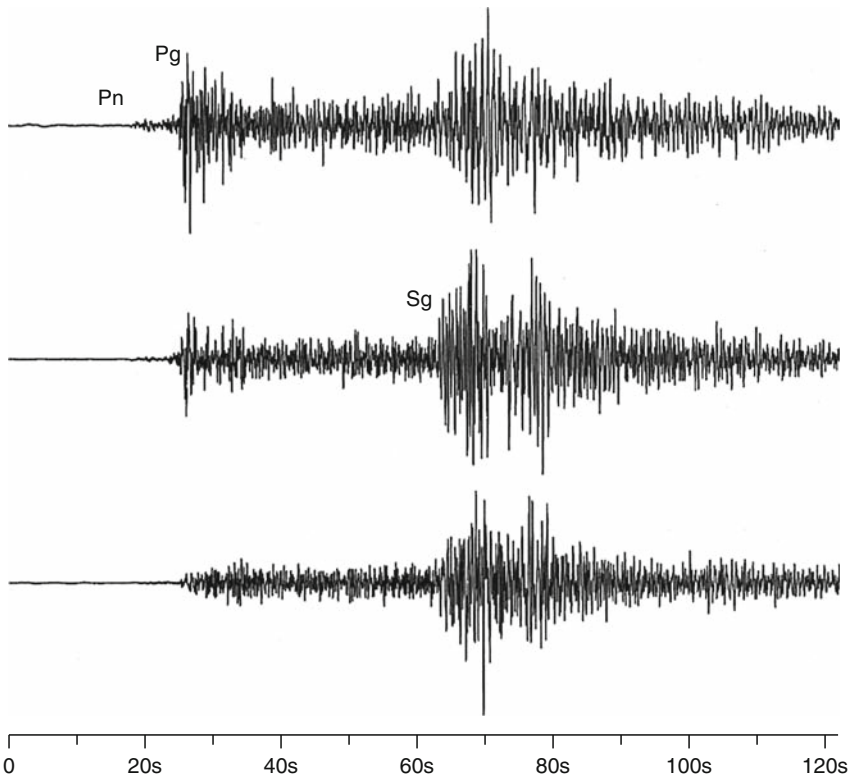


Seismogram Interpretation, Figure 1 Long-period, vertical-component, ink-pen seismogram of the Greek earthquake of February 25, 1981 (M = 6.3, h = 33 km) made at UPP (Uppsala), Sweden, at an epicentral distance of 22°. There is 1 min between successive time marks (small downward offsets).

Phase Names: IASPEI Standard). A reflected wave is also possible from the outer side of the Moho, and the corresponding reflected *P* and *S* waves are labeled as *PmP* and *SmS*, respectively. At larger distances (beyond the critical distance), we shall record so-called head waves, that is, *P* and *S* waves refracted along the Moho discontinuity and labeled *Pn* and *Sn*. Head waves propagate with velocities of the uppermost mantle. Note that *Pg* and *Sg* exist for all epicentral distances from Δ=0 and outwards, while *Pn* and *Sn* cannot be observed at distances shorter than the critical distance, which for a continental crust is about 100 km. Waves reflected from Moho are rather scarce and difficult to identify. The best chance to discern *PmP* or *SmS* on records is at very short epicentral distances where the contamination by *Pg* and *Pn* (or *Sg* and *Sn*) is not severe.

At epicentral distances shorter than about 10°, records are complicated because of lateral heterogeneities in the crust. In a two-layer crustal model, which includes the Conrad discontinuity, we record new phases. For epicentral distances larger than about 100 km, these are the refracted *P* and *S*, traveling along the Conrad discontinuity. An asterisk in the superscript position, P^* and S^*, indicates this phase. An alternative code is *Pb* and *Sb*. The subscript *b* refers to basaltic layer.

Let us assume a continental crust with propagation velocities for *Pg*, P^*, and *Pn* of 6.0, 6.6, and 8.0 km/s, respectively. At short distances, less than about 150 km or so, the first seismic wave arriving at the recording station is *Pg*. For distances larger than critical but less than about 150 km/s, *Pg* is followed by P^* and *Pn*, in this order. P^* and *Pn* travel with velocities significantly higher than *Pg*. Therefore, at distances larger than approximately 150–200 km crustal waves change their order of arrival. For distances larger than about 200 km, the first arriving phase is *Pn*, next arrives P^*, and then *Pg*. This is true only for continental travel paths. Seismograms from earthquakes beneath the sea bottom, made at islands or coastal stations, will not show *Pg* or *Sg* since there is no granitic layer in the oceanic crust. Similarly, quakes originating in the lower crust, beneath the Conrad discontinuity, do not produce *Pg* or *Sg* phases. Hence, first arrivals on records from these events will be *Pn* or P^*. With a certain time delay following the *P* phases, proportional to the epicentral distance, the crustal *S* waves arrive in the same order as *P* waves. For local events the order of *S* onsets will be *Sg*, S^*, *Sn* while for events from distances larger than about 300 km, we observe first *Sn* followed by S^* and *Sg*. As an example, a record from a regional earthquake is displayed in Figure 2. The first discernible phase



Seismogram Interpretation, Figure 2 The Kaliningrad, Russia, earthquake of September 21, 2004 (M = 5.0, h = 15 km) recorded at broadband station GOT (Gotland), Sweden, at an epicentral distance of 335 km. From top to bottom: vertical, N–S and E–W components. There are 10 s between successive time marks.

is *Pn*, weakly recorded on the vertical and N-S channels. It is followed after about 6 s by strong *Pg*, and after another 39 s by clear *Sg*, visible on all three components. *Sn* expected to precede *Sg* by 9 s cannot be identified on the seismograms.

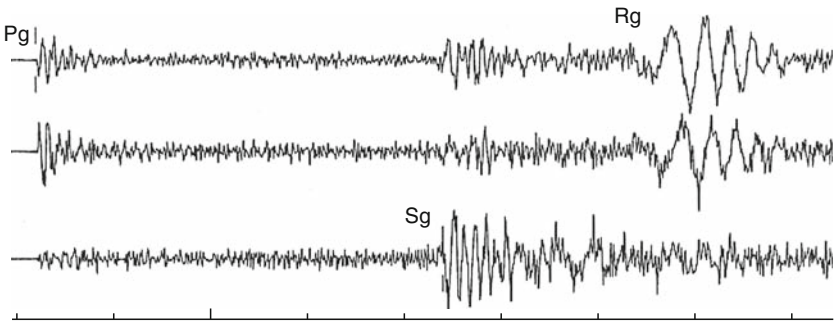
Short-period *S* waves, multiply reflected between the free surface and Moho or other crustal velocity discontinuities, interfere with each other and give rise to a wave group labeled *Lg*. There is no clear distinction between *Sg* and *Lg*. *Lg* waves propagate as guided waves, supercritically incident on the Moho and multiply reflected within the (continental) crust with a velocity of about 3.5 km/s. They may dominate the seismograms made usually at a distance of 5° and larger. *Lg* are best seen on horizontal-component records. Some rare cases are known where *Lg* propagated over distances of several thousand kilometers (Kulhanek, 1990).

Near-surface local and regional events (earthquakes, industrial explosions, rockbursts, etc.) also generate short-period surface wave of Rayleigh type, labeled *Rg*. The presence of *Rg* in the seismogram is a reliable indicator of a very shallow event with focal depth of the order of one or a few kilometers. On the other hand, if *Rg* waves are absent (epicentral distance of several hundred kilometers or less), we are concerned with a deeper natural event, that is, with a crustal quake at a depth most likely between 5 and 25 km, since all types of man-made events can be excluded. *Rg* waves travel with a velocity of 3 km/s or slightly higher and are usually well recorded up to distances of about 600 km (Båth, 1983). These waves are best, but not exclusively, seen on vertical-component records. An example of a recorded *Rg* wave is displayed in Figure 3. The *Rg* phase is well developed (large amplitudes, clear dispersion) indicating a focal depth of 2 km or less.

Island and coastal seismographic stations frequently record so-called *T* waves (tertiary waves) arriving after *P* and *S* (see *T Waves*). They are characterized by propagation within the oceans as ordinary sound waves emitted by earthquakes near the sea bottom or by submarine volcanic eruptions. The propagation of *T* waves is very efficient and observations at distances as large as about 80° have been reported. Observations of *T* phases have proved useful in discriminating between underground nuclear explosions, detonated beneath oceanic islands and tectonic earthquakes (Adams, 1979). On records, *T* phases often exhibit rather monochromatic oscillations (periods usually less than 1 s) with a gradual increase and decrease of amplitudes of total duration up to several minutes. There is no sharp onset in the *T* phase group, which creates difficulties when reading the *T* arrival times. In general, there is a great variety in the appearance of *T* phases due to the dependence upon the bottom topography in the vicinity of generation, oceanic stratification, and water-land conversion and transmission.

Appearance of seismograms made at local and/or regional distances varies from place to place mainly due to lateral variations in crustal structure. It is, therefore, difficult to list generally valid clues for record interpretation. Nevertheless, following principles may guide the analyst to read seismograms and evaluate software solutions of local and regional earthquakes.

- Predominant periods of recorded crustal waves *Pg*, P^*, *Pn*, *Sg*, S^*, *Sn*, etc., are normally less than 1 s. *Rg* periods are usually not longer than several seconds.
- Often, *Sg* has the largest amplitude (when large short-period *Rg* is missing), best on horizontal-component records. At larger distances, *Lg* may dominate the records.
- For epicentral distances less than about 200 km (depending upon the crustal structure and focal depth), the first arriving phase is *Pg*. For larger distances, *Pn* arrives first.
- Near-surface events, from distances less than about 600 km, often generate short-period *Rg* with clear dispersion, best seen on vertical channels.
- Local and regional events of low or moderate magnitude are characterized by short total record duration, usually not exceeding several minutes.
- Island and coastal seismographic stations frequently record various types of *T*-phases.



Seismogram Interpretation, Figure 3 Weak, near-surface event ($M \sim 2$) in southern Sweden, recorded at broadband station NYN (Nynäshamn) at an epicentral distance of 36 km. From top to bottom: vertical, N–S and E–W components. There are strong onsets of *Pg* (vertical, N–S) and *Sg* (E–W) and a clear *Rg*-phase with distinct dispersion, about 2 s after *Sg*, best developed on the vertical and N–S components. There is 1 s between successive time marks at the bottom. (Note: epicenter almost due north of NYN).

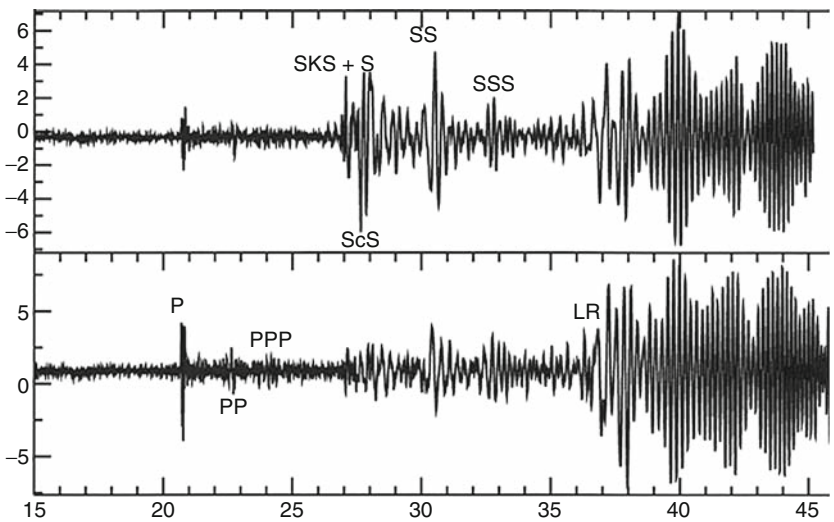
Body waves traversing the mantle; recording distances 10–103°

Mantle, in contrast to the overlying crust, may, in the first approximation, be considered as laterally homogeneous. At distances around 10°, *Pn* and *Sn* become difficult to identify in the records. Instead, *P* and *S* phases show on seismograms. Some workers consider the distance range between 10° and 103° as ideal to record not only the direct *P* and *S* waves, but also the whole family of reflected and converted waves. Travel paths of these waves are dominated by the mantle and corresponding seismograms are relatively simple. *P* is usually stronger on the vertical component, while *S* is more clearly seen on horizontal components. *S* often exhibits wave trains with longer periods when compared with corresponding *P*. Large-amplitude *S* waves are often observed at distances up to about 100°.

A direct *P* reflected from the free surface once or twice is called *PP* or *PPP*, respectively. In the same way we have also *SS* or *SSS*. For distances larger than about 40°, the free-surface reflected phases become very distinct. At distances around 100° and larger, *PP* and *SS* often belong to the largest recorded body waves. Converted waves like *PS* and *SP* appear only at distances larger than 40°. Examples of seismograms with free-surface reflections are displayed in Figure 4.

Core-reflected phases, that is, waves reflected back into the mantle from the outer core-mantle boundary are labeled *PcP* and *ScS*. Including mode converted waves, we have also *PcS* and *ScP*. Because core-reflected phases emerge steeply, *ScP* is usually stronger on vertical component records than *PcS*. Large core-reflected phases are usually recorded at shorter epicentral distances, say at 40° or less. At distances around 39°, *ScP* and *PcS* (surface foci) are often contaminated with the arrival of direct *S* and the phase separation is difficult. When the ray path of *PcP* grazes the outer core boundary, the combination of direct *P* and *PcP* is called *P* diffracted and labeled *Pdif* (older *Pdiff*).

Waves ascending from the focus to the free surface (in continents) or to the sea bottom (under oceans), where they are reflected back into the mantle, are commonly called depth phases. We can list the four possibilities of reflections near the epicenter, which are *pP*, *sP*, *pS*, and *sS*. The first case, for example, denotes the wave that traveled upward from the focus as *P* (short leg) and had been reflected back off the free surface again as *P* (long leg). Depth phases, primarily *pP*, are the most important phases routinely used in focal-depth estimations. The deeper the focus, the later is the *pP* phase in relation to direct *P*. Thus, accurately measured arrival-time differences, *pP-P*, are reliable indicators of the depth of the focus. Most teleseismic shallow events (depth of focus around 33 km) will reveal a *pP* 9–11 s after *P* (see, e.g., Herrin et al., 1968). In case of a deeper focus, it is sometimes possible to recognize several different reflections/conversions from the free surface, for example, *pPP*, *sPP*, *pPS*, *sPS*, *pSP*, etc. Interpretation of depth phases must be done with utmost care since, for example, *pP* from a deep event can easily be erroneously interpreted as *P* when the first arrival (*P*) is weak. Similar difficulty emerges for multiple shocks. Depending on focal orientation and other factors, *sP* may be stronger than *pP* and may be mistaken for it. Depth phases are sometimes stronger than the direct *P*, and may be the first readable phase. We usually require several records made at different epicentral distances to make a reliable identification of the depth phase. We can



Seismogram Interpretation, Figure 4 The Costa Rica earthquake of August 20, 1999, ($M = 6.9$, $h = 40$ km). Exhibited seismograms are long-period, E–W (*upper trace*) and vertical-component (*lower trace*), records made at KONO (Kongsberg), Norway. The epicentral distance is 84°. There are 100 s between two successive time marks at the bottom of the figure. For this distance range, *SKS* arrives ahead of *S*, but the separation is difficult. Both displayed channels are dominated by a fundamental *LR* wave, developed along a mainly oceanic propagation path.

also mention less common phases like *pmP* and *pwP* (first identified by Mendiguren, 1971), corresponding to Moho underside reflection and to water surface reflection, respectively (Schenk et al., 1989). A thin layer of low-velocity sediments at the sea bottom may have small impedance contrast. Hence, short-period records may show large *pwP* when compared with *pP* reflecting at the sea bottom (Engdahl et al., 1998). *pwP* can easily be misinterpreted as *pP* leading to an overestimation of the focal depth.

Bolt (1982) introduced symbols like *P*400*P* or *P*650*P* to indicate seismic waves reflected at the underside of a secondary discontinuity, in the upper mantle, at a depth of 400 and 650 km, respectively. These phases arrive at the recording station ahead of the expected (calculated) arrival time for the main *PP* phase and are interpreted as reflections from upper mantle discontinuities, that is, as *PdP*. When the early arrival time cannot be explained in terms of known discontinuities as *PdP*, we call these onsets early *PP* or precursors to *PP*.

Body waves traversing the core; recording distances 103° and beyond

Due to the diffraction around the core-mantle boundary (see *Earth's Structure, Global*), amplitudes of direct *P* waves decay dramatically at distances larger than 100°. The short-period *P* reappear consistently on records first at distances of about 140°. The distance range $103° < \Delta < 140°$ is called the shadow zone. On seismograms, *Pdif* waves usually show small amplitudes, emergent or gradual onsets and the energy shifts to longer periods. Long-period *Pdif* are sometimes observed out to distances of 160° or more. *S* waves are affected at the core-mantle boundary in a similar way.

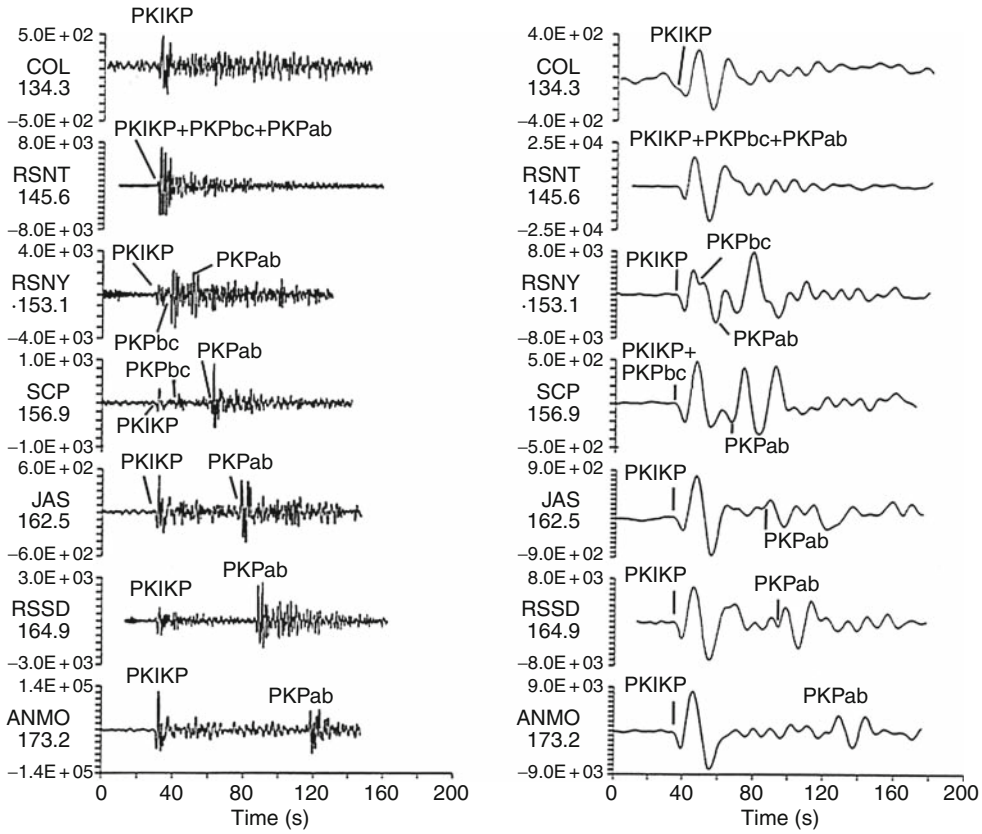
Waves that traveled through the outer core but do not enter the inner core are labeled *PKP* (also *P′*), *PKS*, *SKS* (also *S′*), and *SKP*. The *SKP* phase is stronger on vertical components than *PKS*. These phases have a caustic near 130° and close to this distance are often the only phase recorded on short-period seismograms. At epicentral distances close to 144°, *PKP* shows a distinct concentration of energy, that is, large amplitudes on records. The phenomenon may be viewed in terms of two *PKP* travel-time branches denoted *PKPbc* and *PKPab* for the first and the second arrival, respectively. At 144°, the waves from the two branches coincide, the waves reinforce one another, which results in energy concentration near that distance.

P waves that traverse the inner core are denoted by *I*, giving rise to phases *PKIKP*, *PKIKS*, *SKIKS*, and *SKIKP*, although these are often still simply referred to as *PKP*, *PKS*, etc. Phases, with an *S* leg in the inner core would include the letter *J*, such as *PKJKP*, but these have been difficult to identify on records. Cao et al. (2005) made use of high-quality, broadband seismograms from the Gräfenberg array station, Germany, and identified a phase with arrival time and slowness consistent with predictions of *PKJKP*.

If the studied event is weak, then usually no *Pdif* is observed in the entire distance interval $\Delta > 103°$ and the first arrival seen on the record will be that of *PKP*. At epicentral distances 105–120°, *PKIKP* usually provides the first onset discernible on the seismogram. In the region of the caustic, that is, around 144°, the wave train of recorded core phases becomes particularly complicated. It is first at distances beyond the caustic point where observed onsets may be separated into individual *PKP* branches. The energy distribution changes with the increasing distance. *PKPbc* is the dominant branch just beyond the caustic, up to about 153°. In records of weaker events (Δ = 144–153°), *PKPbc* is often the first visible onset since *PKIKP* (*alt. PKPdf*), theoretically preceding *PKPbc*, is too weak to be observed. As the distance increases, *PKPbc* becomes weaker and vanishes from records at distances of about 160° and larger. For distances beyond, say, 157°, *PKPab* usually dominates the seismogram. *PKIKP* in the distance range from about 125° to the caustic is often preceded by early arrivals or precursors, which can arrive many seconds ahead of the main phase. These are often explained by scattering phenomena at or near the core-mantle boundary. Subscripts *ab*, *bc*, and *df* are used in agreement with travel-time charts of Jeffreys and Bullen (1940). Recorded core phases made at a suite of seismographic stations at a distance range from 134° to 173° are shown in Figure 5.

We may form new symbols for the whole family of waves propagating through the outer core. For example, *PKKP* is a *P* wave reflected from the inside of the core-mantle boundary, often very pronounced on records made at distances between 60° and 80°. However, the striking onset may easily be misinterpreted as a first *P* arrival of another event. *P* waves trapped inside the Earth's liquid core and with multiple *K* legs are called *PNKP*, where $N-1$ is the number of reflections. Multiple reflections within Earth's outer core were first observed by Engdahl (1968). He used records from two deep earthquakes and an event in Novaya Zemlya ($h = 0$) and identified recorded seismic waves reflected as many as four times (i.e., *P5KP*) within the Earth's outer core. Cases like *P4KP* and *P7KP* have been reported by Bolt (1982). Waves that traverse the Earth's interior and are reflected at the outside or inside of the inner core are labeled *PKiKP* or *PKIIKP*, respectively.

The best chance to observe *PKPPKP*, or for short *P′P′*, is around distances $2 \times 144° = 288°$, or 72° if we take the shortest distance from source to station. *P′P′* is often well recorded, arriving about 30 min after *P*, when most of the coda amplitudes of preceding phases have already become faint. *P′P′* may in some cases be wrongly interpreted as a new *P* or *PKP*. 72° is also equivalent to $3 \times 144° = 432°$, so the phase *P′P′P′* is also strong at this distance, and may be observed, for strong earthquakes, about another 20 min after *P′P′*. In 1969, first observations of precursors to *P′P′*, sometimes called early *P′P′*, were made (Engdahl and Flinn, 1969). These were interpreted as *P′dP′* analogous to *PdP*, that is, as reflections of *PKP* at



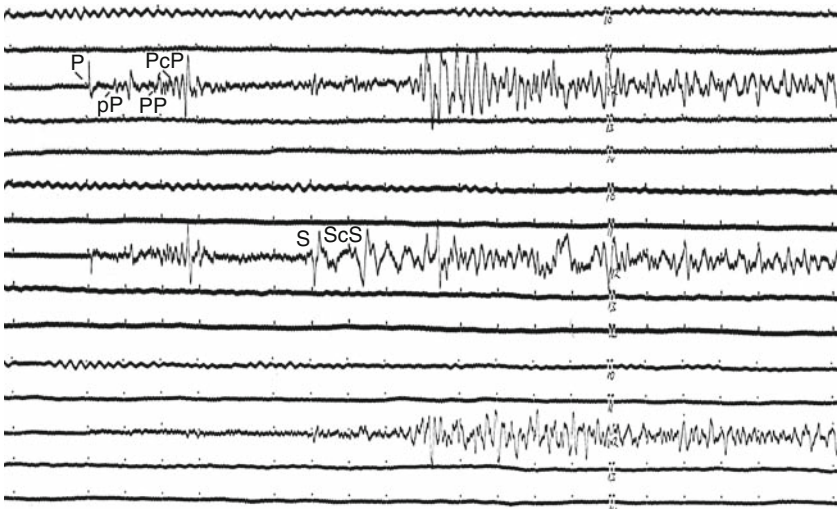
Seismogram Interpretation, Figure 5 Seismograms from a Mid-Indian-Rise earthquake of May 16, 1985 (M = 6.0, h = 10 km) made at a suite of seismographic stations that sample the epicentral distance between 134.3° and 173.2°. Short-period (*left*) and long-period (*right*), vertical-component records are exhibited. Station codes, epicentral distances, and amplitude scaling are given to the left of each trace (G. Choy, personal communication; reproduced from Kulhanek, 1990, with permission from Elsevier, Science).

secondary velocity discontinuities within Earth's upper mantle. For example, $P'650P'$ passes through the core twice and on seismograms precedes $P'P'$ by about 2 min.

Similar to *PKP* and *PNKP*, there are *SKS* and *SNKS* waves, respectively. First *SKS* waves are observed at distances between 60° and 70° and the range of observations extends to distances of 180° or so. *SKS* exhibits a caustic point at a distance of about 80° so that the best region to study *SKS* waves is that between 70° and 90°. The phase identification has to be made with utmost care since *SKS* recorded at this distance range are often contaminated with direct *S*. To mistake *S* for *SKS* and vice versa will adversely affect the epicentral location. At about 82° (depending upon details in the structural model), *SKS* begins to arrive ahead of *S* (Figure 4). For distances shorter than about 95°, *SKS* is usually smaller than *S*, however, at distances beyond 95°, *SKS* amplitudes are quite large. *S* and *SKS* are best recorded on long-period horizontal-component seismograms. The period of *SKS* phases may reach several tens of seconds. Occasionally, these body waves are also seen on short-period records, although the onset time of the later of the two phases is usually very emergent due to the contamination by the coda of the earlier phase.

Body waves from intermediate-focus and deep-focus earthquakes

Later studies confirmed conclusions from Wadati's pioneering work (Wadati, 1927) that intermediate-focus and deep-focus shocks produce simpler seismograms with exceptionally well recorded impulsive body waves while surface-wave amplitudes decrease as the quake becomes deeper. Strong depth phases, such as *pP* and *sS*, are also frequently very distinct on records from deep events. However, the duplication of principle phases by surface reflection (e.g., confusion between *pP* and *PP*) often complicates the seismogram interpretation. Weak precursors, *pmP*, (Moho underside reflections) to surface reflections, *pP*, are discussed in Schenk et al. (1989). They are best observed in long-period records and in continents often produce clear arrivals. In a more retrospective-type interpretation, the absence of aftershocks (see *Earthquake, Aftershocks*) will support the classification of the shock as



Seismogram Interpretation, Figure 6 Seismograms from an intermediate-focus earthquake (M = 6, h = 199 km) in the Hindu-Kush region on September 4, 1993, made at UPP, Sweden, at an epicentral distance of 41°. The traces show long-period channels from top to bottom: vertical, E–W and N–S components.

a deep-focus or intermediate-focus event. Figure 6 shows seismograms from an intermediate-focus earthquake made at an epicentral distance of 41°. Note the impulsive character of the *P*, *pP*, *PcP*, *S*, and *ScS* phases; virtually no surface waves have been recorded from this event.

Surface waves

With exception of very short epicentral distances, long-period surface waves, *LQ*, and *LR* dominate the seismograms of shallow events. Deep events of the same magnitude will generate abnormally small (insignificant) surface waves. This feature provides the interpreter with a viable tool to discriminate, at first glance, between shallow and deep-focus earthquakes. (Note a paradox: underground nuclear explosions, being very shallow events, generate only small, sometimes invisible, surface waves). The analyst has several clues to identify surface waves on the record and to distinguish *LQ* from *LR*. While Love waves are best displayed on horizontal-component seismograms, Rayleigh waves are best seen on vertical-component records. Both *LQ* and *LR* propagate slower than *P* or *S*, but since *LQ* propagate faster than *LR*, they are recorded ahead of *LR*. Due to dispersion, long-period surface waves advance on records toward the beginning of the wave train as it travels through the medium. An experienced analyst will distinguish between recorded surface waves that have traveled along pure oceanic or continental path. Dispersion of oceanic routes give rise to long wave trains with rather slow and sometimes hardly visible period change over relatively long (10–20 min) record segments (see Figure 4). In contrast, continental paths generate surface waves with characteristic fast period decrease with time, which is often easily recognized on records (see Figure 1). Surface waves can also travel by different modes (overtones), which are often seen on records as high-frequency components superimposed on the surface-wave train. We talk then about fundamental-mode and higher-mode surface waves (see *Surface Waves*). Higher modes are most frequently observed for waves traversing purely continental paths. Nevertheless, higher modes have in some cases also been associated with oceanic paths. Surface-wave higher modes disappear when the waves cross the transition between continental and oceanic structures. Higher modes propagate faster than the fundamental mode and are, therefore, recorded ahead of *LQ* and *LR*.

Dispersion curves (see *Surface Waves*) show a rather complicated pattern with several local minima and maxima. Surface waves traveling with these minima or maxima group velocities are called Airy phases. On seismograms, an Airy phase is characterized by a constant-frequency compact wave train, often with a remarkable amplitude buildup of dispersed surface waves traveling by fundamental-mode propagation. In the period range from approximately 50–200 s, the group velocity of *LR* (both the oceanic and continental paths) monotonically decreases with increasing period. Physically this means that in this period range, long-period *RL* waves follow the law of inverse dispersion. Observations of this phenomenon are rather scarce. An example is exhibited in Kulhanek (1990).

Extremely long-period surface waves called mantle waves, with periods from somewhat less than 1 min to several minutes, have been observed from large distant shocks. They can be of either Love- or Rayleigh-wave type. The former propagates with nearly constant speed of 4.4 km/s and shows an impulsive shape on the seismogram. The latter travels with velocity between 3.6 and 4.1 km/s. Wavelengths of mantle waves vary from several

hundreds to more than 1,000 km, so that a large part of Earth's mantle is affected by these waves. An interesting feature of mantle waves is their repeated appearance on records, which is due to their multiple travel around the Earth. The *LQ* mantle wave was given the label *G* (after B. Gutenberg) and the *LR* type mantle wave, the label *R*. The older nomenclature sometimes uses *W* instead for *R* (from German *Wiederkehrewellen*, meaning repeated waves). *G* waves that propagate the direct and anticenter routes are labeled *G1* and *G2*, respectively. Waves that have in addition traveled once around the Earth are denoted *G3* and *G4*, and so on. Similarly, we have *R1*, *R2*, *R3*, *R4*, etc. As an exceptional case we can mention records of the 1960 Chile earthquake, $M = 9.5$. Seismograms made at Uppsala, Sweden, reveal mantle waves *G20* and *R20* that have traveled a total distance equal to that from the Earth to the Moon (Båth, 1979).

Volcanic earthquakes and unusual seismic sources

During eruptive episodes, volcanoes can produce up to thousands of small earthquakes per day, recorded only at short distances, say, less than 50 km, from the volcanoes (see *Earthquakes, Volcanogenic*). Different categorization of volcanic earthquakes may be found in the literature. For example, Minakami (1961) classifies volcanic earthquakes into three groups, in accordance with different generation mechanisms and signal characteristics. (1) A-type earthquakes with focal depth between 1 and 10 km near the volcanic magma system. Corresponding records show clear high-frequency *P* and *S* phases. (2) B-type earthquakes with foci at depth of 1 km or less. Records reveal low-frequency coda, emergent onsets, and usually no distinct *S*. (3) Explosion-type earthquakes taking place at the very surface of the Earth. Close to active volcanoes, we also frequently detect so-called volcanic tremors, which are due to long-duration, more or less continuous, volcanic vibration.

Implosion earthquakes, impact earthquakes (e.g., the Tunguska, Siberia, impact in 1908), frost actions, low-magnitude icequakes generated by temperature changes in glaciers, earthquakes related to large-scale landslides, etc. are some of the types of events that, together with tectonic earthquakes, volcanic earthquakes, and oceanic microseisms, belong to the category of natural seismic sources. There is also a variety of man-made seismic sources such as industrial and military explosions, cultural noise (traffic, industry work), mining activity, high dams (seismicity, triggered/induced), fluid injections, etc. The source identification, for earthquakes other than tectonic or volcanic, is usually a task in itself. A classical example of source identification is the well-known problem of discriminating underground nuclear explosions from earthquakes (see *Seismic Monitoring of Nuclear Explosions*).

Conclusions

Seismogram interpretation, described in this article, is essentially devoted to the art of identification of various seismic "arrivals" or wave types visible on seismograms. It is usually followed by seismogram analysis, which may include determination of basic source parameters (origin time, hypocenter location, size) but may also cover more advanced studies, such as wave-form modeling, determination of velocity distribution, etc. Obviously, a large part of seismogram analysis is a domain of research. Nevertheless, phase identification is a doorway and without correct seismogram interpretation hardly any analysis would be possible. Repeated observations of peculiar phases on seismic records often led to new discoveries of details in Earth's structure and/or dynamics. Sometimes, theories were developed in advance, to be later confirmed by observations (e.g., free oscillations of the Earth). Seismogram interpretation is a fundamental, and in our view, also fascinating and rewarding part of modern seismology.

Seismological Networks. Networks of seismographic stations for the recording of ground motions produced by seismic waves propagating from natural and anthropogenic sources.

Introduction

Seismology has its roots in observations of earthquakes and earthquake-generated ground motion. Seismological networks as envisioned by the pioneers in seismology are now a reality, a reality that is frequently upgraded and expanded as technology improves. A global system of broadband seismographs with high dynamic range is now in place. This is supplemented by many national, regional, and local networks capable of high-resolution monitoring of the frequent smaller earthquakes in seismically active places. Parametric data derived from these networks make a major contribution to national and international information services. Because of page limitations, we can only hope to provide the reader with a glimpse of all there is to know about seismographic networks.

Global seismic networks

Seismological recordings have been made on Earth for hundreds of years in some form or another. However, global monitoring of earthquakes only began in the 1890s when John Milne created 40 seismic observatories to measure the waves from these events (see Figure 1). Shortly after the International Geophysical Year (1957–1958), a concerted effort was made to establish and maintain a more modern standardized seismic network on the global scale.

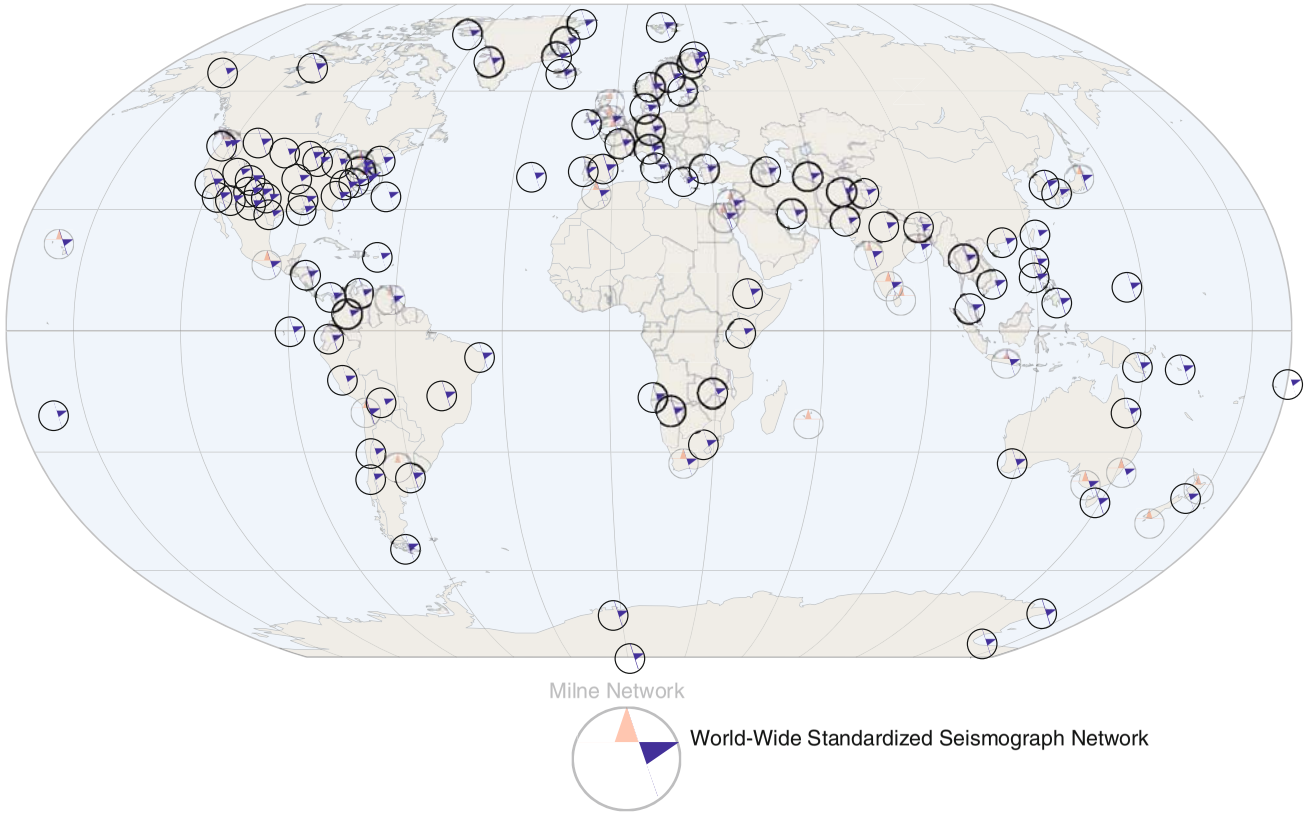
Worldwide Standardized Seismograph Network

In the early 1960s, the World-Wide Standardized Seismograph Network (WWSSN) was established. Between 1961 and 1966, 120 WWSSN stations with identical seismic instruments were deployed in more than 60 countries and islands throughout the world. The WWSSN program included the collection, review, and copying of the recorded seismograms, and the distribution of copies to researchers throughout the world. Considered one of the most important advances ever in observational seismology, the WWSSN produced the data needed to support unprecedented progress in earthquake, explosion, and tectonic research. In the years that followed the deployment of the WWSSN, many of the stations were modernized and expanded into regions not initially covered. Eighty of the original WWSSN stations are still in operation and still supported.

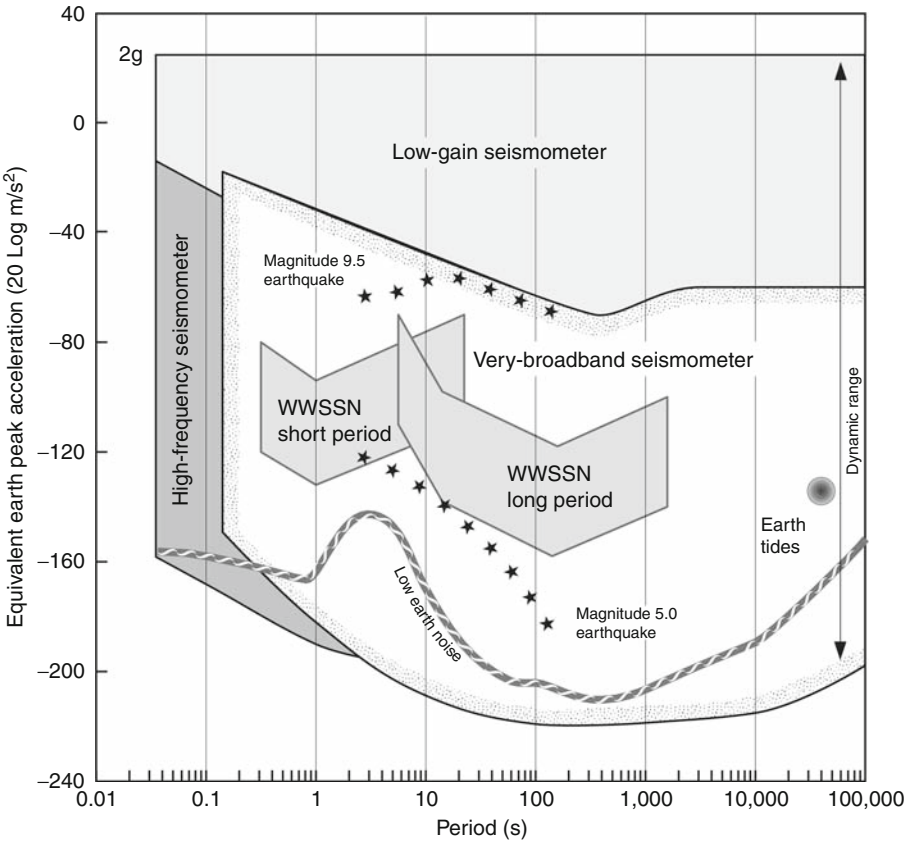
International Federation of Digital Seismograph Networks

In the 1980s, the international seismological community recognized the new opportunities within its field for improved understanding of the internal structure and dynamical properties of the Earth provided by recent developments in seismograph network technology. It also recognized that rapid access to seismic data networks of modern broadband digital instruments wherever they might be was now possible. The developments included greatly improved broadband seismographic systems that capture the entire seismic wave field with high fidelity (see Figure 2), efficient and economical data communications and storage, and widely available, powerful computing facilities.

In view of the above and to take advantage of existing developing global and regional networks, the International Federation of Digital Seismograph Networks (FDSN, http://www.fdsn.org/) was formed to provide a forum for: developing common minimum standards in seismographs (e.g., bandwidth) and recording characteristics (e.g., resolution and dynamic range); developing



Seismological Networks, Figure 1 Locations of stations in the Milne network and the World-Wide Standardized Seismograph Network. (Courtesy of KentAnderson, Incorporated Research Institutions for Seismology.)



Seismological Networks, Figure 2 Bandwidth and dynamic range of WWSSN and modern seismographic systems. (Courtesy of Rhett Butler, Incorporated Research Institutions for Seismology.)

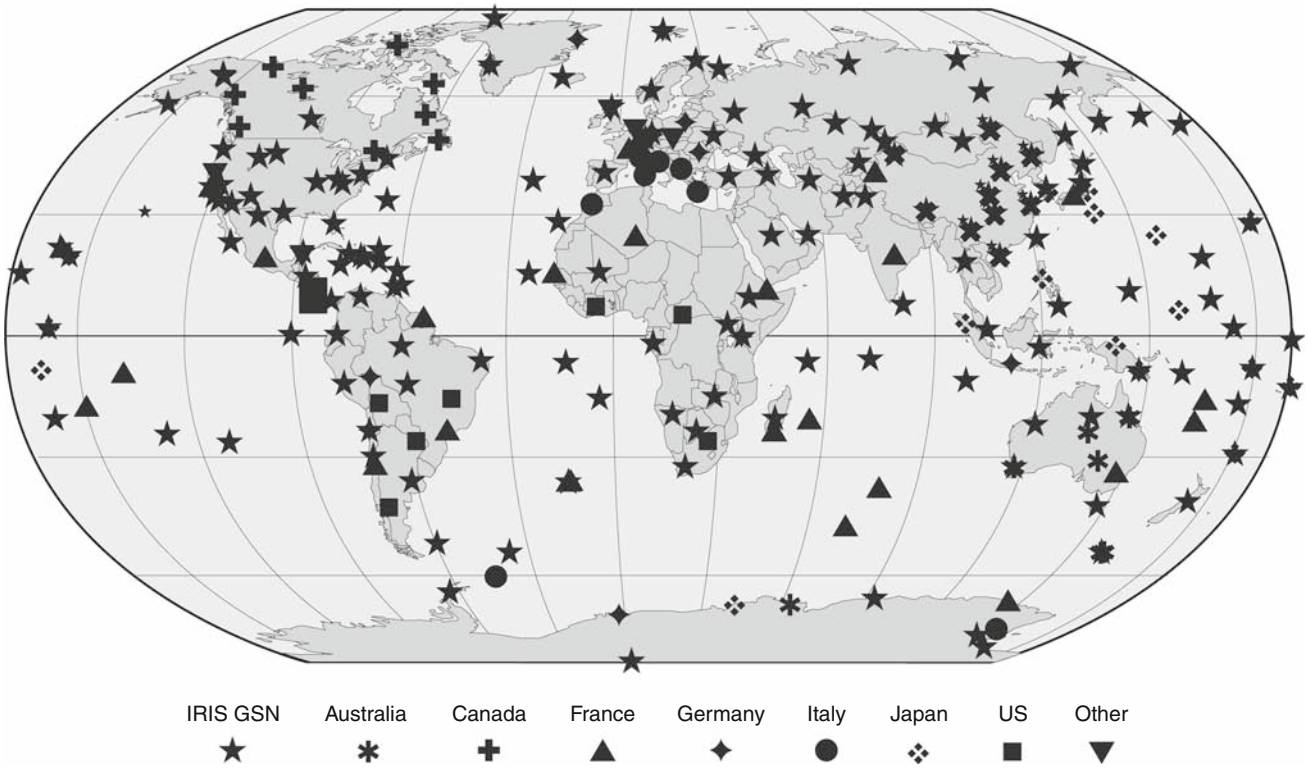
standards for quality control and procedures for archiving and exchange of data among component networks; and coordinating the siting of additional stations in locations that will provide optimum global coverage.

The FDSN was formed as a global organization, open to all national and international programs committed to the deployment of broadband seismographs and willing to contribute to the establishment of an optimum global system with timely data exchange. Its membership is comprised of groups responsible for the installation and maintenance of seismographs either within their geographic borders or globally. Membership in the FDSN is open to all organizations that operate more than one broadband station. However, among the most important contributors is the Global Seismographic Network (GSN) of the Incorporated Research Institutions for Seismology (IRIS), and the French GEOSCOPE and German GEOFON global networks. It is important to note that many stations in the FDSN were formerly part of the WWSSN program. Members agree to coordinate station siting and provide free and open access to their data. This cooperation helps scientists all over the world to further the advancement of earth science and particularly the study of global seismic activity.

The FDSN goals related to station siting and instrumentation are to provide stations with good geographic distribution, recording data with 24 bits of resolution in continuous time series with at least a 20 sample per second sampling rate. The FDSN was also instrumental in development of a universal standard (SEED) for distribution of broadband waveform data and related parametric information. The FDSN system of global network observatories includes contributions from many international partners (Figure 3), forming a large backbone of permanent seismological observatories. Developments in communications and other technological advances have expanded the role of the FDSN in rapid earthquake analysis, tsunami warning, and nuclear test monitoring. With such long-term observations, scientists are now getting a glimpse of Earth structure changes on human time scales, such as the rotation of the inner core. Continued observations for the next 50 years will enhance our image of the Earth and its processes.

International Monitoring System

Under the Comprehensive Test-Ban Treaty (CTBT, http://www.ctbto.org/), it is a requirement that there will be an International Monitoring System (IMS) to detect any clandestine nuclear weapon detonation in any environment – underground, under-water, or above ground. The aim of



Seismological Networks, Figure 3 Locations of backbone stations in the International Federation of Digital Seismograph Networks with major partners indicated by *symbols*. (Courtesy of Rhett Butler, Incorporated Research Institutions for Seismology.)

the IMS is detection, identification, and location of any such test, and the technologies involved will be seismological, hydroacoustic, infrasound, and atmospheric radionuclide monitoring. In support of these technologies, there will be appropriate means of global communication and an International Data Centre (IDC) to which monitoring data will be transmitted.

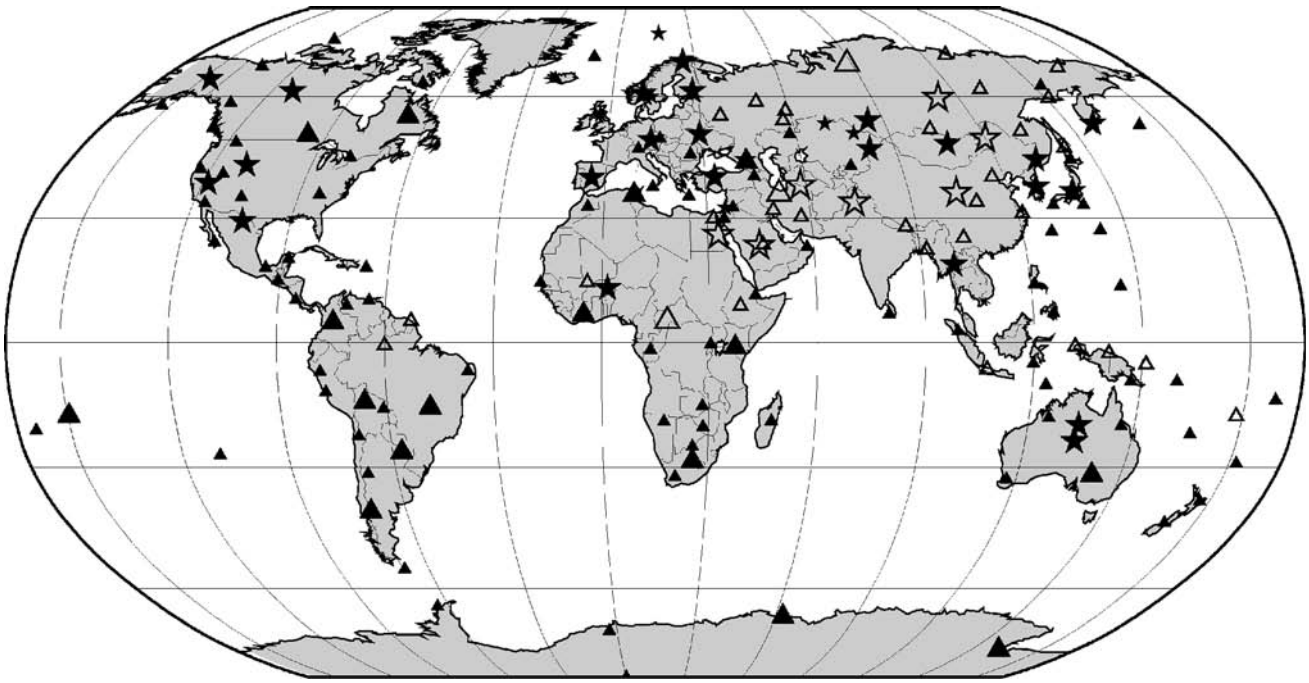
Seismological monitoring is considered the cornerstone of the IMS because of the likelihood that tests would be conducted underground and out of sight. The seismological technology required for the detection of earthquakes is well known, but the problem for the IMS is to distinguish between signals from weapons detonations, earthquakes, and non-nuclear explosions in quarrying or mining. There are so many earthquakes (>200,000 per year) and mining events worldwide, of similar magnitude to a small nuclear explosion, that data analysis becomes a key problem. The seismological verification program therefore includes intensive study of seismicity and mining operations in order to develop regional backgrounds.

A global network of 50 "primary" stations in 34 countries is planned, with two basic equipment packages: "three-component" (3-C) broadband seismometers, which act as single detection systems monitoring ground movement in 3 directions – vertically, and horizontally east-west and north-south; or "arrays" which include 3-C systems plus a cluster of narrowly spaced vertical-component short-period sensors distributed to gain optimum signal-to-noise ratios by waveform correlation. Arrays may contain many detectors located over large areas (up to 200 km^2). The advantage of an array station is that it allows approximate event location on a stand-alone basis. Important historical developments such as the LASA, NORSAR, Graefenberg arrays, and more recently the wide but densely distributed USArray, have marked important steps in seismological network development that have facilitated new research fields and services in seismology. As Figure 4 indicates, approximately half of the proposed stations will be arrays.

In addition to the primary network, there is to be an "auxiliary" network comprising 120 stations distributed among 61 countries (Figure 4). Stations in this network will mainly consist of existing 3-C stations, which already form part of the host countries' seismological monitoring operations. The purpose of the auxiliary network is simply to provide additional data to support that from the primary network in order to facilitate signal discrimination and hence event detection and location.

Regional seismic networks

National seismographic networks operate within the political boundaries of a country, and their primary mission is to issue rapid alerts to government agencies and the general public for potentially damaging earthquakes. National



Seismological Networks, Figure 4 Locations of stations in the CTBTO IMS network (Courtesy of Ronan LeBras, Comprehensive Test-Ban-Treaty Organization). Symbols defined as follows: filled symbols – operational; open symbols – not yet operational; *stars* – array stations: *triangles* – three-component stations; *large symbols* – primary stations; and *small symbols* – auxiliary stations.

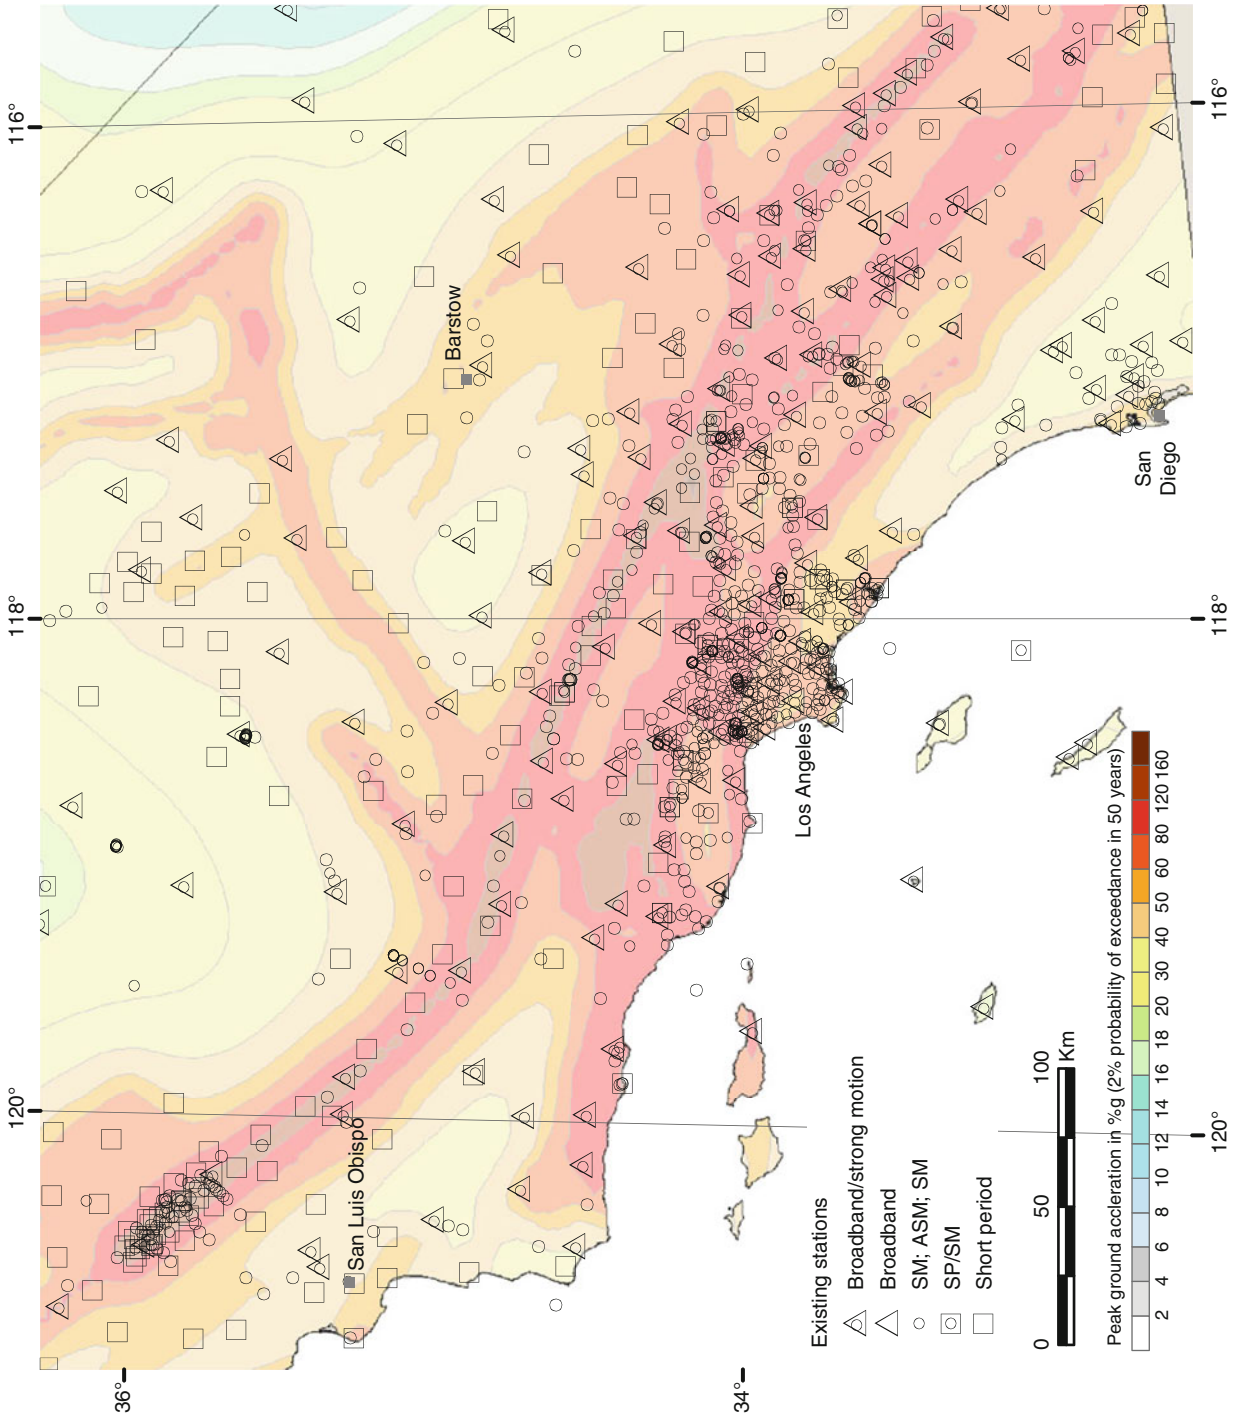
Seismological Networks, Figure 6 Permanent seismic stations in the 48 conterminous states of the United States. (Courtesy of Susan Rhea, U.S. Geological Survey, National Earthquake Information Center.)



Seismological Networks, Figure 7 The Southern California Seismic Network: an example for a very dense regional network. (Courtesy of Susan Rhea, U.S. Geological Survey, National Earthquake Information Center.)

networks typically exchange data with neighboring countries in order to improve the accuracy of the determination of earthquake parameters in border regions.

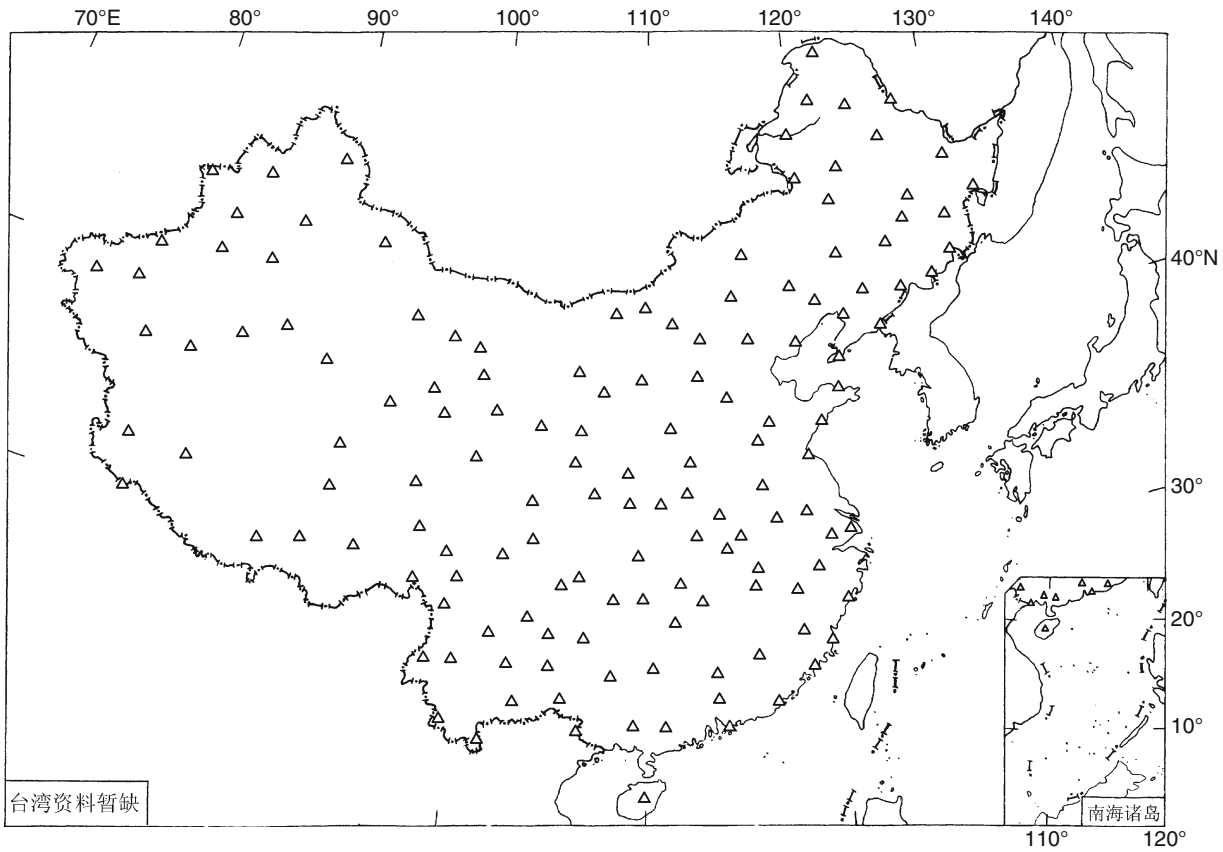
Regional networks play an important role in monitoring the seismicity of the Earth within a well-defined region. Regional networks may be part of a national network (e.g., USA, China, Japan, and Russia) or may be constituted from multinational networks (e.g., Euro-Mediterranean region). The magnitude detection threshold of regional networks is typically lower than that of the global networks, which allows for producing bulletins for a specific region that are more complete than it could be achieved at a global scale.

Local networks focus on a much smaller area than regional networks. Examples of local networks include temporary deployments to capture aftershock sequences of a large earthquake, networks monitoring volcano activities, and dense local networks installed in urban areas with elevated seismic risk.

Euro-Med region

The Euro-Med region encompasses Europe, North Africa, and the Middle East. The European-Mediterranean Seismological Centre (CSEM/EMSC, http://www.emsc-csem.org) produces earthquake bulletins in the region since 1998, using parametric data reported by national and local networks in the region. Its mission is to produce a rapid comprehensive seismological bulletin and issue alerts for potentially damaging earthquakes in the region. The EMSC and the National Earthquake Information Center (NEIC) routinely exchange data, and NEIC bulletin data for the European-Mediterranean region are incorporated in the EMSC bulletin. Earthquake parameters (location, magnitude, phase picks, moment tensors, etc.) provided by the EMSC are incorporated in the global bulletin prepared by the International Seismological Centre (ISC).

Figure 5 shows the seismic station network that currently contributes to the EMSC bulletin (Godey et al., 2006; Godey et al., 2009). All stations are registered at the International Registry of Seismograph Stations jointly maintained by the ISC and the NEIC. The recent years saw a dramatic increase in the number of stations in the region, especially in North Africa and the Middle East. These networks are vital for improving the azimuthal station coverage for the events, and thus improving their location accuracy. Waveform data from most stations contributing to the EMSC can be obtained from Observatories and Research Facilities for European Seismology (ORFEUS)



Seismological Networks, Figure 8 Locations of stations belonging to the China Digital Seismograph Network. (Courtesy of Liu Ruifeng, China Earthquake Network Center.)

the coordinating organization for seismic networks in Europe (http://www.orfeus-eu.org).

United States

In the United States, the U.S. Geological Survey's National Earthquake Information Center (NEIC, http://earthquake.usgs.gov/regional/neic) is the national data center and archive for earthquake information. Its mission is to determine as rapidly and accurately as possible the location and size of all significant earthquakes that occur worldwide. The NEIC operates 24-h-a-day and issues rapid alerts for earthquakes larger than magnitude 3 in the conterminous states of the United States and for those larger than magnitude 5 globally. The NEIC publishes global earthquake bulletins on a daily, weekly, and monthly basis.

The NEIC serves as the National Operations Center of the Advanced National Seismic System (ANSS), which includes the ANSS backbone network and regional seismic networks across the United States. Figure 6 shows the permanent digital seismic and strong motion stations in the 48 conterminous states of the United States. The strong motion stations (circles) represent an integral part of the ANSS network as first arriving phases are picked on strong motion records and used in the earthquake location procedures. Figure 7 shows the regional Southern California Seismic Network. As in Figure 6, the map is colored by the peak ground acceleration, a measure of seismic hazard. The network is much denser in urban areas and regions with high seismic hazard.

China

The China Digital Seismograph Network (CDSN) has been established in 1986, with nine digital seismic stations. During the past 10 years, the Chinese seismic network, both at the national and regional levels, went through unprecedented improvements. The China Earthquake Administration (CEA) has completed the analog-to-digital transition of the existing analog stations and deployed a large number of new digital stations (Liu et al., 2008). Figure 8 shows the currently operating national network of 145 broadband seismographic stations. Some of these stations also belong to the FDSN. Dense regional networks further support the national network. Each of the 31 provinces, autonomous regions, and municipalities operates regional digital networks. Figure 9 shows the distribution of the 792 regional seismic stations.

Seismological Networks, Figure 10 Number of stations reporting to the ISC between 1964 and 2009. (Courtesy of James Harris, International Seismological Centre.)

The National Earthquake Network Center (NENC) archives the continuous waveform data from the national and regional networks and performs real-time data processing. The NENC issues rapid earthquake alerts for Ms >4.5 events inside China within 10 min and focal mechanism solutions in no more than 30 min after the earthquake occurred.

International Registry of Seismograph Stations

Since the humble beginnings of instrumental global seismology in the late nineteenth century, the number of seismographic stations has steadily increased every year. Figure 10 shows the number of stations reporting to the ISC in each year since its operations began. In order to be able to uniquely identify seismographic stations, the ISC and the NEIC, in its capacity as World Data Center A for Seismology, jointly maintain the International Registry of Seismograph Stations (IRSS). The IRSS represents a global catalog of seismic stations (currently with some 15,000 registered stations) and contains information about the station coordinates, instruments, operating networks, and when a station began/stopped operating. To facilitate data exchange between networks and organizations, it is strongly recommended that network operators register their stations and use the international station codes.

Summary

The high-quality data recorded by seismographic networks would be of limited value without international cooperation by all countries worldwide in the acquisition and exchange of seismic measurements and waveforms. This cooperation is essential for the location of earthquakes, for understanding the physics of earthquakes, and for studies of Earth's internal structure, properties, and processes. One of the latest challenges to acquiring, processing, and distributing data from seismographic networks by data centers globally is the automatic performance of traditional tasks in as close to real time as current technology permits.

SEISMOLOGY, GLOBAL EARTHQUAKE MODEL

Peter Suhadolc
Department of Geosciences, University of Trieste, Trieste, Italy

Definition

Exposure: Elements at risk; an inventory of those people or artifacts (and their characteristics) that are exposed to a hazard.

Seismic Hazard: A potentially damaging physical event, a phenomenon induced by an earthquake that may cause loss of life or injury, property damage, social and economic disruption, or environmental degradation. Seismic hazards can be single, sequential, or combined in their origin and effects. Each hazard is characterized by its location, intensity, frequency, and probability.

Seismic Risk: The probability of harmful consequences, or loss of life or injury, property damage, social and economic disruption or environmental degradation, resulting from interactions between seismic hazards and vulnerable conditions.

Vulnerability: The degree of loss of life or injury, property damage, social and economic disruption, or environmental degradation to a given element (or set of elements) resulting from a given hazard at a given level of intensity.

Introduction

A Global Earthquake Model (GEM) is being developed to establish an independent, uniform standard to calculate and communicate earthquake risk worldwide. By developing much-needed tools and software for reliable seismic risk assessment for basic and expert users in all regions of the world, GEM will provide necessary input for increased earthquake risk awareness and the undertaking of mitigating action.

The GEM initiative is organized as a public–private partnership, while an international community of scientists and professionals drives the development of the global earthquake model.

The work for GEM started in 2009, and a first comprehensive model plus accompanying tools and software, will become available by the end of 2013. Although much of the work is under development at the moment this article is being written, it is felt to be important to report on the initiative in this encyclopedia, because the global earthquake model will constitute an important contribution to the scientific community.

Scientific needs for GEM

The assessment and subsequent mitigation of earthquake risks is among the ultimate goals of both applied seismology and earthquake engineering. In spite of the fact that earthquake occurrence is globally a steady process and that most seismic events occur in uninhabited areas, the explosion in urban development and the enormous growth in the number of megacities in earthquake-prone areas (Figure 1), has considerably increased the seismic risk worldwide. Both cities in developed countries, like Tokyo or Los Angeles, and cities in developing countries, like Kathmandu or Jakarta, can suffer substantial damage due to a large earthquake in the next future. In fact, over 600,000 people died in the last century due to earthquakes (reference to USGS web site). Most of those deaths occurred in developing and emerging countries.

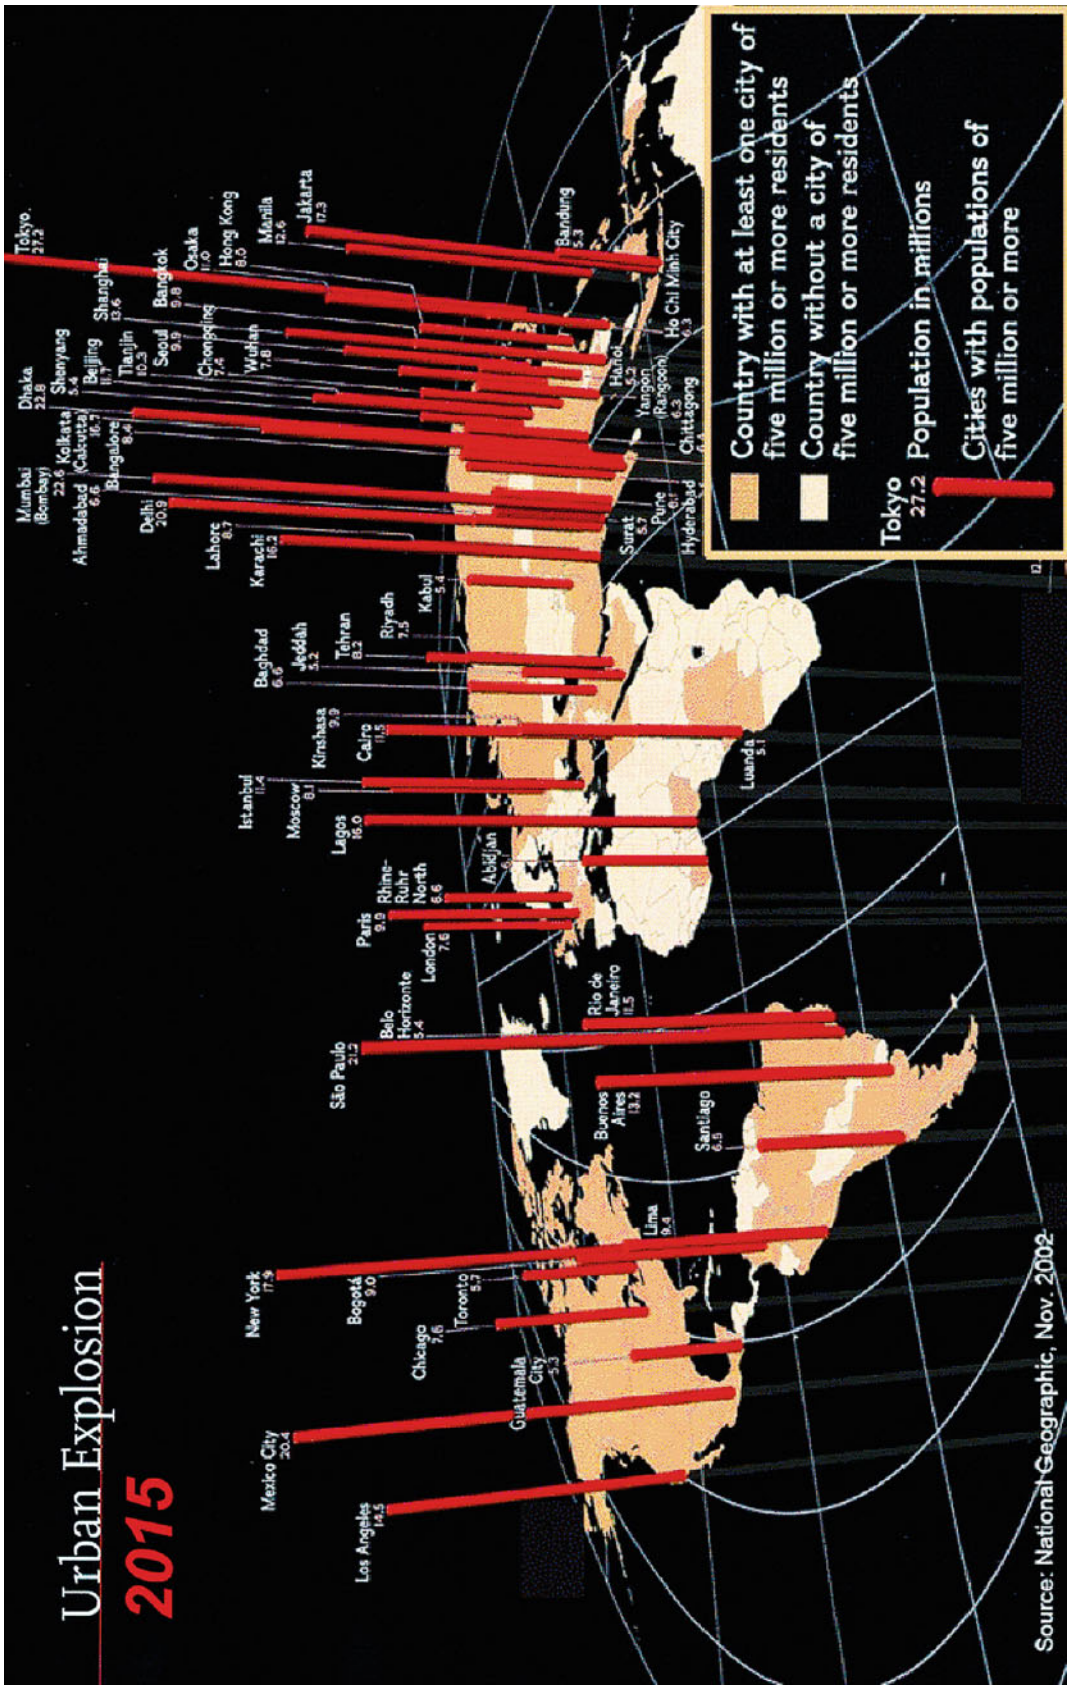
In many earthquake-prone regions, no seismic risk models exist, and even where they exist, they are not widely accessible. Such models are needed for accurate assessment of risks by (local) scientists, engineers, and practitioners, in order to promote mitigating actions, such as improvement of building codes and construction, sustainable land use, improved response, and protection of critical infrastructures. In order to have an effect on society at large, however, such models and the information resulting from it are needed as well by individuals and (international) organizations, to become aware of seismic risk and to undertake mitigating actions such as obtaining insurance, improved project management, and allocation of budgets for hazard mitigation.

The GEM initiative

By functioning as a community effort, the GEM initiative will produce a state-of-the-art dynamic and updatable model for the assessment of seismic risk worldwide; a model that is based on the probabilistic assessment of earthquake occurrence, the resulting ground motions, and the impact these have on structures and populations in terms of damage, social and economic loss. A model with underlying databases, that can be improved and enlarged with future data, and can be openly accessed through user-friendly software for data analysis and production of results, that can be also improved as our knowledge and technical capabilities rise in the future.

The global earthquake model is being designed and built by hundreds of experts and practitioners around the world, to ensure that less-monitored areas are also covered and to establish uniform standard, which allow for risk comparisons between countries and regions and for benchmarking output obtained through other sources. The model will reflect the needs, knowledge, and data of a variety of end users through GEM's extensive partner network. Such partnerships are essential in making sure that the information reaches the people that need it.

Technology transfer on the use of the software together with workshop opportunities will be provided, especially



Seismology, Global Earthquake Model, Figure 1 Urban explosion; it is predicted that by 2015 the projected increase in global population of 3 billion will concentrate itself in urban areas. (From National Geographic, 2002.)

in areas where risk assessment tools and data are currently less available.

A cooperative public–private partnership

The construction of the Global Earthquake Model is a cooperative public–private endeavor, and GEM is, therefore, structured as a partnership among country governments, private organizations, research institutions, international organizations and global risk initiatives, NGOs and individuals. The partnership includes a number of authoritative global institutions, such as the World Bank, the OECD, UNESCO, and UN's International Strategy for Disaster Reduction, but also the two largest international professional associations in the field: IASPEI (International Association of Seismology and Physics of the Earth's Interior) and IAEE (International Association for Earthquake Engineering), countries such as New Zealand, Norway, and Switzerland, and a number of prominent private corporations. Moreover, there are hundreds of institutions, organizations, and individuals involved in GEM that contribute expertise, data, or software, respond to requests for proposals, participate in regional programs, and take part in reviews and public assessments. Participation of individuals and institutions worldwide ensures that the model is owned by the global community and reflects its needs and knowledge.

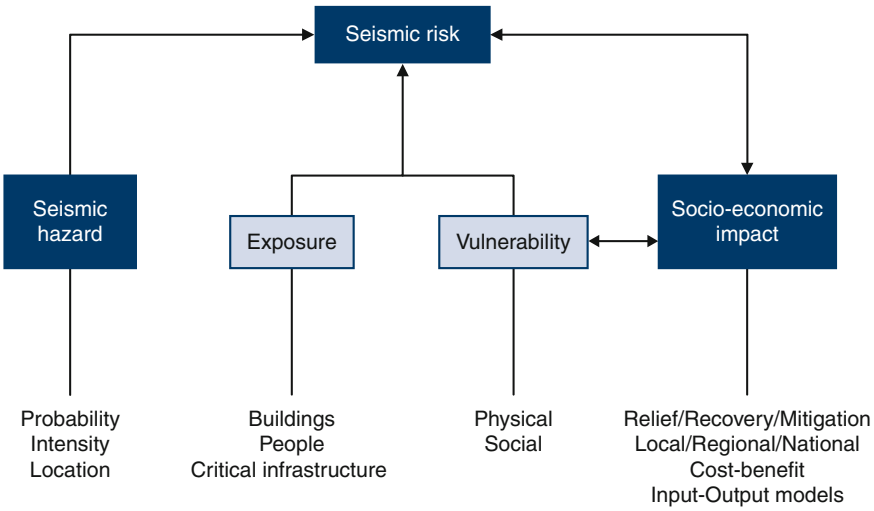
History

The idea for a Global Earthquake Model was born during a workshop called "Earthquake Science and its Contribution to Society" organized by the OECD's Global Science Forum in 2006. It was felt that a Global Earthquake Risk Scenario Map should be created. Various workshops followed in which the idea transformed into the creation of a Global Earthquake Model. Munich Re decided to sponsor the initiative in 2007. In 2008, the business plan for GEM was finalized and more partners were brought in to create a public–private partnership. The Eucentre was awarded the GEM Secretariat at the end of that year. In March 2009, the GEM Foundation was incorporated as a nonprofit foundation and that marked the start of the GEM initiative.

Scientific framework

The GEM scientific framework serves as the underlying basis for constructing the model, and consists of three principal integrated modules (Figure 2: Scientific Framework): Hazard, Risk, and Socioeconomic Impact.

Seismic risk is defined as a product of seismic hazard (the probability of levels of ground shaking, resulting from earthquakes, within a given time span), seismic vulnerability (the probability of loss given a level of ground shaking), and exposure (the elements at risk – mainly buildings, critical infrastructure, and humans). Risk gives an indication of the extent of loss (damage, fatalities, casualties) that can be expected in a given location in the world. Risk can, therefore, be high in an area without significant probabilities of ground shaking, because it has an older, more vulnerable, and densely populated building stock, and lower in an area with high levels of seismicity, but with well-constructed structures that are sparsely inhabited. Earthquakes, however, have an impact that goes beyond physical damage or casualties. Earthquakes can severely damage the economy and influence society and social well-being. Therefore, GEM will include innovative methods for analysis and evaluation of the impacts of earthquakes on the short, medium and long term, on local and global scales. There will also be applications that build upon the model, such as a tool for cost-benefit analysis, allowing users to understand what effect certain mitigation actions, strengthening of the building stock for example, will have on the risk. Insight into earthquake effects over time will directly support decisions on



Seismology, Global Earthquake Model, Figure 2 The current design of the scientific framework of GEM.

short-term needs after an event (relief, shelter), medium-term needs (recovery and reconstruction), and long-term needs related to policies on risk mitigation.

Implementation and current status

In June 2010, the GEM initiative has been able to deliver a proof-of-concept for hazard and risk calculations on a global scale. This will be the basis for development of the final GEM risk engine and the model. The model building process and engine are described in more detail further on.

International consortia, involving hundreds of professionals and institutions, are working on the creation of necessary standards, databases, and methodologies on a global level. These are the global components of the model. The work on Hazard Global Components has started and will be delivered in 2012. The work on Risk Global Components will start in the fall of 2010 and will be delivered in 2012 and 2013 and the work on the Socio-economic Global Components will take off in early 2011, with the goal to be finalized in 2013. The Global Components are further specified below.

Programs are being setup in many regions of the world as independently run, bottom-up projects, and links are established with ongoing regional programs. Both such programs are defined as GEM Regional Programs and involve a great number of local experts who will use GEM software, will generate local data, will validate the data and standards that were created on a global level, and will serve as a starting point for technology transfer in the region. Currently, three GEM Regional Programs are operational: in the regions of Europe and the Middle East, and collaboration is ongoing in Central America. Programs are being prepared in Africa, South-Asia, South-East Asia and Oceania, Central Asia, South America, the Caribbean, North-East Asia.

Global components

Global Components are the scientific modules of GEM that are developed at a global scale to provide standards, models, tools and data. Global components will provide the basic input to the model, but the Regional Programs will deliver detailed feedback and input from a local point of view.

To ensure that Global Components are developed by the international scientific community, GEM releases Requests for Proposals. These RfPs are developed by a group of international experts on the topic, and peer reviewed through an open public commenting system. International consortia, groups of institutions, and individual experts respond to these calls. All proposals are peer-reviewed by at least four external reviewers and extensively discussed by GEM's Scientific Board, who prepares an advice for GEM's Governing Board. Finally, for each component, one consortium is selected to carry out the work.

At the moment of this writing, proposals for the hazard and risk global components have been selected and the work has started or is about to start. The global component for socioeconomic impact is under development.

The hazard module

Five global components on seismic hazard are being developed as input to the global earthquake model:

Global historical catalog and database

The record of past earthquakes is among the most important means to evaluate earthquake hazard, and the distribution of damage associated with past earthquakes is a key to assessment of seismic risk. The instrumental seismic record has only a 100-year span, and yet no plate boundary is so active that this period is sufficient to capture the full range of seismic behavior. Extending the record of large damaging earthquakes several hundred years longer, and in exceptional cases by 1,000 years, is thus extremely valuable. This requires damage descriptions to be converted to numerical intensity scales, and the estimation of magnitude, location, and their uncertainties. Currently, an International consortia is working on the best and most efficient way to make use of the historical earthquake record, honoring at the same time its uncertainties and regional differences in quality and extent.

Global instrumental seismic catalog

An International consortium is building a reliable and uniform global instrumental earthquake database (1900–2009). A uniform location procedure to relocate global earthquakes from 1900 to 2009 shall be used, and standardized methods for computing both associated homogeneous surface-wave magnitude ($M_{S(\mathrm{BB})}$) using amplitude and period data and associated moment magnitude (M_W) from published seismic moments (M_0) and also proxy values, $M_{W[\mathrm{Mx}]}$, converted from other types of primary magnitudes [$\mathrm{M_x}$] using empirical relationships (Scordilis, 2006; Bormann et al., 2009; Bormann and Yadav, 2010). A recent example of such catalog structure and philosophy has been published by Yadav et al. (2009). In addition to producing a uniform global earthquake catalog, the database will also keep track of original input data files and documentation. These materials will allow seismologists to extend earthquake studies to a lower magnitude threshold for a better coverage of seismicity, especially in local and regional areas. The catalog will be the primary tool to be used to characterize the spatial distribution of seismicity, the magnitude–frequency relation, and the maximum magnitude.

Global active fault and seismic source database

Tectonic earthquakes are fault ruptures; seismic hazard assessments should, therefore, incorporate an inventory of active faults. Despite this, many seismic hazard assessments do not consider faults at all, or do so only sparingly because the requisite fault data are absent or inadequate. The need to incorporate active faults in the computation of a seismic hazard map, in order to estimate reliably the future strong ground motion, has been recognized long ago (Wesnousky et al., 1984; Wesnousky, 1986). Within the scope of GEM, a uniform global active fault and seismic source database is built, with a common set of

strategies, standards, and formats. The database will be publicly available. The effort is building upon the 1989–2004 International Lithosphere Program's Major Active Faults of the World. Since some faults cut the earth's surface and others do not, there will be both observational elements (active faults and folds that have slipped in the past 10–100 kyr) and interpretative elements (inferred seismic sources) to the database. In addition to collecting the best fault information presently available, appropriate mechanisms to capture new fault data as it becomes available, to capture the rapid expansion of fault knowledge and the ongoing debate about fault geometry, kinematics, and interaction are also being developed.

Global geodetic strain rate model
In the assessment of seismic hazard, seismic catalogs and active faults database provide complementary means for identifying zones of earthquake hazard. The geodetically measured secular strain rate provides an independent benchmark for crustal deformation and thus the recurrence of large earthquakes. The creation of a comprehensive and uniform model for geodetic strain rates is the scope of this global component. The consortium will critically review all global and regional studies since 1994 and will significantly update the Global Strain Rate Model of 2004. Moreover, they will assess whether the estimated fault slip rates and earthquake activity rates are consistent with the long-term strain accumulation measured from Global Positioning System (GPS) (or derived from interferometric synthetic aperture radar – InSAR).

Global ground-motion prediction equations (GMPEs)
A source of variability in hazard results obtained in small regions has traditionally been the derivation and use of local GMPEs, which are often based on insufficient data. Another factor influencing the variability of hazard results is the large statistical uncertainty of ground motion predictions; in recent years, a number of promising advances have been made – the Next Generation Attenuation (NGA) models (Power et al., 2006) – allowing to correctly account for various effects such as local site conditions, style-of-faulting effect, hanging-wall effect, etc., on ground motion predictions. Within the scope of GEM, by compiling a global reference hazard assessment model, a harmonized suite of GMPEs is developed, built on the most recent advances in the field.

Local soil conditions have a large influence on the seismic ground motions. The International consortium involved in this component is furthermore working on adopting a unified strategy to (a) determine seismically effective soil parameters, preferably based on the average S-wave velocity over the upper 30 m, V_{S30}, or, alternatively, derived from topography data (Wald and Allen, 2007; Allen and Wald, 2009) on a worldwide level, and (b) to represent the spatial distribution of soil classification, as for example proposed by NEHRP (Martin, 1994; BSSC, 2004) or EuroCode8 (CEN, 2004), compatible with the GMPE models.

The risk module

Five Global Components on seismic risk are being developed as input to the global earthquake model:

GEM ontology and taxonomy
Within the fields of hazard and risk assessment, diverse terminology is used and different meanings are sometimes attached to the same words. In order to achieve a shared understanding across the disparate fields and endeavors encompassed by GEM, an international consortium will develop some methodological foundation and terminology. Ontology refers to the entire framework that guides the development of the global earthquake model – the set of concepts and the relationship between these concepts that will allow determination and communication of earthquakes risk. The GEM Ontology will be general and comprehensive enough to be long-lasting, but must be adaptable to future conditions. Taxonomy, a part of ontology, refers to the classification of things in an ordered system, reflecting their relationships. The GEM Taxonomy will be an earthquake-related system of classification, set of terminology, encompassing hazard, risk, and socioeconomic realms. The adopted Ontology and Taxonomy will be evaluated and tested and finally globally promoted and disseminated in a continuous way.

Global earthquake consequences database
The international consortium working on this global component will create a global database of earthquake impacts and consequences. They will assemble and store in a structured and web-accessible way both data (including photos) already acquired and data yet to be acquired following future events. Data (both statistical and observational) typically covers building damage, damage to lifelines and other infrastructures, ground failure, human casualties, social disruption, and financial and economic impacts. All damages will be geographically referenced and viewable on a global mapping system. The database will be equipped with analytical tools enabling data fields to be post-processed across events, globally or within regions.

Global exposure database
Compiling an open database of the global building stock distribution with associated uncertainties containing the spatial, structural, and occupancy-related information for damage, loss, and human casualty estimation models is the focus of this Global Component. The International Consortium working on this will identify, evaluate, and homogenate the various existing databases at country, regional, and city levels throughout the world. Within an appropriate grid cell resolution, the inventory will include the total number of buildings, their floor area, the relative distribution of building types (e.g., timber, masonry, R/C, steel) along with some performance-influencing features, such as construction quality and year of construction. Moreover, the relative distribution of occupancy types (e.g., residential, industrial or agricultural) and the

temporal population (e.g., day- and nighttime) within each cell and for each building type will be considered. Finally, the presence of critical facilities and infrastructures for emergency relief will also be identified for each cell.

Inventory data capture tools

This Global Component aims to provide the tools that will enable the capture and transfer of high-resolution inventory data into either the Global Exposure Database or Global Earthquake Consequences Database. Both data collected using remote sensing or acquired from direct observation will be merged in this process.

Interpretation of low, medium, or high spatial resolution satellite imagery and of aerial images is foreseen for data capturing. This will involve the determination of geo-referenced footprints of buildings, vegetation (important for post-event fire spread), and other infrastructure (e.g., roads, lines, reservoirs). Appropriate software will upload and aggregate such data into a neighborhood or grid level of resolution. Direct observation on the other hand implies street-front direct inspection or interpretation of street-front data from photographs.

Global vulnerability estimation methods

The global vulnerability assessment comprises the estimation of the degree of direct loss due to building damage. Direct loss means both human losses (injuries and fatalities) as well as economic losses (repair costs, downtime, etc.) arising from the damage due to ground shaking at a given level. The goal of this global component is to provide methods and standards for vulnerability assessment that can be applied to a wide taxonomy of structures. The International consortium working on the component will derive a number of initial "default" functions that can be applied on a global scale. The methods will account for varying levels of detail in the input data, include the characterization of uncertainties, and account for the influence of retrofitting on the vulnerability.

The socioeconomic impact module

This module is considered as a single global component, which will allow for assessment of social and economic consequences of earthquakes, further and beyond those direct losses considered in the risk module, with the goal to provide users with a wide array of methods useful to communicate impacts of seismic events. The module is envisioned as a toolbox that shall gather a comprehensive set of models, metrics, data, and tools to be organized following spatial, temporal, and user principles under a standardized, clear, and simple framework.

To achieve this goal, GEM will propitiate the development of a framework for compiling state-of-the-art, widely accepted, useful methods for diagnostics and decision-making. The toolbox will be initially populated with methods generated by GEM in partnership with an international consortium, and after that through a constant process of interactions and consulting with the wider community. The toolbox will permit, to the extent possible, the integration of methods, and include interfaces for end users to input data and parameters, to conduct sensitivity and counterfactual analysis, to evaluate alternative policy interventions, and, to visualize results. Case studies are expected to be generated using the methods included in the toolbox.

All the tasks to be conducted within the social and economic impact module shall be performed following a participatory framework that will encompass GEM, its partners, and the wider community. This must be the case, given the multidimensional character and the complexities involved in linking variables from the natural, social, and economic systems, and considering that no consensus has been perceived regarding a precise definition of social and economic impacts of earthquakes and the methods for measuring or addressing them.

Model building

Currently, GEM risk engine is being developed. The engine will allow for calculations on a global level and, therefore, needs to be able to incorporate the data, standards, models, and methods developed by the international community through the Global Components and Regional Programs. A proof-of-concept of the engine has been delivered in June 2010, demonstrated by first hazard and risk calculations on a global scale, which resulted in preliminary global output. This output, however, has not been validated and will only be used internally to propel further development. The GEM risk engine is characterized by open-source development; hence development and enhancement by a wider community of expert users and programmers. It will be platform-independent, modular (using object-oriented language), flexible (as to allow for future multi-hazard calculations), expandable (in terms of methodologies employed), and scalable.

In order to serve the needs of various users, an understandable user interface is being constructed encompassing tools and software for transparent earthquake risk calculations, and risk communication, incorporating the latest technologies for sharing and contributing data between users.

Outcome and future

GEM is going through a continual user-needs assessment effort, to ensure that the software and tools that are being developed meet the needs of a wide range of possible users. Partnerships and an active user-community are the ingredients that support the initial use of the tools and subsequent adoption of the information that the global earthquake model produces, as a necessary first step toward awareness and risk-mitigating behavior.

The main output of GEM's first 5-year working program will be the OpenGEM platform, which will allow basic and expert users to run applications, access seismic risk information on local, national and regional scale, and visualize the latter in maps, curves, tables and export these in compatible formats. Basic users are likely to want

to view output produced by the global earthquake model, perhaps that related to the location of their own house. Expert users will be able to "plug in" their own data and run their own calculations. Because not everyone will be able to access an internet portal, or would like to run calculations through the internet, a stand-alone OpenGEM software package will be an important derivative.

GEM will, however, produce more than a platform for risk assessment. Global harmonized databases within the fields of earthquake hazard, vulnerability, exposure, and socioeconomic impact will be made available, such as a global earthquake consequences database and a global historical seismic catalog. GEM will also produce best practices and standards related to many aspects of seismic risk assessment, which will help the community to work together under a common framework at a global scale. A community development platform for the computational engine will allow for open-source and object-oriented development of the GEM risk engine by the community. Programmers and other experts will be able to test, use, and further improve GEM's software code. Finally, there will be technical reports for the (scientific) community to use, and technical training programs and workshops for diffusion of the knowledge on GEM software and use.

After completion of the first working program, GEM will continue its activities and work on extending the model, maintenance and improvement of the tools, will support the needs of an ever-growing user community, will work on dissemination of products and results and the development of new applications and partnerships.

The future challenge for the scientists will probably be not so much to invalidate the concept of GEM, but to improve its global components (methods, data and standards), as our scientific knowledge of the earthquake generation, seismic wave propagation, and their impact on the built environment – with all the related consequences – will advance in the years to come.

Current developments of the GEM initiative can be followed on www.globalquakemodel.org.

Acknowledgments

I would like to thank Nicole Keller, the GEM Outreach and Communications Officer, for the help she has given me and for providing Figure 1. Thanks also to David Wald for his constructive criticism on the preliminary version of this contribution.

SEISMOLOGY, MONITORING OF CTBT

Scientific and Technical Advances in Seismology and their Relevance

Wu Zhongliang[1], Paul G. Richards[2]
[1]Institute of Geophysics, China Earthquake Administration, Beijing, China
[2]Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY, USA

Introduction

Monitoring of the *Comprehensive Nuclear-Test-Ban Treaty* (CTBT) entails the detection, identification, and

characterization of atmospheric, underwater, and specifically underground nuclear tests, and the discrimination of nuclear explosions from other artificial and/or natural events such as quarry blasts and earthquakes (CTBTO PrepComm., 2009a). Matching the needs of verification deals with seismic, infrasound, and hydro-acoustic, as well as radionuclide monitoring systems. At present the CTBT verification system specified by the treaty has three major components: the International Monitoring System (IMS) with a global network of 337 monitoring facilities; the International Data Centre (IDC) for the processing of observational data; and an On-Site Inspection (OSI) regime that utilizes a series of high-resolution technologies and has many similarities to the emergency on-site observation of disaster areas such as the meizo-seismal regions of large earthquakes. In this verification system, seismic monitoring has been the leading subject, due to three aspects: (1) Since 1980 up to this time of writing (2010), all nuclear tests have been conducted underground, and seismic monitoring is the most efficient way to monitor tests in that environment. (2) Development of seismic monitoring played the leading role in the development of IMS. Compared to other monitoring techniques, seismic monitoring data, characterized by the real-time transmission of broadband/high-frequency continuous waveforms, plays a major role in the whole monitoring system. (3) Important concepts in CTBT monitoring, including evasion scenarios such as decoupling and mine-masking which are most directly a challenge to seismic monitoring, were directly or indirectly developed from seismic monitoring practice.

Entry *seismic monitoring of nuclear explosions* describes in detail the basic properties of explosion and earthquake signals and seismic technologies for the detection and identification of explosions. The main tools for such a monitoring purpose, local, regional, and global seismic networks, are introduced in the entry *seismological networks*. Sections following focus on recent scientific and technical advances in seismology and their relevance to CTBT monitoring.

Evaluation and design of the seismic monitoring system: a systems engineering perspective

Monitoring and verification require an international observational system composed of the following components: observational stations, communication links from the stations to data center/s, and tools for the analysis of signals recorded for verification purposes. The evaluation and design of the seismic monitoring system from the perspective of systems engineering is one of the significant advances in recent years. It is useful not only for the functioning and sustainability of the CTBT monitoring system but also for the operation of modern seismological networks, which not only record earthquakes but also have missions such as the fast seismological information service and the managing of huge amount of observational data. In 2008, the Project "International Scientific Studies of the Implementation of the CTBT Verification System" (ISS) was organized by the Preparatory Commission of CTBT Organization (CTBTO PrepComm., 2009b), in which *system performance evaluation* provided useful tools for the evaluation and design of the seismic monitoring system.

Evaluation is to assess the readiness and capability of the monitoring and verification system, while design is to plan the road map to ensure the expected readiness and capability. Design and evaluation of a seismological monitoring system includes four perspectives: (1) *physical perspective,* including primary seismic stations and arrays, auxiliary stations, national data centers, international data center, network maintenance centers, communication links, system for the automatic data processing and review of analyst, database, and data sharing devices; (2) *functional perspective,* including data transmission, automatic data processing, automatic seismic phase picking and event location, interactive phase picking and location by analysts, array processing for location, magnitude determination, determination of earthquake parameters such as moment tensor and radiated energy, discrimination tools, and tools for routine evaluation of the state-of-health; (3) *operational perspective,* including the design, implementation, management, and upgrading of the whole system; and (4) *scientific perspective,* dealing with Earth structure model, travel-time database, algorithm for location and phase picking, attenuation model and site correction for magnitude determination, Green functions or attenuation relations for source parameter determination, azimuth correction database for array detection, and event database for discrimination. It may be unnecessary for a seismologist to directly use the concepts and tools of systems engineering. However, methodologies such as specification of the system and its components as well as the relationships among the components, specification of the functions of the system and decomposition of system functional requirements into component functional requirements, and development of measures of performance at system level and component level, respectively, provide a clear concept for the systematic evaluation and design of the seismic monitoring system. This becomes especially important when dealing with a modern seismological monitoring system with many stations, working continuously in a real-time mode, being a technically complex system.

Advances in seismology, potentially relevant to CTBT monitoring

Recent decades have witnessed the fast development of seismology (*Seismological Grand Challenges* Writing Group, 2008). These advances have apparent relevance to CTBT monitoring. Location of earthquake epicenters using conventional methods has the uncertainty of up to 10^1–10^2 km. This uncertainty is significantly reduced by the modern methods of earthquake location using waveform cross-correlation and relative location technique (Richards et al., 2006). Recent investigation reveals that "repeating earthquakes," identified by waveform

cross-correlation, seem to be much more common than expected in seismic activity (e.g., Schaff and Richards, 2004), providing the evaluation of location accuracy with an innovative and efficient tool (e.g., Jiang and Wu, 2006). By waveform comparison and relative location, it becomes possible for seismologists to determine the accurate location of new tests if data from previous nearby tests is available (e.g., Wen and Long, 2010). As archives grow, new seismic events that appear problematic often can best be resolved by comparison of their signals with those of previously recorded events from the same region.

In the evaluation of location accuracy, one of the key concepts is the *ground truth* (GT) *events* (International Seismological Centre, 2009), a database of reference earthquakes and/or explosions for which the epicenter information is known with high confidence (to ±5 km or better) with seismic signals recorded at regional and/or teleseismic distances. GT events are used as "calibrating information" to assess the location accuracy of the monitoring system. Furthermore, a GT database is useful to facilitate better visualization of Earth structure, better modeling of velocities of seismic waves, and more accurate travel-time determinations, which are all essential to the enhancement of monitoring capability. Using and developing the GT event database is thus endorsed by international seismological organizations such as the International Association of Seismology and Physics of the Earth's Interior (IASPEI, 2009a).

Recent developments of seismology kept challenging some of the conventional ideas well-accepted in the CTBT monitoring practice. At present, there are several complementary methods for the identification of an explosion from an earthquake, such as the difference between m_b and M_S, and the ratio of high-frequency (>2 Hz) P to S energy (Richards and Zavales, 1990; Bowers and Selby, 2009). One of the important measures is the minimum size of earthquakes and/or explosions for the discrimination, called the *magnitude threshold,* below which the discrimination tool fails to work. Conventionally, the *magnitude threshold* for discrimination is regarded as different from, often 0.5 magnitude unit larger than, the *magnitude threshold* for detection (Hannon, 1985). However, new results (CTBTO PrepComm., 2009b) showed that these thresholds appear to be very similar if regional data, adequate for measurement of spectral ratios, is available. For purposes of estimating the location and yield of underground explosions, it is always important to have accurate information on the inhomogeneous structure of the Earth within which seismic waves propagate. New approaches to this problem using seismic noise (e.g., Shapiro et al., 2005) provide an innovative tool for imaging the Earth structure. Increase of seismic stations and development of inversion techniques kept improving the Earth structure model (*Seismological Grand Challenges* Writing Group, 2008). Accordingly, traditionally problematic earthquake parameters such as focal depth, and "modern" earthquake parameters such as moment tensor and radiated energy potentially can contribute more to CTBT monitoring, along with improved 3D Earth models, and accurate account of wave propagation in complex 3D media.

With the development of digital seismic waveform analysis techniques, it has also become possible for seismologists to capture the time-lapse behavior of Earth medium with considerable accuracy (e.g., Grêt and Snieder, 2005). Combining with the recent advances in active source technology, this development in turn has direct impact on the OSI technology. Combination of seismic data with remote sensing images shows potential in revealing more details of the explosion source, such as decoupling (Sykes et al., 1993). This combination, enabled by modern information technology such as "Digital Earth" (Wu and Chen, 2000), or more practically Google Earth®, provides an alternative approach that supplements the traditional concepts of OSI and even verification.

"Forensic seismology": evidences and judgments

Seismology is a branch of observational science based on the analysis of signals from different sources, penetrating through the Earth, and at last recorded by seismic networks. The field related to seismological observatory practice (Bormann, 2002) and the operation of seismic networks is sometimes called *seismological observation and interpretation* (IASPEI, 2009b). When seismology is applied to the monitoring of CTBT, more considerations are needed beyond the recording and analysis of seismic signals. Key concepts related to the practical functioning of the seismic monitoring system are *monitoring* and *verification*. The term *monitoring* refers to technical activities and analyses associated with data from observational systems that acquire signals from different sources, either explosions or earthquakes, in a continuous and, in some cases, real-time regime. The term *verification* refers to evaluations that include non-seismologists, to enable authorities and the public to judge whether some detected phenomena had its origin in a nuclear explosion. To this end, *verification* is regarded as a branch of *forensic seismology* (Bowers and Selby, 2009), in which the word "forensic" means answering questions of interest to (international) legal system/s.

In concept, *monitoring* is different from *verification* in that *monitoring* basically provides objective observational evidences, while *verification* has to have some subjective decision-making processes based on the objective (but in some cases limited) evidences provided by monitoring. An example is the announced test of DPRK in 2009. It was declared by DPRK authorities that the nuclear test was successfully conducted, but there were no direct evidences (radionuclide) to prove that the explosion, recorded clearly by seismic networks, was really a successful *nuclear* test. Another example is the 1998, Indian-Pakistan announced tests – even if seismic monitoring data could not provide persuasive evidences that *all* the tests were conducted as successfully as announced. In most cases, however, the monitoring system serves for

the clarification of special events, such as the earthquake near Lop Nor of China on March 13, 2003 (Bowers and Selby, 2009). In fact, an important task of the seismic monitoring system is to *screen* events of interest, to identify events that are definitely not nuclear tests. Note that in the context of forensic science, to verify that a nuclear test has been conducted somewhere and to verify that no nuclear test has been conducted in a certain place for a specific time duration, even when using the same monitoring system, need different sets of evidence from that system.

Concluding remarks: interaction between science and CTBT monitoring

The concept of seismic monitoring of nuclear tests can be traced back to the earliest underground nuclear explosions (Bolt, 1976; Richards and Kim, 2009). In September 1957, during the General Assembly of the International Union of Geodesy and Geophysics (IUGG), Toronto, K. E. Bullen gave the address "Seismology in our Atomic Age." Needs of nuclear test monitoring played an important role in the development of global seismic networks in the 1960s (Richards, 2002). In the meantime, researches have been carried out extensively for the detection and identification of nuclear tests (Husebye and Mykkeltveit, 1981; Richards, 2002), in which one of the remarkable techniques is seismic array for the detection of explosion signals smaller than those monitored by conventional stations (Douglas, 2002).

In recent years, the international CTBT monitoring system has been in operation as a "big science device" that is similar in scale to accelerators in high-energy physics and satellites in space science. It provides not only experiences and lessons in the practice of monitoring, but also unique datasets which are interesting in basic research and the science and technology for sustainability. Advances in science and technology also promote the implementation and development of CTBT monitoring practice, and assessments of the overall capability. In the above sections, these relevant advances are introduced via three components: *engineering*, *science*, and *decision making*. It is worth mentioning that, as indicated by a series of important events, especially the Conference "CTBT: Synergies with Science, 1996–2006 and Beyond" (CTBTO PrepComm., 2006) and the ISS Project (CTBTO PrepComm., 2009b), a new era of cooperation between CTBT monitoring communities and scientific research communities has started, which will in turn contribute both to the CTBT monitoring practice and to the development of geophysical science. In the ISS Project, *science and technology foresight*, a professional practice that emerged in recent years, aiming at identifying today's research and innovation priorities on the basis of scenarios of future developments in science and technology, society and economy, was introduced to the scientific assessment of CTBT monitoring, which indicates that the interaction between science and CTBT monitoring has started to be systematic and comprehensive through a professionally planned road map.

SEISMOLOGY, ROTATIONAL

William H. K. Lee
U.S. Geological Survey, Menlo Park, CA, USA

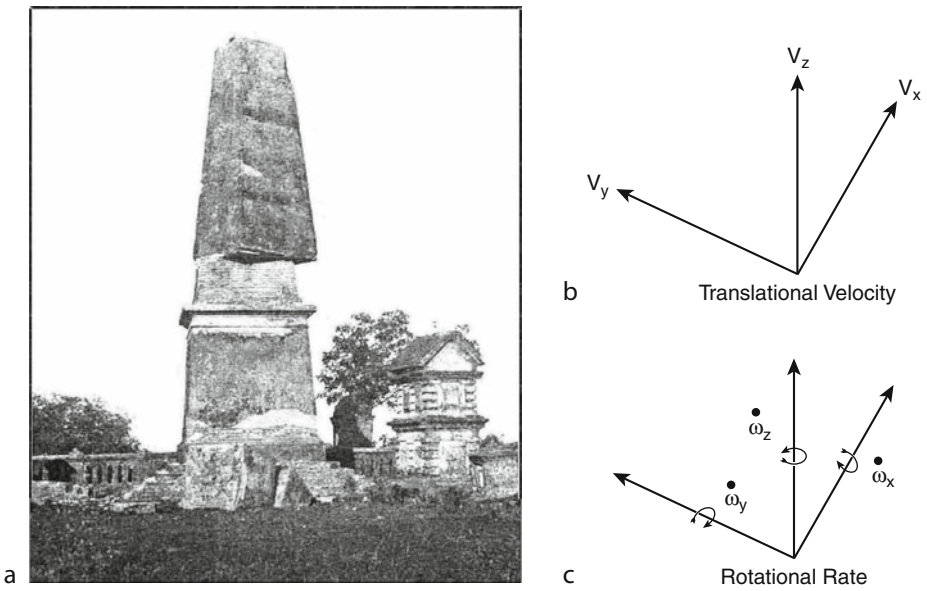
Definition

Rotational seismology is an emerging study of all aspects of rotational motions induced by earthquakes, explosions, and ambient vibrations. The subject is of interest to several disciplines, including seismology, earthquake engineering, geodesy, and earth-based detection of Einstein's gravitation waves.

Introduction

Rotational effects of earthquake waves together with rotations caused by soil-structure interaction have been observed for centuries (e.g., rotated chimneys, monuments, and tombstones relative to their supports). A summary of historical examples of observations on earthquake rotational effects is provided by Kozák (2009), including reproduction of the relevant sections from Mallet (1862) and Reid (1910). Figure 1a shows the rotation of the monument to George Inglis (erected in 1850 at Chatak, India) as observed by Oldham (1899) after the 1897 Great Shillong earthquake. This monument had the form of an obelisk rising over 60 ft. high from a base 12 ft. on each side. During the earthquake, the topmost six-foot section was broken off and fell to the south and the next nine-foot section was thrown to the east. The remnant is about 20 ft. in height and is rotated about 15° relative to the base.

A few early authors proposed rotational waves or at least some "vortical" motions. Many different terms were used for the rotational motion components at this early stage of the field's development. For example, "rocking" is rotation around a horizontal axis, sometimes also referred to as "tilt." Mallet (1862) proposed that rotations of a body on the Earth's surface are due to a sequence of different seismic phases emerging at different angles. Reid (1910) studied this phenomenon, which was observed in the 1906 San Francisco earthquake, and pointed out that the observed rotations are too large to be produced by waves of elastic distortion. Such waves "*produce very small rotations, whose maximum amount, . . . is given by the expression* $2\pi A = \lambda$*, where A is the amplitude and* λ *the wavelength; with a wave as short as 10,000 feet (3 km) and an amplitude as large as 0.2 of a foot (6 cm), the maximum rotation would only be about 0.25 of*



Seismology, Rotational, Figure 1 (**a**) Rotation of the monument to George Inglis (erected in 1850 at Chatak, India) as observed by Oldham (1899) after the 1897 Great Shillong earthquake. (**b**) Coordinate system for translational velocity. (**c**) Coordinate system for body-fixed or instantaneous rotational rate.

a minute of arc [0.0042 degrees, or 7.3 micro-radians (μrad)], *a quantity far too small to be noticeable*" (Reid, 1910, p. 44). A modern analysis of such rotational effects is presented in Todorovska and Trifunac (1990).

Observational seismology is based mainly on measuring *translational* motions because of a widespread belief that *rotational* motions are insignificant. For example, Richter (1958, footnote on p. 213) states that "Theory indicates, and observation confirms, that such rotations are negligible." Richter provided no references, and there were no instruments at that time sensitive enough to either confirm or refute this claim. Recent advances in rotational seismology become possible because sensitive rotational sensors have been developed in aeronautical and astronomical instrumentation. In this article we provide some background information and selected highlights of recent advances in rotational seismology. An extensive list of references to original papers is given because few "synthesis" articles exist.

Early attempts in studying rotational motions

Ferrari (2006) summarized two models of an electrical seismograph with sliding smoked paper, developed by P. Filippo Cecchi in 1876 to record three-component *translation* motions and also the *torsion* movements from earthquakes. Although these instruments operated for several years, no rotational motion could be recorded because of low transducer sensitivity. Pioneers in several countries attempted to measure rotational motions induced by earthquakes. Nearly a century ago, Galitzin (1912) suggested using two identical pendulums installed on different sides of the same axis of rotation for separate measurement of rotational and translational motion. This was later implemented, for example, by Kharin and Simonov (1969) in an instrument designed to record strong ground motion. Using an azimuthal array of seismographs, Droste and Teisseyre (1976) derived rotational seismograms for rock bursts in a nearby mine. Inspired by Walter Munk, Farrell (1969) constructed a gyroscopic seismometer, and obtained a static displacement of <1 cm and a tilt of <0.5 μrad at La Jolla, California, during the Borrego Mountain earthquake of April 9, 1968 (magnitude 6.5), at an epicentral distance of 115 km.

Early efforts also included studies of explosions. For example, Graizer (1991) recorded tilts and translational motions in the near field of two nuclear explosions using seismological observatory sensors to measure point rotations directly. Nigbor (1994) measured rotational and translational point ground motions directly with a commercial rotational MEMS sensor and found significant near-field rotational motions (660 μrad at 1 km distance) from a one-kiloton explosion.

Rotations and strains of the ground and of response of structures have been deduced indirectly from accelerometer arrays using methods valid for seismic waves having wavelengths that are long compared to the distances between sensors (e.g., Trifunac, 1979, 1982; Oliveira and Bolt, 1989; Spudich et al., 1995; Bodin et al., 1997; Huang, 2003, Suryanto et al., 2006; Wassermann et al., 2009). The rotational components of ground motion have also been estimated theoretically, using kinematic source models (Bouchon and Aki, 1982; Wang et al., 2009) and linear elastodynamic theory of wave propagation in elastic solids (Lee and Trifunac, 1985, 1987).

Measuring rotational motions

The general motion of the particles or a small volume in a solid body can be divided into three parts: translation (along the X-, Y-, and Z-axes), rotation (about the X- Y-, and Z-axes), and strain (six components). Figure 1b shows the axes in a Cartesian coordinate system for *translational velocity* measured by the usual seismometers in seismology, and Figure 1c shows the corresponding axes of *rotation rate* measured by rotational sensors (Evans, 2009). These are "body attached" coordinates, those that a seismic instrument would measure at a given instant as the sensors move and rotate through space. Converting an extended record of these body-fixed motions to recover motions in an Earth-fixed, quasi-inertial coordinate system has been performed for decades in "strapped down" inertial navigation systems such as those attached to a moving airplane. Lin et al. (2010) introduce these equations into seismology and earthquake engineering for recovering inertial-frame ground and structure motions.

Rotational ground motions can be measured directly by gyroscopic sensors or inferred indirectly from an array of translational sensors. According to Cochard et al. (2006), in a linear elastic medium the displacement $\mathbf{u}$ of a point $\mathbf{x}$ is related to a neighboring point $\mathbf{x} + \delta\mathbf{x}$ by

$$\mathbf{u}(\mathbf{x} + \delta\mathbf{x}) = \mathbf{u}(\mathbf{x}) + \boldsymbol{\varepsilon}\,\delta\mathbf{x} + \omega \times \delta\mathbf{x} \tag{1}$$

where $\boldsymbol{\varepsilon}$ is the strain tensor and

$$\omega = {}^1\!/_2 \nabla \times \mathbf{u}(\mathbf{x}) \tag{2}$$

is a pseudo-vector representing the infinitesimal angle of rigid rotation generated by the disturbance. The three components of rotation about the X-axis, Y-axis, and Z-axis are given by the following equations for such infinitesimal motions:

$$\begin{aligned} \omega_x &= {}^1\!/_2\left(\partial u_z/\partial y - \partial u_y/\partial z\right), \\ \omega_y &= {}^1\!/_2\left(\partial u_x/\partial z - \partial u_z/\partial x\right), \\ \omega_z &= {}^1\!/_2\left(\partial u_y/\partial x - \partial u_x/\partial y\right) \end{aligned} \tag{3}$$

Therefore, rigid rotations can be observed by: (1) an array of translational seismometers indirectly for "cord" rotations associated with long wave lengths by assuming that contamination of translational signals by rotational motions is small, and that the linear elasticity theory is valid (e.g., Spudich and Fletcher, 2008), or (2) rotational sensors directly for "point" body-fixed rotations (e.g., Lee et al., 2009b; Lin et al., 2010).

In the past decade, rotational motions from small local earthquakes to large teleseisms were successfully recorded by sensitive rotational sensors in several countries (e.g., Takeo, 1998; McLeod et al., 1998; Igel et al., 2005, 2007; Suryanto et al., 2006; Cochard et al., 2006). In particular, the application of Sagnac interferometry in large ring laser gyros provided greatly improved sensitivity to rotations at teleseismic distances and showed that they are a good match to those estimated from linear elastic wave theory. Such motions provide additional observations that – combined with translations – lead to new approaches to the seismic inverse problem (Bernauer et al., 2009; Fichtner and Igel, 2009). Recently Kurrle et al. (2010b) reported the first observations of Earth's free oscillations using ring laser recordings, and opened up potential applications of rotational seismology at long periods.

In contrast, strong-motion observations near the source in both Japan and Taiwan showed that the amplitudes of these rotations can be one to two orders of magnitude greater than that expected from linear elasticity theory (e.g., Takeo, 1998; Lee et al., 2009b). Theoretical work suggests that in shallow granular or cracked continua (e.g., weathered rock at or near Earth's surface), asymmetries of the stress and strain fields can create rotations separate from and larger than those predicted by classical elastodynamic theory (e.g., Teisseyre et al., 2006, 2008). Unlike the traditional fault-slip model, Knopoff and Chen (2009) consider the case for faulting that takes place on a fault of finite thickness. They show that there is an additional single-couple term in the body-force equivalence and additional terms in the far-field displacement. They also show that the single-couple equivalent does not violate the principles of Newtonian mechanics because the torque imbalance in the single-couple is counterbalanced by rotations within the fault zone, with torque waves being radiated.

Large ring laser gyros

An unexpected advance in studying rotational ground motions came from a different field of geophysics. Recent developments of highly sensitive ring laser gyroscopes to monitor the Earth's rotation also yield valuable data on rotational motions from large teleseismic events. The most important property that makes such rotation sensors useful for seismology is its very low noise floor and high sensitivity to rotational motions and its insensitivity to translational and cross-rotational motions. The rotation rates expected and observed in seismology range from the order of 10^{-1} rad/s (e.g., Nigbor, 1994; Trifunac, 2009) near seismic sources down to order 10^{-11} rad/s for large earthquakes at teleseismic distances (e.g., Igel et al., 2005, 2007). This range spans at least 10 orders of magnitude, 200 dB, much as for translational motions, and it is unlikely that one instrument or one instrumental technology will be capable of providing accurate measurements over such a large range of amplitudes. Ring laser technology is currently the most promising approach to recording the small rotational motions induced by teleseisms, but the primary drawback is its very high cost.

Ring lasers detect the Sagnac beat frequency of two counter-propagating laser beams (Stedman, 1997; and Figure 2c). These active interferometers generally form triangular or square closed loops several meters across and are evacuated. If this instrument is rotating on a platform with respect to inertial space, the effective cavity length between co-rotating and counter-rotating laser cavity differs and one observes frequency splitting resulting in a beat frequency. This beat frequency δf is directly proportional to the rotation rate $\boldsymbol{\Omega}$ around the surface normal $\mathbf{n}$ of the ring laser system, as given by the Sagnac equation:

$$\delta f = \frac{4A}{\lambda P}\mathbf{n}\cdot\boldsymbol{\Omega}\,, \tag{4}$$

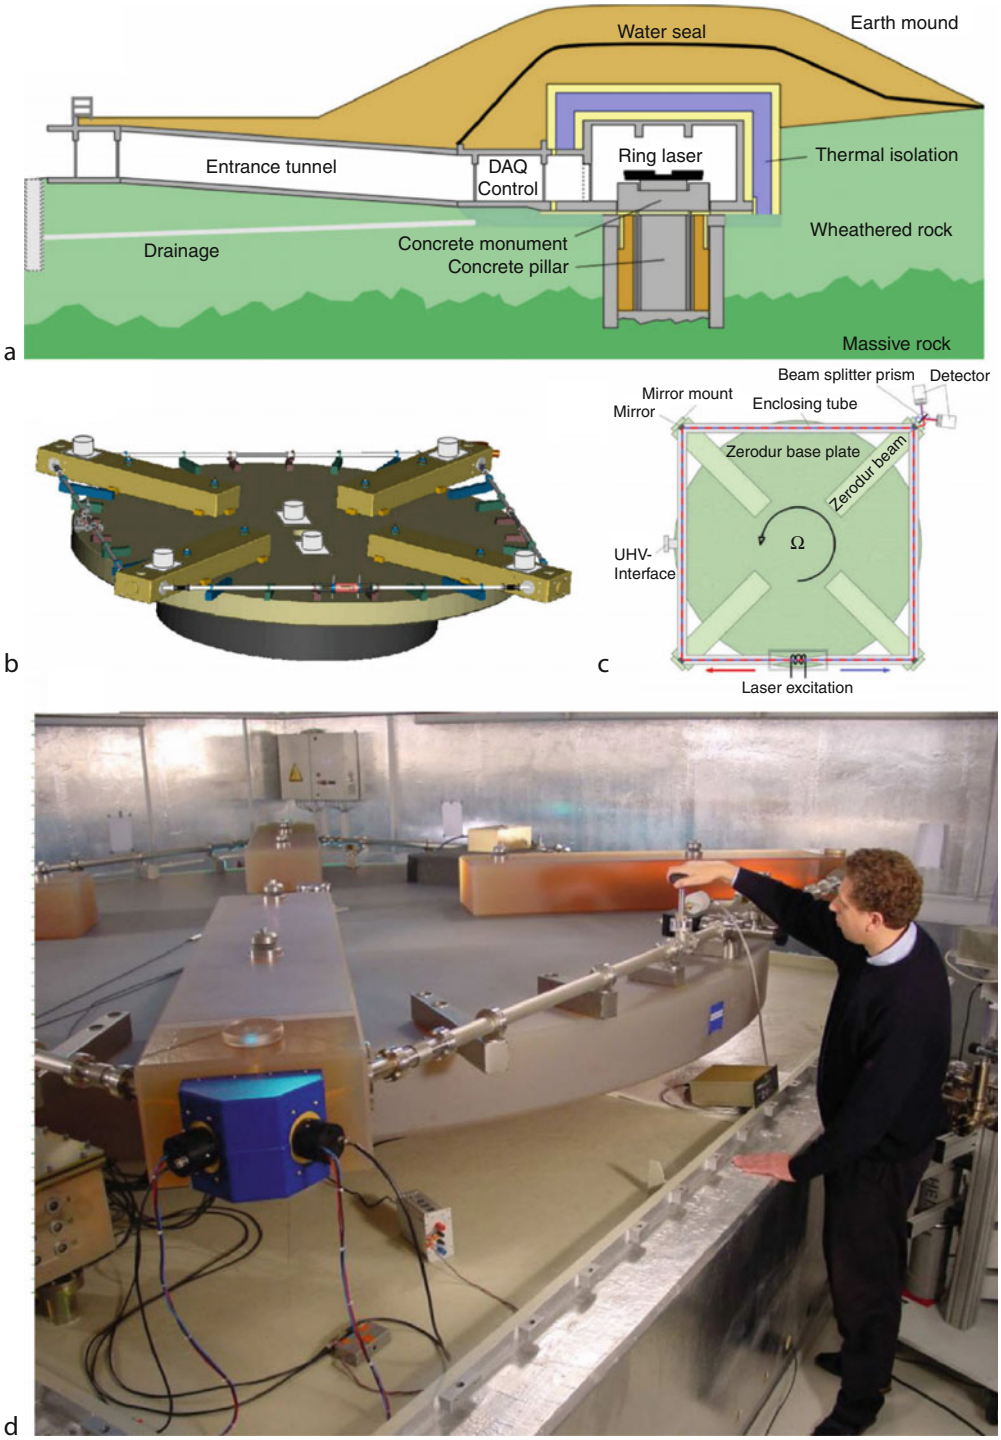
where P is the perimeter of the instrument, A its area, and λ the laser wavelength. This equation has three contributions that influence the beat frequency δf: (1) variations in the scale factor $(4A/\lambda P)$ have to be avoided by making the instrument mechanically as rigid and stable as possible, (2) changes in orientation $\mathbf{n}$ (tilting relative to Earth's rotation axis) enter the beat frequency via the inner product, and (3) variations in $\boldsymbol{\Omega}$ (e.g., changes in Earth's rotation rate and seismically induced rotations). Thankfully, the dominant contribution to δf is $\boldsymbol{\Omega}$. Note that translations do not contribute to the Sagnac frequency unless they affect P or A in some indirect manner.

Ring lasers are sensitive to rotations only, assuming stable ring geometry and lasing. However, for co-seismic observations at the Earth's surface the horizontal components of rotation (i.e., tilts) will contribute to the vertical component of rotation rate. As shown by Pham et al. (2009), the tilt-coupling effect is several orders of magnitude below the level of the earthquake-induced rotational signal unless one is very close to the source (where sensitive ring lasers would not be the appropriate technology).

At present, there are ring laser gyros capable of measuring rotation (induced by small local earthquakes or distant large teleseisms) at four sites: (1) Cashmere cavern, Christchurch, New Zealand (McLeod et al., 1998); (2) Wettzell, Germany (Schreiber et al., 2005); (3) Conway, Arkansas (Dunn et al., 2009); and (4) Piñon Flat, California (Schreiber et al., 2009a).

G Ring laser and recording teleseisms

Since 2001, the "G Ring" laser (capable of measuring rotation rate of about 10^{-10} rad/s) has been operating at the primary geodetic station (Fundamentalstation) at Wettzell, in Bavaria, (http://www.fs.wettzell.de/). A cross-sectional view of the site of the G Ring laser is shown in Figure 2a. The instrument is resting on a polished granite table (Figure 2b) embedded in a 90-t concrete monument. As shown in Figure 2a, the monument is



Seismology, Rotational, Figure 2 G Ring laser gyro at the Wettzell Superstation, Germany. (**a**) Cross-sectional view of the instrument site. (**b**) Instrument resting on a granite table. (**c**) Schematic drawing. (**d**) Photo of G Ring laser gyro with its designer, Ulli Schreiber.

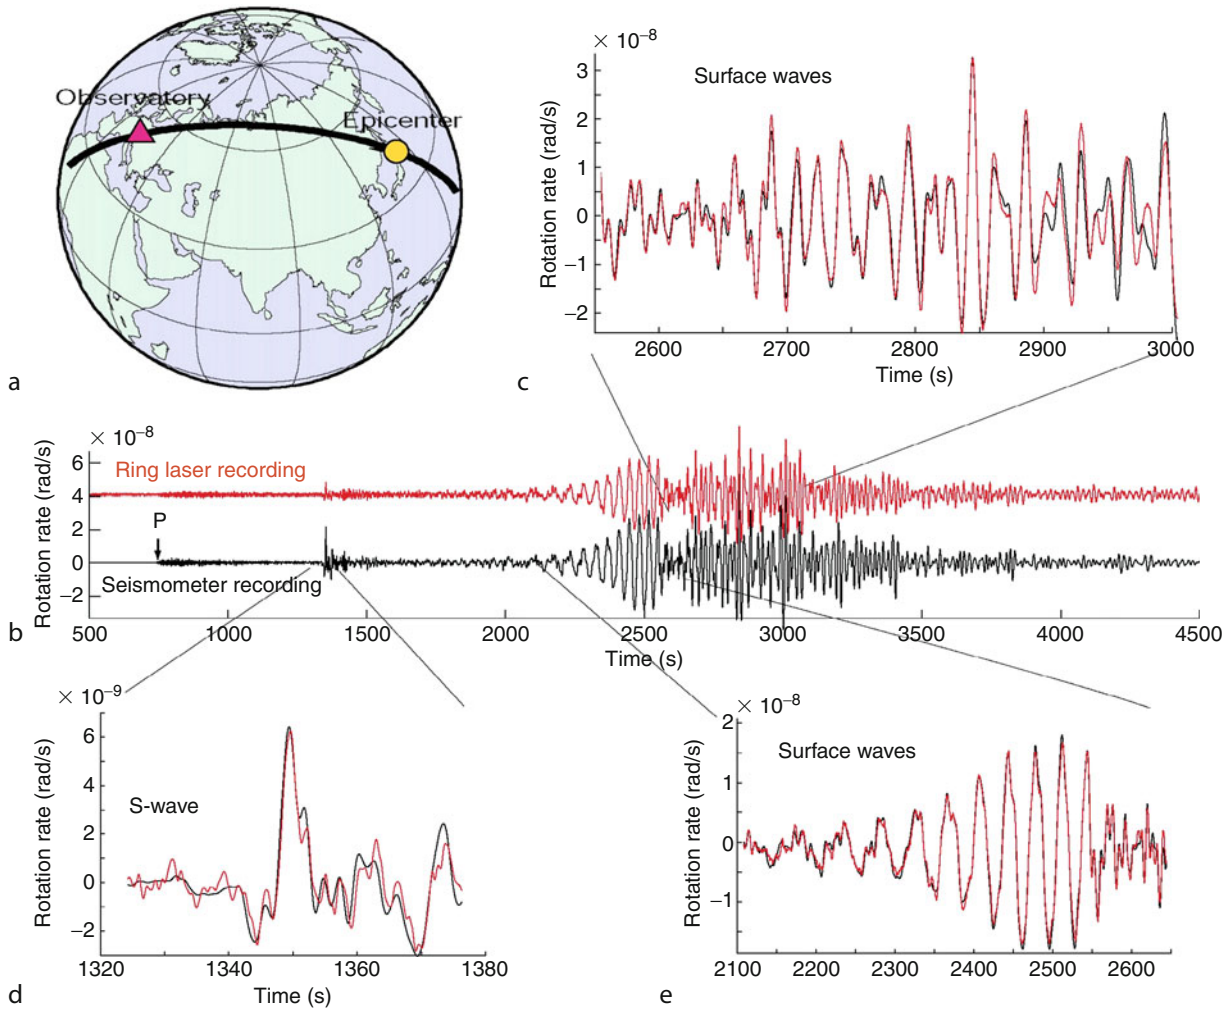
attached to a massive 2.7-m diameter concrete pillar and this is founded on crystalline bedrock 10 m below. A system of concrete rings and isolation material shields the monument and pillar from adjacent weathered rock to eliminate its deformation and heat-flow contributions. The G Ring laser is protected against external influences by a subsurface installation with passive thermal stability provided by a 2-m layer alternating between Styrofoam

and wet clay, this beneath a 4-m soil mound. A lateral entrance tunnel with five isolating doors and a separate control room minimize thermal perturbations during maintenance. After 2 years of thermal adaptation, the average temperature reached 12.2°C with seasonal variations of less than 0.6°C. Figure 2c shows the schematic drawing of instrument, and Figure 2d is a photo of the G Ring laser with its designer, Ulli Schreiber.

Figure 3 is a comparison of direct point measurements of ground rotations around a vertical axis (red lines) to transverse accelerations (black lines, converted to rotation rate for each time window) for the M8.1 Tokachi-oki earthquake, September 25, 2003 (Igel et al., 2005). Figure 3a is a schematic view of the great-circle-path through the epicenter in Hokkaido, Japan, and the observatory in Wettzell, Germany. 3b–e show the superposition of the rotation rate derived from transverse translations (black) and measured directly (red) for various time windows: Figure 3b the complete signal, Figure 3c the latter part of the surface wave train, Figure 3d the direct *S*-wave arrival, and Figure 3e for the initial part of the surface wave train. These results confirm the expectation from linear elasticity that the waveforms of transverse acceleration and rotation rate (around the vertical axis) should be identical assuming plane harmonic waves. Information on subsurface structure is contained in the ratio between the corresponding motion amplitudes.

Strong-motion inertial angular sensors

In aerospace, automotive, and mechanical engineering, smaller rotational-motion sensors are common and generically known as gyroscopic or inertial angular sensors. Nigbor (1994) used a MEMS-based Coriolis rotation-rate sensor to measure the rotational components of strong



Seismology, Rotational, Figure 3 Comparison of direct measurements of ground rotational motions around a vertical axis (*red lines*) with transverse accelerations (*black lines*, converted to rotation rate for each time window) for the M8.1 Tokachi-oki earthquake, September 25, 2003.

ground motions close to a large chemical explosion. Similar sensors were used by Takeo (1998) to measure rotational motions from an earthquake swarm ~3 km away. However, such sensors do not have the sensitivity to record rotations from small local earthquakes (magnitude ~4) at distances of tens of kilometers.

The eentec™ model R-1™ rotational seismometer is the first modestly priced sensor capable of recording small earthquakes at distances up to several tens of kilometers. It uses electrochemical technology in which the motion of an electrolytic fluid inside a torus is sensed electronically, yielding a voltage signal proportional to rotational velocity. Nigbor et al. (2009) carried out extensive tests of commercial rotational sensors and concluded that the R-1 sensor generally meets the specifications given by the manufacturer but that clip level and frequency response vary from those specifications and between individual channels enough that more detailed calibrations are warranted for each unit. A typical transfer function for the R-1 can be found at the manufacturer's website (http://www.eentec.com/). The instrument response is roughly "flat" from 0.1 to 20 Hz, and its self noise (rms) is <10 μrad/s over the same frequency band.

The R-1 rotational seismometers successfully recorded several hundred local earthquakes and two explosions in Taiwan (Lee et al., 2009b). Figure 4a shows the instruments deployed at station HGSD in eastern Taiwan (Liu et al., 2009). The top frame is a schematic drawing of the various seismic, geodetic, and strain instruments there. The bottom frame shows the subset of the instruments deployed in the shallow vault at the left hand side of the upper drawing; these include a datalogger (Quanterra Q330), an accelerometer (Kinemetrics Episensor), a six-channel digital accelerograph (Kinemetrics K2 with an external rotational seismometer, R-1 by eentec), and a short-period seismometer (Mark Products L-4A). The K2+R-1 instrument is at the left hand side, and the yellow-color box is the R-1 rotational seismometer.

The largest peak rotational rate recorded at the HGSD station (to early 2008) is from a M_w 5.1 earthquake at a hypocentral distance of 51 km at 13:40 UTC, 23 July 2007. Figure 4c shows the amplitudes and spectra of translational accelerations recorded by the K2's accelerometer. The peak ground acceleration was 0.47 m/s^2, and the two horizontal components have much higher amplitude than the vertical. Figure 4d shows the amplitudes and spectra for rotational rates recorded from its external R-1 seismometer. The peak rotational rate was 0.63×10^{-3} rad/s for the vertical component, much more than that for the horizontal components. The spectra in Figure 4c show that the dominant frequency band in ground acceleration is about 2–5 Hz (horizontal components) while those in Figure 4d show that the dominant frequency band in ground rotation rate is about 2.5–5.5 Hz for the vertical component. Other studies report observations with the R-1 sensor and compare their point measurements of rotation to array-derived area rotations (e.g., Wassermann et al., 2009).

Discussions

Many authors have emphasized the benefits of studying rotational motions (e.g., Twiss et al., 1993; Spudich et al., 1995; Takeo and Ito, 1997; Teisseyre et al., 2006; Trifunac, 2006, 2009; Igel et al., 2007; and Fichtner and Igel, 2009). We discuss some basic issues briefly.

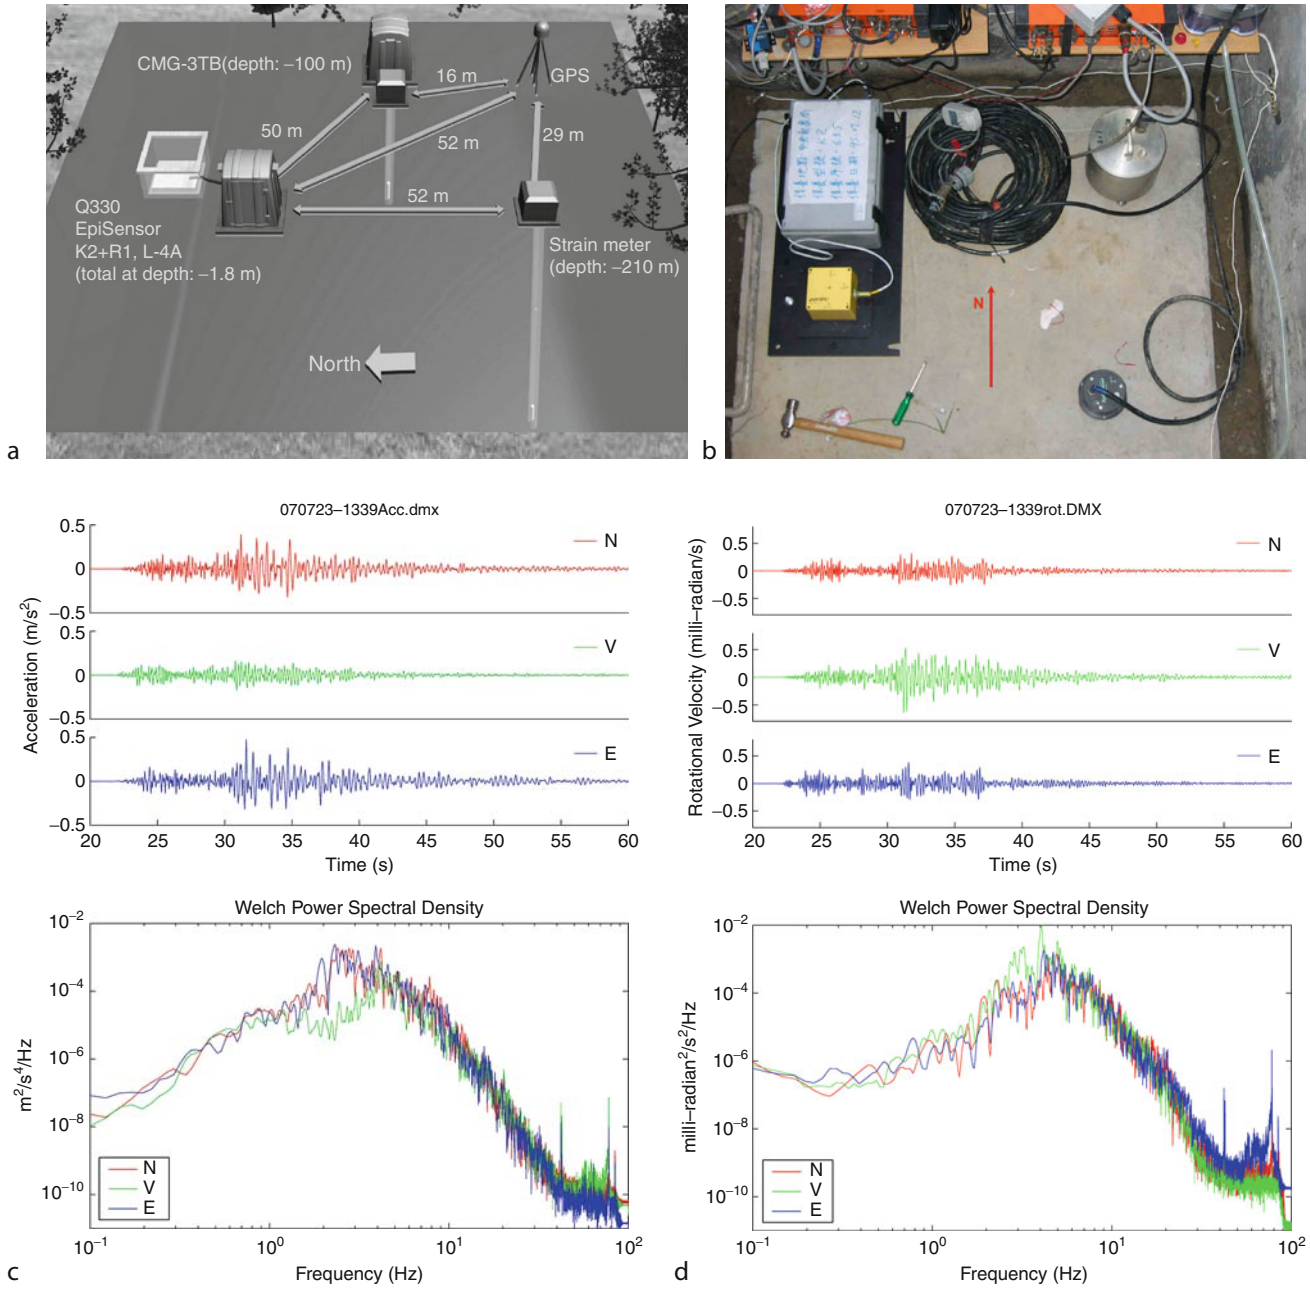
Linear and nonlinear elasticity

Real materials of the Earth are heterogeneous, anisotropic, and nonlinear, especially in the damage zone surrounding faults and in poorly consolidated sediments, soil, and weathered, fractured rock just beneath seismic instruments, particularly typically installed strong-motion instruments. In the presence of significant nonlinearity we are forced to consider the mechanics of chaos (Trifunac, 2009) and to interpret such complexities must record both the rotational and translational components of strong motion.

Seismology is primarily based on the linear elasticity theory, which is applicable to simple homogeneous materials under infinitesimal strain. "Cord" rotation is defined as the curl of the displacement field in Equation 2, and in the classical elasticity theory, the rotational components of motion are contained in the S waves. Meanwhile, continuum mechanics has advanced far beyond the classical theory. In particular, the elasticity theory of the Cosserat brothers (Cosserat and Cosserat, 1909) incorporates (1) a local rotation of continuum particles as well as the translational motion assumed in classical theory, and (2) a couple stress (a torque per unit area) as well as the force stress (force per unit area). In the constitutive equation of classical elasticity theory there are two independent elastic constants while in Cosserat elastic theory there are six or more elastic constants. Pujol (2009) provides a tutorial on rotations in the theories of finite deformation and micropolar (Cosserat) elasticity. Twiss (2009) derives an objective asymmetric micropolar moment tensor from a discrete-block model for a deforming granular material. He also investigates seismogenic deformation associated with volumes of distributed seismicity in three different geographic areas, and finds support in the micropolar model for the effects of a granular substructure on the characteristics of seismic focal mechanisms.

Near-field seismology

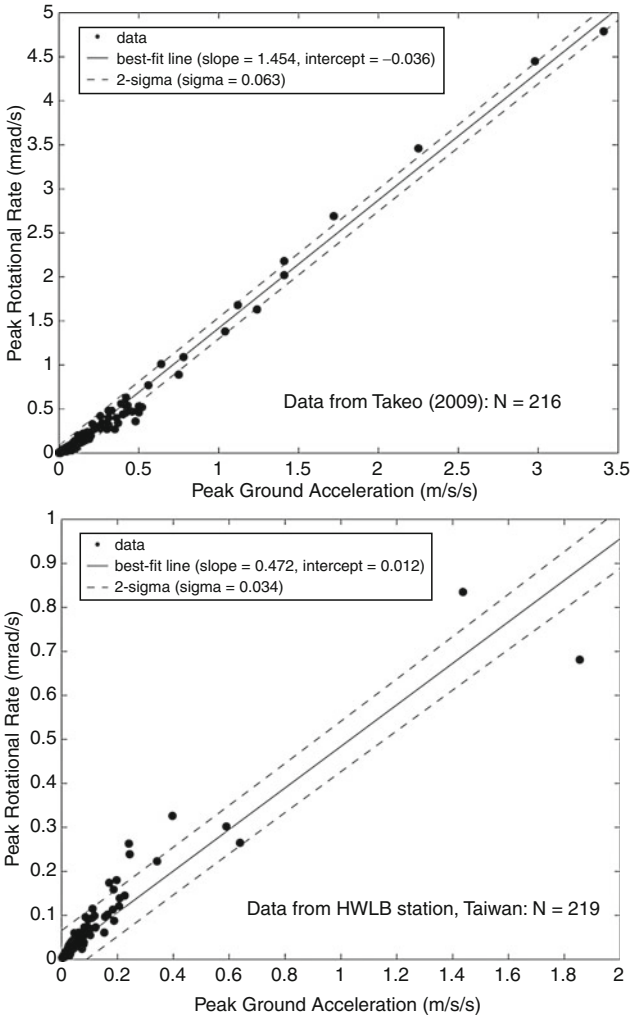
Although the observed rotational motions agree well with the classical elasticity theory for teleseisms, it is not the case for local earthquakes. As first noted by Takeo (1998) and confirmed by Lee et al. (2009b), observed rotational rates from local earthquakes are much larger than those predicted from the classical elasticity theory. For example, Bouchon and Aki (1982) obtained theoretically a maximum rotational rate of 1.5×10^{-3} rad/s for a magnitude 6.5 earthquake, whereas a maximum rotational rate of $>1 \times 10^{-3}$ rad/s for several magnitude 4.5–5.5 earthquakes had been observed in Japan and Taiwan. Takeo (1998) reported the largest rotational rate



Seismology, Rotational, Figure 4 (**a**) Schematic of instrument layout at station HGSD in Taiwan. (**b**) Photo showing the instrument vault containing a K-2 accelerograph, an R-1 rotational seismometer (*yellow*), an EpiSensor accelerometer, and an L-4A velocity seismometer. (**d**) Recorded rotational rates (top) and their spectra (*bottom*) from the same earthquake.

was 2.6×10^{-2} rad/s around the north-south axis from the second largest earthquake (magnitude 5.2) during the 1997 swarm (at 14:09 UTC, 3 March), east of Cape Kawana, offshore Ito, Japan (about 3 km away). As of the end of 2009, the largest rotational rate recorded at the HWLB station (Hualien, Taiwan) was 2.58×10^{-3} rad/s around the east–west axis from a M_w 6.4 earthquake offshore (at UTC 13:02, 19 December 2009) at a hypocentral distance of about 49 km. The peak rotational rate is 1.57×10^{-3} rad/s around the north-south axis, and 0.68×10^{-3} rad/s around the vertical axis. The corresponding peak ground acceleration is 1.16, 1.85, and 0.50 m/s^2 for the east–west, north–south, and vertical component, respectively.

Figure 5 shows the *vertical* peak rotational rate versus *horizontal* peak ground acceleration for the earthquake data set from Takeo (2009) (top frame), and for the earthquake data set (22 August, 2008 to 25 December, 2009) recorded at the HWLB station, Taiwan (bottom frame), where N = number of data points. As noted by Takeo (1998, 2009), there is a reasonable linear relationship in such plots. The data scatter is larger in the Taiwan data than the Takeo (2009) data. This may due to the fact that the earthquake sources for the Takeo (2009) data were from a nearby offshore swarm, whereas the Taiwan data were recorded from many different earthquake sources. Several authors noted similar linear relationships before (see e.g., Spudich and Fletcher, 2008; Stupazzini et al., 2009; Takeo, 2009; and Wang et al., 2009). In particular,



Seismology, Rotational, Figure 5 Vertical peak rotational rate (PRR) versus horizontal peak ground acceleration (PGA) for the earthquake data set from Takeo (2009) (top frame), and for the earthquake data set (22 August, 2008 to 25 December, 2009) recorded at the HWLB station, Taiwan (bottom frame). *N* number of data points.

Takeo (2009) showed "*a linear correlation between the maximum rotational displacements around vertical axis and the maximum* [ground] *velocities*." The two plots in Figure 5 are equivalent to Takeo's linear relationship, without performing the integration for the measured rotational rate and ground acceleration to obtain rotational displacements and ground velocities. The linear slope in Figure 5 has the dimension unit of s/km, or unit for slowness. Spudich and Fletcher (2008) interpreted this "slowness" as the inverse of an "apparent velocity," characterizing the seismic wavefield beneath the recording station.

Spudich and Fletcher (2008) computed peak values of ground strain, torsions, and tilts for the 2004 Parkfield earthquake (M_w 6.0) and four aftershocks (M_w 4.7–5.1) using the data recorded by an array of accelerators. Takeo (2009) noted that his observations of peak rotation values are about 100 times larger for earthquakes with similar magnitudes and distances, and proposed the following explanations: the different spatial scale of rotational motion by a single-point gyro measurement and by an array observation, the effect of topography, and the difference of the degree of maturation between the San Andreas fault and the swarm volume of offshore Ito. Two arrays of both rotational and translational sensors have been deployed by Wu et al. (2009) in Taiwan to study this discrepancy problem, and hopeful a resolution may be found after recording sufficient numbers of earthquakes.

Using explosions to study rotational motions

Since a large earthquake occurring near a station is rare, explosions have been used to study rotational motions by several pioneers (e.g., Graizer, 1991; Nigbor, 1994). Lin et al. (2009) deployed an array of 8 triaxial rotational sensors, 13 triaxial accelerometers, and 12 six-channel, 24-bit dataloggers with GPS time receivers to record two explosions in northeastern Taiwan. These instruments were installed at about 250 m (1 station), 500 m (11 stations), and 600 m (1 station) from the explosions. The 11 stations form a "Center Array" with station spacing of about 5 m. The code name for the first shot with 3,000 kg explosives is "N3P," and that for the second shot with 750 kg explosives is "N3." Although the N3P shot used four times larger amounts of explosives than that used for the N3 shot, the peak ground translational acceleration and rotational velocity at the 13 station sites from the N3P shot are only about 1.5 times larger than that for the N3 shot. Large variations (by tens of %) of translational accelerations and rotational velocities were observed at the very small Center Array. The largest peak rotational rate was observed for the horizontal transverse component: 2.74 $\times$ 10^{-3} and 1.75 $\times$ 10^{-3} rad/s at a distance of 254 m from the N3P and N3 shots, respectively.

The acceleration data from these two explosions were used by Langston et al. (2009) to compute acceleration spatial gradients, horizontal strains and horizontal rotation, and to perform a gradiometric analysis of the strong ground motion wave train. The analysis yields a complex, frequency-dependent view of the nature of seismic wave

propagation over short propagation distances that imply significant lateral velocity changes in the near-surface crustal structure. Areal strain and rotation about the vertical have equal amplitudes and suggest significant wave scattering within the confines of the river valley where the experiment was performed and/or significant departure from an axisymmetric explosion source. Gradiometry shows that the P wave arrives at the array 35° off-azimuth clockwise from the straight-line path and appears to have been refracted from the northern side of the valley. Chi et al. (2011) successfully recovered the first order features of vertical rotational rate ground motions from the translational velocity waveforms in the 0.5–20 Hz bandwidth using the software of Spudich and Fletcher (2009), and strain as large as 10^{-4} was deduced. To fulfill the uniform rotation assumption in the linear elasticity theory, it is necessary to use a small-aperture array. However, inverting data from an array of small spatial dimension requires accurate waveforms of high signal to noise ratio and high sampling rates; since waveforms from adjacent stations are very similar, small noises have strong influence on displacement gradients due to the small station spacing. The Lin et al. (2009) recordings were limited to 200 samples per second, and much higher sampling rate will be necessary to record explosions in the near field.

Processing collocated measurements of translations and rotations

Processing collocated observations of rotation and translation is routinely performed in the inertial navigation units of aircraft and other vehicles. A similar analysis is possible for various combinations of strain components, rotations, and translations. With the exception of velocity–strain combinations (e.g., Gomberg and Agnew, 1996) this terrain was largely unexplored until the work of Lin et al. (2010), who have demonstrated an appropriate set of these equations for earthquake engineering and seismology to recover inertial-frame displacements and rotations. Further, it is already apparent that rotational motions provide useful additional analysis opportunities, simply put, that more data at a site yield more results.

Phase Velocities and propagation directions. A simple calculation for non-dispersive linear-elastic plane waves with transverse polarization shows that the ratio of transverse acceleration to vertical-axis rotation rate is proportional to local phase velocity. This result implies that information on subsurface velocity structure (otherwise only accessible through seismic array measurements and combined analyses) is contained in any single-point measurement that includes rotational sensors. It has been shown that such ratio-derived phase velocities agree with velocities predicted by theory (Igel et al., 2005, Kurrle et al., 2010a). In a recent theoretical study based on full ray theory for Love waves (normal mode summation), Ferreira and Igel (2009) demonstrated that the Love wave dispersion relation also can be obtained by taking the spectral ratio of transverse acceleration to vertical-axis rotation rate. This result implies that seismic shear wave tomography is possible without requiring sub-arrays to determine local mean phase velocities. Information on the direction of propagation also is contained in the azimuth-dependent phase fit between rotations and translations; this fit is optimal in the direction of propagation, from which back azimuths can be estimated to within a few degrees (Igel et al., 2007). Linking observational translations, strains, and rotations together also is advocated by Langston (2007) to yield a snapshot of the wavefield including wave direction, slownesses, and radial/azimuthal amplitude gradients independently at each such station.

Toward a new kind of tomography. The possibility of deriving local dispersion relations from single-station records leads to the question of what subsurface volume one resolves and to what depth velocity perturbations can be recovered. The method of choice to answer this type of question is the adjoint method (Fichtner and Igel, 2009), with which sensitivity kernels (first Fresnel zones) can be calculated to indicate the volume in which the observable (typically travel times) is sensitive to structural perturbations. Fichtner and Igel (2009) introduced a new observable quantity – apparent shear wave velocity – which is a time-windowed ratio of the moduli of translational velocity and rotation angle. It turns out that the sensitivity near the source vanishes, leading to a new type of kernel that shows high sensitivity only in the vicinity of the receiver and in a somewhat smaller portion of that volume than the kernels of translational motions alone. This result implies that a tomographic inversion for near-receiver structures based on rotations and translations is possible and further highlights the potential of rotation measurements. Synthetic tomographic inversions are given in Bernauer et al. (2009).

Scattering properties of the crust: Partitioning of P and S waves. The partitioning of *P* and *S* energy and stabilizing the ratio between the two is an important constraint on the scattering properties of a medium. Igel et al. (2007) discovered surprisingly great rotational energy in a time window prior to teleseismic *S*, containing the *P*-coda. Detailed analysis of the signals and modeling of wave propagation through three-dimensional random media demonstrate that these signals can be explained with *P–SH* scattering in the crust with scatterers of very roughly 5-km correlation length and rms perturbation amplitude of 5% (better constrained). This result further illustrates the efficacy of rotation measurements in their own right, for example, as a filter for SH type motion, as noted by Takeo and Ito (1997).

Similar processing steps will be possible for the horizontal components of rotation and the corresponding components of translation, both to reduce the effects of tilt on the horizontal translational sensors and to extract new information. It is conceivable that the combination of these various components might lead to tight constraints on near-receiver structure, results otherwise only available from array measurements.

Conclusion

Seismology has been very successful in the *far field* because large (magnitude >6) earthquakes occur every week somewhere on Earth, and because classical elasticity

theory works very well for interpreting the recorded *translational* motions at large distances. Because of this success and limited instrumentation options, most funding for earthquake monitoring historically has gone into global and regional seismic networks using only translational seismometers. However, to improve our understandings of damaging earthquakes we must also deploy rotational and translational instruments in the *near field* of active faults where potentially damaging earthquakes (magnitude > 6.5) occur *infrequently*. For strong-motion seismology and engineering, this is a risky business because a damaging earthquake on any given fault may not take place for hundreds of years. Recording ground motions in the near field would require extensive seismic instrumentation along some well-chosen active faults and luck.

Ring laser observations at Wettzell, Germany, and at Piñon Flat, California, demonstrated consistent measurements of rotational ground motions in the *far field*. So far this success can only be demonstrated with one component of rotation. The high cost of present high-precision ring laser gyros makes widespread deployment unlikely. Less expensive and/or less sensitive alternatives are now being pursued by five academic groups (Cowsik et al., 2009; Dunn et al., 2009; Jedlička et al., 2009; Schreiber et al., 2009b; and Takamori et al., 2009). As of the end of 2009, only Taiwan has a modest program (Lee et al., 2009b) to monitor both translational and rotational ground motions from local and regional earthquakes at several permanent seismic stations, as well as by two arrays in a building and a nearby free-field site. These two arrays are designed to "capture" a repeat of the 1906 Meishan earthquake (magnitude 7.1) in the *near field* with both translational and rotational instruments (Wu et al., 2009).

Based on the developments described in the BSSA Special Issue on rotational seismology and engineering (Lee et al., 2009a), observation, analysis, and interpretations of both rotational and translational ground motions will soon play a significant role in seismology and earthquake engineering. An international working group on rotational seismology (IWGoRS) was organized in 2006 to promote investigations of rotational motions and their implications, and for sharing experience, data, software, and results in an open Web-based environment (Todorovska et al., 2008). Anyone can join IWGoRS at http://www.rotational-seismology.org, subscribe to the mailing list, and contribute to the content (publications, data, links, etc.). Rotational seismology is also of interest to physicists using Earth-based observatories for detecting Einstein's gravitational waves (e.g., Lantz et al., 2009) because they must correct for the underlying Earth motion.

SHEAR-WAVE SPLITTING: NEW GEOPHYSICS AND EARTHQUAKE STRESS-FORECASTING

Stuart Crampin
British Geological Survey, Murchison House, Edinburgh, Scotland, UK

Synonyms

Birefringence; Double refraction

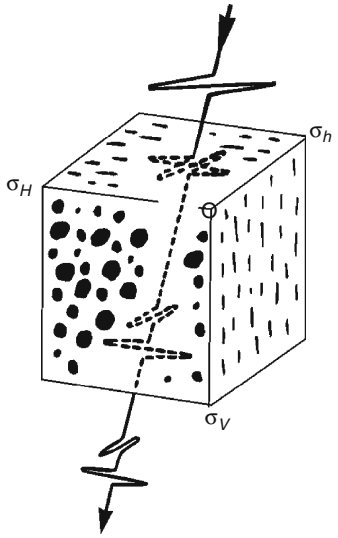
Definition

Observations of shear-wave splitting in the Earth lead to a new understanding of fluid-rock deformation: a New Geophysics, where earthquakes can be stress-forecast.
Shear-wave splitting: Seismic shear-waves propagating through effectively anisotropic solids, such as aligned crystals or aligned microcracks, split into two phases with different velocities and approximately orthogonal polarizations.
New Geophysics: A new understanding of fluid-rock deformation in distributions of stress-aligned fluid-saturated microcracks where microcracks in the crust are so closely spaced that they verge on fracturing and hence are critical-systems (also known as complex-systems). Critical-systems impose fundamentally new properties on conventional subcritical geophysics and hence are a New Geophysics.
Earthquake stress-forecasting: Shear-wave splitting above swarms of small earthquakes can be used as stress-measuring stations to monitor stress-accumulation and stress-relaxation (crack-coalescence) before earthquakes, and hence *stress-forecast* the time, magnitude, and, in some cases, fault-break of impending large earthquakes.

Introduction

Transversely polarized seismic shear-waves propagating through in situ rocks with some form of elastic anisotropy, such as aligned microcracks, split into two orthogonal polarizations which propagate with different velocities, and hence lead to shear-wave splitting. The polarizations are strictly orthogonal for phase-velocity propagation, and approximately orthogonal for group-velocity propagation. Figure 1 is a schematic illustration of shear-wave splitting in the parallel vertical stress-aligned microcracks characteristic of most rocks in the Earth's crust, once below near-surface weathering and stress-release anomalies. Originally referred to as birefringence or double refraction, shear-wave splitting was known to exist from the properties of anisotropic elastic solids (Love, 1927; Nye, 1957).

Double refraction has been observed experimentally as two orthogonally polarized shear-waves with different velocities in a stressed rock sample (Nur and Simmons, 1969). The phenomenon of shear-wave splitting was first



Shear-Wave Splitting: New Geophysics and Earthquake Stress-Forecasting, Figure 1 Schematic illustration of stress-aligned shear-wave splitting through parallel vertical microcracks (after Crampin,1994). σ_V, σ_H, and σ_h are principal axes of vertical stress, and maximum and minimum horizontal stress, respectively.

recognized (and named) in synthetic seismograms in an anisotropic crystalline Earth model (Keith and Crampin, 1977) and in distributions of parallel vertical microcracks (Crampin, 1978). Shear-wave splitting was first positively identified in the field (above swarms of small earthquakes) by Crampin et al. (1980) and in seismic reflection surveys in hydrocarbon reservoirs by Alford (1986). An earlier attempt by Gupta (1973) to demonstrate double refraction in shear-waves some 100 km from small earthquakes failed because of misunderstanding the behavior of shear-wave splitting and the shear-wave window (Crampin et al., 1981).

Although variation of velocity with direction is certainly characteristic of seismic propagation in anisotropic media, shear-wave splitting (or the generalized three-dimensional coupling of surface-wave motion), easily identifiable in particle-motion diagrams (hodograms), is highly diagnostic of some form of effective anisotropy. One of the major difficulties is that observations of shear-wave splitting are path-integration phenomena that give no indication of where the anisotropy is located along the ray path, nor its extent or strength. The only exception is in sedimentary basins where the processing seismic surveys in exploration seismology may locate the anisotropy more accurately (for example, in Angerer et al., 2002).

Note that shear-wave splitting, as in Figure 1, seems quite simple in concept which may tempt authors, such as Gupta (1973), to make unfounded assumptions which lead to incorrect and misleading conclusions. Shear-wave splitting *is* comparatively straightforward, but requires a jump in comprehension from previous isotropic experience. Two early comprehensive reviews (Crampin, 1977, 1981) outlined seismic-wave propagation in anisotropic and cracked elastic media. Crampin and Peacock (2008) recently reviewed the current understanding of shear-wave splitting and identified 17 commonly assumed fallacies in understanding shear-wave splitting that can lead to unjustified conclusions.

It is suggested that the behaviour of shear-wave splitting is now comparatively well-understood. The major new advance is that observations of shear-wave splitting indicate that the stress-aligned fluid-saturated microcracks in almost all rocks are so closely spaced that they verge on failure by fracturing (and earthquakes). Such verging on failure indicates that the distributions of microcracks are critical-systems. Critical systems are a *New Physics* (Davies, 1989), hence a *New Geophysics* that imposes a range of fundamentally new properties on the previous subcritical geophysics. This is a major advance in understanding fluid-rock deformation that has applications to many branches of solid-earth geophysics (Crampin and Peacock, 2005, 2008; Crampin, 2006).

This entry will not discuss the theory of seismic anisotropy and shear-wave splitting which is adequately outlined in Crampin (1977, 1981), Helbig (1994), Maupin and Park (2007), and elsewhere. Here, we merely outline the behaviour of shear-wave splitting in the crust that leads to the New Geophysics and stress-forecasting earthquakes.

Terminology: *references to terminology in the text will be indicated by* (qv).

APE: anisotropic poro-elasticity is a model for deformation/evolution of critical-systems of distributions of stress-aligned fluid-saturated microcracks under changing conditions (Zatsepin and Crampin, 1997; Crampin and Zatsepin, 1997).

Aspect-ratio: Crack thickness over crack diameter.

Band-1 directions: Band-1 ray-path directions are the solid angle between 15° and 45° either side of the crack planes in a distribution of vertical parallel microcracks (Crampin, 1999). APE shows that the effect of increasing (or decreasing) stress is to increase (or decrease) the average time-delays in Band-1 directions.

Band-2 directions: Band-2 ray-path directions are in the solid angle ±15° to the crack planes (Crampin, 1999). Band-2 directions are sensitive to crack density, but APE shows that crack density does not vary consistently for small changes of stress.

Complex-systems: see critical-systems.

Crack density: Dimensionless crack density, *CD,* is specified by $CD = N a^3$ where N is number of cracks of radius a per unit cube.

Critical-systems: Critical-systems (also known as complex-systems, Davies, 1989) are complex heterogeneous interactive systems which verge on fracture-criticality and failure. Extremely common in a huge range of different phenomena, critical-systems impose fundamentally new properties on the previously

subcritical physics and subcritical solid-earth geophysics, and hence are a New Geophysics (Crampin, 2006).

Earthquake prediction: The prediction of time, magnitude, and location of earthquakes by conventional subcritical techniques, but not using shear-wave splitting which implies critical techniques.

Earthquake stress-forecasting: Using shear-wave splitting to monitor stress-accumulation and stress-relaxation in the surrounding rock mass that allows the time and magnitude of earthquakes to be stress-forecast, where other precursory phenomena may indicate the fault-break.

EDA: Extensive-Dilatancy Anisotropy is the name given to the distributions of fluid-saturated microcracks pervading most rocks in the crust (Crampin et al., 1984). EDA-cracks, in ostensibly unfractured rocks, are observed to have crack densities between ~0.015 and ~0.045: that is shear-wave velocity anisotropy of ~1.5 – ~4.5% (Crampin, 1994). This comparatively small percentage of velocity anisotropy has massive implications for a huge range of phenomena and leads to the New Geophysics.

Fracture-criticality: The value of crack density, ~0.055, at which stress-aligned microcracks are so closely spaced they verge on fracturing, and hence are critical-systems (qv) (Crampin, 1994, 1999; Crampin and Zatsepin, 1997).

New Geophysics: Shear-wave splitting indicates that microcracks in the crust are so closely spaced they verge on fracture-criticality and fracturing, and hence are critical-systems. Critical-systems are a *New Physics* (Davies, 1989), hence a *New Geophysics*, that imposes a range of fundamentally new properties on conventional subcritical geophysics (Crampin, 2006). Most of these properties have been observed in the field (Crampin and Peacock, 2005, 2008).

PTL-anisotropy: Distributions of horizontal Periodic Thin Layers lead to a form of anisotropy (hexagonal symmetry, commonly known as transverse isotropy, with a vertical axis of symmetry) that is common in sedimentary basins, including many hydrocarbon reservoirs (Wild and Crampin, 1991). Shear-wave velocity anisotropy in PTL-anisotropy may exceed 30% and would be likely to generate cusps in shear-wave velocity sheets. Such cusps have been observed (and modeled) in hydrocarbon reservoirs in the field (Slater et al., 1993).

Seismic anisotropy: Seismic anisotropy describes an elastic solid; these properties vary with direction as in aligned crystals or solids pervaded by aligned microcracks.

Seismic isotropy: Isotropy describes an elastic solid which has the same elastic properties in all directions.

Stress-forecasting earthquakes: see Shear-Wave Splitting: New Geophysics and Earthquake Stress-Forecasting.

TIH- (or HTI-) anisotropy: Transverse isotropy with a horizontal axis of cylindrical symmetry: the typical symmetry of EDA-cracks. Note that although transverse isotropy is specified by five elastic constants, distributions of vertical parallel EDA-cracks are specified by only three: crack density, crack aspect-ratio, and crack strike.

TIV- (or VTI-) anisotropy: Transverse isotropy with a vertical axis of cylindrical symmetry: the typical symmetry of PTL-anisotropy. In TIV-anisotropy, propagation in the horizontal plane is isotropic with no variation with azimuth.

Time-delay: The time-delay between the arrivals of the two split shear-wave phases in seismic anisotropy. Time-delays above earthquakes are frequently normalized by path length to ms/km.

Transverse isotropy: Transverse isotropy (strictly hexagonal symmetry) is the anisotropic symmetry system with five elastic constants, and is isotropic in directions perpendicular to an axis of cylindrical rotational symmetry.

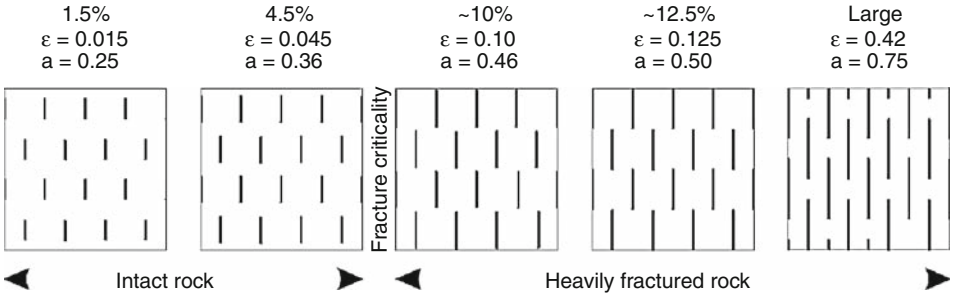
90°-flips in shear-wave polarisations: Abrupt 90° changes in shear-wave polarisations (90°-flips) have been observed and modeled along shear-wave ray paths passing near to point-singularities (see below) (Bush and Crampin, 1991; Crampin, 1991). 90°-flips can also be caused by critically high pore-fluid pressures locally re-orienting stress-aligned fluid-saturated EDA-cracks, both in fluid-injection in critically pressurized hydrocarbon reservoirs (Angerer et al., 2002) and adjacent to seismically-active (critically-pressurized) faults (Crampin et al., 2002).

Fundamental features of shear-wave splitting in the crust

Observations of shear-wave splitting at a horizontal free surface typically display stress-aligned parallel polarisations. Since only transverse isotropy with a horizontal axis of symmetry (TIH-anisotropy) has such parallelism, and only parallel vertical cracks have such symmetry, the splitting is necessarily caused by stress-aligned EDA-microcracks. Microcracks is conformed as temporal changes in time-delays are observed, in fluid-injections (Angerer et al., 2002) and before earthquakes (Crampin and Peacock, 2008). Only microcracks have sufficient compliance to allow such changes.

Observations of azimuthally varying stress-aligned shear-wave splitting, in almost all igneous, metamorphic, and sedimentary rocks in the crust, indicate a minimum of ~1.5% shear-wave velocity anisotropy and a maximum in ostensibly unfractured rock of ~4.5% (Crampin, 1994, 1999; Crampin and Peacock, 2008). Since crack density can be written as a dimensionless quantity $CD = N\,a^3$, where N is the number of cracks of radius a per unit cube and if Poisson's ratio is 0.25, $CD \approx 1/100$ of the percentage of shear-wave velocity anisotropy, observed shear-wave splitting can be imaged as uniform distributions of parallel vertical dimensionless cracks in Figure 2 (Crampin, 1994; Crampin and Peacock, 2008).

The evolution of an initially random distribution of stress-aligned fluid-saturated microcracks under changing



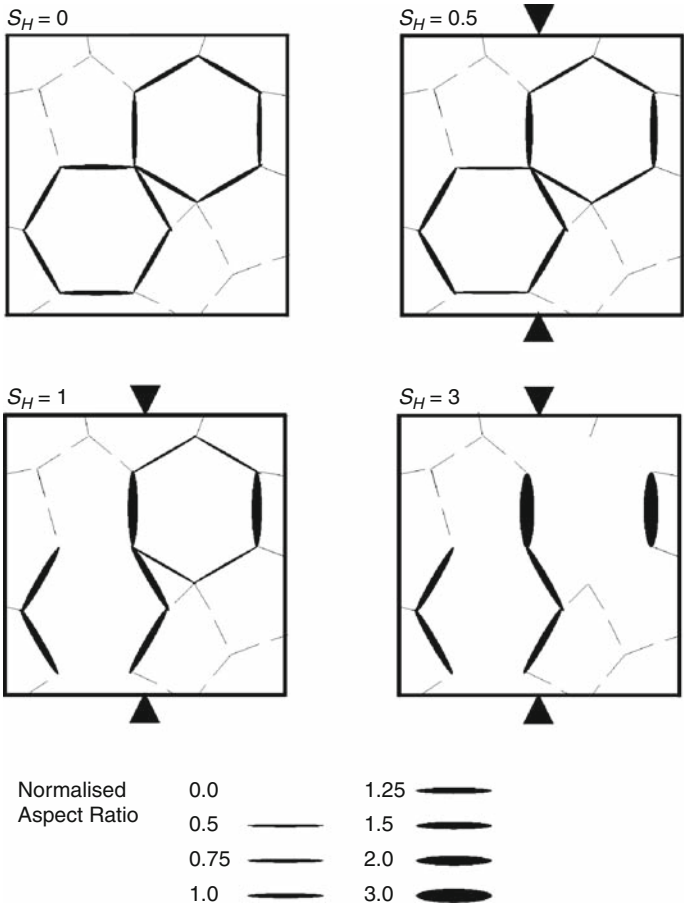
Shear-Wave Splitting: New Geophysics and Earthquake Stress-Forecasting, Figure 2 Schematic illustration of dimensionless three-dimensional crack distributions in in situ rocks for a range of percentages shear-wave velocity anisotropy, where ε is crack density and *a* is normalized crack radius (after Crampin, 1994). Fracture-criticality is at ~5.5% shear-wave velocity anisotropy (Crampin and Zatsepin, 1997).

conditions can be modeled by the equations of anisotropic poro-elasticity, APE, (Crampin and Zatsepin, 1997). Figure 3 gives a schematic illustration of APE-deformation. The effect of increasing (or decreasing) stress is to increase (or decrease) the average aspect-ratio for cracks parallel to the increasing stress. APE-deformation is almost without parameters and yet matches a huge range of phenomena in exploration and earthquake seismology (Crampin and Peacock, 2008), where the general applicability is because microcracks are so closely spaced that they are critical-systems and lead to the New Geophysics. Note that APE-modeling, because of the universality of critical-systems, is almost without parameters, and yet is widely applicable.

Classes of anisotropic symmetry and shear-wave splitting

Shear-wave splitting has characteristic patterns of polarizations and velocities in three-dimensional propagation depending on the class of anisotropic symmetry (Nye, 1957; Crampin, 1977; Crampin and Kirkwood, 1981). Elastic constants allow eight classes of anisotropic symmetry (including isotropic symmetry which describes a material with two elastic constants, usually written λ and μ, and has identical elastic properties in all directions of propagation). It is the characteristic 3D patterns of planes of mirror symmetry which define the classes of anisotropic symmetry. Four types of anisotropic symmetry are commonly found in the Earth (where the horizontal plane is typically a plane of mirror symmetry):

1. *Orthorhombic symmetry* with nine independent elastic constants has three mutually-orthogonal planes of mirror symmetry. Crystalline olivine, a possible upper mantle constituent has orthorhombic symmetry, where shear-waves split in 3D patterns of polarizations. In addition, simple combinations of EDA- and PTL-anisotropy also have orthorhombic symmetry (Wild and Crampin, 1991). The effects of combinations of EDA- and PTL-anisotropies have been observed in hydrocarbon reservoirs (Bush and Crampin, 1991).
2. *Transverse isotropy with a vertical axis of cylindrical symmetry* commonly referred to as TIV-anisotropy. In TIV, shear-waves split strictly into phases oscillating in the vertical plane (*SV* waves) and phases oscillating horizontally (*SH* waves). There is no azimuthal variation. TIV is the effective anisotropic symmetry of finely divided horizontal layers found in many hydrocarbon reservoirs. It is also the symmetry of small horizontal platelets in shales. Thomsen (1986) derived three highly important approximations (the Thomsen parameters) for the behaviour of seismic waves in TIV media which are directly analogous to parameters measured in reflection surveys. Thomsen parameters are widely used and highly effective in interpreting exploration surveys. Thomsen parameters cannot be used to describe *azimuthally varying* anisotropy, except in isolated directions of sagittal symmetry.
3. *Transverse isotropy with a horizontal axis of cylindrical symmetry* commonly referred to as TIH-anisotropy. TIH is commonly observed above small earthquakes where the faster split shear-wave is polarized parallel to the direction of maximum horizontal stress. Only TIH-anisotropy can produce such parallelism. Only fluid-saturated microcracks are common to the huge variety of geological materials where TIH is observed, and since temporal changes before earthquakes are observed in the field, only fluid-saturated microcracks have sufficient compliance to display temporal changes for small changes in parameters. Consequently, the observed parallelism of fast polarizations directly confirms stress-aligned microcracks throughout almost all rocks in the crust (Crampin and Peacock, 2008).
4. *Monoclinic symmetry* has 13 elastic constants and is the symmetry of two (or more) sets of intersecting non-orthogonal vertical parallel EDA-cracks. Shear-wave splitting in such monoclinic symmetry has been observed and modeled in the field (Liu et al., 1993a). If two intersecting sets of vertical EDA-cracks are orthogonal, the symmetry is orthorhombic. Liu et al. (1993b) display the theoretical effects of intersecting sets of parallel vertical EDA-cracks for a range of parameters and a range of angles of intersection.



Shear-Wave Splitting: New Geophysics and Earthquake Stress-Forecasting, Figure 3 Schematic illustration of anisotropic poro-elastic (APE) modelling of the effects of increasing stress on aspect-ratios of (6% porosity) microcracks, where aspect-ratios are given below (Crampin and Zatsepin, 1995; Crampin, 2006).

Cusps

In strong shear-wave velocity anisotropy, the direction of group-velocity (energy) propagation of the faster of the two split shear-wave may deviate so strongly that they overlap themselves and cause large amplitude cusps. Cusps have been observed and modeled in hydrocarbon reservoirs (Slater et al., 1993). However, the commonest form of cusps that occur in all anisotropic symmetry systems are the cuspoidal lids, fins, and ridges associated with point- and line-singularities in group-velocity shear-wave surfaces (Crampin, 1991; Wild and Crampin, 1991).

Shear-wave window

Shear-waves with *SV* orientations incident on the free surface of an isotropic medium are identical to the incoming shear-wave (but double the amplitude) *only within* the shear-wave window. Outside the window, *S*-wave energy is lost to *SV*-to-*P* conversions so that *SV* waves are heavily distorted and even the arrival of the direct *S* wave may be unreadable. The edge of the shear-wave window is outlined by the critical angle of incidence, $i_c = \sin^{-1}$ (Vs/Vp), where Vp and Vs are the isotropic *P*-wave and *S*-wave velocities, and i_c is the critical angle for *S*-to-*P* conversions (Evans, 1984; Booth and Crampin, 1985). The conical solid angle of the shear-wave window may be considered as *above* small earthquakes or *below* surface recorders.

Other features of the shear-wave window:

1. The critical angle of incidence i_c is $\sim 35^\circ$ for a uniform isotropic medium with a Poisson's ratio of 0.25, where Lamé parameters $\lambda = \mu$.
2. Because of near-surface low-velocity layers, ray paths tend to curve upwards as they approach the free surface, so that the effective shear-wave window is often out to straight-line source-to-receiver incidence of 45° or greater.
3. Topographic irregularities may seriously distort the shear-wave window and may cause *S*-to-*P* conversions (the Local *SP*-waves) both inside and outside the theoretical shear-wave window. Local *SP*-waves are frequently observed in the field as large single-sided pulses on the *SV*-component, and may be mistakenly interpreted as anomalous shear-wave splitting (Crampin, 1990).

4. The shear-wave window only refers to *SV*-propagation. No energy is lost by *SH* waves at any angle of incidence on a plane horizontal free surface. Consequently, only the *SV*-component of any incident-split shear-wave is affected by the shear-wave window.
5. In anisotropic propagation, the shear-wave window may severely disturb shear-wave splitting.

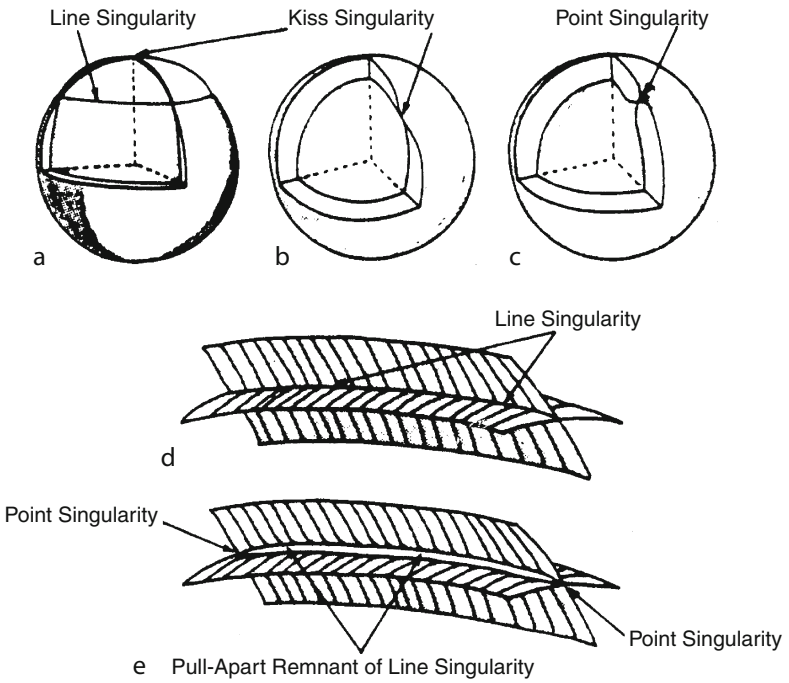
These various anomalies mean that shear-wave splitting recorded at a free surface needs to be interpreted with caution (Crampin and Peacock, 2008).

Shear-wave singularities

The three body waves in anisotropic solids trace out three velocity surfaces for propagation in three-dimensional propagation: a *P* wave; and two orthogonally-polarized shear-wave surfaces. The phase-velocity shear-wave surfaces from a point of propagation necessarily touch and are continuous in a variety of singularities in three-dimensional patterns of direction characteristic of the anisotropic symmetry class (Crampin and Yedlin, 1981; Crampin and Kirkwood, 1981; Wild and Crampin, 1991). The only way for energy of a split shear-wave arrival to pass from one shear-wave surface to the other is along directions passing directly through a singularity.

Figure 4 shows the three types of singularity in *phase-velocity surfaces*:

1. *Kiss-singularities* where two shear-wave surfaces touch tangentially (Figure 4a, 4b). Kiss-singularities occur in directions of principal crystallographic axes and are restricted to cubic, tetragonal anisotropic symmetry, and along the cylindrical symmetry direction of transversely isotropic symmetry. Kiss-singularities can also occur in orthorhombic and monoclinic anisotropic symmetry when two shear-wave surfaces happen to touch serendipitously.
2. *Point-singularities* (sometimes called conical points) where the two shear-wave surfaces touch at the vertices of convex and concave cones (Figure 4c). Shear-waves in all classes of anisotropic symmetry possess point-singularities except transverse isotropy (hexagonal symmetry), which only has kiss- and line-singularities (Figure 4a). Point-singularities are particularly numerous in combinations of PTL- and EDA-anisotropy, where thin layers are pervaded by vertical microcracks (Wild and Crampin, 1991).
3. *Line- or intersection-singularities* occur only in transverse isotropy where the two shear-wave phase-velocity surfaces intersect each other in circular line-(intersection-) singularities about the symmetry axis (Figure 4a, 4d). In even marginally disturbed transverse isotropy, there are dramatic changes. Since both PTL- and EDA-anisotropy have transversely isotropy symmetry with line-singularities, Wild and Crampin



Shear-Wave Splitting: New Geophysics and Earthquake Stress-Forecasting, Figure 4 Schematic illustration of the intersection of two shear-wave phase-velocity surfaces showing topography near: (**a**) line-singularity or intersection-singularity (with kiss-singularity); (**b**) kiss-singularity; and (**c**) point-singularity (after Crampin and Yedlin, 1981). (**d**) A segment of a representation of a line-singularity, and (**e**) a *pull-apart remnant of a line-singularity* when the transverse isotropy symmetry is disturbed (after Wild and Crampin, 1991).

(1991) show that the phase-velocity representations of combinations of PTL and EDA have *pull-apart remnants of line-singularities*. The intersections of the inner and outer shear-wave surfaces separate, and 'pinch' together, in varying degrees of tightness, between a string of point-singularities (Figure 4e).

Singularities in *group-velocity surfaces* have a variety of behaviour:

1. *Kiss-singularities* have simple group-velocity representation, the shear-wave surfaces again touch tangentially.
2. *Point-singularities* in group-velocity surfaces: the faster shear-wave surfaces transform into open almost circular "holes", whereas the slower surfaces transform into flat cuspoidal "lids" which exactly fit into the open holes. The effects of such point-singularities have been observed and modeled in a hydrocarbon reservoir the field (Bush and Crampin, 1991). Crampin (1991) modeled synthetic seismograms for ray path directions passing close to point-singularities. The effects can be dramatic with possibly great amplification or attenuation of amplitudes and abrupt 90° changes in shear-wave polarisations (90°-flips) either side of point-singularities.
3. *Line- or intersection-singularities*. In undisturbed transverse isotropy, the group-velocity representations of line-singularities merely intersect with each sheet showing no evidence of intersection, as in the phase-velocity representation in Figure 4d. However, group-velocity representations of pull-apart remnants of line-singularities in disturbed transverse isotropy typically display thin cuspoidal "fins", "ridges", and "lids" of extraordinary complexity (and beauty) (Wild and Crampin, 1991).

There are two conclusions. The effects of pull-apart remnants of line-singularities are sensitive to very small differences in direction of propagation or microcrack geometry, say. The subtleties of shear-wave propagation near the extensive pull-apart remnants of line-singularities are likely to be the reason for many of the complications frequently observed in field records of shear-waves in sedimentary basins. If correctly interpreted, such features can provide crucial information particularly about the relative proportions of PTL- and EDA-anisotropy (Bush and Crampin, 1991).

Sources of shear-wave splitting

There are three common areas of investigation into shear-wave splitting (and seismic anisotropy).

1. *Shear-wave splitting in the upper mantle*, which is typically assumed to be caused by strain-aligned crystals such as olivine, and is used to demonstrate directions of stress and flow in plate tectonics (reviewed by Savage, 1999).
2. *Shear-wave splitting in hydrocarbon reservoirs* in seismic exploration in industrial seismology, where initially "anisotropy is a nuisance" (Helbig, 1994) because many well-established processing procedures assume isotropic propagation and are no longer valid if the rocks are anisotropic. More recently, however, azimuthally varying shear-wave splitting in TIH-anisotropy is being actively used to determine fracture orientations and improve fluid-flow for hydrocarbon recovery (reviewed by Helbig and Thomsen, 2005).
3. *Shear-wave splitting above small earthquakes* initially stimulated development of the theory (reviewed by Crampin, 1981) and observation (Crampin et al., 1980; Alford, 1986), and is now demonstrating the *New Geophysics* of a crack-critical crust (Crampin, 2006), where time-delays directly monitor low-level fluid-rock deformation at levels of deformation well-below those at which fracturing takes place (Crampin and Zatsepin, 1997).

Remarkably, there has been very little interaction between these three areas of investigation. Each has developed largely independently where papers in one area seldom cite other areas of research. Shear-wave splitting in these three areas of investigation will be discussed separately.

Shear-wave splitting in the upper mantle

Seismic anisotropy in the mantle was first recognized from the incompatibility of Rayleigh and Love surface-wave inversions (Anderson, 1961) and from the velocity anisotropy of horizontally propagating *Pn*-waves in oceanic basins (Hess, 1964; Raitt et al., 1969). Another anisotropic surface-wave phenomenon directly analogous to shear-wave splitting of body waves is the coupling of surface-wave motion of Raleigh and Love modes into Generalized modes varying in three-dimensions (Crampin and King, 1977). Just as shear-wave splitting is highly diagnostic of some form of seismic anisotropy, coupled surface-wave motion is highly diagnostic of anisotropy in the mantle. The pronounced coupling between Second Mode Rayleigh and Second Mode Love waves across Eurasia could be caused by as little as 4 km of 4% shear-wave velocity anisotropy at the top of the upper mantle (Crampin and King, 1977).

Shear-wave splitting of body waves in the mantle only became observable with advances in digital instrumentation. The first reports of such shear-wave splitting were by Ando et al. (1980) who reported time-delays of ~1s on 2s-period shear-waves propagating vertically. This was attributed to 2–4% shear-wave velocity anisotropy in propagation through a magma reservoir, 100–200 km in depth beneath a volcanic area in Japan above the subducting Pacific Plate.

Since that time, shear-wave splitting has been observed extensively in the uppermost 200 km of the mantle and in the D region (Silver and Chan, 1988, 1991), reviewed by Savage (1999), and Long and Silver (2009) and others. These observations are principally of shear-wave splitting in *SKS*-phases, which are frequently large amplitude,

where the *P*-S conversion on exiting from the core provides a known *SV* orientation at the start the final shear-wave path to the surface. Frequencies are typically 0.5–0.25 Hz leading to 2–4% shear-wave velocity anisotropy, similar to the crack-induced shear-wave velocity anisotropy in the crust.

The cause of the shear-wave splitting in the mantle is not wholly resolved. The most frequently cited cause is referred as lattice-preferred orientation (LPO) of the crystallographic axes of elastically anisotropic crystals, such as olivine (Karato and Wu, 1993) or orthopyroxene (Ben-Ismail et al., 2001). These crystals are assumed to be aligned by convective flow where the presence of water, induced by bending of subducting slabs (Faccenda et al., 2009), say, could have major effects on crystal orientations and shear-wave splitting (Karato and Jung, 1998; Katayama et al., 2005).

However, the similarities in the degree of shear-wave splitting and the polarization to splitting in the crust which is certainly caused by EDA-cracks suggests the alternative source of anisotropy of fluid-saturated stress-aligned cracks. There is water in much of the upper mantle. Water lowers the melting point of rock, and when crystalline rock first begins to melt, it melts along grain boundaries. Thus the anisotropy in the mantle could be caused by aligned cracks of films of liquid melt (Crampin, 2003).

Shear-wave splitting in hydrocarbon reservoirs

The effective TIV-anisotropy of finely stratified rocks was demonstrated by Postma (1955) and others, where double refraction (shear-wave splitting) only has *SV*- and *SH*-polarisations. Shear-wave splitting of TIV-anisotropy was not much investigated at that time since the predominant single-component vertical seismometers only recorded *SV* waves.

Azimuthally varying shear-wave splitting in hydrocarbon reservoirs burst onto the seismic exploration industry in a series of some dozen papers in two sessions at the 1986 SEG symposium in Houston. Alford (1986) rotated ("Alford rotations") the polarisations of reflection surveys recorded on two-component horizontal geophones from two-component horizontal vibrators, and showed that seismic shear-wave reflection sections displayed coherent behavior only when both source and receivers were rotated into the preferred (anisotropic) polarizations. These papers stimulated great activity in exploring seismics in order to obtain preferred directions of fluid-flow by locating fracture orientations (reviewed by Helbig and Thomsen, 2005). This interest in anisotropy still continues today but is frequently investigated by wide-angle and other *P*-wave surveys because of the expense of three-component shear-wave surveys including instrumentation as well as the tripling of the quantity of data to be recorded and processed.

Note that azimuthally varying shear-wave splitting in hydrocarbon reservoirs has been typically interpreted by the hydrocarbon industry as being caused by *aligned fractures*, where dimensions of the fractures are unspecified but are expected to be large enough to lead to improved hydrocarbon recovery. In contrast, Crampin and Peacock (2008) suggest that the remarkable compliance of shear-wave splitting to low-level deformation necessarily means that the splitting is caused by stress-aligned fluid-saturated *microcracks*. Since in many circumstances microcracks are parallel to macro-fractures, the difference in interpretation is often immaterial. However, the recent demonstration, both in theory (Chapman, 2003) and observations (Maultzsch et al., 2003), that anisotropy is frequency-dependent and varies with the dimensions of microcracks may change this interpretation.

Shear-wave splitting above small earthquakes

Shear-wave splitting was first positively identified in the crust above a swarm of small earthquakes near the North Anatolian Fault in Turkey in the Turkish Dilatancy Project (TDP1) experiment, (Crampin et al., 1980). This experiment was designed to search for the microcrack-induced shear-wave splitting suggested by Crampin (1978). Similar observations have now been observed above earthquakes worldwide (reviewed by Crampin and Peacock, 2008). However observations above earthquakes need to be recorded by three-component seismic networks within the shear-wave window of the earthquakes. This is a severe restriction as swarms of small earthquakes are scarce and intermittent, and seldom observed by seismic networks. Nevertheless, such swarms of small earthquakes have been used as 'stress-measuring stations' to monitor the effects of stress changes before impending earthquakes (Crampin and Peacock, 2008).

Iceland is an optimum location for studying shear-wave splitting. It is an offset of the Mid-Atlantic Ridge where, uniquely, (two) transform faults run onshore. These transform faults have persistent swarm activity monitored by a state-of-the-art seismic network (Stefánsson et al., 1993) available over the Internet (Volti and Crampin, 2003).

The APE model of microcrack deformation (Crampin and Zatsepin, 1997) shows that increases of stress increase crack aspect-ratios (crack thicknesses), and increases of aspect-ratio can be recognized by increases of average time-delays in Band-1 directions of the shear-wave window (Crampin, 1999), and have been used to stress-forecast earthquakes (Crampin et al., 1999, 2008).

The new geophysics

The shear-wave velocity anisotropy observed in the crust of the Earth indicates that the distributions of stress-aligned fluid-saturated microcracks (EDA-cracks) are so closely spaced they verge on fracturing and hence are critical-systems (Figure 2). Such critical microcracks are the most compliant elements of in situ rock, and indicate profound differences from conventional subcritical solid-earth geophysics. Critical systems are a *New Physics* (Davies, 1989), hence a *New Geophysics*, which imposes

a range of fundamentally new properties on conventional subcritical physics (Crampin and Peacock, 2005; Crampin, 2006). All complex heterogeneous interactive systems are critical-systems, and they are extremely common: the weather, clustering of traffic on roads, the life-cycle of fruit flies, and a huge range of physical phenomena from stellar radiation to quantum mechanics. Since the Earth is an archetypal complex heterogeneous interactive system, it is necessarily expected to be a critical system.

The new geophysical properties include:

1. *Monitorability* – effects of criticality (on the geometry of EDA-cracks) can be monitored within the interior of the crust by shear-wave splitting (Crampin, 1994, 2006).
2. *Calculability* – the evolution of microcrack geometry can be calculated by APE (Crampin and Zatsepin, 1997; Crampin, 1999; Angerer et al., 2002).
3. *Predictability* – if changing conditions are known, the effects on crack geometry can be predicted (as in Angerer et al., 2002).
4. *Controllability* – if the intended effects of some operation (fluid-injection, say) are desired (the opening of specific fractures for fluid-flow, say), the effects can be calculated by APE, and the effects can be controlled by feedback by analyzing shear-wave splitting. Crack aspect-ratios, as in Angerer et al. (2002) where the effects of fluid-injections were calculated, could be controlled by feedback.
5. *Universality* – the changes in critical-systems are pervasive over all available space where appropriate conditions are maintained. The coincidence of observations of 1.5–4.5% shear-wave velocity anisotropy with similar stress-oriented polarizations in all types of rock regardless of porosity, rock types, or geology (Crampin, 1994; Crampin and Peacock, 2005, 2008) is an example of universality in the crack-critical Earth, that is difficult to explain in a conventional subcritical Earth.
6. *Sensitivity* – extreme (butterfly wings) sensitivity to initial conditions. A prime example of such sensitivity is the SMSITES experiment in Iceland where distinctive variations in *P*- and shear-wave travel-time variations were observed at 70 km from swarm activity with an energy equivalent to a $M = 3.5$ earthquake at 70 km distance. A $M = 3.5$ earthquake is small, so these effects are observed at hundreds of times the likely source diameter in a conventional subcritical earth and are a clear demonstration of critical-system sensitivity (Crampin et al., 2003).

Stress-forecasting earthquakes

Shear-wave splitting and the New Geophysics lead to a new understanding of tectonic deformation before earthquakes. Initially, tectonic stress accumulates by interactions at plate boundaries leading to deformation of EDA-cracks which can be monitored by shear-wave splitting. Such stress-accumulations are not initially associated with any particular source-zone and may be observable at great distances from any potential source. As the stress-field approaches, fracture-criticality weaknesses are identified and microcracks begin to coalesce onto the potential slip-plane. There is stress-relaxation, and eventually the impending earthquake occurs (Gao and Crampin, 2004). Logarithms of the durations of increases (stress-accumulation) and decreases (crack-coalescence) are each separately proportional (self-similar) to impending earthquake magnitudes (Crampin et al., 2008), similar to the linearity of the Gutenberg–Richter relationship. Consequently, shear-waves above swarms of small earthquakes can be used as "stress-measuring stations" to monitor such stress-accumulation and stress-relaxation before impending earthquakes.

Peacock et al. (1988) were the first to recognize such changes in shear-wave time-delays (now identified with stress-accumulation), using seismic station KNW as a stress- measuring station, before a $M = 6$ earthquake near the San Andreas Fault in California. A few other examples were found worldwide (reviewed by Crampin and Peacock, 2008), but the significant advances came when persistent seismicity in Iceland become available for analysis online. Volti and Crampin (2003) displayed increases of Band-1 time-delays before five earthquakes in Iceland monitoring stress-accumulation. The time, magnitude, and fault-plane of a fifth earthquake were successfully stress-forecast 3 days before it occurred in a comparatively tight time/magnitude window (Crampin et al., 1999, 2008).

Crack-coalescence (stress-relaxation), before the impending earthquake occurs when the increasing stress-accumulation abruptly begin to decrease, was first recognized by Gao and Crampin (2004). Since then, stress-accumulation has been recognized before 15 earthquakes worldwide, of which nine had sufficient seismicity beneath stress-measuring stations to also display crack-coalescence (Crampin and Peacock, 2008).

Unfortunately, swarms of small earthquakes are far too scarce and irregular to be used as stress-measuring stations for reliable routine stress-forecasting. Reliable stress-forecasting requires three 1–1.5 km-deep borehole Stress-Monitoring Sites (SMSs), where a Downhole-Orbital Vibrator source (DOV) (Leary and Walter, 2005) radiate shear-waves to borehole geophones in Band-1 directions. A prototype SMS in non-optimal source-to-geophone geometry between existing boreholes in Iceland recorded exceptional sensitivity to low-level seismicity equivalent to a $M = 3.5$ earthquake at 70 km-distance (Crampin et al., 2003) demonstrating that SMSs have sufficient sensitivity to stress-forecast times and magnitudes of $M = 5$ earthquakes up to 1,000 km from impending source zones (Crampin and Gao, 2010).

Summary

Shear-wave splitting in the Earth reveals a fundamentally new understanding of fluid-rock deformation, where

APE-modeling shows that modifications to shear-wave splitting directly monitor stress-induced modifications to microcrack geometry. Since if the changing conditions can be specified, the deformation can be calculated and predicted by APE; this is a substantial advance, a New Geophysics, on conventional subcritical solid-earth geophysics. Changes in microcrack geometry can be monitored, calculated, predicted, and in some circumstances potentially controlled. There is extreme sensitivity to initial conditions, and universality, so that effects are widely and uniformly distributed.

The New Geophysics allows stress-accumulation and stress-relaxation (crack-coalescence) before earthquakes to be recognized and impending large earthquakes stress-forecast. There are many important implications and applications. In particular, any solid-earth application that cannot accommodate compliant stress-aligned fluid-saturated EDA-microcracks pervading most in situ rocks is in error and may lead to serious misunderstandings. New Geophysics leading to monitorability; calculability; predictability; potential controllability; universality; extreme sensitivity; and earthquake stress-forecasting, is likely to be the most fundamental advance in solid-earth geoscience for many decades.

SINGLE AND MULTICHANNEL SEISMICS

Tamás Tóth
Geomega Limited, Budapest, Hungary

Definition

Seismics or Seismic survey. The method of imaging the subsurface with reflected and refracted seismic waves, which are generated by controlled sources and sensed by seismic detectors.

Single-channel seismics. Seismic survey using one detector (channel) for sensing returning seismic waves.

Multichannel seismics. Seismic survey using multiple detectors (channels) at different locations for sensing returning seismic waves generated by each source points.

Introduction

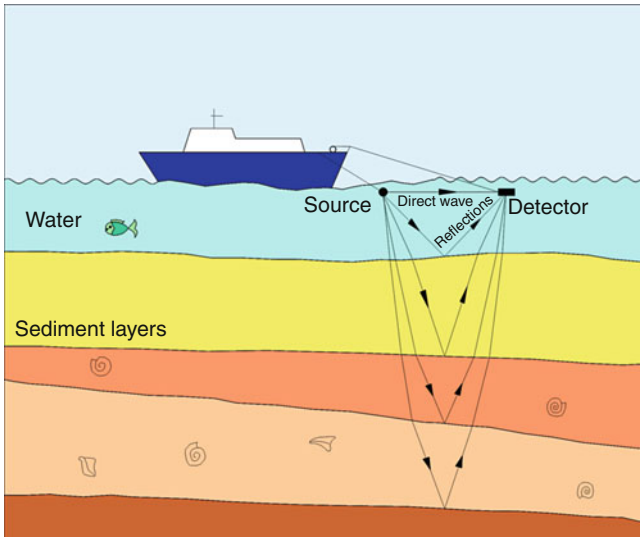
Reflection and refraction seismology has been applied for imaging the subsurface since the 1920s (Karcher, 1987 and Keppner, 1991) and is still one of the most powerful methods of exploration geophysics. Applied technology has evolved considerably over the decades, but the principles have not changed. Imaging is performed by elastic waves generated by controlled sources, such as explosive, vibroseis, air gun, sparker, boomer, or similar sources. Generated waves propagate through the subsurface layers and part of them get reflected or refracted back from layer boundaries. These returning waves are sensed on the surface by seismic detectors, geophones on land, and hydrophones in water.

In case of single-channel seismic recording, elastic waves generated by each shot are recorded by one single detector or a group of detectors. On the other hand, multichannel seismic recording utilizes multiple detectors or groups of detectors located at different positions for recording the wavefield generated by each shot. Multichannel seismics provide several advantages over single-channel seismics; however, simplicity of the recording equipment and high resolution of the recorded seismic profiles make single-channel seismics still a powerful and cost-effective tool for shallow investigations.

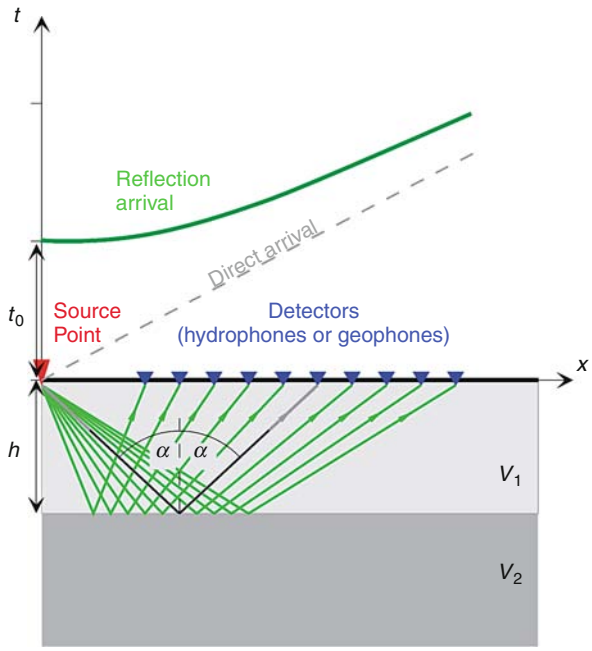
Single-channel seismics

Simplest possible configuration for a seismic reflection survey is single-channel recording. Reflected energy from each shot is sensed by only one receiver or one group of receivers, normally positioned at a constant distance from the source (see Figure 1).

The source–receiver pair is moved, and each shot generates one seismic trace for the profile. In case of single-channel recording, each shot provides information from one subsurface location only, therefore it is critical to have a low cost and high repetition rate source. Shot generation is more labor intensive on land; hence, single-channel recording is hardly used for onshore surveys. Situation is



Single and Multichannel Seismics, Figure 1 During single-channel recording, seismic energy generated by each source point images one subsurface point of each layer boundary, generating one seismic trace.



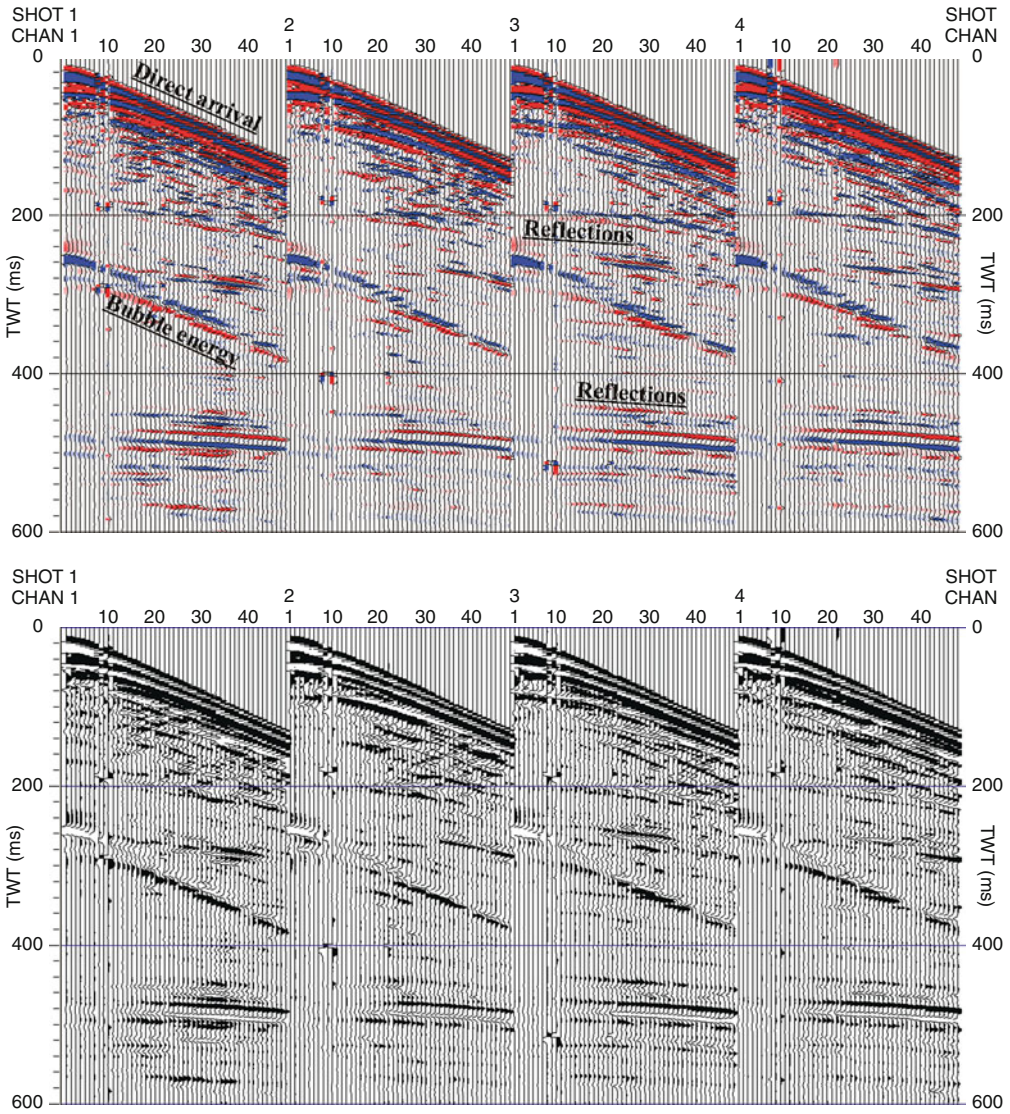
Single and Multichannel Seismics, Figure 2 Reflected energy generated by each source point is recorded by multiple detectors. Each detector images a different subsurface point. Reflection at each subsurface point follows Snell's law. Angles of incidence and reflection (marked α) are equal; hence, distance between the subsurface reflection points is half of the distance between the detectors. Upper part of the Figure shows the theoretical hyperbola of the reflection arrivals and the direct arrival between source point and detectors.

more favorable for offshore surveys, as easy-to-operate sources with high repeatability are available and make single-channel recording an attractive alternative. This is especially true, when relatively shallow "penetration" is sufficient, but *high resolution* is needed.

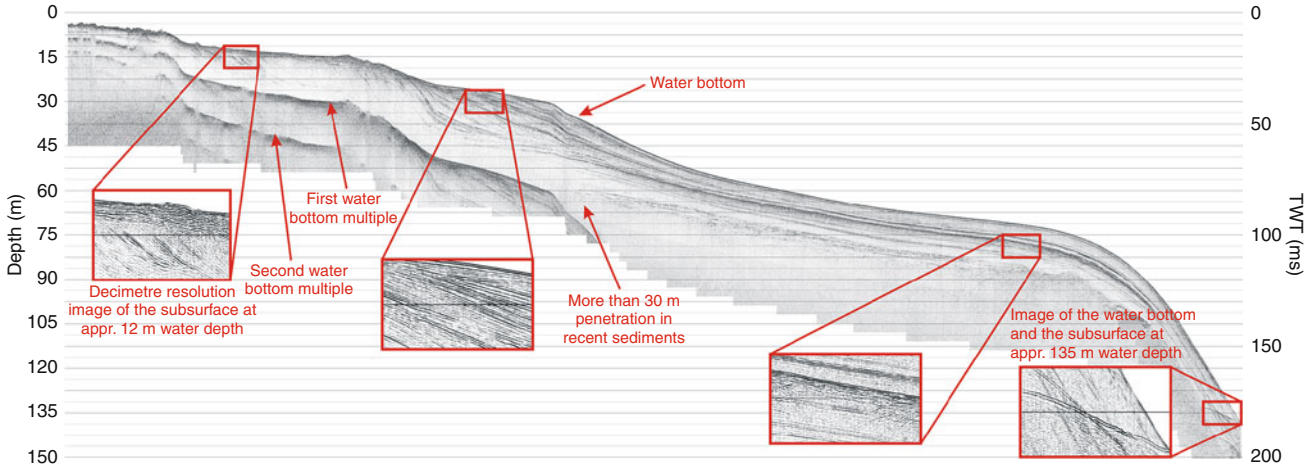
Penetration, on the one hand, strongly depends on the seismic source used; on the other hand, it is also determined by the physical properties of the subsurface strata. Seismic *resolution* is a function of the frequency content of the source used. It is important to note that penetration and resolution are not independent parameters. Higher frequency sources ensure maximum resolution, but as high frequencies attenuate quicker, they provide less penetration. Highest frequency sources are Compressed High Intensity Radar Pulse *(CHIRP)* and boomers, while sparkers and small volume air gun sources with their higher energy provide deeper penetration, but generally lower resolution.

Multichannel seismics

Several advantages are gained by recording the reflected energy of each shot by multiple detectors, which is called multichannel seismic recording (see sketch in Figure 2 and sample shot gathers in Figure 3). The most important of



Single and Multichannel Seismics, Figure 3 The figure shows four subsequent shot gathers recorded by a 48-channel recording system. Upper series displays the shot gathers in red-blue color display with wiggle trace overlay, while the lower series shows the same traces in wiggle trace – varying area (WT/VA) display. Seismic energy was generated by an air gun and the direct arrival, bubble energy and reflections are clearly visible on all of four shot gathers.



Single and Multichannel Seismics, Figure 4 Single-channel boomer profile recorded in the Bay of Napoli showing decimeter resolution and more than 30 m penetration. Comparing the left and right inserts, the attenuation of high frequencies and decreasing of seismic resolution with depth are also visible. High resolution of the seismic combined with gravity coring enabled exceptional dating along the recorded profiles. Details of the research can be found in Sacchi et al., 2009.

these advantages are multifold imaging of the same location, called the common depth point (CDP) and the possibility to estimate seismic velocity from the recorded data itself. Multifold imaging enhances the signal/noise ratio of the final seismic section through stacking. The best possible estimate of velocity field of the subsurface layers is necessary for normal move out *(NMO) correction* and "*migration*" before and after stacking. This information is derived from the parameters of the hyperbola fitted on the reflections in the CDP gathers, a process called "velocity analysis."

Commonly used high-resolution single- and multichannel seismic sources

The CHIRP systems use sweep signals for generating pressure waves. Electromagnetic sweep signals are commonly used in commercial and military radar systems, while acoustic sweeps are used in sonar systems for marine applications, and for *vibroseis* on land. CHIRP systems (e.g., Schock and LeBlanc, 1990; Gutowski et al., 2002) became very popular in marine surveys, while vibroseis is the most commonly used seismic source on land. Marine CHIRP systems typically operate in the 400 Hz–25 kHz frequency range, providing decimeter resolution of the sub-bottom layers down to a few meters or maximum few tens of meters depth in unconsolidated sediments. Advantage of the CHIRP systems is the high repeatability and good S/N (signal-to-noise) ratio. Disadvantage is the loss of phase information of the signal due to the cross-correlation during signal recording. CHIRP sources are used mainly for single-channel seismic recording; however, high-resolution 3D Chirp system has also been developed and used for decimeter-scale object detection (Vardy et al., 2008; Plets et al., 2009).

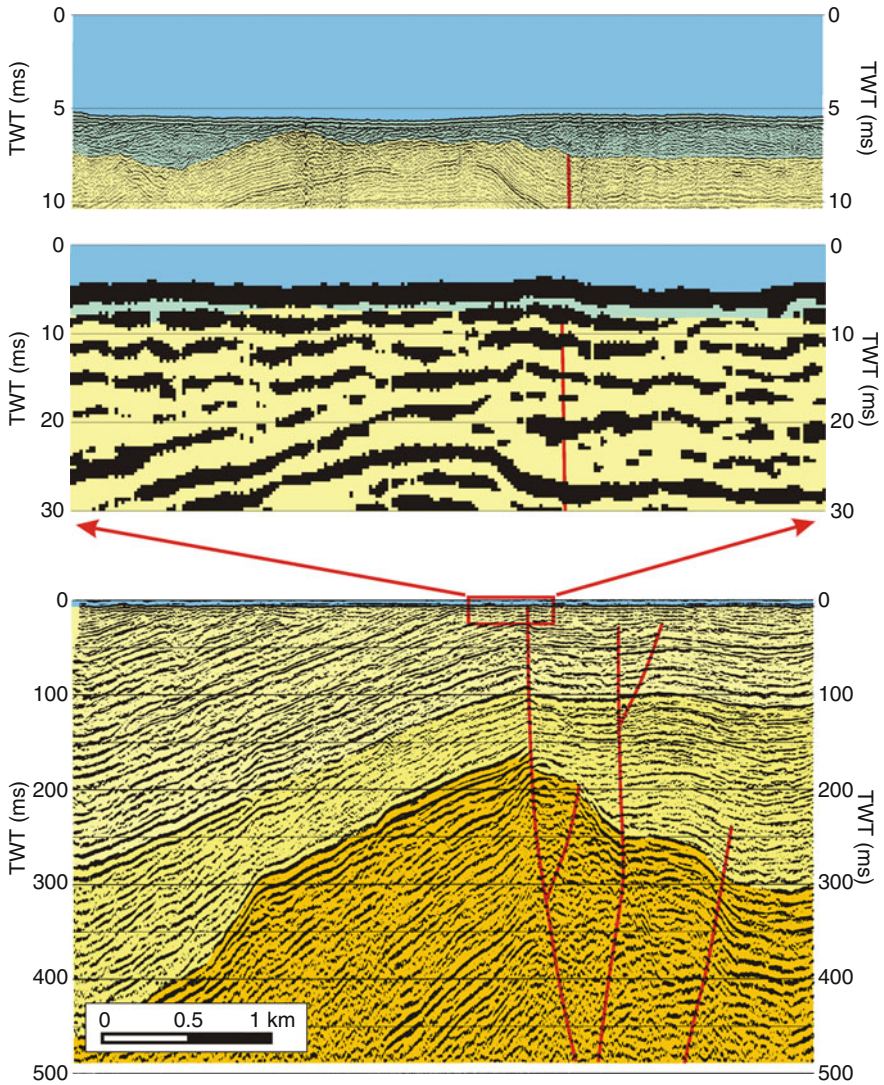
*Boomer*s are electromagnetically driven sources consisting of a flat coil and a metal plate below the coil (Edgerton and Hayward, 1964). Discharge of a high-voltage capacitor bank through the coil generates Eddy-current in the metal plate. The generated Eddy-current violently repels the plate from the coil. Pulling back the plate by strong springs or rubber bands creates a cavitation in the water acting as a sound source. Energy of the source depends on the capacitor bank, which is typically ranging between few 100 and 1,000 J, but several kJ systems have also been used. Boomers generate highly repeatable source signatures in the frequency range of 300 Hz–20 kHz with decimeter resolution and several tens of meters penetration. Innovative system design, such as the IKB-Seistec system utilizing a boomer source and a hydrophone group shielded by a focusing cone (Simpkin and Davis, 1993), can further improve S/N ratio of boomer-based systems providing exceptional combination of resolution and penetration, as shown in Figure 4. Boomers used to be typical single-channel seismic sources; however, multichannel systems developed for high-resolution 3D data acquisition are also built around boomer sources (Müller et al., 2009).

In *sparker* sources, similar to the sparking plug of an engine, discharge of a capacitor bank creates a spark between the positive and negative electrodes of the sparker. This spark vaporizes water between the electrodes and generates a pressure impulse. Energy and shape of the sparker wavelet are influenced by the physical design of the sparker, but is mainly controlled by the capacitance and the voltage of the high-voltage capacitor bank, commonly called "shot box." Typical energy values per shot range between few 100 J and several thousand or even tens of thousands of Joules (Allen, 1972). Large energy sparkers are rarely used nowadays as air gun sources mainly replaced them. Small-energy sparkers are still in use for engineering and research applications as they provide an alternative source fitting between boomers and small air guns. Sparkers

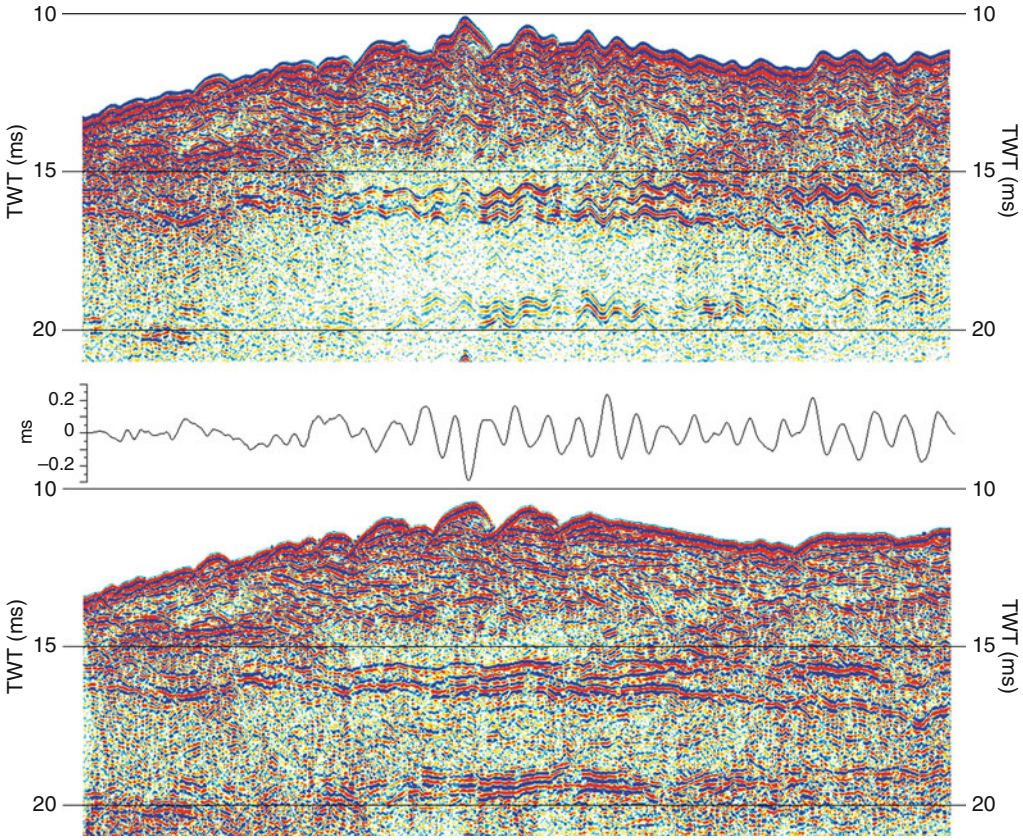
are cost-effective to run, but shape of the wavelet, directivity, and repeatability are better controlled for other sources. Use of the sparker is also limited by the conductivity of the water. It is normally used in saltwater environment as in fresh water, extra care has to be taken to increase the conductivity of the fluid between the electrodes. This can be achieved, for example, by wrapping the sparker in a plastic bag and adding salt inside.

Air gun is a pneumatic seismic energy source generating pressure waves by the sudden release of high-pressure (70–200 bar) air into the water (Giles, 1968). The gun is charged with high-pressure air from a compressor or air container and explosively releases the air from its chamber. The release of the high-pressure air produces a shock wave followed by bubble forming and several oscillations resulting from the expansion and collapse of the air bubble. Good example of bubble energy from the first oscillation is shown in Figure 3.

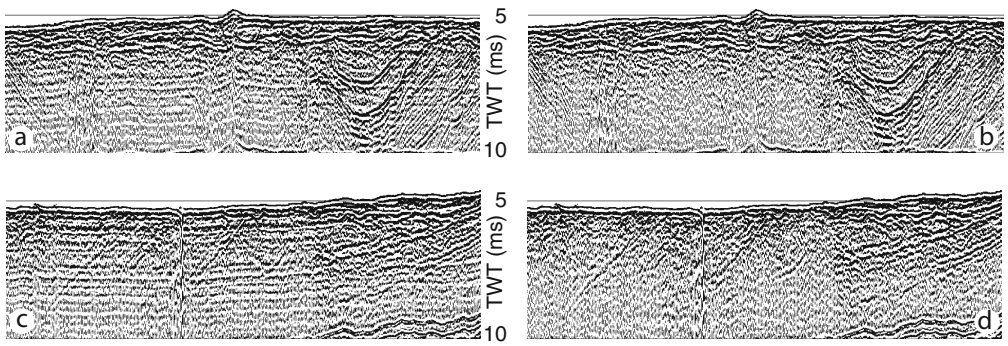
Energy and frequency content of the air gun are determined by the volume of the gun, the pressure of the air and tow depth of the gun. High-resolution surveys require the smallest volume guns, typically 5–20 in^3 (1 in^3 = 16.39 cm^3); however, gun clusters of 1,000–10,000 in^3 are also commonly used during surveys with deeper targets. High-frequency content of small air guns can exceed 1,000 Hz, and large volume guns or gun clusters may



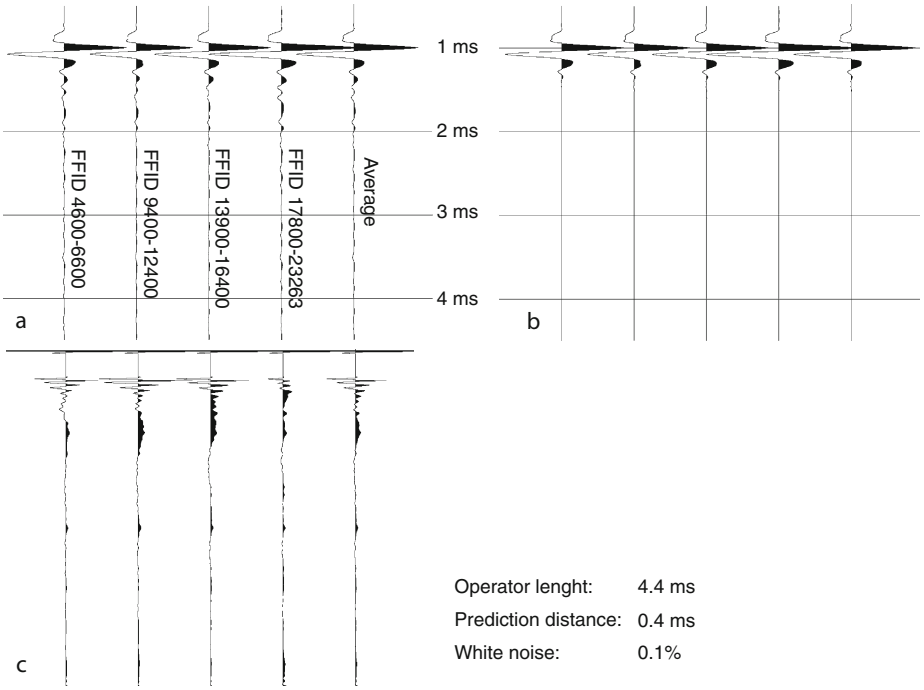
Single and Multichannel Seismics, Figure 5 Bottom image shows a multichannel seismic profile recorded on river Danube, Hungary. Middle image is an optical zoom of the area in the red rectangle. Top image shows the corresponding single-channel boomer profile recorded along the same section of the river. Blue color indicates water, green, recent river sediments, while shades of yellow, Pliocene-Pleistocene sediments. Note the order of magnitude difference in resolution but also in penetration between the two profiles.



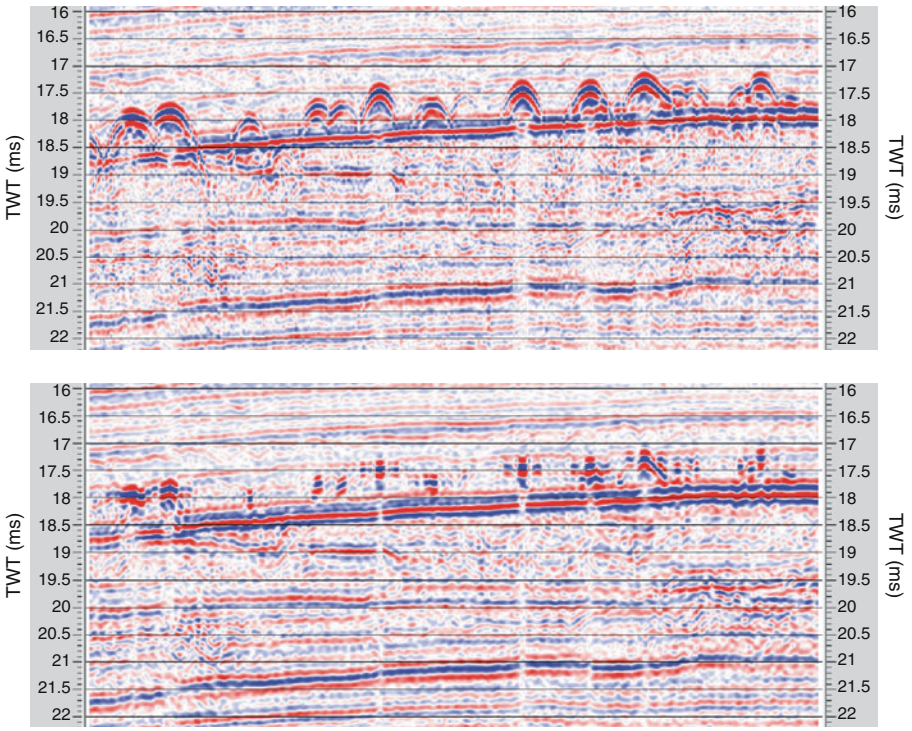
Single and Multichannel Seismics, Figure 6 Top image shows single-channel boomer data recorded on river Rhine with several decimeter amplitude waces. Wave action has been estimated from the cross-correlation of the seismic tarces and the necessary time shift is displayed in the middle graph. Lower image shows the seismic profile after correction for surface wave action. Note that the velocity pull-up and push-down effects due to the velocity difference between water and sediments are clearly visible along the reflector just below 15 ms in the lower image.



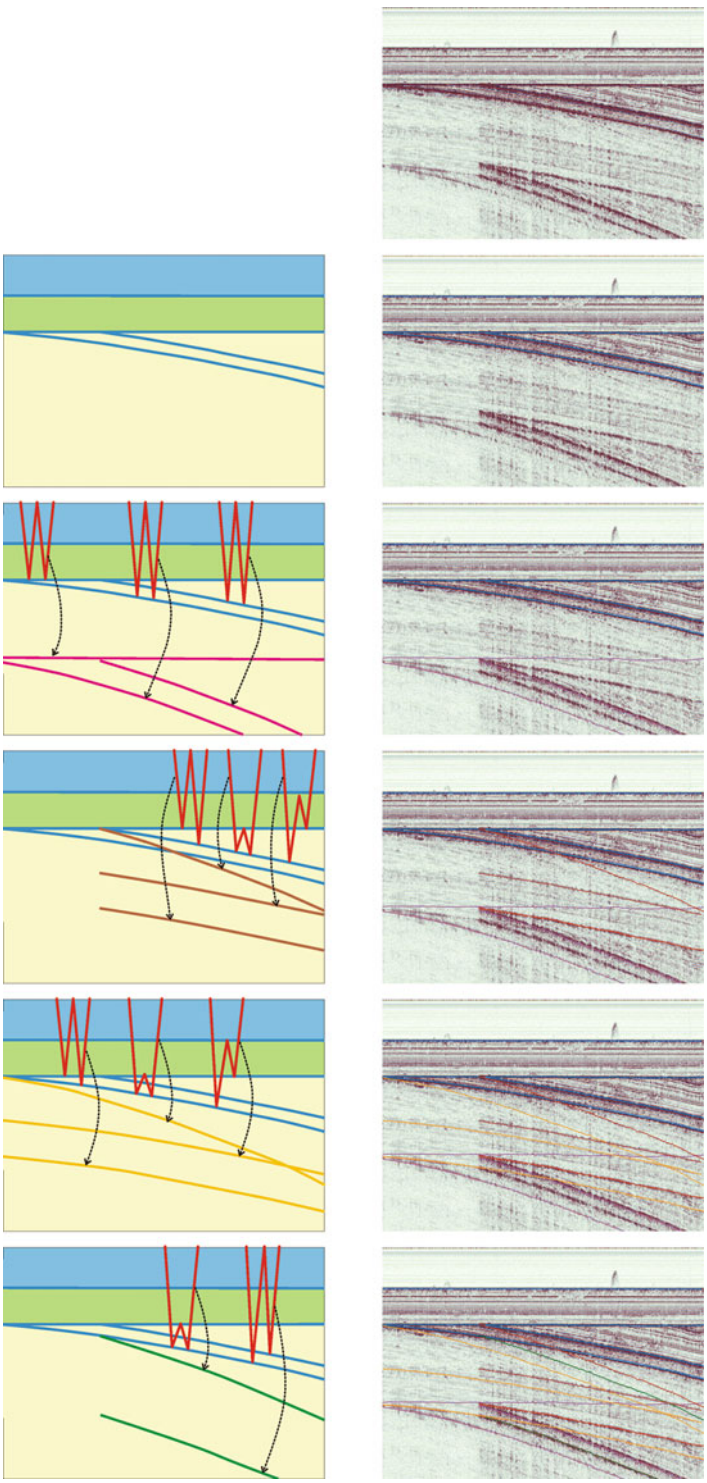
Single and Multichannel Seismics, Figure 7 Two images on the left show profiles without wavelet deconvolution applied. Note the "ringing" of the wavelet running parallel with the water bottom and intersecting genuine reflectors below the water bottom. Profiles on the right have been deconvolved using wavelet-based deterministic deconvolution. The ringing of the wavelet is completely eliminated.



Single and Multichannel Seismics, Figure 8 Wavelets before (**a**) and after (**b**) deterministic deconvolution applied and the deconvolution operator applied (**c**).



Single and Multichannel Seismics, Figure 9 Upper and lower images show the same detail of the seismic profile before and after migration, respectively. Note the collapse of the diffraction hyperbolae around 18 ms TWT. Lateral resolution of the profile is significantly improved by the migration process.



Single and Multichannel Seismics, Figure 10 Top right image shows the original seismic profile recorded in lake Balaton, Hungary. In the lake, approx. 4 m water and 4 m soft, unconsolidated mud can be found above the older Pliocene strata. This, together with the dipping strata in the Pliocene, presents an ideal condition for multiple generation. Top sketch marks with blue the interfaces considered for multiple generation. These are: water surface, water bottom, mud bottom, and two dipping intra-Pliocene strata. First, the free surface multiples (marked by *pink*) are calculated for each of these interfaces. This is followed by different peg-leg multiples calculated and marked by brown, yellow, and green lines on the profile. It is very interesting to observe that very many of the reflections recorded on the seismic profile are actually multiple energies generated by the above mentioned surfaces only.

provide enough energy for several kilometer deep penetration. Air guns are highly repeatable sources with considerable literature on measuring and designing their wavelet (Ziolkowski et al., 1982).

Bubble oscillation can be decreased or even completely diminished by the timely injection of a second volume of high-pressure air. Guns operating under this principle are called *Generated Injection Air Guns* or simply *GI guns*. GI guns have two chambers. The primary chamber (generator) produces the actual pressure impulse, while the secondary chamber (injector) is used to inject a second air volume near the maximum expansion of the first bubble in order to prevent its collapse.

Air gun and *GI* sources due to their higher energy and deeper penetration are mainly used for multichannel recording. A good comparison of single-channel boomer profile and a multichannel air gun profile is shown in Figure 5.

Processing considerations for high-resolution single- and multichannel seismic profiles

Static correction is always a key issue for proper imaging of the subsurface with seismic waves. This is especially true for high-resolution surveys. Offshore seismic surveys present a special static problem due to the wave motion. This equally effects single- and multichannel surveys, but the higher the resolution of the seismics, the more severe the problem can be. Coherency of the reflections in a decimeter resolution boomer survey can be severely affected by surface waves. Heave motion detectors offer a compensation via measuring the wave motions together with the seismic profile; however, if no heave motion is available for the survey, the necessary correction can be calculated from the data. Example of this is shown in Figure 6.

High repeatability of many of the sources (boomer, air guns) offers good opportunity for wavelet determination and application of deterministic *deconvolution* using the calculated wavelet. This is illustrated in Figures 7 and 8 showing two seismic profiles before and after deterministic wavelet deconvolution and the calculated wavelets and deconvolution operators.

Migration is also a key processing step not only for the multichannel, but also for the single-channel seismic profiles. In the later case, estimation of the migration velocity is more complicated, as there is no a priori information available from stacking velocity analysis. Velocity estimates from other measurements or migration velocity analysis can be used for migrating single-channel data. An example of this is shown in Figure 9.

Multiples generated by the free water surface present a significant problem for single-channel seismic profiles. Several processing algorithms exist for multichannel seismic data in order to suppress multiple energy, but almost all of them fail in case of single-channel seismic profiles. Figure 10 shows a single-channel profile recorded in lake Balaton, Hungary with significant multiple energy.

Summary

Seismic surveys provide one of the most detailed image of the subsurface from shallow (few tens of meters) to deep (several kilometers or even tens of kilometers) intervals. Although most of the recent seismic surveys utilize multichannel recording, high-resolution single-channel seismic surveys can also provide a cost-effective solution for offshore surveys. Main advantage of single-channel seismics is high-resolution imaging and relative simplicity of the survey. Multichannel surveys, on the other hand, can significantly improve the signal-to-noise ratio of the seismic profile by applying multifold imaging and at the same time also provide additional information, for example, estimates of the velocity field.

SLOW EARTHQUAKE

Teruyuki Kato
Earthquake Research Institute, The University of Tokyo, Bunkyo-ku, Tokyo, Japan

Definition

An earthquake is a sudden rupture of a fault embedded in the crust or upper mantle, and radiates elastic waves toward the earth's surface to vibrate the ground. Ground vibration includes wide spectrum of frequencies from tens of hertz to hundredth of seconds or lower. The ground vibration is recorded by a pendulum called a seismograph. Since the pendulum has its own frequency characteristics, components of longer periods becomes less visible and are not recognizable in the longest period.

Some types of fault ruptures have predominant component in long-period seismogram and such earthquakes are called slow earthquakes. The earthquake that does not radiate enough energy to be recorded on seismogram is called a silent earthquake or slow slip event (SSE). In this definition, observed pre-seismic or post-seismic slip, or creep events may all be categorized in the silent earthquake or SSE.

Early studies on slow and silent earthquake

Earlier studies of slow earthquake were made by examining difference in magnitude determined by different frequency ranges (e.g., Kanamori, 1972; Kanamori and Stewart, 1979). Seismic magnitude of large earthquakes estimated from shorter period wave such as body waves are significantly smaller than that determined from longer period seismic waves. Ultimately, magnitude determined by seismic wave analysis is often much smaller than the moment magnitude or that estimated by the geodetic data inversion analysis that includes longest period (or permanent displacement) data. These have been interpreted such that the significant amount of moment release was achieved by the component of fault rupture that is slow enough not radiating much seismic wave. Kanamori and Stewart (1979), for example, showed that a series of such slow events were triggered after the June 6, 1960, Chilean earthquake (Mw 9.5).

One of such difference could be manifested by a type of earthquake called "tsunami earthquake." The tsunami earthquake is characterized by anomalously high tsunami generation than that expected from body wave or surface wave magnitude. This can be interpreted by source characteristic such that the fault rupture was slow enough not radiating shorter seismic wave but rapid enough to generate tsunami. The 1896 Sanriku, Japan, earthquake (Ms 7.2, Mw 8.0), 1992 Nicaragua earthquake (Ms 7.0, Mw 7.6) are examples (e.g., Kanamori and Kikuchi, 1993).

If the rupture is much slower and does not radiate any seismic energy, then it is called a silent earthquake. Beroza and Jordan (1990) tested if such very slow or silent earthquake could be detected using spectra of Earth's free oscillations. Another trial is the comparison of long-term moment release rate at subduction zones. If all of strain accumulated along plate boundaries is released by seismic energy, then the released moment at the time of earthquake should be equal to the accumulated moment. Kawasaki et al. (2001) examined this hypothesis and found that the total moment released by earthquakes along the plate boundary is far smaller than the totally accumulated moment in an interseismic stage. This means that there are other unknown slow processes that release remaining moment at the plate boundaries.

One of possible mechanisms of slow strain release would be post-seismic transient displacement. Earlier discovery of post-seismic crustal deformation was found due to the 1946 Nankai, Japan, earthquake (Mw 8.1) (e.g., Okada and Nagata, 1953). The cause of such a post-seismic crustal deformation was interpreted as a retarded slip after the earthquake (Fitch and Scholz, 1971). Kawasaki et al. (1995) asserted that a post-seismic slow rupture was generated after the 1992 Sanriku, Japan, earthquake (Ms 6.9), by examining the strain records observed at the Esashi, Northern Japan, station. However, the question if such post-seismic transients on the records of strain sensors might stem from instrumental drifts after a strong shake was not well resolved.

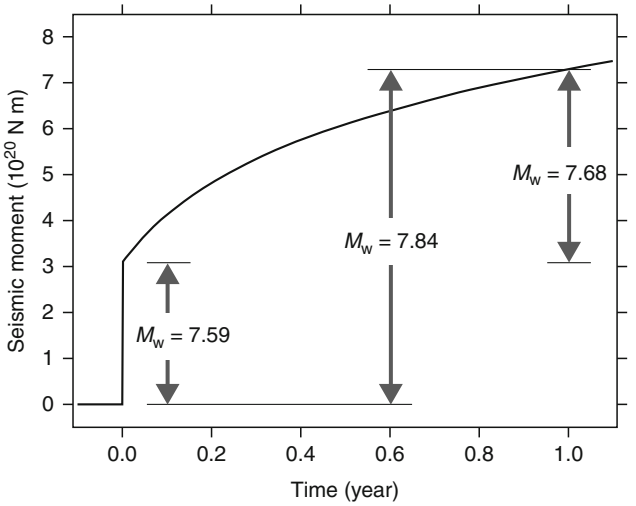
More direct and convincing finding of slow slip events was brought in 1990s by the advent of the Global Positioning System (GPS). Geographical Survey Institute of Japan (GSI) first deployed nationwide GPS network to monitor crustal deformation of the Japanese Islands starting in 1992. The network was much densified in 1996 with more than 600 permanent GPS sites together with near real-time monitoring facility. The network is called GPS Earth Observation Network System (GEONET). It has been further augmented to more than 1,200 sites all over the Japanese Islands. This nationwide array of continuous GPS observation provided such a powerful tool to discover slow slip events around the Japanese Islands, as described in the following section.

Also, the USA deployed a large array of GPS together with strain and tilt meters along the western coast of the North American continent and is called Plate Boundary Observatory (PBO), which also enabled discoveries of slow slip events.

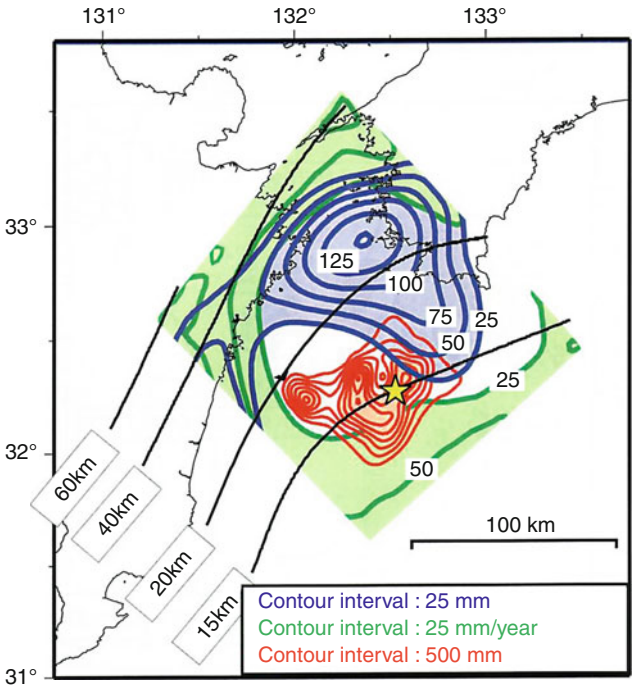
Rapid developments of GPS arrays all over the world, in particular along the Pacific Rim areas, enabled us to discover that silent earthquakes or slow slip events (SSE) are occurring at various areas around the glove, in particular, along the subducting plate interface. Comprehensive description on where do those slow events are taking place are found in Schwartz and Rokosky (2007) and Schwartz (2009).

Long-term slow slip events

A variety of slow slip events, including post-seismic slip, whose time durations are months to years have been discovered along the subducting plate boundaries.



Slow Earthquake, Figure 1 Moment release rate due to the 1994 Sanriku-Haruka-oki, Japan, earthquake. Figure suggests that the moment released in 1 year after the earthquake is bigger than the co-seismic moment release (Heki et al., 1997).



Slow Earthquake, Figure 2 Slip distributions on the subducting plate interface shown by equi-depth contours, projected on the earth's surface: (*Blue*) The slip distribution due to the 1997 slow event at the Bungo Channel, Japan (After Yagi and Kikuchi, 2003). (*Red*) the slip distribution due to the 1968 Hyuganada earthquake, and (*Green*) area of steady slip. (Courtesy by Y. Yagi.)

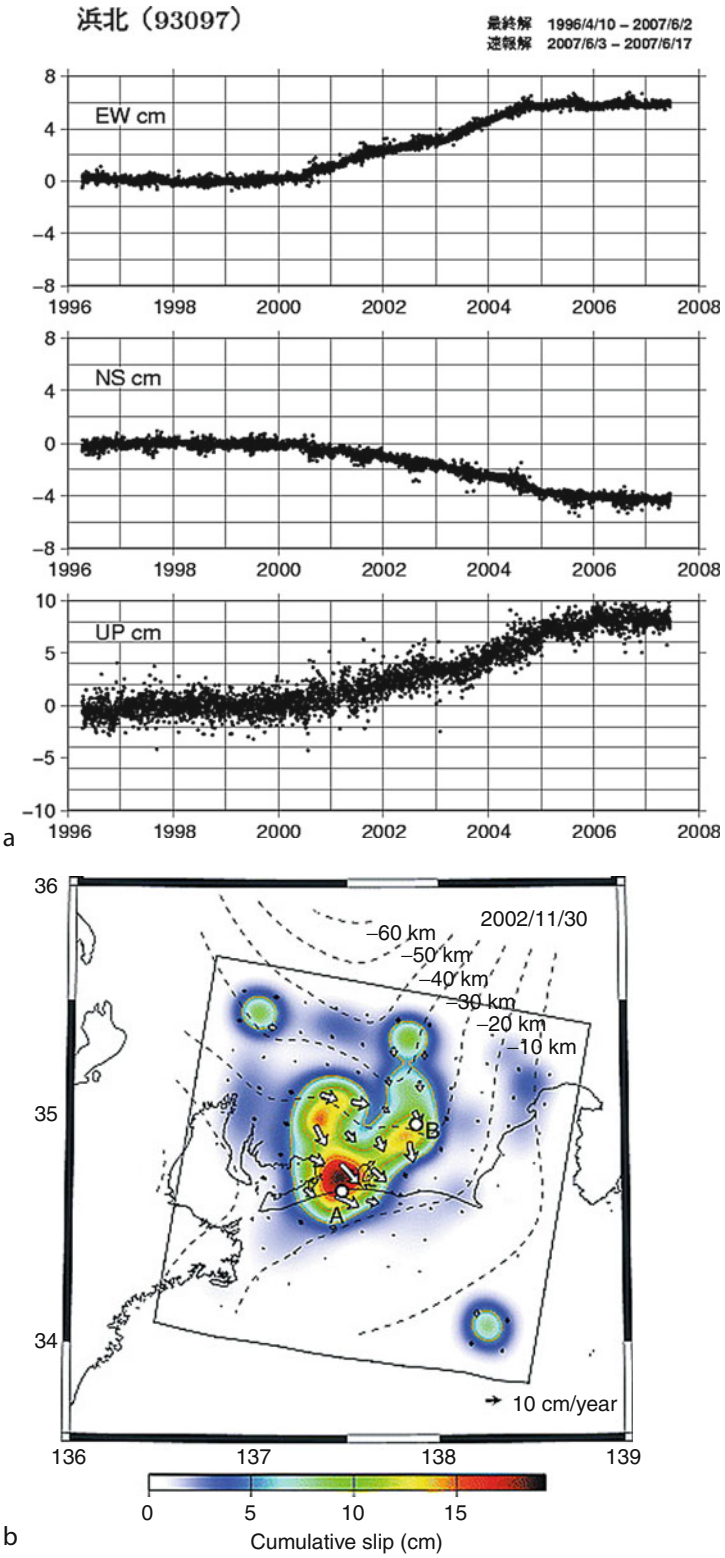
The first eminent case of large slow slip events found using GPS network data would be the post-seismic slip due to the 1994 Sanriku-haruka-oki earthquake (Heki et al., 1997). Heki et al. (1997) analyzed the GEONET data and found that the moment released by the post-seismic slow slips is bigger than that released at the time of earthquake (Figure 1). Then, Hirose et al. (1999) found a slow slip event in the Bungo Channel, western part of Japan, that occurred after the two 1996 Hyuganada earthquakes of Mw 6.6 on October 19 and Mw 6.7 on December 3 that occurred in the south of the region. This slip continued about 1 year in 1997 and was assumed to be due to a slip on the subducting Philippine Sea plate. Their geodetic inversion suggested that the slip occurred on about 60 km × 60 km surface with the maximum fault slip of about 18 cm, which is equivalent to Mw 6.6 earthquake (Figure 2).

Other examples of slow events found in the Japanese region include (1) east off the Boso Peninsula where slow slip events have repeated in 1996 and in 2002 and they were followed by earthquake swarms (Sagiya, 2004, Ozawa et al., 2003) and (2) a post-seismic transient slip after the 2003 Tokachi earthquake (Mw 8.0) (Miyazaki et al., 2004).

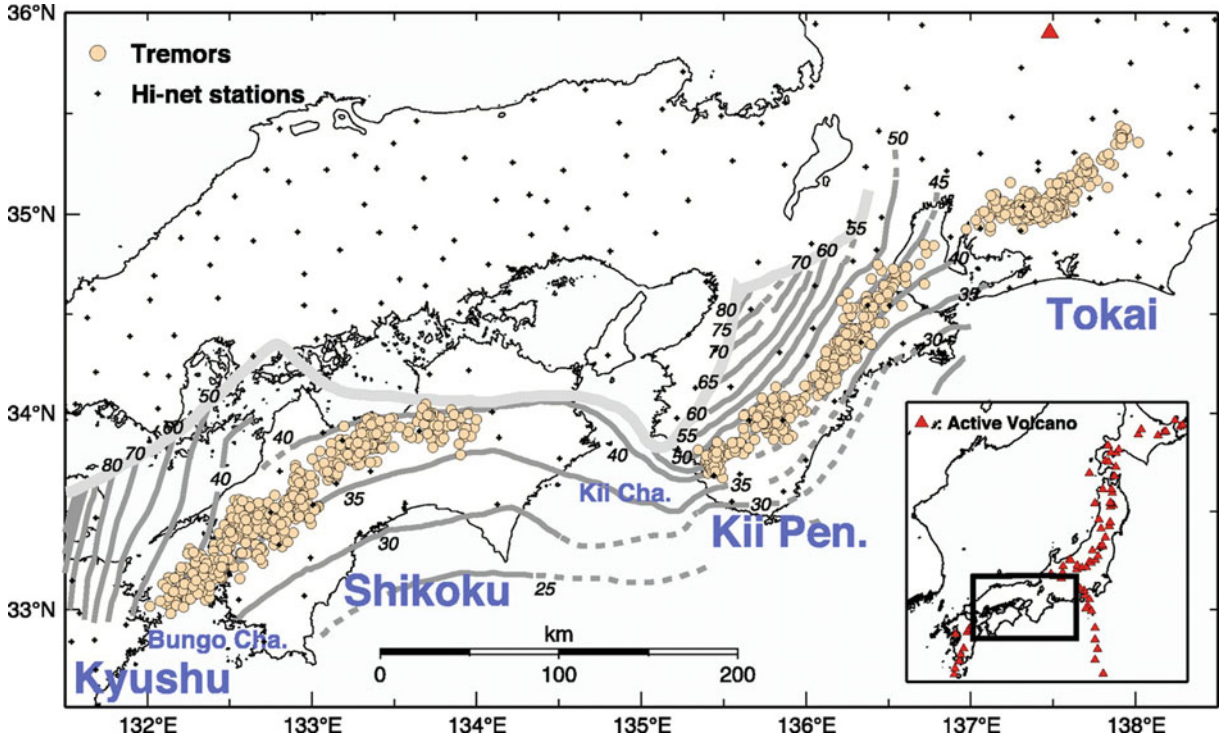
Lowry et al. (2001) found a transient movement at a continuous GPS site established at Cayaco, Guerero region, Mexico in early 1998. The area has been considered as a seismic gap. The event lasted about several months with 2 mm east, 26 mm south, and 16 mm up of displacements. They suggested that the displacement is consistent with a slip along the subduction interface that propagated from east to west. The transient displacement repeated in 2001–2002 for about 6 months. Kostoglodov et al. (2003) and Yoshioka et al. (2004) further investigated the mechanism of the event. Another repeated transient event in Mexico has been found in Oaxaca segment, hundreds of kilometers southeast of Guerrero segment, with more dense GPS array, and was studied by Brudzinski et al. (2007) and Correa-Mora et al. (2008).

Other long-term slow events have been found in Costa Rica (Protti et al., 2004), Alaska-Aleutian (Ohta et al., 2006), and New Zealand (Douglas et al., 2005). SSEs have also been found along the shallower part of the San Andreas fault (e.g., Wesson, 1987; Gladwin et al., 1994; Linde et al., 1996), and in Italy (Crescentini et al., 1999; Amoruso et al., 2002). Readers are asked to refer to Schwartz and Rokosky (2007) and Schwartz (2009) for a detailed review.

Yagi et al. (2001), and Yagi and Kikuchi (2003) used GPS data to examine areal distribution of co-seismic slip, post-seismic slip, and slow slip events for two Hyudanada earthquakes of 1996 (Mw 6.6 and Mw 6.7). They found that these areas complementarily share the areas and postulated that this complementarity may come from different constitutive parameters of slip at respective regions (Figure 2). A similar complementary region of seismic slip and aseismic slip is found also in the northeastern Japan (Yagi et al., 2003). Correa-Mora et al. (2008) indicated that the repeated transients at the Oaxaca segment occurred at the lower extension of the locked part of the



Slow Earthquake, Figure 3 (**a**) A sample GPS time series at the Hamakita site for the Tokai slow slip event. Permanent trend for the period from 1996 to 2000 was removed. Slow slip event was attributed in the period from late 2000 to early 2005. (From webpage of the Geographical Survey Institute) (**b**) Cumulative slip inferred from the extended Network Inversion Filter. *Arrows* show the direction and magnitude of slip of the upper plate (Miyazaki et al., 2006).



Slow Earthquake, Figure 4 Distribution of low-frequency tremor shown in dots (Obara, 2002).

seismogenic zone. These lines of evidence may suggest distinct physical rock properties along the different segments of the subducting plate interface.

The largest and the longest slow slip event, that has ever been found, lasted for about 5 years. It was recorded along the northern margin of the subducting Philippine Sea plate, namely, Tokai district (Figure 3). The event started in the middle of 2000 and continued until mid-2005. Both Ozawa et al. (2002) and Miyazaki et al. (2006) employed a state-space model to delineate temporal evolution of the slow slip event (Segall and Matthews, 1997). The slip amounted to be about several tens of centimeters, which is equivalent to moment magnitude of about 7.2–7.3 earthquake. Figure 3 shows a sample time series of coordinate change at a GEONET station that is located right above the slowly slipping region.

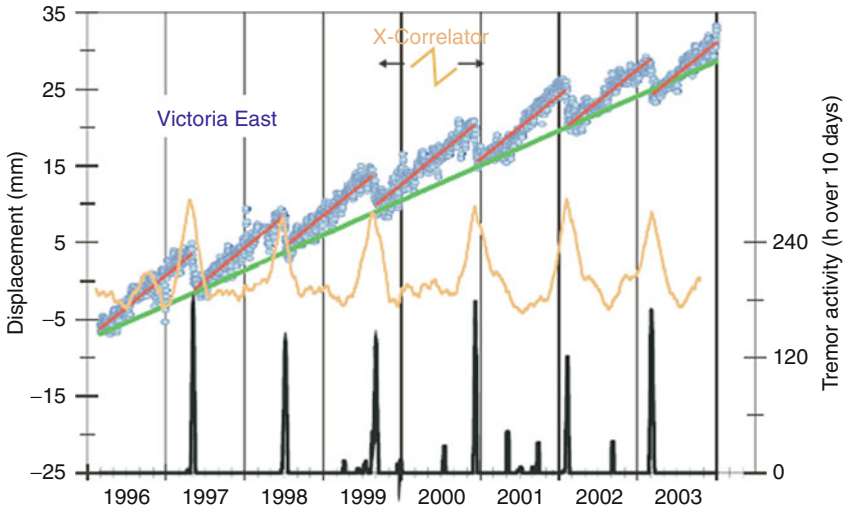
Low-frequency tremor and short-term slow slip

Obara (2002) discovered so-called deep low-frequency tremor using a nationwide seismic array in Japan, which is named as HiNet (High Sensitivity Seismograph Network) constituting of about 600 sites all over Japan. The deep low-frequency tremor is about 1 h of tremor activity, which is located nearly at the plate interface of 35–40 km in depth (Figure 4). The tremor has 0.2–2 Hz in predominant frequency. And then, the tremor was found to be accompanied by small silent slips of a few to several days (Obara and Hirose, 2006; Hirose and Obara, 2006).

Similar nonvolcanic tremor accompanied by short-term slow events were found also in the Northwestern Pacific (Dragart et al., 2001; Rogers and Dragart, 2003; Miller et al., 2002). Dragart et al. (2001) indicated that the SSE rather regularly repeats with interval of about 14 months and is associated with seismic swarm activities (Figure 5). The estimated slip is about 3 cm. Such slow events associated with swarm activities are called episodic tremor and slip (ETS) (Rogers and Dragart, 2003).

Hirose and Obara (2005) found that mid-term (about a month) and short-term (1 or 2 weeks) of slow slip events are accompanied by low-frequency tremors. The short-term silent slip was too small to be monitored by GPS but can be observed on highly sensitive tiltmeters, which are mostly embedded in HiNet boreholes. The estimated amount of slip was only 1–2 cm. They also found repeated similar short-term slow slip events associated with low-frequency tremors at the Tokai region (Hirose and Obara, 2006; Figure 6). Observed slow events were modeled by a slip at the depth of 25 km and the slip amounted only 1.2 cm.

Several lines of evidence from seismological studies suggest that the occurrence of low-frequency tremors and slow slip events may somehow be related to the existence of fluid flow. Shelly et al. (2006) and Obara and Hirose (2006) suggested that episodic tremors that include low-frequency earthquakes are generated by a slow shear slip on the plate interface. Fluids might play a key role for the generation of such low-frequency earthquakes.



Slow Earthquake, Figure 5 Frequently and regularly repeating slow slip events and low-frequency tremors along the Cascadia subduction zones (Dragart et al., 2004).

Matsubara et al. (2009) and Kato et al. (2010) also indicated that the high-pressure fluids released by dehydration from the subducting oceanic crust generates those tremors and slow slip events.

In addition to the low-frequency tremor that occurs at a deeper extension of the seismogenic zone, low-frequency earthquakes (LFE) of a characteristic period of 10–20 s have also been observed at very shallow areas at the updip extension of the seismogenic zones along the subducting plate. They are found along the Nankai trough (e.g., Ishihara, 2003; Obara and Ito, 2005) and at the junction between the Japan trench and the Kuril trench (Asano et al., 2008). Considering that the LFEs along the Nankai trough are occurring within the accretionary prism and have higher dip angle compared with the subucting plate interface, Ito and Obara (2006a) hypothesized that they may occur in the spray faults (or out-of-sequence thrusts) in the wedge.

Existence of fluid would have a key role for generating such low-frequency events, for both deep and shallow low-frequency earthquakes (e.g., Davis et al., 2006; Ito and Obara, 2006b).

Pre-seismic slip

A number of possible pre-seismic slips have been reported. Roeloffs (2006), among others, compared ten distinct examples of reported pre-seismic deformation rate changes before large earthquakes. For example, anomalous crustal deformations were observed before the 1944 Tonankai and 1946 Nankai earthquakes in Japan. Linde and Sacks (2002) showed that these deformations are consistent with the assumed aseismic slip of about 2 m in the down dip extension of the seismically slipped interface. Kanamori and Cipar (1974) and Linde and Silver (1989) postulated that a slow event had preceded the 1960 Chile earthquake.

It might be pointed out that the mechanism of precursory slow slip would be physically the same as slow slip event. Only the difference would be that while the precursory slip is an accelerating phase toward the rapid rupture, slow slip event is the slip that is not grown to a rapid rupture. Studies to clarify the mechanism that creates such difference are yet to be conducted in the future.

Scaling relation

An important question raised is if the discovered slow earthquakes or slow events are just the slow version of "regular" or "normal" earthquakes. If this is the case, those slow events may have the similar scaling relations as the other regular earthquakes. Ide et al. (2007), however, suggested that the slow earthquakes including silent earthquake, slow slip, etc., had different scaling relation and spectral behavior compared with normal earthquakes (Figure 7). They suggested that the characteristic duration (T sec) and the released moment (M_0 Nm) has linear relationship:

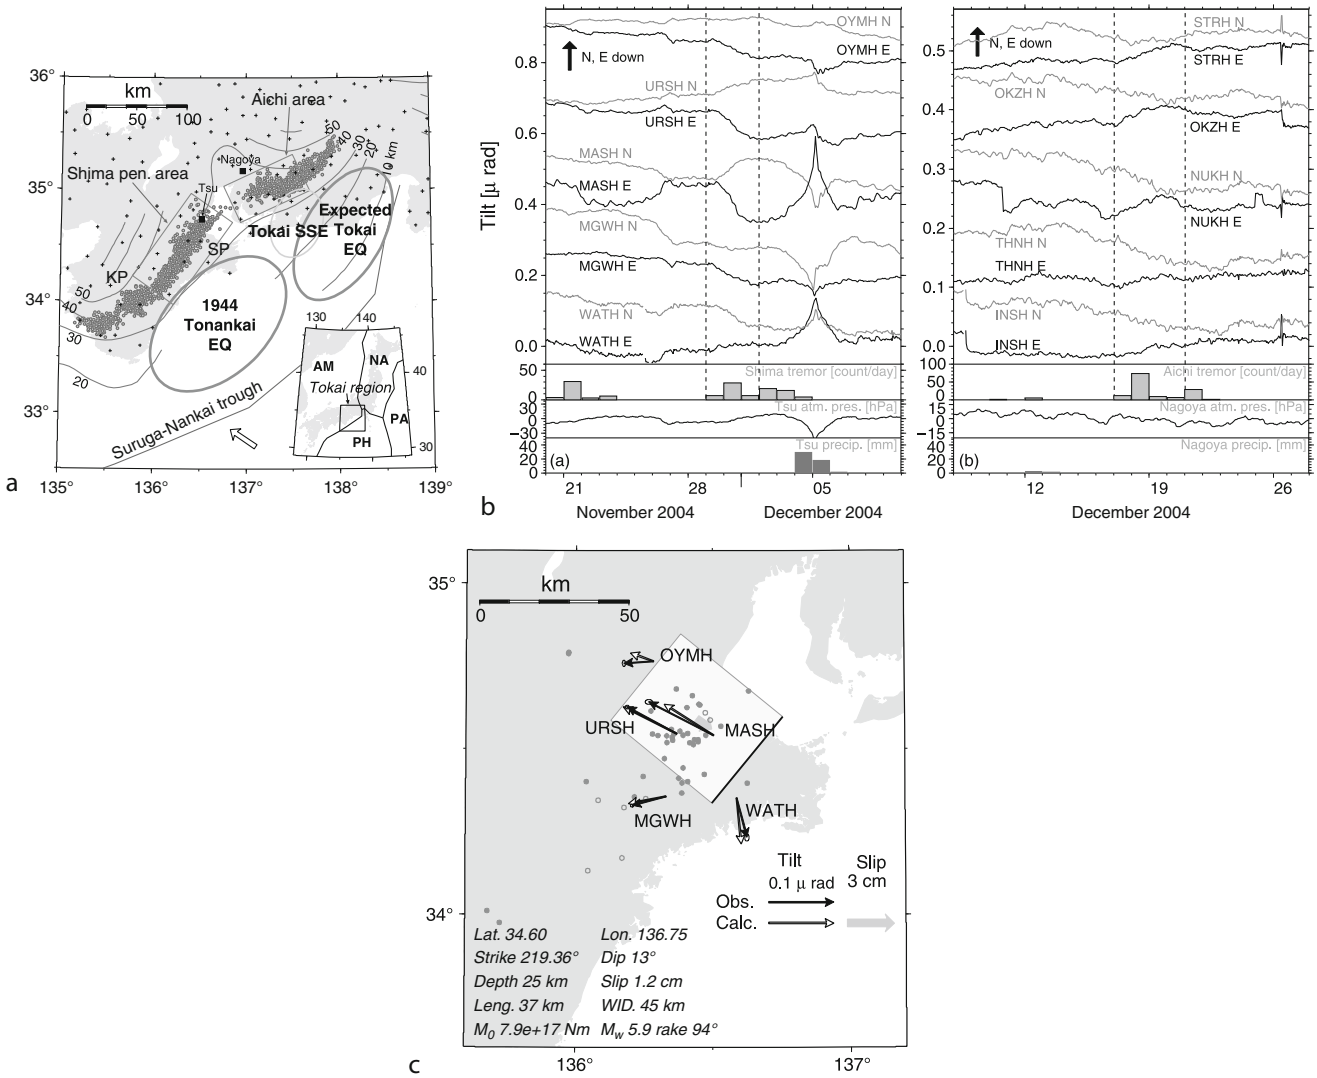
$$M_0 \approx T \times 10^{12-13} \quad (1)$$

While this relation for the regular earthquake is

$$M_0 \approx T^3 \times 10^{15-16} \quad (2)$$

Thus, the characteristics of moment rate spectrum are also different between these events.

This finding may tell us that the slow events are not just a slower extension of seismic slip but rather has a physically different nature. They suggest that such difference would be interpreted by "a constant low-stress drop model or a diffusional constant-slip model" (Ide



Slow Earthquake, Figure 6 (**a**) Map of studied area. (**b**) Observed tilt changes in November and December 2004, due to short-term slow slip events in the Tokai region. Periods of slow events are bounded by *dashed lines*. Recorded low-frequency tremors are also shown. (**c**) Modeled source region and estimated parameters. Observed and predicted tilt changes are shown in vectors (Hirose and Obara, 2006).

et al., 2007). Though the idea is yet to be tested, this might bring us a new insight for understanding the mechanism of fault slip or "earthquake" itself.

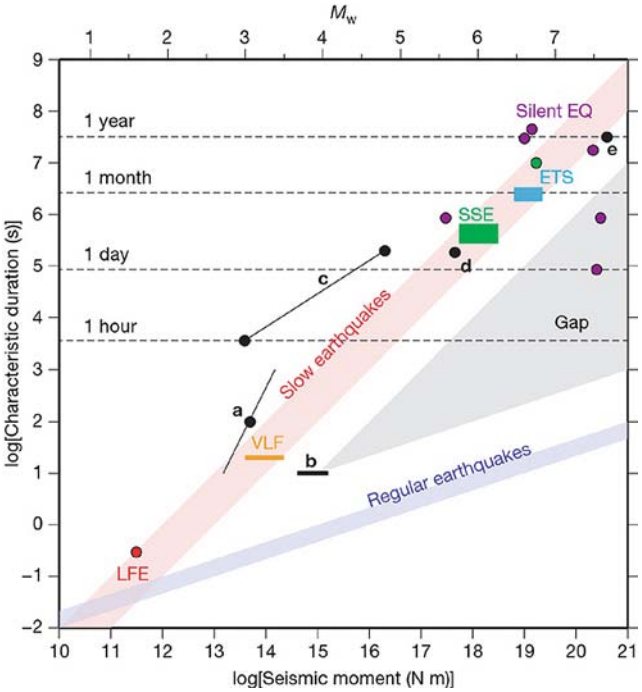
Mechanism of slow earthquake

The mechanism of fault slip has been extensively studied in the field of rock mechanics including theoretical treatments. It is inevitable to clarify the constitutive relations of fault ruptures to understand what mechanism controls the occurrence of slow earthquake (or earthquake itself). Numerous experimental and theoretical studies have been conducted for this purpose in decades. Among various proposed constitutive laws, the rate- and state-dependent friction law has been widely accepted (Dieterich, 1979; Ruina, 1983). The law is expressed by the following equations:

$$\mu\left(=\frac{\tau}{\sigma}\right)=\mu^{-}+a\ln\left(\frac{V}{V^{*}}+\theta\right) \tag{3}$$

$$\frac{\mathrm{d}\theta}{\mathrm{d}t}=-\left(\frac{V}{L}\right)\left[\theta+b\ln\left(\frac{V}{V^{*}}\right)\right] \tag{4}$$

Where, μ is friction coefficient, τ is shear stress, σ is normal stress, μ^{-} is friction coefficient at V^{*} where V^{*} is constant, L is characteristic slip distance, and θ is so-called state variable that represents the state along the fault



Slow Earthquake, Figure 7 Comparison between seismic moment and the characteristic duration of various slow earthquakes. LFE (*red*), VLF (*orange*), SSE (*green*), and ETS (*light blue*) are low-frequency earthquake, very low frequency earthquake, slow slip event, and episodic tremor and slip, respectively. See Ide et al. (2007) for more details.

surface. Coefficients a and b are constant. When the state θ does not change with time, it is called steady state and the friction coefficient in such steady state μ^{ss} is shown as

$$\mu^{ss} = \mu_0 + (a - b) \ln\left(\frac{V}{V^-}\right). \quad (5)$$

A simple spring-slider model is often used to model the fault slips (Ruina, 1983; Rice and Ruina, 1983). The system is characterized by the normal stress, shear stress, and the stiffness (or spring constant) k. Studies suggest that the type of slip, either rapid or slow slip, is controlled by several parameters. From Equation 5, it is suggested that, if $(a - b)$ is negative, the friction coefficient μ_{ss} becomes smaller when slip velocity V increases, which is called velocity weakening. In case of velocity weakening, system stiffness k controls the slip mode; if k is smaller than a critical value k_c which is given by $(b - a)\ \sigma/L$ (e.g., Dieterich, 1979), then the slip is unstable. Even in case of velocity weakening, the slip becomes slow if $(a - b)$ is close to zero. When $(a - b) > 0$, it is called velocity strengthening and the slip is decelerated.

Marone et al. (1991) used the case of velocity strengthening to interpret the post-seismic transient slow slip along the San Andreas fault and estimated the thickness of surface velocity strengthening layer to be 2–5 km. Yoshida and Kato (2003) used two tethered spring-sliders model to investigate fault interactions and examined what kind of conditions controls the occurrence of slow slip events. They showed that the repeated slow slip events may occur if the stiffness of the first block k is smaller than k_c and the second block is such that k is slightly bigger than k_c (which means that the condition is close to the boundary between stable and unstable slip). They also examined the case that an earthquake triggers the slow slip events in the adjacent region as was observed in the case of 2003 Tokachi-oki earthquake.

Further application of the rate- and state-dependent friction law to the numerical simulation of slip along the fault has been developed by a number of researchers. Tse and Rice (1986), for example, applied the relation to the two-dimensional San Andreas fault and suggested that unstable sliding may be limited to the depth shallower than 5–7 km and the steady slow slips prevails below 13–15 km of depth. Three-dimensional application was, for example, done by Rice (1993) and Stuart and Tullis (1995).

Concluding remarks

Although the slow earthquake has been studied for decades, its rapid progress was realized since the advent of the Global Positioning System observations in the middle of 1990s. Slow slip events would be one of the most important discoveries in seismology in the recent decades, thanks to GPS. In addition, the discoveries of other low-frequency events by high-sensitivity seismic arrays provided another important progress in understanding the mechanism of earthquake generation.

It may be reminded that the whole earthquake cycle was once categorized into four stages, namely, inter-seismic, pre-seismic, co-seismic, and post-seismic stages, and they had been studied rather independently. However, these stages are now recognized as cross-sectional views of single continuous series of progress of slips along the fault under the unified governing fault constitutive law.

Synthetic image of earthquake from high frequency that has been recorded by seismometers to very low frequency including transient slow events provided seismologists with opportunities of ultimate understanding of what "earthquake" is. In order, however, to realize this, a lot of more advanced researches are to be conducted and the results should be synthesized; for example, detailed deep sounding of structures of the lower crust and upper mantle where brittle and ductile ruptures are taking place should be conducted to clarify the field of earthquakes. Also, laboratory experiments for developing more conclusive governing laws of rapid and slow ruptures are indispensable. In addition, further findings of slow slip events and slow earthquakes at various fields in the world will provide deeper insights on the mechanism of earthquake generation. Such progresses might lead to a further development toward the most difficult seismological problem of earthquake prediction.

Definition

A square integrable function, defined on a surface that has a one-to-one correspondence with the unit sphere, may be

represented as a linear combination of *Surface Spherical Harmonic functions*. *Spherical Harmonic Analysis* (SHA) is the process by which the coefficients defining this linear combination are determined. These coefficients constitute the *Surface Spherical Harmonic spectrum* of the function. Functions that satisfy Laplace's partial differential equation are called *harmonic*. These can be decomposed into series of *Solid Spherical Harmonic functions*. Although SHA is *not* restricted to functions that represent potential fields, it plays a special role in the determination of such fields through the solution of *Boundary Value Problems* (BVP).

Introduction: basic formulas

A scalar function V, representing a potential field such as the Earth's gravitational or magnetic field, satisfies Laplace's partial differential equation (PDE), in the space outside of the sources generating the field. In geocentric spherical polar coordinates (r, θ, λ), where r is the radial distance, θ is the geocentric colatitude (defined as 90° minus the geocentric latitude), and λ is the longitude, Laplace's PDE takes the form (Heiskanen and Moritz, 1967, Equation 1–41):

$$\Delta V \equiv \nabla^2 V = \frac{\partial^2 V}{\partial r^2} + \frac{2}{r}\frac{\partial V}{\partial r} + \frac{1}{r^2}\frac{\partial^2 V}{\partial \theta^2} + \frac{\cot\theta}{r^2}\frac{\partial V}{\partial \theta} + \frac{1}{r^2 \sin^2\theta}\frac{\partial^2 V}{\partial \lambda^2} = 0. \tag{1}$$

Equation 1 may be solved using the method of separation of variables. For the space outside a sphere of radius $r = a$, its solution may be written in the form (see Heiskanen and Moritz, 1967 for a complete derivation):

$$V(r,\theta,\lambda) = \sum_{n=0}^{\infty}\left(\frac{a}{r}\right)^{n+1}\sum_{m=-n}^{n} v_{nm} Y_{nm}(\theta,\lambda). \tag{2}$$

The functions $\left[(a/r)^{n+1} Y_{nm}(\theta,\lambda)\right]$ are called *Solid Spherical Harmonic functions*. The *Surface Spherical Harmonic functions* $Y_{nm}(\theta,\lambda)$ are defined as:

$$Y_{nm}(\theta,\lambda) = \overline{P}_{n|m|}(\cos\theta)\cdot\left\{\begin{array}{l}\cos m\lambda\\ \sin|m|\lambda\end{array}\right\}\begin{array}{l}\text{if } m \geq 0\\ \text{if } m < 0\end{array}. \tag{3}$$

$\overline{P}_{n|m|}(\cos\theta)$ is the fully normalized *Associated Legendre function* of the first kind, of degree n and order $|m|$ (Heiskanen and Moritz, 1967, Sects. 1–11 and 1–14). *Fully normalized* Associated Legendre functions are commonly used in geodesy. These are related to their unnormalized counterparts $P_{n|m|}(\cos\theta)$ by:

$$\overline{P}_{n|m|}(\cos\theta) = \sqrt{(2-\delta_{|m|0})(2n+1)\frac{(n-|m|)!}{(n+|m|)!}}\cdot P_{n|m|}(\cos\theta), \tag{4}$$

where:

$$\delta_{|m|0} = \left\{\begin{array}{ll}1 & \text{if } m = 0\\ 0 & \text{if } m \neq 0\end{array}\right. . \tag{5}$$

For the surface spherical harmonic functions Y_{nm}, this normalization implies that:

$$\frac{1}{4\pi}\iint_{\sigma} Y_{nm}^2(\theta,\lambda)\,d\sigma = 1, \tag{6}$$

with the integration being performed over the unit sphere σ, whose area element is $d\sigma$ ($d\sigma = \sin\theta d\theta d\lambda$). Note that in geomagnetism, the *Schmidt seminormalized* Associated Legendre functions (Blakely, 1995, p. 113) $\breve{P}_{n|m|}(\cos\theta)$ are used instead. These are defined by:

$$\breve{P}_{n|m|}(\cos\theta) = \sqrt{(2-\delta_{|m|0})\frac{(n-|m|)!}{(n+|m|)!}}\cdot P_{n|m|}(\cos\theta). \tag{7}$$

Surface spherical harmonics constitute a set of *orthogonal* basis functions on the unit sphere, i.e.:

$$\iint_{\sigma} Y_{nm}(\theta,\lambda) Y_{sr}(\theta,\lambda)\,d\sigma = 0 \quad \text{if } n \neq s \text{ or } m \neq r \text{ or both.} \tag{8}$$

This property of *orthogonality* permits the determination of the spherical harmonic coefficients v_{nm}, which appear in Equation 2, as follows. Assume for the sake of this discussion that the function $V(r,\theta,\lambda)$ is observable everywhere on the surface of the sphere $r = a$. Equation 2 then takes the form:

$$V(a,\theta,\lambda) = \sum_{n=0}^{\infty}\sum_{m=-n}^{n} v_{nm} Y_{nm}(\theta,\lambda). \tag{9}$$

In this case, the orthogonality of surface spherical harmonics implies that:

$$v_{nm} = \frac{1}{4\pi}\iint_{\sigma} V(a,\theta,\lambda) Y_{nm}(\theta,\lambda)\,d\sigma. \tag{10}$$

The coefficients v_{nm} constitute the *surface spherical harmonic spectrum* of the function $V(r,\theta,\lambda)$, pertinent to the surface of the sphere of radius $r = a$. It should be emphasized that *spherical harmonic expansions*, as the one given in Equation 9, are *not* restricted to functions satisfying Laplace's equation (*harmonic functions*). Any square integrable function $f(\theta,\lambda)$, defined over a surface S that has a one-to-one correspondence with the unit sphere, may be expanded in surface spherical harmonics as:

$$f^S(\theta,\lambda) = \sum_{n=0}^{\infty}\sum_{m=-n}^{n} f_{nm}^S Y_{nm}(\theta,\lambda), \tag{11}$$

with the coefficients f_{nm}^S given by:

$$f_{nm}^S = \frac{1}{4\pi} \iint_\sigma f^S(\theta,\lambda) Y_{nm}(\theta,\lambda) d\sigma. \tag{12}$$

The superscript "S" emphasizes the dependence of the spectrum f_{nm}^S of the function $f(\theta,\lambda)$, on the particular surface S over which its values $f^S(\theta,\lambda)$ are given. Jekeli (1988) carefully distinguishes between the direct Legendre transform (i.e., the spectrum) of an arbitrary square integrable function $f(\theta,\lambda)$, defined on a surface S that has a one-to-one correspondence with the unit sphere, and the special case of the solution of Laplace's equation when the boundary data reside on the surface of the sphere $r = a$. The former is expressed in Equations 11 and 12 above; the latter in Equations 9 and 10. Obviously the two quantities take the same form with an appropriate choice of coordinates. Furthermore, note that while rather arbitrary functions can be expanded in surface spherical harmonics, *only* harmonic functions (i.e., functions satisfying Laplace's equation) can be expanded into solid spherical harmonics, within their region of harmonicity.

The total power of the function $f(\theta,\lambda)$, defined over the surface S, is defined to be:

$$M\left\{\left[f^S\right]^2\right\} = \frac{1}{4\pi} \iint_\sigma \left[f^S(\theta,\lambda)\right]^2 d\sigma. \tag{13}$$

A generalization of Parseval's theorem permits the computation of $M\left\{\left[f^S\right]^2\right\}$ from the spectrum f_{nm}^S, by:

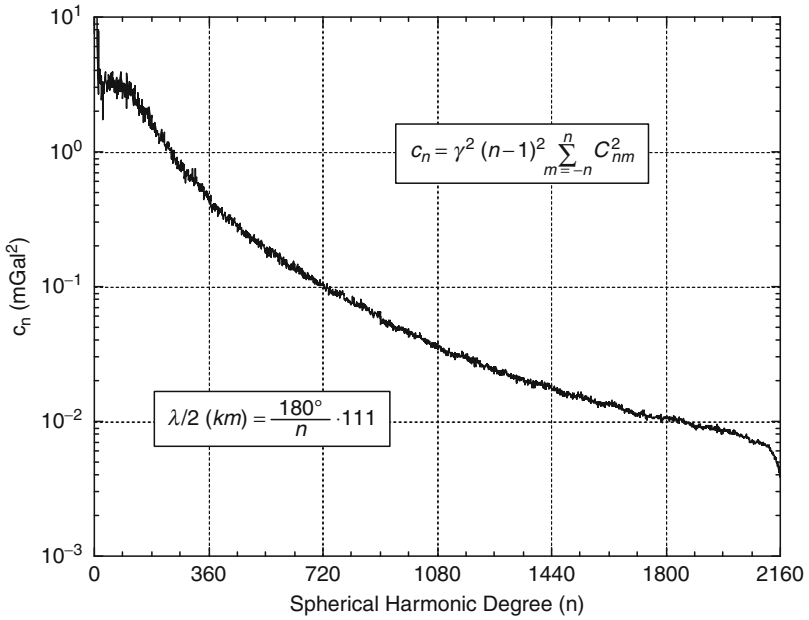
$$M\left\{\left[f^S\right]^2\right\} = \sum_{n=0}^{\infty} f_n^S = \sum_{n=0}^{\infty} \sum_{m=-n}^{n} \left[f_{nm}^S\right]^2. \tag{14}$$

The quantities f_n^S, defined as:

$$f_n^S = \sum_{m=-n}^{n} \left[f_{nm}^S\right]^2, \tag{15}$$

represent the total power (or variance) per spherical harmonic degree. In geodetic literature, they are known as *degree variances*. A direct correspondence exists between spherical harmonic degree and spatial wavelength. Therefore, the degree variances enable the study of the distribution of power within the function $f^S(\theta,\lambda)$, in terms of spatial wavelength. For example, Figure 1 (Pavlis et al., 2008) shows the degree variances implied by the Earth Gravitational Model 2008 (EGM2008) for the *free-air gravity anomaly* signal.

Spherical harmonic expansions of functions, such as the Earth's topography (heights above and depths below the Mean Sea Level), surface temperature, atmospheric pressure, etc., are very useful since they permit the study of the spectral properties of these functions. Furthermore, the decomposition of these functions into their spectral components permits the efficient application of *convolutions* on the sphere (Driscoll and Healy, 1994), and of



Spherical Harmonic Analysis Applied to Potential Fields, Figure 1 Degree variances (c_n) of the free-air gravity anomaly signal (in mGal^2) implied by the EGM2008 global gravitational model, as a function of spherical harmonic degree n. The degree variances refer to the surface of a sphere of radius $a = 6,378,136.3$ m. The relationship between half-wavelength $(\lambda/2)$ resolution and spherical harmonic degree is provided in the *insert*. In SI units, $1\ \mathrm{mGal} = 10^{-5}\ \mathrm{m\,s^{-2}}$.

band-pass filtering of data, with strict control on the filter's spherical harmonic-degree bandwidth. For functions representing potential fields, in addition to these spectral analysis applications, spherical harmonic analysis offers one approach for the solution of the underlying *Boundary Value Problem* that is associated with the specific *functional* of the field that has been observed. We discuss these aspects next.

Boundary Value Problems (BVP) of potential theory

In general, a BVP consists of a differential equation that is subject to a set of boundary conditions. In potential theory, the unknown (scalar) function to be determined is the potential, V, which satisfies Laplace's PDE, in the space outside of its generating sources. The function V should vanish at infinity as the reciprocal of the distance between the point in question and the generating source element. The boundary conditions, in order to be of practical use, should represent quantities related to V (*field functionals*) that are observable over some surface S. Two general approaches exist for the solution of a BVP:

(a) Solution using spectral analysis, i.e., spherical harmonics
(b) Solution using *Greens functions*, i.e., integral formulas

Traditionally, in gravimetric geodesy, the following three BVP of potential theory have been considered:

1. First BVP of potential theory, or *Dirichlet*'s problem (Heiskanen and Moritz, 1967, Sects. 1–16): given an arbitrary function f on a surface S, determine a function V that is harmonic either inside or outside S and which assumes on S the values of the prescribed function f. If the surface S is a sphere of radius $r = a$, the solution in terms of spherical harmonics, for the region outside S, is given by Equation 2. The corresponding Greens function solution is given by *Poisson*'s integral formula (Heiskanen and Moritz, 1967, Equation 1–89).
2. Second BVP of potential theory, or *Neumann*'s problem (Heiskanen and Moritz, 1967, Sects. 1–17): here, instead of the values of the potential V itself, one is given on a surface S the values of its normal derivative $\partial V/\partial n$. The normal derivative is the derivative along the outward-directed surface normal n to S. If the surface S is a sphere of radius $r = a$, the solution in terms of spherical harmonics, for the region outside S, is given by:

$$V(r,\theta,\lambda) = -a\sum_{n=0}^{\infty}\frac{1}{n+1}\left(\frac{a}{r}\right)^{n+1}\sum_{m=-n}^{n}u_{nm}Y_{nm}(\theta,\lambda), \tag{16}$$

where u_{nm} is the spectrum of the $\partial V/\partial n$ boundary values, given on the sphere $r = a$, i.e.:

$$\left(\frac{\partial V}{\partial n}\right)_{r=a} = \left(\frac{\partial V}{\partial r}\right)_{r=a} = \sum_{n=0}^{\infty}\sum_{m=-n}^{n}u_{nm}Y_{nm}(\theta,\lambda). \tag{17}$$

The values of u_{nm} can be obtained from:

$$u_{nm} = \frac{1}{4\pi}\iint_{\sigma}\left(\frac{\partial V}{\partial r}\right)_{r=a}Y_{nm}(\theta,\lambda)d\sigma. \tag{18}$$

The corresponding Greens function solution to the second BVP is given by *Hotine*'s integral formula (Hotine, 1969).

3. Third BVP of potential theory (Heiskanen and Moritz, 1967, Sects. 1–17): here, a linear combination of V and of its normal derivative $\partial V/\partial n$ is given on the surface S, i.e., $hV + k(\partial V/\partial n)$ is given on S. Again, if the surface S is a sphere of radius $r = a$, the solution in terms of spherical harmonics, for the region outside S, is given by:

$$V(r,\theta,\lambda) = \sum_{n=0}^{\infty}\frac{1}{h-(k/a)(n+1)}\left(\frac{a}{r}\right)^{n+1}\sum_{m=-n}^{n}w_{nm}Y_{nm}(\theta,\lambda), \tag{19}$$

where w_{nm} is the spectrum of the $hV + k(\partial V/\partial n)$ boundary values, given on the sphere $r = a$, i.e.:

$$\left(hV + k\frac{\partial V}{\partial n}\right)_{r=a} = \left(hV + k\frac{\partial V}{\partial r}\right)_{r=a} = \sum_{n=0}^{\infty}\sum_{m=-n}^{n}w_{nm}Y_{nm}(\theta,\lambda). \tag{20}$$

The values of w_{nm} can be obtained from:

$$w_{nm} = \frac{1}{4\pi}\iint_{\sigma}\left(hV + k\frac{\partial V}{\partial r}\right)_{r=a}Y_{nm}(\theta,\lambda)d\sigma. \tag{21}$$

This particular BVP is of great importance to physical geodesy. The determination of the *geoid* given *gravity anomalies* as boundary data – called the BVP of physical geodesy – represents a specific case of this third BVP, where $h = -2/a$ and $k = -1$. With these values for h and k, if the surface S is a sphere of radius $r = a$, the solution in terms of spherical harmonics, for the region outside S, is given by:

$$V(r,\theta,\lambda) = a\sum_{n=0}^{\infty}\frac{1}{n-1}\left(\frac{a}{r}\right)^{n+1}\sum_{m=-n}^{n}g_{nm}Y_{nm}(\theta,\lambda), \tag{22}$$

where g_{nm} is the spectrum generated from the SHA of the gravity anomaly boundary values that are given on the sphere $r = a$. The corresponding Greens

function solution to the BVP of physical geodesy is given by *Stokes'* integral formula (Heiskanen and Moritz, 1967, Sects. 2–16).

Other BVP may also be formulated and solved, which correspond to other observable boundary data. For example, one may consider the *tensor* of second-order gradients of the gravitational potential (Moritz, 1980, p. 4) (or some subset of the elements of this tensor) as boundary data, which give rise to BVP corresponding to *gravity gradiometry*.

Equations 9, 17, and 20 are all of the same form as Equation 11. Therefore, provided that the boundary data are given on, or can be reduced to, the surface of a sphere of radius $r = a$, surface SHA may be used to determine the surface spherical harmonic spectrum of the field. This surface spectrum, multiplied by the appropriate radial terms that appear in Equations 2, 16, and 19, provides then a solution in terms of solid spherical harmonics, to the corresponding BVP. The convergence of the series 2, 16, and 19 is guaranteed in the space outside of the sphere $r = a$.

Laplace's PDE can also be expressed in terms of the *ellipsoidal coordinates* (u, δ, λ), where u is the semi-minor axis of the confocal ellipsoid, δ is the *reduced* colatitude (defined as 90° minus the reduced latitude), and λ is the longitude (Heiskanen and Moritz, 1967, Sects. 1–19). The Cartesian coordinates (x, y, z) of a point are related to its spherical (r, θ, λ) and ellipsoidal (u, δ, λ) coordinates as follows:

$$\begin{aligned} x &= r\sin\theta\cos\lambda = \left(u^2 + E^2\right)^{1/2}\sin\delta\cos\lambda \\ y &= r\sin\theta\sin\lambda = \left(u^2 + E^2\right)^{1/2}\sin\delta\sin\lambda, \\ z &= r\cos\theta = u\cos\delta \end{aligned} \tag{23}$$

where E is the constant linear eccentricity of the family of confocal ellipsoids defining the coordinate system. Expressed in the (u, δ, λ) coordinate system, Laplace's PDE can also be solved using the method of separation of variables. The solution, for the space exterior to a reference ellipsoid with semi-minor axis $u = b$, is given by (Heiskanen and Moritz, 1967, Sects. 1–20):

$$V(u,\delta,\lambda) = \sum_{n=0}^{\infty}\sum_{m=-n}^{n}\frac{Q_{n|m|}(i(u/E))}{Q_{n|m|}(i(b/E))}z_{nm}Y_{nm}(\delta,\lambda). \tag{24}$$

$Q_{n|m|}(i(u/E))$ is the *Associated Legendre function* of the second kind, of degree n and order $|m|$ (Heiskanen and Moritz, 1967, Sects. 1–12). i is the imaginary unit $(i = \sqrt{-1})$. On the surface of the reference ellipsoid $u = b$, Equation 24 becomes:

$$V(b,\delta,\lambda) = \sum_{n=0}^{\infty}\sum_{m=-n}^{n} z_{nm}Y_{nm}(\delta,\lambda). \tag{25}$$

Equation 25 is of the same general form as Equations 9 and 11, with the important distinction that δ now represents the *reduced* colatitude. The surface *ellipsoidal* harmonic spectrum z_{nm} can be determined from:

$$z_{nm} = \frac{1}{4\pi}\iint_{\sigma} V(b,\delta,\lambda)Y_{nm}(\delta,\lambda)d\sigma, \tag{26}$$

in exactly the same fashion as in the case of the surface *spherical* harmonic spectrum in 10 and 12. Note that the integration is again over the unit sphere, whose area element is now defined as $d\sigma = \sin\delta d\delta d\lambda$.

Spherical harmonics are used extensively in geodesy because of their simplicity, and because the Earth, to a first-order approximation, is a sphere. Since, to a second-order approximation, the Earth resembles more an ellipsoid of revolution, ellipsoidal harmonics are more suitable for the solution of BVP, when the boundary data reside on or near the surface of the Earth. The transformation between ellipsoidal and spherical harmonics can be performed using the exact analytical relationships formulated by Jekeli (1988) and implemented by Gleason (1988). In this fashion, the use of the rather complicated solid ellipsoidal harmonics of Equation 24 may be avoided altogether.

Spherical Harmonic Analysis (SHA): numerical techniques

Let us consider Equations 11 and 12. Equation 11 is representative of Equations 9, 17, 20, and 25, while Equation 12 is representative of Equations 10, 18, 21, and 26. Each one of Equations 11 and 12 suggests an alternative approach for the estimation of the coefficients f^S_{nm}, as we discuss next.

Least Squares Adjustment. The first approach uses the linear mathematical model of Equation 11 to set up a system of *observation equations*. With f^S_{obs} representing the observable quantity and $\hat{f}^S_{nm}$ the estimates of the unknown parameters, the observation equations can be written as:

$$\upsilon(\theta,\lambda) = \sum_{n=0}^{N}\sum_{m=-n}^{n}\hat{f}^S_{nm}Y_{nm}(\theta,\lambda) - f^S_{obs}(\theta,\lambda), \tag{27}$$

where $\upsilon(\theta,\lambda)$ is the residual associated with the observation $f^S_{obs}(\theta,\lambda)$. Notice that in Equation 27 the summation over spherical harmonic degree was truncated to a finite maximum degree N. In vector-matrix notation, Equation 27 takes the form:

$$\mathbf{v} = \mathbf{A}\hat{\mathbf{x}} - \mathbf{l}. \tag{28}$$

$\mathbf{v}$ is the vector representing the residuals $\upsilon(\theta,\lambda)$, $\mathbf{A}$ is the *design matrix* containing the terms that multiply the unknown parameters $\hat{f}^S_{nm}$, $\hat{\mathbf{x}}$ is the vector representing the unknown parameters $\hat{f}^S_{nm}$, and $\mathbf{l}$ is the vector containing the observations $f^S_{obs}(\theta,\lambda)$. In Equation 28, only the matrix

$\mathbf{A}$ and the vector $\mathbf{l}$ are known quantities. The linear system (28) can be solved using the method of *Least Squares Adjustment*. If $\boldsymbol{\Sigma}$ denotes the variance–covariance matrix of the errors associated with the observations $f^S_{obs}(\theta,\lambda)$, then, minimization of the quadratic form:

$$\phi = \mathbf{v}^{\mathbf{T}}\boldsymbol{\Sigma}^{-1}\mathbf{v}, \tag{29}$$

subject to the condition (28), leads to the *normal equations*:

$$\mathbf{N}\hat{\mathbf{x}} = \mathbf{U}, \text{where} \quad \mathbf{N} = \mathbf{A}^{\mathbf{T}}\boldsymbol{\Sigma}^{-1}\mathbf{A} \quad \text{and} \quad \mathbf{U} = \mathbf{A}^{\mathbf{T}}\boldsymbol{\Sigma}^{-1}\mathbf{l}. \tag{30}$$

A scaled version of the inverse of the variance–covariance matrix is the weight matrix $\mathbf{P}$. $\mathbf{P} = \sigma_0^2\boldsymbol{\Sigma}^{-1}$ and σ_0^2 is called the a priori variance of unit weight. σ_0^2 represents the error variance of an observation whose weight is equal to 1. The solution of the system of normal equations is:

$$\hat{\mathbf{x}} = \mathbf{N}^{-1}\mathbf{U}. \tag{31}$$

The variance-covariance matrix of the errors associated with the estimated values $\hat{\mathbf{x}}$ is given by:

$$\boldsymbol{\Sigma}_{\hat{\mathbf{x}}} = \mathbf{N}^{-1} = \left(\mathbf{A}^{\mathbf{T}}\boldsymbol{\Sigma}^{-1}\mathbf{A}\right)^{-1}. \tag{32}$$

Carl Friedrich Gauss (1777–1855), who is credited with the development of the Least Squares Adjustment technique, used this approach in the analysis of geomagnetic data. Herein, we abbreviate the Least Squares Adjustment technique by LS.

Although in the previous discussion we presented the application of the LS method to a mathematical model that describes a *surface* spherical harmonic expansion, the LS method could be applied equally well to mathematical models describing *solid* spherical harmonic expansions, like those of Equations 2, 16, and 19. This means that one may use the LS method to estimate the spectra of potential fields, even when the boundary data are arbitrarily located in the three-dimensional space. In contrast, the *Numerical Quadrature* technique that we discuss next, when used for the determination of potential fields, requires that the boundary data are located over surfaces that are coordinate surfaces in the coordinate system in which Laplace's equation is formulated and solved ($r = const.$ for spherical harmonics, $u = const.$ for ellipsoidal harmonics). In theory, these coordinate surfaces must also encompass all the sources generating the field.

Numerical Quadrature. In the above discussion of the LS technique, the distribution, both in terms of location and in terms of number, of the measured values $f^S_{obs}(\theta,\lambda)$ remained unspecified. Consider now an equiangular ($\Delta\theta = \Delta\lambda$) partition of the unit sphere, along meridians ($\lambda = const.$) and parallels ($\theta = const.$). Such a partition creates a grid of $L \times 2L$ cells on the unit sphere, where $L = \pi/\Delta\theta$. Let us assume that the function $f(\theta,\lambda)$ was sampled in such a way that, for each one of the $L \times 2L$ cells, a value $f^S_{obs}(\theta,\lambda)$ exists that corresponds, for example, to the center of that cell. Such a sampling suggests a possible *discretization* of the surface integral of Equation 12, leading to the following *Numerical Quadrature* (NQ) formula (Colombo, 1981, Equation 1.5):

$$\tilde{f}^S_{nm} = \frac{1}{4\pi}\sum_{i=0}^{L-1}\sum_{j=0}^{2L-1} f^S_{obs}(\theta_i,\lambda_j)\,Y_{nm}(\theta_i,\lambda_j)\,\Delta\sigma_i, \tag{33}$$

where the area element $\Delta\sigma_i$ of the cells residing on the ith "row" is given by:

$$\Delta\sigma_i = \Delta\lambda\int_{\theta_i}^{\theta_{i+1}} \sin\theta d\theta = \Delta\lambda\cdot(\cos\theta_i - \cos\theta_{i+1}). \tag{34}$$

Equation 33 is a simple NQ formula, applicable to data $f^S_{obs}(\theta,\lambda)$ that represent point values.

In general, the estimate of the spectrum obtained either by using LS or by using NQ, will be different from the "true" spectrum f_{nm} of the function $f(\theta,\lambda)$. Furthermore, even when the two techniques are applied to the same data $f^S_{obs}(\theta,\lambda)$, their estimates will be, in general, different, i.e.:

$$\hat{f}^S_{nm} \neq \tilde{f}^S_{nm}. \tag{35}$$

It is therefore appropriate to consider the specific errors that affect $\hat{f}^S_{nm}$ and $\tilde{f}^S_{nm}$, compare the LS and NQ techniques, and determine if it is possible to design and formulate any other SHA technique(s) that would satisfy some desirable optimality criterion. This study was essentially carried out by Colombo (1981), in his treatise of the subject, entitled *Numerical Methods for Harmonic Analysis on the Sphere*. We summarize in the following Colombo's developments and provide some examples of practical application of his formulations. Before this, however, we need to define and discuss briefly the error sources that affect any estimate of the spectrum of a function that is obtained on the basis of observed data, regardless of the technique that is used to obtain this spectrum.

- *Error Sources.* Two types of errors affect any estimate of the spectrum that is obtained from observations of a function: (a) Sampling error, and, (b) Propagated noise. The sampling error arises due to the fact that in reality, observations can only be made at a finite number of discrete points, while Equations 11 and 12 require the function $f(\theta,\lambda)$ to be known at *every* point on the surface S. Propagated noise, on the other hand, arises due to the fact that observations can never be error-free. Therefore, errors in the observations (both random and systematic) will generally propagate into the spectrum that is estimated from them.

Optimal Estimation. The particular way that sampling errors and propagated noise affect the estimated spectrum depends on the particular technique used to estimate the

spectrum. Colombo (1981) designed and formulated a linear estimator of the spectrum, which is optimal in the sense that it minimizes the sum of the squares of the sampling error and the propagated noise. His *Optimal Estimation* (OE) technique is a form of Numerical Quadrature, where the *optimal* quadrature weights are defined using the formalism of *Least Squares Collocation* (LSC) (Moritz, 1980). By exploiting the geometry of regular grids (i.e., grids where at least the longitude increment is constant) of data located over surfaces that have rotational symmetry (such as a sphere or a rotational ellipsoid), and by imposing certain conditions on the *covariance functions* of the signal and the data noise, Colombo (1981) demonstrated that the variance–covariance matrix of such data sets consists of *Toeplitz-circulant* blocks. These matrix blocks can be formed and inverted very efficiently, even when the size of the data set is very large. Colombo's OE technique was used in the gravitational field expansion developed by Hajela (1984), and in the OSU86C/D global gravitational models developed by Rapp and Cruz (1986a). Additional discussion about the estimation of gravitational spectra using LSC can be found in Tscherning (2001).

Colombo (1981, p. 76) also investigated the use of a semiempirical set of numerical quadrature weights, which depend only on the spherical harmonic degree, and can be evaluated very easily as a function of Pellinen's smoothing factors (Colombo, 1981, p. 85). Although suboptimal, these numerical quadrature weights proved to be quite adequate and were used in several gravitational modeling studies. The OSU86E/F (Rapp and Cruz, 1986b) and the OSU89A/B (Rapp and Pavlis, 1990) global gravitational models were developed using these semiempirical numerical quadrature weights.

Practical aspects

Several factors complicate the application of SHA techniques when analyzing real data. These are related on the one hand to the inherent properties of the alternative SHA techniques, and on the other to the properties of the data to be analyzed. The former have to do with the computational capabilities and requirements (i.e., the flexibility and efficiency) of the different SHA techniques. The latter include issues related to the distribution and type (point or area-mean values) of the available data, the geometry of the grid to which the original data are reduced, the spectral properties of the function $f(\theta, \lambda)$ that is being approximated, and the spectral properties of the errors that may affect the observed values $f^S_{obs}(\theta, \lambda)$. We discuss briefly these factors in the following paragraphs.

- *Computational Issues.* An inspection of Equations such as (11) indicates that a spherical harmonic expansion complete to degree and order N contains $(N+1)^2$ harmonic coefficients f^S_{nm} in total. Therefore, the normal matrix $\mathbf{N}$ of Equation 30 has dimensions $(N+1)^2 \times (N+1)^2$. The structure and characteristics of the matrix $\mathbf{N}$ depends on the geometry of the available data distribution and on the characteristics of the variance–covariance matrix $\mathbf{\Sigma}$ of the data errors. If the data to be analyzed are arbitrarily located in latitude and longitude, as is the case with most raw geophysical data collected in the field (e.g., gravimetric or magnetometric data), then, apart from symmetry, the matrix $\mathbf{N}$ would be fully occupied. The same is true (in general) if the error variance–covariance matrix $\mathbf{\Sigma}$ is arbitrary. The size of the normal matrix $\mathbf{N}$ is already formidable for expansions complete to degree and order 200 or so. Normal matrices for expansions to degree and order 2160, as the one corresponding to the EGM2008 model (Pavlis et al., 2008), are well beyond current computational capabilities. Nevertheless, provided that the size of the normal matrix can be handled computationally, LS adjustment and LSC are the *only* techniques that can handle arbitrarily located data, with arbitrary error variance–covariance matrices. NQ and OE require the data to be input in the form of a grid, and impose restrictions on the stochastic properties of the noise, represented within the matrix $\mathbf{\Sigma}$. In the following, we assume that the raw data have been preprocessed in some fashion, so that the input data to the various estimators are available in gridded form.

As we mentioned previously, unlike estimators based on orthogonality relations, LS permits also the use of *solid* spherical harmonics in the formation of observation equations. Assume for the sake of this example, that a grid of potential values V is available over the physical surface of the Earth (the topography). One may then form observation equations on the basis of the mathematical model given in Equation Equation 2. In such a case, even if the V values are given over a regular latitude-longitude grid, these values would still be located arbitrarily in the radial direction. This would then require the formation and inversion of a fully occupied normal matrix, as it is described by Pavlis (1988), who performed such estimations to degree 36, 50, and 70, using equiangular grids of free-air gravity anomalies defined on the surface of the Earth's topography.

- *Data Organization, Types, and Distribution.* In most geodetic and geophysical SHA applications, the data are organized in geographic grids. Equiangular grids are most often used, although grids with cells of equal area are also possible, and have been used in some cases. There is therefore a need to transition from the arbitrarily located point measurements, to "artificial" measurements referring to the nodes of some specified grid. In geodetic practice, this transition is accomplished by predicting what the "artificial" grid measurements would have been, given the available arbitrarily scattered data. The prediction is done using the LSC formalism, which requires some knowledge of the signal and noise covariance functions of the data (Moritz, 1980). One usually applies LSC to predict area-mean values for the grid cells, rather than point values. SHA can be applied equally well using either point or

area-mean gridded data. In the case of area-mean values, the mathematical models have to be modified appropriately, so that they accurately represent the area-mean character of the data. This is done by integrating the surface spherical harmonic functions over the specific latitudinal and longitudinal limits of each grid cell. From Equation 3 one has:

$$\int_{\theta_i}^{\theta_{i+1}} \int_{\lambda_j}^{\lambda_{j+1}} Y_{nm}(\theta,\lambda)\sin\theta d\theta d\lambda = \int_{\theta_i}^{\theta_{i+1}} \overline{P}_{n|m|}(\cos\theta)\sin\theta d\theta \int_{\lambda_j}^{\lambda_{j+1}} \begin{Bmatrix} \cos m\lambda \\ \sin|m|\lambda \end{Bmatrix} d\lambda \quad \begin{matrix} \text{if } m \geq 0 \\ \text{if } m < 0 \end{matrix}. \tag{36}$$

Efficient recurrence relationships for evaluating the integrals of the Associated Legendre functions have been derived by Paul (1978). The numerical treatment of the evaluation of Associated Legendre functions of very high degree (e.g., $n > 1,400$ or so) requires special care since some of the values of these functions become exceedingly small, which could cause numerical problems.

Even after the gridding of geophysical data collected on or near the Earth's surface, the radial location of these data, corresponding to the Earth's topography, remains arbitrary. Solutions of BVP that are based on orthogonality relations, formulated in either spherical or ellipsoidal harmonics, require these data to be located over a sphere or an ellipsoid, respectively. This artificial (approximately radial) "movement" of the data can be accomplished using *analytical continuation*. Wang (1987, 1988) discusses some techniques that can be applied to analytically continue gravity anomaly data.

In many geophysical problems where SHA techniques are applied, the available data do not suffice to cover completely the Earth. Data gaps can produce undesirable *leakage* effects in the spectral estimates, which by definition are of global character, and require global coverage. These undesirable effects are different depending on the particular technique used to estimate the spectrum. In LS, the spectral estimator "interprets" a data gap as an undefined data value with infinite error, i.e., zero weight (see Pavlis, 1988 for details). In NQ techniques, the estimator "interprets" a data gap as a data value that is equal to zero. In either case, the estimated spectrum would produce undesirable results when evaluated over the region of the data gap. It is therefore preferable to "fill in" data gaps with some reasonable values of the quantity under consideration. These "fill-in" values may be obtained on the basis of other data and/or models. For example, in gravity modeling, topographic elevations and models of the *isostatic compensation* may be used to "fill in" areas void of actual gravity measurements (cf. Pavlis and Rapp, 1990).

- *LS versus NQ techniques*. It is of interest to compare the LS and the NQ techniques from an analytical as well as a numerical perspective. Such studies have been reported by Rapp (1969, 1986), Colombo (1981), and Pavlis (1988). Sneeuw (1994) discussed the two techniques from a historical perspective. A brief review of the conclusions reached by these investigations follows. Detailed derivations and analyses supporting these conclusions can be found in the cited references. NQ is used here to identify the simple numerical quadratures formula with the semiempirical set of suboptimal quadrature weights proposed by Colombo (1981, p. 76).
  1. NQ determines each harmonic coefficient independently of all others. In contrast, LS estimates a correlated set of coefficients; thus, solutions to different maximum degrees will yield different values for the common harmonic coefficients. This will occur even if the input data are uncorrelated, and arises from the loss of orthogonality between the discrete (point or integrated) samples of the Associated Legendre functions (Pavlis, 1988, Sect. 4.2.1). Unlike the Legendre functions, discrete (point, as well as integrated) samples of $\cos m\lambda$ and $\sin m\lambda$ preserve their orthogonality in the interval $[0, 2\pi)$, as long as the sampling interval $\Delta\lambda$ is constant. It is this orthogonality property of sines and cosines, along with the equatorial symmetry and the parity properties of Legendre functions, which produce the sparsity patterns of the *Block-Diagonal* (*BD*) *Least Squares* technique that we discuss next.
  2. NQ cannot account for varying accuracies of the input data, while the LS estimator is capable of accounting for any (positive-definite) error variance–covariance matrix $\boldsymbol{\Sigma}$ associated with the input data.
  3. If $L(=\pi/\Delta\theta)$ denotes the *Nyquist degree* implied by the data sampling interval, then the normal equations formed based on observation equations like (27) become singular if $N \geq L$ (Colombo, 1981), where N is the maximum solved-for degree.
  4. LS estimation (and LSC) can recover *exactly* a set of coefficients from "synthetic" noiseless data, provided that the data are band-limited and their frequency content does not exceed the Nyquist degree. This property offers also one verification test that any software developed to perform SHA using the LS technique should pass (Pavlis, 1988, Sect. 4.2.2). The simple NQ technique is incapable of recovering the original "true" coefficients from which the "synthetic" data were computed, as Rapp's (1986) numerical experiments have also demonstrated.
  5. Unlike the LS technique, the simple NQ does not involve any matrix formation or inversion. In this

regard, the simple NQ is considerably less demanding computationally than LS. In addition, if the sampling interval $\Delta\lambda$ in the longitude direction is constant, then the NQ SHA algorithm can benefit enormously from the application of *Fast Fourier Transform* (FFT) techniques, as it was pioneered by Colombo (1981).

6. In contrast to the simple NQ, the LS technique produces not only the estimates of the coefficients, but also an estimate of their error variance–covariance matrix (see Equation 32). This matrix can then be used to propagate the errors of the estimated coefficients onto other quantities that may be computed from them.

Block-Diagonal (BD) Least Squares. From the previous discussion, it becomes clear that a SHA technique that would combine the computational efficiency of the simple NQ, with the rigor and flexibility of LS, is highly desirable. Such a technique would attempt to retain the advantages of both techniques, while avoiding their respective limitations. The Block-Diagonal (BD) Least Squares may be viewed as such a "best of both worlds" type of technique. Colombo (1981) has shown that if:

(a) The data reside on a surface of revolution (e.g., a rotational ellipsoid or a sphere)
(b) The grid is complete and the longitude increment is constant
(c) The data weights are longitude-independent
(d) The data weights are symmetric with respect to the equator

then, the elements of the normal matrix **N**, corresponding to the coefficients f^S_{nm} and f^S_{rq}, would be zero as prescribed by (see also Pavlis, 1988 for details):

$$[\mathbf{N}]_{f^S_{nm} f^S_{rq}} = 0 \quad \text{if } m \neq q, \quad \text{or if } m = q \text{ and } n - r = 2k + 1. \tag{37}$$

Note that in this notation the order subscript is a signed integer, whose sign identifies the type of coefficient (positive: cosine, negative: sine). If condition (d) does not hold true, then:

$$[\mathbf{N}]_{f^S_{nm} f^S_{rq}} = 0 \quad \text{if } m \neq q. \tag{38}$$

The sparsity patterns implied by Equations 37 and 38 will be referred to as BD1 and BD2 respectively. In addition, a BD3 pattern may be considered, defined by:

$$[\mathbf{N}]_{f^S_{nm} f^S_{rq}} = 0 \quad \text{if } |m| \neq |q|, \tag{39}$$

which admits nonzero off-diagonal elements across coefficients of different type within a given order. It is instructive to consider the computational efficiency implied by these patterns. Table 1, which is taken from Pavlis, pp. 8–5, in Lemoine et al. (1998), provides relevant statistics for an expansion complete from degree and order 0 to degree and order 360, excluding degree $n = 1$ terms. Such an expansion involves 130,318 unknown coefficients and the upper (or lower) triangular part of the symmetric but fully occupied normal matrix **N** has 8,491,455,721 elements in total.

The enormous computational savings that can be inferred from Table 1 make the BD approximations very attractive estimation techniques. These savings, however, come at the expense of the rigor exercised in the implementation of the SHA. Any approximation of a normal matrix by a BD structure should be simple enough to permit efficient numerical implementation, and, on the same time, rigorous enough to maintain the most important characteristics of the full matrix. Therefore, one has to consider carefully whether the approximations leading to the various BD sparsity patterns can be tolerated, given the characteristics of the particular data set that is analyzed. For example, in global gravitational modeling applications, the real-world gravity anomaly data to be analyzed comply *only* with the conditions (a) and (b) above. In fact, to comply even with the (a) and (b) conditions, "filling-in" techniques and analytical continuation have to be employed, since the original data set is neither complete, nor residing on any surface of revolution, since it refers to the Earth's topography. These aspects were carefully considered in the development of the OSU91A (Rapp et al., 1991) and the EGM96 (Lemoine et al., 1998) gravitational models. In both these models, different SHA techniques were used toward the estimation of different spectral portions of the models. This was due to the fact that different spectral portions of these models were determined on the basis of different gravimetric data sets.

In the case of *band-limited* data, one can show that the LS adjustment approach using a priori information is

Spherical Harmonic Analysis Applied to Potential Fields, Table 1 Statistics of normal matrices related to an expansion complete to degree $N = 360$ (excluding degree $n = 1$ coefficients) using different sparsity patterns

	Sparsity pattern		
Statistic	BD1	BD2	BD3
Total number of nonzero elements	7,905,721	15,746,100	31,362,241
Percentage of full matrix elements	0.09	0.19	0.37
Number of blocks	1,440	721	361
Number of unknowns in largest block	181	360	718
Number of elements in largest block	16,471	64,980	258,121

formally equivalent to LSC (Moritz, 1980, p. 166; Colombo, 1981, Sect. 2.13). In such a case, the BD approaches discussed previously are the Least Squares counterpart of Colombo's (1981) Optimal Estimation technique.

BD techniques of varying sophistication have been used to develop GPM2 (Wenzel, 1985), DGFI92A (Gruber and Bosch, 1992), GFZ95A (Gruber et al., 1996), the GPM98A, B, and C models (Wenzel, 1998, 1999), and the EGM2008 model (Pavlis et al., 2008).

Some of the BD structures of the normal matrix that were discussed above arise also in the analysis of data from certain configurations of *Satellite-to-Satellite Tracking* (SST) and of *Satellite Gravity Gradiometry* (SGG). This was also recognized and studied by Colombo (1984, 1989). Schuh (1996) provides a detailed study of the numerical solution strategies applicable to the analysis of such observables. SST data (in the "low-low" configuration) are currently available from the GRACE mission (GRACE, 1998), and SGG data are currently being collected from the GOCE mission (ESA, 1999). The availability of BD normal matrices resulting from the analysis of SST and SGG data is very important when considering the combination of these matrices with corresponding matrices derived from the analysis of global grids of gravimetric data. Such a combination of BD normal matrices permits the efficient development of global gravitational models to a very high degree (2160), as it was done in the case of EGM2008 (Pavlis et al., 2008).

Summary

Spherical Harmonic Analysis (SHA) is a critical element of the solution of Boundary Value Problems associated with potential fields. SHA is applicable not only to potential fields but also to a rather wide class of functions that are sampled over surfaces which have a one-to-one correspondence with the unit sphere. Least Squares (using either fully occupied or block-diagonal normal matrices), Numerical Quadrature, and Optimal Estimation techniques have been used to perform SHA within gravitational and magnetic field modeling efforts. The organization of the data to be analyzed in the form of geographic grids defined by meridians and parallels enables the use of highly efficient numerical algorithms for SHA. In particular, grids with constant longitudinal spacing of data permit the application of Fast Fourier Transform techniques, thereby increasing tremendously the efficiency of the SHA algorithms.

STATISTICAL SEISMOLOGY

David A. Rhoades
GNS Science, Lower Hutt, New Zealand

Synonyms

Earthquake statistics; Statistical methods in seismology

Definition

Stochastic process. A process evolving in time governed partly by probability distributions.

Point process. Stochastic process of point events in time or space or both.

Renewal process. Point process in which the probability distribution of the time to the next event depends only on the time since the last event.

Stationary Poisson process. Point process in which the numbers of events in distinct time intervals of the same length are independent and have the same distribution.

Branching process. Process involving ancestors and offspring.

Introduction

Statistical seismology is an emerging field of research at the interface of statistical and physical modeling of earthquake occurrence. It is concerned with quantifying and understanding the distribution of earthquakes in time, magnitude, and location. It includes empirical analysis of earthquake catalogues, stochastic modeling of earthquake occurrence, estimation of the probability of earthquake occurrence and of earthquake-induced ground shaking, and testing the forecasting power of physical and statistical models of seismicity (Vere-Jones et al., 2005). It provides input to the management of seismic hazard and risk. Although efforts have so far focused mainly on the study of earthquake catalogues, there is scope to incorporate other geophysical measurements into the analyses.

Empirical relations

One of the classical empirical relations of statistical seismology is the Gutenberg and Richter (1944) law, according to which the distribution of earthquake magnitudes M within a large time-space volume has a probability density proportional to 10^{-bM}, where the parameter b is close to 1. Physical upper limits to earthquake size necessitate tapering of the density at high magnitudes (Kagan, 1999). For small space-time volumes and in certain tectonic settings, the b-value can differ markedly from 1. Temporal variation in b-value has been proposed as an earthquake precursor. Since the radiated seismic energy E_S of an earthquake is approximately proportional to $10^{1.5M}$, the Gutenberg–Richter law implies that the distribution of radiated seismic energy has density proportional to $E_S^{-(\beta+1)}$, where $\beta = 2/3b$. Thus, the Gutenberg–Richter law can be viewed as a power law. The existence of such power laws is often taken as evidence of fractality and self-organized criticality in the earthquake process (Bak and Tang, 1989).

Earthquakes tend to occur in clusters. A common type of cluster is the main shock – aftershock sequence. The Omori–Utsu law, first noted by Fusakichi Omori in 1894, describes how an aftershock sequence decays over time (Utsu et al., 1995). According to this relation, which is also a power law, the rate of aftershock occurrence is proportional to $(t + c)^{-p}$, where t is the elapsed time following the occurrence of the main shock, and c and p are adjustable parameters, typically with $c << 1$ day, and $p \approx 1$. In some large aftershock sequences, the relation

can be seen to hold for decades after the occurrence of the main shock.

The area occupied by an aftershock sequence is approximately 10^{M-4} km^2, where M is the main shock magnitude (Utsu, 1961). This is consistent with scaling relations derived for earthquake source dimensions – fault length, width, and displacement – all of which are approximately proportional to $10^{0.5M}$ (Wells and Coppersmith, 1994). However, sometimes major earthquakes appear to trigger aftershocks at long distances from the earthquake source. These can be accommodated by a power law in which the aftershock density is proportional to $(d^2 + r^2)^{-q}$, where r is the distance from the source, q is an adjustable parameter, typically about 1.5, and d is a function proportional to$10^{0.5M}$.

According to Båth's law (Båth, 1965), the largest aftershock is typically about 1.2 magnitude units smaller than the main shock. This indicates that the main shock and its aftershocks do not by themselves conform to the Gutenberg–Richter relation, the main shock being too large relative to the other earthquakes in the set. The existence of other types of earthquake clusters than main shock – aftershock sequences, such as swarms (which have no main shock) and multiplets (which may have several main shocks) is a confounding element in attempts to systematically examine Båth's relation.

Rules for defining and classifying earthquake clusters are necessarily somewhat arbitrary. Sometimes a stochastic model of earthquake clustering is used to calculate the probability that a given earthquake belongs to a cluster, and then the analysis considers many different possible groupings of the earthquakes into clusters (Zhuang et al., 2002).

Data quality is an ever-present issue affecting statistical analysis of earthquake catalogues. It is necessary to establish the quality of a catalogue at the outset, because an analysis can be seriously compromised by changes in the quality of the catalogue over time, such as temporal and spatial variation of the magnitude threshold of completeness. On the positive side, catalogue data are generally improving in both quality and quantity as better seismograph networks and earthquake location techniques are employed, and this is creating opportunities for more detailed analyses.

Precursors

Studies aimed at identifying precursors of large earthquake are faced with a dual challenge: Whereas large earthquakes are relatively rare, the number of degrees of freedom available when attempting to identify precursors is large. Therefore, a careful analysis is required before the conclusion is drawn that a proposed precursory phenomenon is real. A retrospective analysis can be used to define a possible precursory phenomenon, but prospective testing is necessary to confirm it.

Many major earthquakes are preceded in the long term by an increase in the rate of occurrence and magnitude of minor earthquakes, in an area not much larger than the major earthquake source. This is called the precursory scale increase (Evison and Rhoades, 2004). Sometimes, it consists of a sequence of swarms. The magnitude of the largest precursor is typically about one unit smaller than that of the main shock, and the precursor time T_P (the time from the onset of the increase to the main shock) and the area in which the precursors, major earthquake, and aftershocks all take place are both approximately proportional to $10^{0.5M}$. Earthquake precursors for which T_P is proportional to $10^{0.5M}$ are known as precursors of the first kind (Rikitake, 1982), and include anomalies in tilt, strain and land deformation, and changes in the relative velocities of seismic P and S waves. A distinguishing feature of the precursory scale increase is that the magnitude of the largest precursor(s) can be used to predict the time of occurrence, magnitude, and source area of the major earthquake.

Models of earthquakes as a critical phenomenon have been invoked to suggest that an accelerating moment release (AMR) should occur in an area much larger than the earthquake source in the approach of criticality, i.e., an accelerating occurrence of minor earthquakes leading up to a major earthquake. Another much-studied phenomenon is precursory seismic quiescence (PSQ) – a proposed reduction in the rate of occurrence of minor earthquakes shortly before a major event. There is apparent empirical support for both AMR and PSQ, but its statistical significance has been questioned. A problem in resolving such matters is that these phenomena, like many other proposed precursors, have only been defined anecdotally and never identified with an explicit stochastic model of earthquake occurrence.

Stochastic models of earthquake occurrence

Early examples of stochastic modeling of earthquake sequences were given by Vere-Jones (1970). Modeling of earthquake occurrence has benefited from the development of the theory of stochastic point processes (Daley and Vere-Jones, 2003).

The idea of successive episodes of stress accumulation and release, as suggested by the elastic rebound theory of Henry Fielding Reid in 1910, is the basis for most modeling of recurrence of major earthquakes on a fault or fault segment. The time sequence of earthquakes is often modeled as a renewal process, assuming a characteristic magnitude for events on the fault. The recurrence-time distribution is variously taken as exponential (for constant hazard), Weibull, lognormal, or Brownian passage-time. The latter three distributions all imply some degree of regularity in the time intervals between earthquakes, and physical arguments have been advanced in support of each. The limited data so far available on earthquake recurrence on fault segments do not support a clear preference for a particular distribution or afford a real opportunity to test how informative renewal models are in this context. It is important to account for data and parameter uncertainties when applying such models to the estimation of earthquake hazard.

The renewal process model does not allow for interactions between neighboring faults or for variation in the size of successive events. Models involving time and magnitude include the time-predictable and slip-predictable models, in which either the time to the next earthquake depends on the magnitude of the last earthquake or the magnitude of the next earthquake depends on the elapsed time. These models are sometimes applied to the earthquakes in a region. In a stress-release model of Zheng and Vere-Jones (1994), also applicable to the earthquakes in a region, the hazard rate steadily increases over time, but drops upon the occurrence of an earthquake by an amount that depends on its magnitude. A coupled version of this model, allowing for stress transfer between discrete regions, has also been developed. Further tests are needed of how well these models perform.

The epidemic-type aftershock (ETAS) model of Ogata (1989) is a nonstationary Poisson process model developed originally as a model of temporal clustering of earthquakes in a discrete region. In this model, each earthquake has its own aftershock sequence, which decays over time according to the Omori-Utsu law. The number of aftershocks is governed by a magnitude-dependent productivity function. Some earthquakes occur independently according to a stationary Poisson process, and the magnitudes of all earthquakes follow the Gutenberg–Richter relation. The ETAS model fits earthquake data much better than a stationary Poisson process, and better than a model in which only the larger events have aftershocks. It is a type of branching process model. A double branching process model has been found to better describe the time-variation of earthquake occurrence (Marzocchi and Lombardi, 2008).

Stochastic models involving location, as well as time and magnitude, allow for a more realistic representation of the earthquake process, including clustering and long-range interactions between earthquakes.

The ETAS model was extended to include the spatial variable (Ogata, 1998) by introducing a distribution for aftershock location, usually a power law of distance similar to that described above. In this form, it can be used to describe the space-time clustering of earthquakes and also as a diagnostic tool for physical changes affecting the earthquake process. As a short-term forecasting model, this model performs far better than smoothed seismicity models, which capture the space and magnitude distributions of past earthquakes but are time-invariant. It is successful at forecasting aftershocks, as well as the minor proportion of major earthquakes which are preceded by a foreshock sequence. For a given location, the rate density of earthquake occurrence in this model can fluctuate in a short time over several orders of magnitude. Changes in the parameters of the spatial ETAS model have been used as indirect indicators of stress-changes in regions of the crust.

The Every Earthquake a Precursor According to Scale (EEPAS) model (Rhoades and Evison, 2004) is a space-time-magnitude model designed for longer-term forecasting of the major earthquakes. In this model, every earthquake contributes to the future distribution of hazard in time, magnitude, and location on a scale determined by its magnitude, through the predictive scaling relations associated with the precursory scale increase phenomenon. Under this model, the rate density can fluctuate slowly in time over about 1.5 orders of magnitude. The EEPAS model outperforms smoothed seismicity models in well-catalogued inter-plate regions such as California, Japan, and New Zealand.

Testing of forecasting methods

Time-varying models of earthquake occurrence have not yet been widely adopted for practical purposes. The stationary Poisson model with characteristic earthquake magnitudes on faults and spatially distributed background seismicity conforming to the Gutenberg–Richter magnitude relation are the basis for most seismic hazard models in practical use. But an international effort by the Collaboratory for the Study of Earthquake Predictability (CSEP) to provide transparent, verifiable prospective tests of time-varying earthquake occurrence models is in progress. Regional earthquake forecast testing centers have been established in California, New Zealand, Europe and Japan, and others are planned. To be testable, a model must provide estimates of the expected number of earthquakes for future time windows within grid cells finely delimited by location and magnitude. Several different time steps are used; for example, 24 h, 3 months, and 5 years. An overview of models submitted for testing in California was given by Field (2007) and first results were presented by Schorlemmer et al. (2010).

The performance of a probabilistic model of earthquake occurrence on a target set of earthquakes in a catalogue independent of the one to which it was fitted, is conveniently measured by the increase in the log likelihood of the earthquake catalogue under the model compared with that under a reference model, such as a stationary Poisson model with spatial smoothing of the locations of past earthquakes.

The CSEP testing centers use additional likelihood-based tests, which aim to identify significant differences between the total number of earthquakes expected and the number observed, and the distributions in time, magnitude, and location of cell expectations and those of the targeted earthquakes (Schorlemmer et al., 2007).

Some earthquake forecasting methods, such as the M8 algorithm, are alarm-based rather than probabilistic. For alarm-based methods, the error diagram (Molchan, 1990), in which the proportion of time or space-time for which a certain level of alarm is exceeded is plotted against the proportion of unpredicted earthquakes, is a useful assessment tool.

Analysis of synthetic earthquake catalogues

Physics-based numerical models of earthquake occurrence (Ben Zion, 2008) can be used to generate synthetic earthquake catalogues incorporating accepted physical

elements such as stress transfer between faults by means of elastic, viscoelastic, and other interactions; frictional or other material instabilities acting on fault surfaces; increasing stress accumulation due to tectonic forces; and the detailed geometry of the fault surfaces. For synthetic catalogues, important physical variables, which cannot be measured in the real earth, such as the distribution of stress, can be tracked in detail. Statistical analysis of synthetic earthquake catalogues can reveal under what physical conditions a particular statistical model is likely to be appropriate and contribute to physical understanding of empirical relations derived from earthquake catalogues.

Conclusion

Statistical seismology is concerned with modeling the empirical observations of earthquake occurrence and testing models against observations while trying to throw light on the physics of earthquake generation. A rapid improvement in seismological databases has been a stimulus to recent developments in the field, and this state of affairs is likely to continue. Improved earthquake catalogues and other systematically collected data, such as earth deformation data derived from Global Positioning System (GPS) networks offer opportunities for enhanced physical understanding of the earthquake process and more informative stochastic models. At the same time, increased computing power allows for increased detail and complexity in physics-based modeling. The major challenge statistical seismology faces is to use the new data, together with physical insights from empirical studies and detailed physical modeling, to develop ever more informative stochastic models of earthquake occurrence that can be applied to mitigating earthquake hazard.

SUBDUCTION ZONES

Geoffrey A. Abers
Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY, USA

Definition

Subduction zones are convergent plate boundaries involving at least one oceanic plate. The oceanic plate descends

beneath the other into the deep mantle, forming a deep-sea trench, often a volcanic arc subparallel to it, an inclined Wadati–Benioff seismic zone, and other subparallel deforming belts.

Introduction

Subduction zones are a fundamental manifestation of planetary convection at the Earth's surface, and can be viewed as regulating two critical systems:

1. They control the primary material flux from the surface to the Earth's interior. Material at the seafloor subducts to depth, some of which emerges in volcanic arcs. These processes control the long-term budgets of volatiles (H_2O, CO_2, etc.), and the major accretion of material to continental crust.
2. Forces at subduction zones result in much of the planet's deformation, including the generation of the largest earthquakes and explosive volcanic eruptions over time scales of seconds, to the formation of the deepest seafloor and the growth of continents over millions of years. The negative buoyancy of subducting lithosphere probably represents the largest driver of global plate motions.

All of these processes ultimately result from the Earth releasing heat, and the deformation and thermal structure that results. At the largest scale, subduction regulates the mixing of material throughout the mantle of the lifetime of the planet, and the onset and termination of subduction represent profound geologic events. This article follows subduction zones from trench to depth, emphasizing the two themes of material flux and of large-scale deformation. It focuses on active systems from outer rise to sub-arc depths.

Morphology and nomenclature

The global subduction oceanic system is over 40,000 km long (Stern, 2002), largely but not entirely subducting oceanic plates of the Pacific basin (Figure 1). For the most part, any part of this subduction zone exhibits a common morphology (Figure 2): a downgoing, oceanic plate flexes into a deep-sea trench, beneath a submarine forearc that sometimes includes an accretionary prism. As the plate interface reaches 10–50 km depth, plate motion is accommodated on a shallow-dipping thrust zone, which in many places can generate great earthquakes. Landward of the thrust zone lies a volcanic arc, typically with a sharp front that overlies the region where the Wadati–Benioff zone seismicity reaches 75–180 km depth, with occasional volcanism further in the back-arc. The upper plate beneath and behind the arc varies between those that generate oceanic back-arc basins, exemplified by the Mariana-Izu-Bonin and Tonga systems, and those that undergo long-term convergence and compression, exemplified by the Andes, with a spectrum of behaviors in between (e.g., Lallemand et al., 2005). This characteristic morphology is a consequence of a regular, repeatable balance between forces that drive plate motions, buoyancy of

Subduction Zones, Figure 2 Common features of subduction zones.

oceanic lithosphere, metamorphic devolatilization, and its rheological/magmatic consequences.

Outer rise, trench, and forearc

The shallow part of subduction systems, where temperatures are relatively cold, are controlled by the mechanics of elastic and brittle deformation. The trench occurs because the downgoing plate is flexed downward, and the shape of the plate seaward of the trench resembles closely that expected for flexure of a thin elastic surface (e.g., Watts and Talwani, 1974). The physics of elastic flexure also explains the outer rise – a region of slightly (100–500 m) elevated seafloor that lies seaward of the trench, typically 50–300 km distant (Parsons and Molnar, 1976). Strong bending leads to faulting in the outer rise, typically manifest as a series of normal faults with <1,000 m offset, seen on the seafloor and generating earthquakes (Chapple and Forsyth, 1979). These normal faults are found seaward of many if not most trenches, and are the most seaward indication of deformation within the subduction zone. They may play an important role in the material cycle as well, since the basins formed by them serve as traps for sediment that can be subducted to great depths (Hilde, 1983), and the faults themselves may act as conduits for water to reach into the mantle of the subducting plate, altering the mineralogy (e.g., Ranero et al., 2003). Such alteration of seafloor in the open ocean plays an important role in preconditioning the downgoing plate prior to subduction: the later metamorphic devolatilization of hydrous sediments and altered oceanic lithosphere releases fluids that lubricate the plate boundary, weaken the overlying material, and ultimately drive arc volcanism.

The sediment supply to the downgoing plate varies enormously between trenches near major continental river systems and those remote from such sources, leading to several variations in subduction zone behavior and characteristics. In the most extreme cases sediment supply overwhelms the rate at which material is subducted and accreted, so the bathymetric trench becomes a sediment-filled basin. Examples include the Lesser Antilles, Makran, and Cascadia subduction zones. A first-order distinction exists between subduction zones considered "accretionary," where a substantial amount of sediment has been offscraped to form an active accretionary prism, and "non-accretionary" subduction zones where all sediment is being subducted bypassing the forearc, and generally sediment supply is low (von Huene and Scholl, 1991). The accretionary prisms typically deform internally to form a critical-taper wedge, a geometry in which gravitational stresses created by the bathymetric slope are balanced by internal friction, similar to wedges in front of bulldozers or snowplows (Davis et al., 1983). Accreted material includes deep-sea sediment, but also fragments of bathymetric features such as seamounts on the incoming plate; subduction of relatively rigid seamounts can have a profound effect on the local morphology of the forearc, and may contribute to heterogeneity along the thrust zone at greater depth.

Thrust zone

As of mid-2010, the nine largest recorded earthquakes, and 22 of the largest 25, occurred on subduction thrust zones or "megathrusts," including all earthquakes with magnitudes of 9.0 and larger (U.S. Geol. Surv. Web site, http://earthquake.usgs.gov/). These great earthquakes also

generate most of the largest tsunamis, because they can displace large portions of the seafloor (see chapter on *Tsunami*). Great earthquakes occur here because the plate-boundary fault system can sustain large rupture areas, and earthquake size scales with rupture area. There are two reasons for the large rupture areas. First, at subduction zones cold material advects downward quickly compared with rates of heat conduction, as discussed below, so temperatures along the fault zone can remain below that of the brittle-ductile transition (or downdip limit of unstable sliding; Scholz, 1998) to greater depths than other environments, typically 30–50 km (Tichelaar and Ruff, 1993). Second, subduction zone thrusts dip at 5–25°, compared with steeper dips for faults in many other tectonic settings, so a greater fault area exists above the brittle-ductile transition. Both of these reasons allow for faults that can exceed 100 km in the downdip direction (e.g., for the Gulf of Alaska megathrust). Along strike, individual ruptures can extend for more than 1,000 km in some cases, most notably Chile (1960; Mw = 9.5) and Sumatra (2004; Mw = 9.2). Magnitudes here (Mw) are moment magnitudes (see chapter on *Earthquake, Magnitude*).

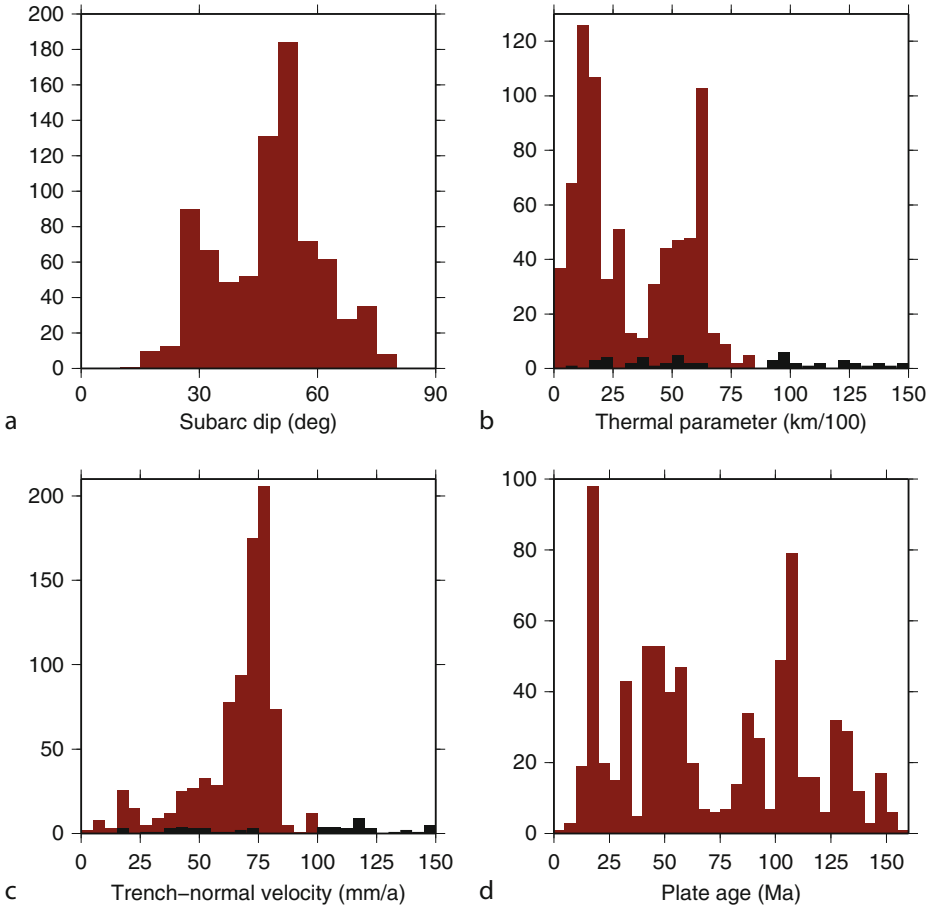
The fault area, and hence the ultimate size of earthquakes, is controlled by updip and downdip changes in material properties. At its updip end, the thrust zone undergoes a transition from aseismic slip on a decollement (subhorizontal plate-boundary fault) to stick–slip behavior or earthquake rupture, at depths of a few kilometers. At these depths the plate interface likely lies at temperatures of 75–150°C. The causes of this transition likely have to do with compaction, lithification, and low-temperature mineral phase transitions that change the frictional properties of this fault surface (Saffer and Marone, 2003). Similarly, the downdip limit can be in many places approximated by a threshold temperature, in this case near 350–500°C, with notable exceptions (e.g., Hyndman et al., 1997). Both transitions must be a consequence of change in frictional properties at this depth, with aseismic creep taking place at greater depths (e.g., Scholz, 1998). In between, the megathrust fault zone shows a variety of slip behaviors from purely creeping or "decoupled" to fully seismic or "coupled." In this usage, "coupling" refers to the ratio of fault slip inferred from summing the seismic moment of earthquakes over some time interval, to the total plate motion expected across that boundary over the same time interval. Coupled or "locked" thrust zones can be identified with geodesy, which shows the elastic strain accumulation building up between large earthquakes.

Recent discoveries of slow, silent creep events indicate that the downdip transition (and perhaps the updip one) may be much more complicated (e.g., Rogers and Dragert, 2003; Ito et al., 2007; Obara, 2002). Continuous geodetic observations have shown that patches of the thrust zone can slip over periods of days to months, in some cases accounting for a large fraction of the plate motion within the patch that slips (usually, adjacent to the locked zone). In some cases these events repeat quasi-periodically at time scales of months to years, although periodicity is not yet established for many regions of slow slip (Schwartz and Rokosky, 2007). Often, the slow slip is accompanied by a variety of exotic seismic phenomena, including nonvolcanic tremor, low-frequency earthquakes, very-low-frequency earthquakes, and creep (Ide et al., 2007). In most cases, the tremor seems to come from the plate boundary or just above it and shows motion consistent with thrusting on the plate boundary; these observations are subject of much current research (Gomberg, 2010). The physics of these quasi-periodic slip transients remain poorly understood; excess fluid pressure is suspected to play a role.

Kinematics

Subduction zones can be divided between those with little upper-plate deformation, with upper-plate compression, and exhibiting back-arc opening. The highest subduction rates, and indeed the highest relative plate motion rates anywhere, reach 240 mm/year at the northern end of the Tonga subduction system (Bevis et al., 1995). Major-plate motion between Australia and the Pacific Plate is only ~80 mm/year, the remainder being accommodated by spreading in the Lau back-arc system. Subduction can in principle be arbitrarily slow, although the lowest rates associated with an active arc probably occur in the Lesser Antilles (20–25 mm/year convergence; DeMets, 2001). A wide range of convergence rates lie in between these end-members with a sharp global peak near 70 mm/year such that half of all subduction zones have arc-normal convergence rates of 53–76 mm/year (Figure 3).

While spreading at mid-ocean ridges is orthogonal to their axes, at subduction zones convergence commonly trends obliquely to trench or arc (e.g., McCaffrey, 1992; Fitch, 1972). The obliquity, ϕ, is the angle between the normal to trench axis and the plate convergence direction. At low obliquities, convergence occurs in the direction of plate motion but commonly at higher obliquities strain is partitioned between a trench-normal component, represented by thrust faulting on the megathrust, and an along-strike component taken up by internal deformation. The along-strike component may be taken up within the forearc, as arc-parallel strike-slip systems, as sequences of strike-slip faults oblique to the trench axis, or by other means. At many subduction zones the obliquity changes along strike as both plate orientation and location relative to Euler pole change; for example, convergence is trench-normal ($\phi \sim 0$) in the Alaska Peninsula segment of the Aleutian subduction zone, $\phi \sim 45°$ from the trench in the central Aleutians, and plate motion is essentially parallel to the trench ($\phi \sim 90°$) in the far western Aleutians (DeMets et al., 1990). The latter case implies that material no longer descends into the mantle in the far western Aleutians, but translates along strike. A primary consequence of obliquity is that the trench-normal component of convergence can be significantly less than plate motion rates.



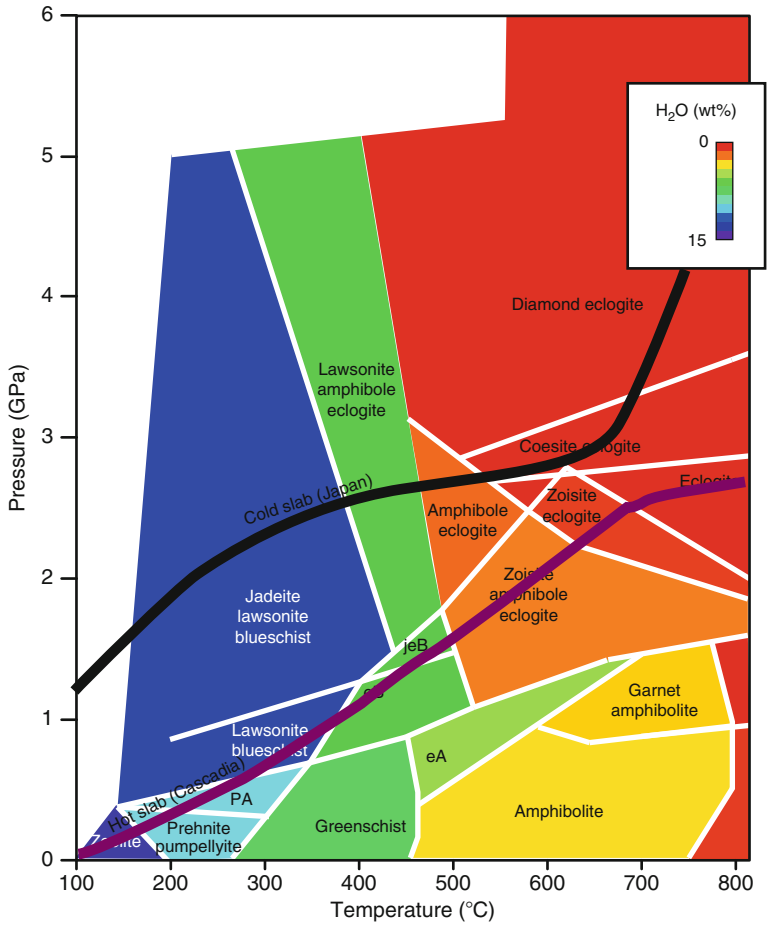
Subduction Zones, Figure 3 Histograms showing common parameters at subduction zones. Each is calculated at arc volcanoes or the nearest point on the plate boundary to them. (Based on data from Syracuse and Abers 2006.)

The kinematics of plates at asthenospheric depths may be more complex. While it is convenient to draw flow lines of subducting plates parallel to their dips, assuming steady-state slab geometry, it is not obvious that is the case. In many geodynamic models (e.g., Billen, 2008) slabs sink vertically faster than they would if they followed their trajectories, in other words, slabs roll back. Such rollback is probably required to accommodate back-arc opening in many places, although few if any constraints exist on these kinematics. Flow kinematics are complicated by inferences of large along-strike flow inferred from seismic anisotropy (e.g., Russo and Silver, 1994; Hoernle et al., 2008; see chapter on *Seismic Anisotropy*), not easily explained by simple models of wedge flow.

Thermal structure, plate buoyancy, mantle flow

At subduction zones, cold oceanic lithosphere advects downward relatively quickly compared with the rate of heat conduction, leading to some of the largest lateral temperature gradients in the planet. Old, fast-subducting slabs can retain temperatures $<600°C$ in their cores to depths exceeding 100 km, where ambient mantle temperatures are otherwise $\sim$1,400°C (e.g., Syracuse et al., 2010; Wada and Wang, 2009). The low temperatures lead to relatively large density differences, giving oceanic lithosphere significant negative buoyancy and probably supplying one of the major forces that drive plate motions (e.g., Forsyth and Uyeda, 1975). Because temperatures are low, mineral phases that hold significant H_2O are stable to much greater depths than elsewhere, making subduction zones major conveyors of volatiles to the deep earth. Still, volcanism occurs in nearly all oceanic subduction zones, indicating that parts of the system remain warm enough to produce melting. As a slab descends, it induces corner flow in the overlying mantle wedge, which draws warm material from the distal back-arc toward the slab corner (Figure 4). This advection of warm material ultimately heats the top of the slab, leading to very strong temperature gradients near the slab surface, and driving critical material-transport processes there.

Where the slab surface lies at depths less than 50 km, plate-boundary motion is mostly localized along the megathrust that defines the plate boundary, so the



Subduction Zones, Figure 4 Pressure-temperature trajectories for the top of slabs in hot (Cascadia) and cold (Japan) subduction zones, and metamorphic facies predicted for hydrated metabasalts, color coded by H_2O content. (Facies from Hacker et al. 2003; trajectories from Syracuse et al., 2010.)

upper-plate deformation accommodates little of the plate motion (at least the downdip component; oblique slip partitions strike-parallel motion into the upper plate). As a consequence, heat transport in this region can be approximated as the balance between conduction through an overlying, stationary upper plate, and downward advection of cold material along the thrust zone (Molnar and England, 1990). Shear heating along the thrust zone may elevate temperatures but its effect seems to be minor in the few places where abundant heat-flow measurements have been made (Cascadia, Japan, Tonga), equivalent to that generated by a fault with shear stress of a few tens of MPa at most (Hyndman and Wang, 1995; von Herzen et al., 2001). Thus, interplate thrust faults are relatively weak, perhaps due to high fluid pressures. One consequence is that metamorphism of subducted material follows a low-temperature high-pressure trajectory through this region, to blueschist facies (Figure 4).

At greater depth, the overlying material flows and transports heat from the back-arc mantle into the wedge. As this hot material is entrained downward by viscous drag, it rapidly heats the top of the downgoing plate, resulting in dehydration of the top of the downgoing plate. Such heating must happen under or trenchward of the volcanic arc, since many arcs erupt basaltic lavas with chemistry that requires temperatures in excess of 1,200°C beneath the arc (Kelemen et al., 2003a). The temperatures predicted for the top of the slab depend upon the assumed rheology of the mantle wedge, but for power-law flows typical of olivine dislocation creep, a narrow (<25–50 km wide) thermal boundary layer should rapidly develop at the top of the slab, leading to slab-surface temperatures of 700–1,000°C directly beneath the volcanic front (Kelemen et al., 2003a; van Keken et al., 2002; Syracuse et al., 2010). This heating appears to be sufficient to drive off most mineral-bound volatiles in the altered oceanic crust and sediment. More complicated modeling that allows secondary flow of buoyant slab-surface material into the wedge (e.g., Gerya and Yuen, 2003) might lead to lower temperatures, if such flows are sustainable.

Heat supplied by the mantle wedge continues to conduct into the slab, gradually warming its interior. Simple

thermal models (e.g., McKenzie, 1969; Molnar et al., 1979) predict that the maximum depth of isotherms should scale with $\Phi = AV\sin\delta$, where A is the age of the incoming lithosphere, V is its downdip velocity, and δ is the slab dip. The quantity Φ, sometimes called the "thermal parameter" (e.g., Kirby et al., 1996), describes in a simple way the overall thermal structure of slabs at great depth, and correlates well with the maximum depth of earthquakes over some depth ranges (Gorbatov and Kostoglodov, 1997), indicating a thermal control for the processes that cause deep earthquakes. Ultimately, the negative buoyancy of cold slabs and their ability to descend into the lower mantle must depend upon Φ as well. The negative thermal buoyancy of the slab counterbalances the positive buoyancy of subducting crust, since gabbro is much less dense than peridotite, such that the net buoyancy is a function of plate age and thickness of subducting crust (Cloos, 1993). For normal (5–8 km) thickness of oceanic crust, lithosphere attains negative buoyancy if more than 10–30 Ma old, while crust thicker than 15–25 km will always resist subduction for any observed age of oceanic crust.

The transition from localized slip along a plate boundary to distributed flow appears to correspond to where the slab reaches 70–90 km depth in many settings (Wada and Wang, 2009; Abers et al., 2006; Syracuse et al., 2010). Evidence for this transition comes from heat-flow observations at a small number of arcs (northern Japan and Cascadia), which show a step from very low forearc heat flow to relatively high sub-arc and back-arc heat flow, at this point. Also, seismic attenuation shows a sharp step at this depth, in a manner consistent with a cold "nose" of mantle material overlying the shallower portion of the slab, transitioning rapidly to hot mantle beneath the arc. The cause of this transition likely has to do with the maximum depth at which plate motion can be accommodated by a localized shear zone, and hence rheology of that shear zone; the location of arcs relative to the slab indicates a transition at temperatures about 550°C (Conder, 2005; Syracuse et al., 2010).

Fate of the downgoing plate: devolatilization and metamorphism

The subducting oceanic lithosphere can be divided into several layers (Figure 2, inset):

(a) Deep-sea sediment, of widely variable thickness and composition,
(b) Variably altered oceanic crust (AOC) – largely the upper, basaltic part where hydrothermal circulation has the largest effect,
(c) Less altered gabbroic lower crust, and
(d) Subducting mantle lithosphere some of which may be hydrated to varying degrees.

Although some of this package will be scraped off in accretionary margins, much probably survives to subduct to sub-arc depths. Arc geochemistry includes signatures of subducted sediment, with lava chemistry that varies systematically in some elements in ways that correlate with variations in sediment chemistry (Plank and Langmuir, 1998). This observation requires that most of the sediment, especially that deposited away from the trench, subduct to sub-arc depths. For example, lavas at several arcs include trace amounts of ^{10}Be, a radionuclide with ~1.6 Ma half-life formed in the atmosphere and deposited with the shallowest sediment (Tera et al., 1986), indicating that the shallowest deep-marine sediment subducts intact and the material reaches the earth's surface within a few Ma (a couple of half-lives). Finally, seismological evidence also supports the deep subduction of oceanic crust relatively intact, to generate images seen in receiver functions (e.g., Rondenay et al., 2008; Kawakatsu and Watada, 2007), high-frequency guided waves (Abers, 2000), and other mode conversions (e.g., Helffrich, 1996).

In its entirety, this package subducts on the order 2×10^9 Tg/Ma of water at the trench (Hacker, 2008), about half of which enters as pore water that is expelled by shallow compaction, and the remainder bound in minerals. Numerous drilling and sampling studies constrain well the H_2O content (and CO_2) of the subducting sediment and AOC, but lower sections are relatively less well known. Perhaps the largest uncertainty in these estimates lies in the water content of subducted mantle lithosphere, a potentially vast reservoir. Peridotite will hydrate to serpentinite and serpentine can hold ~14 wt% H_2O, giving this very thick layer potential to dominate the global water budget. However, it is not yet known how much H_2O reaches mantle depths; probably mantle hydration at mid-ocean ridges is minor because near-ridge mantle temperatures there should exceed that of serpentine stability (~600°C) but later faulting such as at fracture zones and the outer rise (see Thermal Structure, Plate Buoyancy, Mantle Flow) could be major conduits. Less is known about concentrations of CO_2 and other volatiles degassed by metamorphism. Depending upon serpentinite contributions, the volatile outputs of volcanic arcs either roughly match the inputs, implying near-complete volatile recycling, or are significantly less, implying a long-term flux of H_2O from the surface ocean to deep mantle.

Anhydrous oceanic crust can be expected to undergo a series of phase transitions from gabbro to eclogite. These result in a major density increase; gabbro has a density ~10% lower than that of peridotite at similar temperatures and pressures, so unmetamorphosed oceanic crust has buoyancy that resists subduction, while eclogite (dominated by garnet and pyroxenes) is significantly denser than peridotite. The density increase, in transforming from gabbro to eclogite, may contribute significantly to the negative buoyancy of slabs that drives plate tectonics. However, reaction rates for garnet growth (a major step in eclogite formation) within coarse-grained, anhydrous gabbro may be relatively slow, such that gabbro may persist metastably to considerable depth within subduction zones (Ahrens and Schubert, 1975). The presence of water should substantially enhance that reaction rate (e.g., Hacker, 1996).

If hydrated, basalt/gabbro (and metasediment) are expected to undergo a lengthy sequence of metamorphic

reactions that, generally, release H_2O (Figure 4). As a consequence, H_2O should be released over a wide range of depths from the thrust zone to sub-arc mantle, hydrating the overlying mantle wedge (Schmidt and Poli, 1998; Hacker, 2008). At typical to cold subduction conditions, oceanic crust can be expected to transition through greenschist and blueschist facies, capable of holding up to ~5 wt% H_2O, with major dehydration occurring in the transformation to eclogite during high-pressure heating (Hacker et al., 2003). In warmer subduction zones, defined as those with fairly young incoming plates and slow subduction rates (e.g., Cascadia, southern Japan), descending crust should follow a higher-temperature path perhaps through amphibolite facies, dehydrating as amphibole breaks down at ~2 GPa. Most thermal models with realistic mantle-wedge viscosity structure predict that subducting crust should dehydrate by depths of 100–200 km (e.g., Syracuse et al., 2010), at least in its shallow parts.

The mantle within the subducting plate potentially holds hydrous minerals as well, primarily serpentine but also chlorite, as might entrained material lying above the downgoing plate. These layers should also dehydrate, at temperatures of 600–700°C for serpentines at <200 km depth (e.g., Schmidt and Poli, 1998) with chlorite breaking down at temperatures about 200° higher. Serpentine dehydration temperatures are probably reached in all subduction zones on the slab surface and, hence, above it, although it is possible that a weakly hydrated zone of chlorite stability may persist past slab depths (e.g., Grove et al., 2009). Subducting mantle lithosphere in most subduction zones should be cold enough for serpentine to be stable past the arc (Syracuse et al., 2010), and may dehydrate gradually past that. Water persisting to depths past 200 km has the potential to remain within the mantle to considerable depth, in the "alphabet" phases of dense hydrous magnesium silicates, which have broad stability fields at near-slab conditions (Thompson, 1992). Water reaching the transition zone (410–660 km depth) may remain for a long time, as the dominant minerals ringwoodite and wadsleyite can retain wt% water as defects in their nominally anhydrous structure (Kohlstedt et al., 1996). This reservoir has potential to hold several times more water than the current surface ocean; thus, the ability of serpentinized mantle lithosphere to transport H_2O to great depths may be a dominant control on the Earth's long-term water budget.

As water is released, it ascends into the overlying mantle wedge, crust, back along the thrust zone, and through the forearc (Peacock, 1990), potentially hydrating it (Hyndman and Peacock, 2003). These pathways provide major controls on rheological properties in all these regions and on the behavior and composition of arc volcanoes. Also, it is often suggested that the dehydration process generates earthquakes at intermediate depths (70–150 km) in subduction zones (Green and Houston, 1995; Kirby et al., 1996; Hacker et al., 2003). These processes are discussed extensively in the chapter on seismicity-subduction zones.

Subduction channel

In many collisional mountain belts and accreted terranes, high-pressure, low-temperature rocks have reached the Earth's surface after having descended to great depths. In some "ultra-high pressure" (UHP) terranes, mineral assemblages or textures in these rocks record pressures in excess of 3–4 GPa (depths > 100 km), indicating that these rocks descended deeply in subduction zones before returning to the surface. In part to explain these observations, a "subduction channel" has been often proposed (Cloos and Shreve, 1988). The subduction of weak, hydrated metasediments and altered oceanic crust, and their subsequent shearing and interaction with metamorphic fluids, suggests the presence of a heterogeneous weak zone at the top of the downgoing plate. Initially, material in this channel will be dragged downward by coupling with the subducting plate, but it should be buoyant relative to overlying mantle, and in the right conditions a return flow could develop delivering high-grade metamorphic rocks to the surface. A weak zone is also indicated by the presence of a "cold nose" in many subduction zones in the forearc mantle wedge, a feature that probably requires a weak decoupling layer to depths of 70–90 km on the top of the downgoing plate (e.g., Wada and Wang, 2009). The presence of UHP rocks at the earth's surface indicates that the return-flow process or something similar probably happens in some instances, but it remains unclear if the subduction channel is a common feature of subduction zones.

Melting and the volcanic arc

Reviews elsewhere describe the geochemical evidence for the nature of melting beneath volcanic arcs and the generation of arc crust (e.g., Stern, 2002; Kelemen et al., 2003b), which briefly summarized here for their relevance to geophysical observations. Magmas emplaced and erupted at subduction zones span a wide range of compositions. Basalts are found at most subduction zones and indicate that primary melting occurs within the mantle beneath the volcanic arc, since basalts primarily form from melting of peridotites (e.g., Gill, 1981). These basalts often differ from those found at mid-ocean ridges or hot spots in several important chemical trends; in particular, many elements that are strongly abundant in subducting sediment and altered crust are found in abundance in many volcanic arc rocks in a manner that correlates with sediment chemistry (Plank and Langmuir, 1998). In some arcs there is strong evidence for andesites forming under high pressure, perhaps requiring melting of downgoing crust (e.g., Kelemen et al., 2003b).

Magmatic differentiation within the crust and mixing with preexisting arc basement result in a wide spectrum of volcanic output. Typically, seismic velocities within arcs show an increase with depth consistent with more silicic, felsic rocks at shallow depths (Vp = 6.0–6.4 km/s) underlain by more gabbroic rocks in the middle-to-lower crust (Vp = 7.0–7.4 km/s) (e.g., Suyehiro et al., 1996;

Shillington et al., 2004). Since they are petrologically fractionated from more basaltic parents, the andesitic or granitic rocks observed at mid-to-upper crustal levels should be balanced by more mafic silica-poor residuals, perhaps in the lower crust. However, such lower-crustal cumulates are not very abundant, as interpreted from seismic velocities, exposed arc sections, and within continents formed by arc accretion. In general, there is good reason to think that continents grew from accretion of arcs since they share many geochemical characteristics (Rudnick, 1995), but overall continents are significantly more silicic than primary arc basalts. This discrepancy probably requires a significant mass loss in the complementary, mafic cumulates that should form in arc lower crust. Where and how this mass loss occurs remains unclear; it may be that the lower crust in arcs occasionally founders or delaminates back into the mantle, since its density may be higher than that of peridotite, but many other possibilities exist. Geophysical observations of the lower crust and upper mantle have potential to place constraints on the formation and evolution of arc crust, and hence the origins of continental material (e.g., Kodaira et al., 2007; Tatsumi et al., 2008).

Primary magmas emerging from the mantle contain several wt% H_2O and elevated CO_2, several times higher than in mid-ocean ridge basalts (e.g., Hirschmann, 2006). Mantle melting beneath arcs often occurs in the presence of H_2O (Grove et al., 2006), leading to the frequent speculation that dehydration reactions within the subducting slab trigger melting in the overlying mantle wedge, and hence the location of dehydration within the slab controls the location of arc volcanism (e.g., Tatsumi, 1986). However, experiments on hydrous metabasalts show that dehydration occurs over a wide range of depths beginning much shallower than the sub-arc mantle wedge (e.g., Schmidt and Poli, 1998), so that H_2O should flux the mantle at many depths, not just under the volcanic arc. Also, primary, dry basalts have been found in some arcs, so H_2O is not always required for melting. It may be that the return flow (the incoming limb of wedge corner flow) sufficiently decompresses hot asthenosphere to trigger melting. The relative importance of wet (flux) melting and dry (decompression) melting within arcs remains poorly understood, as do the pathways that magmas take from their locus of formation to volcanic arcs. In particular, it is not obvious why the arc front is a narrow, well-defined feature while the conditions for melting should be more widely spread. The depth to slabs beneath the arc front averages 110 km but varies coherently by a factor of 2 from arc to arc, suggesting some other controlling process probably related to thermal structure (England et al., 2004; Syracuse and Abers, 2006).

Seismic imaging of the subduction zone

Although subduction zones exhibit a characteristic surface morphology of trench, forearc, volcanic arc, etc., the evidence that these associations represent subduction of deep material comes primarily from geophysical imaging of deep structure. Early observations of seismic wave propagation in Tonga showed that the Wadati–Benioff zone lies in a cold, low-attenuation structure unlike mantle elsewhere on the planet, and provided some of the first evidence that these were sites of descending cold lithosphere (Oliver and Isacks, 1967). Since then, methods of seismic tomography have improved greatly (see *Seismic Tomography*) as has the global data set of earthquake travel times, leading to a clear picture of P-wave high-velocity anomalies that show cold slabs descending through the upper mantle and in some cases into the lower mantle (e.g., van der Hilst et al., 1997). These data show slabs as seismic anomalies 4–10% faster than surrounding mantle (see compilation by Lay, 1997), consistent with thermal models that predict temperatures 400–800°C colder than surroundings. These images, based on global earthquake travel time data sets, show that in some cases slabs reach the mantle transition zone and flatten out, as if reaching a partial barrier to flow (e.g., Japan) while in other cases they pass through the transition zone delivering subducted material to the lower mantle.

Seismic recordings from networks and arrays in subduction zones provide strong constraints on the subduction zone structure of a scale relevant to slab metamorphism, arc petrogenesis, and wedge flow. For example, as dehydration occurs, densities increase as do seismic velocities; basalts are 10–15% slower than surrounding peridotites while eclogites have similar velocities. Furthermore, serpentinized peridotite can be tens of percent slower than peridotite particularly for shear waves, depending upon the extent of serpentinization (hydration). As a result, seismic imaging has potential to show where and how metamorphism within slabs occurs. For example, with migration of P-to-S scattered waves (see *Seismic, Receiver Function Technique*) subducting crust has been observed to ~45 km depth in Cascadia and depths exceeding 100 km in Alaska and Japan, consistent with expected depths of basalt dehydration and differences in thermal structure (Rondenay et al., 2008). Studies of earthquake travel times and signal attenuation also provide information on structure of the mantle wedge where melting initiates, and have shown a clear hot mantle wedge, with a variety of structures suggesting melt transport pathways. Probably the densest long-lived monitoring effort exists in Japan, although a variety of portable array experiments have illuminated subduction zones in parts of the Andes, Central America, Tonga, the Marianas, Alaska, Cascadia, Greece, and other locales.

One of the more complex suites of seismic observations comes from the anisotropic fabric within the mantle of subduction zones, which results in "splitting" of shear waves into orthogonally polarized fast and slow pulses (see *Seismic Anisotropy*). Mantle flow in the dislocation creep regime leads to lattice-preferred orientation of olivine, and olivine is moderately (~10%) anisotropic, leading to an association between seismic anisotropy and mantle flow. However, observations in many subduction zones lie counter to expectation (e.g., Russo and Silver, 1994).

Simple models of mantle flow in subduction zones predict "corner flow," in which mantle on either side of the descending plate is entrained via viscous drag (Figure 2). To fill the potential void left by the downward advection, mantle far from the subducting slab flows inward toward it, eventually turning and flowing downward. While details of this flow depend upon the viscosity structure and its sensitivity to temperature, stress, water, and other variables, the overall pattern of flow is one in which the maximum strain or stretch should be perpendicular to trench and arc, in the direction of flow. In many subduction zones, anisotropic fabric does not show this pattern, and instead the fast direction for shear wave propagation is more often than not parallel to the trench, at least below and behind the volcanic arc (Fischer et al., 1998). More complicated fabrics are also observed, with sharp 90° changes in fabric between sub-arc mantle and the shallower part of the forearc (e.g., in North Japan and Alaska), and the pattern varies between different subduction zones. Explanations for these unexpected patterns remain a matter of much debate, and include strong along-strike flow, secondary flows within the wedge, influence of melt on fabric, activation of unusual olivine slip systems at some subduction zone conditions, abundance of hydrous, foliated minerals in the forearc, extensive fabric within the downgoing slab, and unexpectedly strong upper-plate fabrics.

Subduction zone hazards

The forces present in subduction zones also produce some of the most violent natural hazards known. The interplate thrust zone generates all of the largest earthquakes, which produce strong shaking but also submarine landslides, meter-scale uplift and subsidence, and most of the largest tsunamis. The 2004 Sumatra earthquake represents the primary example of the last 50 years; a magnitude 9.2 earthquake ruptured over 1,000 km of plate boundary, producing an ocean-crossing tsunami that directly resulted in over 150,000 deaths and huge devastation to property. These earthquakes are devastating because subduction zone thrust faults are very large, because they are submarine but can break the sea surface, and because they occur in places with often oversteepened bathymetry. Subduction zones are also site to many of the most violent volcanic eruptions. Large volatile (especially water) contents of subduction zone magmas, compared with most other settings, lead to magmas rich in gas that exsolve at shallow depths. Magmatic differentiation leads to relatively viscous, felsic magmas that rise slowly and do not degas easily. The combination leads to explosive and sometimes very large eruptions; in the last half century, Mt St Helens (Cascadia), Pinatubo (Philippines), and Montserrat (Lesser Antilles) all produced violent and well-documented eruptions in subduction zones, among many others. Worldwide, about 500 volcanoes have known historic eruptions, roughly two-thirds in subduction zones.

Summary

Subduction zones represent the primary return of material from the earth's surface to its interior. In the process of doing so, great earthquakes occur, violent volcanoes erupt, and the largest lateral temperature gradients in the Earth's interior are generated. At shallow depths, elastic and brittle processes control deformation including most of the planet's large earthquakes, while at greater depths the subduction system deforms by large-scale ductile flow. Along with oceanic crust, sediment and volatiles enter the trench, lubricating the plate boundary at shallow depths, and then are metamorphosed where slabs descend below hot mantle, releasing H_2O and other volatiles into the overlying mantle wedge. While some of this material may mechanically ascend back to the surface, in the form of high-pressure metamorphic rocks, much feeds explosive volcanism in the volcanic arc or descends into the deep mantle. Melting at sub-arc depths is controlled by a combination of advection via flow of hot mantle from the back-arc, and fluxing by slab-derived fluids, a combination of which produces a sharp volcanic front. Magmas ascend to form arc crust and differentiate, some fraction of which persists to form the basis of continental crust. This transfer of energy and material leads to a rich set of phenomena that play a major role in creating the geologic record.

SURFACE WAVES

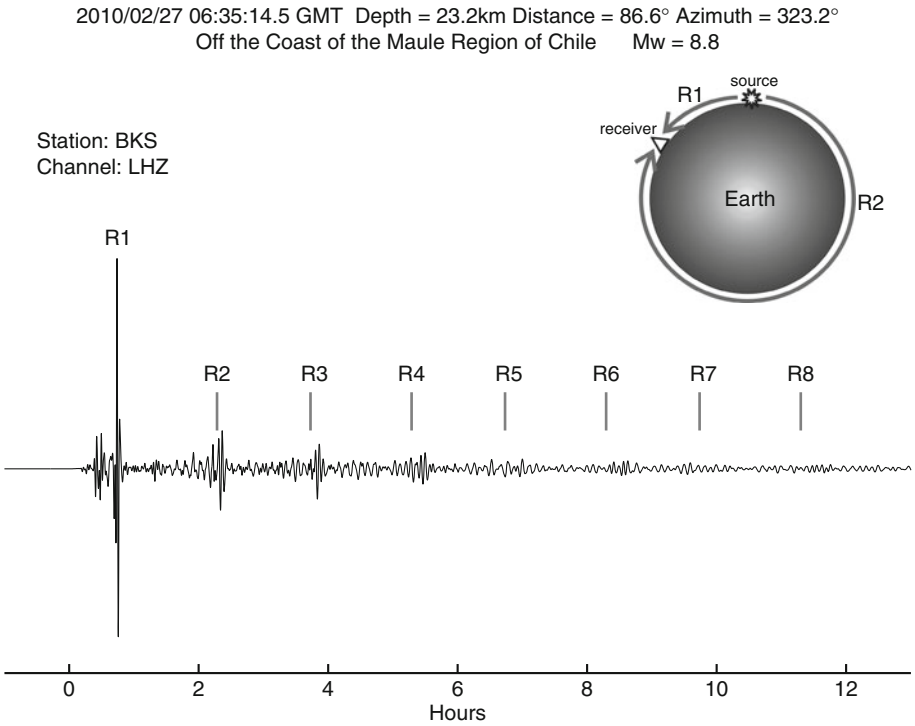
Barbara Romanowicz
Berkeley Seismological Laboratory, Berkeley, CA, USA

Definition

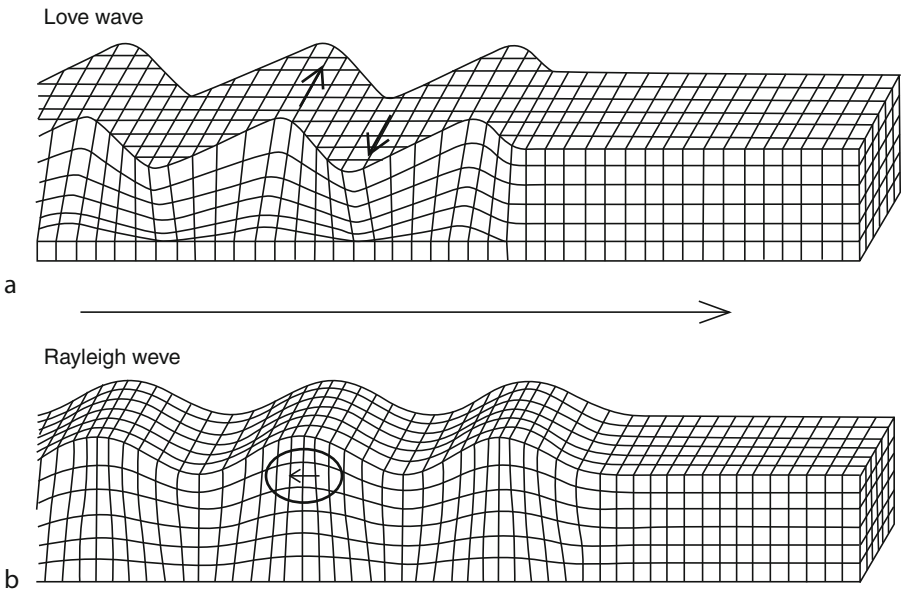
Surface waves are elastic waves which propagate along the surface of the earth and whose energy decays exponentially with depth.

Surface waves contain most of the long period energy (periods greater than 20 s) generated by earthquakes and recorded at teleseismic distances. Most prominent on records of moderate ($M \geq 5.5$) earthquakes are the fundamental mode wave trains that have propagated along the direct great circle path between the epicenter and the station. The dispersive and attenuative properties of these wave trains have been used extensively, since the 1950s, to infer crust and upper mantle structure at the regional scale. For earthquakes of magnitude 7 or larger, successive, earth-circling surface wave trains can be followed for many hours (Figure 1) and are either analyzed individually or, at the longest periods ($T > 250$ s) they are combined over time lengths of tens of hours or days to produce a spectrum of Earth's free oscillations (see *Free Oscillations of the Earth*).

In an isotropic medium, there are two types of surface waves which propagate independently (Figure 2). Rayleigh waves, polarized in the vertical plane containing the source and the receiver (P-SV energy), have a retrograde elliptical particle motion. These waves have generally good signal-to-noise ratio on the vertical component records and have been studied the most. On the other hand, the analysis of Love waves, polarized



Surface Waves, Figure 1 Example of vertical component record showing earth-circling Rayleigh wave trains (marked R1...R8) following the M8.8 Maule Chile earthquake of February 27, 2010. This record is from station BKS of the Berkeley Digital Seismic Network (BDSN). The successive wavepackets are well separated from each other at this epicentral distance (86.6°). The long period surface waves are often referred to as "mantle waves." (Courtesy of Shan Dou.)



Surface Waves, Figure 2 Particle motion for Rayleigh and Love waves. Rayleigh waves have retrograde particle motion confined to the vertical plane of propagation. Love waves have purely transverse motion in the horizontal plane. (After Bolt, B. A., 1976. *Nuclear Explosions and Earthquakes*. W. H. Freeman.)

horizontally in a direction perpendicular to the propagation direction (SH energy), suffers from the more complex data processing required, and from higher levels of long period background noise on the horizontal component records, due primarily to the effect of atmospheric pressure variations, inducing ground tilts. Love waves, unlike Rayleigh waves, can exist only in a heterogeneous medium (i.e., a layered medium).

The most striking property of surface waves is their dispersive character, with, in general, waves of longer periods traveling faster, directly reflecting the increase of elastic velocity with depth in the earth's crust and mantle. Indeed, studies of crustal and upper mantle structure progressed rapidly in the 1950s and early 1960s, as the tools developed to measure group and phase velocity dispersion and interpret them in terms of layered mantle and crust models (e.g., Ewing et al., 1957).

In a spherical earth, the theory of generation and propagation of surface waves is intimately linked to that of Earth's free oscillations, leading to the distinction of various modes. The lowest mode is termed fundamental mode, followed by higher modes, or overtones. Fundamental mode Love and Rayleigh waves are generally well separated from other seismic phases on the seismograms, and are well excited by shallow, crustal earthquakes, while higher modes (i.e., overtones) travel at higher group velocities and appear as compact packets of mixed overtones. They are better excited by deeper earthquakes (Figure 3).

Surface waves recorded at teleseismic distances contain information about both the characteristics of the earthquake source and the structure of the earth's crust and mantle along the source-station path. Separating the two effects has been one of the long-standing challenges faced by seismologists.

Group and phase velocity

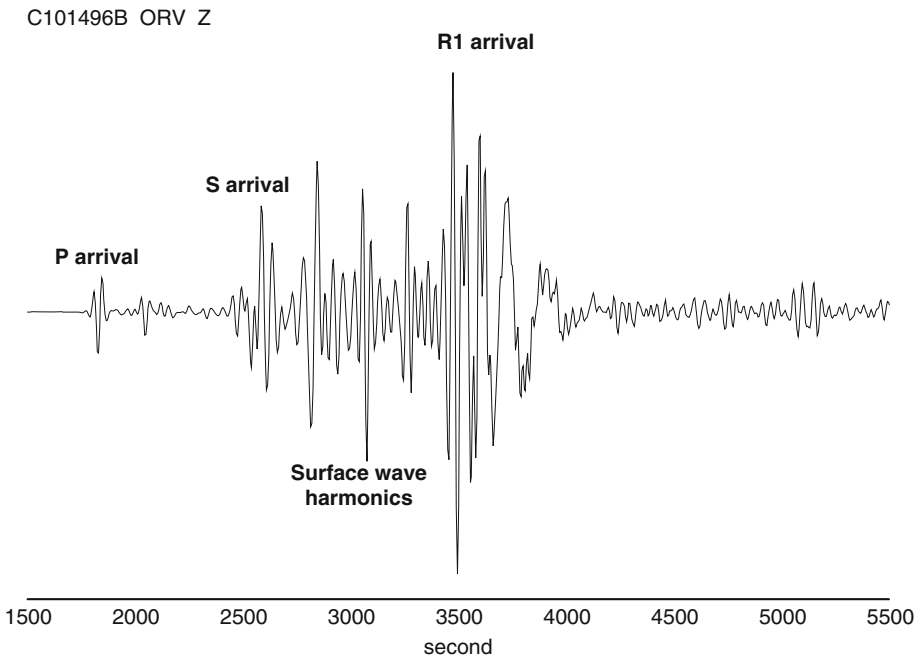
The velocity of propagation of surface waves can be described in terms of either group velocity or phase velocity. Phase velocity is the velocity of a specific frequency component of the wave train. Phase velocity derives from the expression of a plane wave of wavenumber k, and angular frequency ω, propagating in the direction x, for example, in one dimension:

$$f(x,t) \sim \exp i(\omega t - kx) \tag{1}$$

It is defined as the velocity of the phase of the component of frequency ω:

$$C(\omega) = \omega/k \tag{2}$$

where ω is the angular frequency and k is the wavenumber. Frequency is related to period of the wave, T, by $\omega = 2\pi/T$, while $k = 1/\lambda$ where λ is wavelength.



Surface Waves, Figure 3 Example of vertical component record for the October 14, 1996 Solomon Islands earthquake (depth = 19 km, *Mw* = 6.7) at BDSN station ORV showing the arrivals of multiply reflected body wave phases forming a higher-mode Rayleigh wave train in front of the fundamental mode (R1). The Airy phase, corresponding to the group velocity minimum around 230 s, is well visible at the end of the R1 train. The seismogram has been bandpass filtered with cutoff frequencies at 35 and 400 s. Courtesy of Yuancheng Gung.

Group velocity is the velocity with which the energy travels. The group velocity is derived from considering a wave train containing multiple frequencies:

$$u(\omega, t) = \int A(\omega) \exp i(\omega t - kx) d\omega \quad (3)$$

and finding the point (x,t) where the phase is stationary:

$$d(\omega t - kx)/d\omega = 0 \quad \text{hence} \quad t = x dk/d\omega \quad (4)$$

This leads to the definition of group velocity U as:

$$U(\omega) = d\omega/dx \quad (5)$$

In general, at any given period, the group velocity of surface waves in the earth will be less than the phase velocity. The minimum in the group velocity curve is termed Airy phase, a major feature of many surface wave records. Note that waves with periods shorter than the period of the Airy phase will exhibit reverse group velocity dispersion, with the shorter periods traveling faster. Phase velocity, on the other hand, always increases with period.

Surface wave generation and propagation

The theoretical formulation for the excitation of surface waves and normal modes of the earth, an eigenvalue problem, was developed in the 1960s (e.g., Haskell, 1964), much stimulated by the occurrence of the great Chilean earthquake of May 22, 1960 (M 9.5). A computational method, following the original theoretical approach of Saito (1967) based on Runge-Kutta matrix integration method, has long been the main reference for the practical calculation of surface waves and normal modes in laterally homogeneous, elastic, flat or spherical earth models. Today, a widely used approach for spherical geometry, efficient to relatively short periods (10 s), is based on a propagator matrix method in which minors of sets of solutions are used effectively (Woodhouse, 1988). The association of a normal mode formalism to compute dispersion and excitation of surface waves (and complete seismograms), with a moment tensor formalism to describe the earthquake source (e.g., Backus and Mulcahy, 1976) led to the rapid development of source studies based on surface waves in the 1980s.

To obtain the frequency spectrum of a single mode surface wave train from the expression of a seismogram obtained by summation of normal modes in a spherically symmetric earth, one uses Poisson's formula (e.g., Aki and Richards, 1980), which decomposes the modes into infinite trains of propagating surface waves traveling in opposite directions around the earth. In this process, a high frequency approximation is used, in which the phase velocity (see below) of a surface wave is related to the corresponding normal mode frequency by Jeans' formula:

$$C(\omega) = \frac{a\omega_l}{l + 1/2} \quad (6)$$

where l is the angular order of the mode and ω_l its eigenfrequency, and a is the radius of the earth. In this high-frequency approximation, surface waves propagate along the great circle path between the epicenter and the station and are sensitive to structure only along this great circle.

The spectrum of a single mode propagating surface wave at distance Δ, azimuth θ, and angular frequency ω can be expanded as follows:

$$U(\Delta, \theta, \omega) = U_s(\theta, \omega) \mathrm{S}(\Delta) U_p(\Delta, \theta, \omega) \mathrm{F}(\omega, \theta_0) \mathrm{D}(\omega) \mathrm{I}(\omega) \quad (7)$$

where U_s is the source spectrum, U_p contains propagation effects, I is the instrument response, $\mathrm{S}(\Delta)$ is the geometrical spreading term, and F and D describe the source process.

The propagation term U_p can be expressed as (e.g., Romanowicz, 2002):

$$U_p(\Delta, \theta, \omega) = \frac{1}{(\sin \Delta)^{1/2}} \exp(i\pi/4) \exp(im\pi/2) \times \exp[-i\omega\Delta/C(\omega, \theta)] \exp[-\eta(\omega, \theta)\Delta] \quad (8)$$

where m denotes the number of polar passages and $C(\omega,\theta)$, $\eta(\omega,\theta)$ are, respectively, the average phase velocity and attenuation coefficient along the source-station path.

On the other hand, the source term $U_s(\theta,\omega)$ can be expressed as a linear combination of the moment tensor elements M_{ij} of the source.

Structure studies using surface waves

Fundamental mode studies (dispersion)

Fundamental mode surface waves are well suited for the study of crust and upper mantle elastic structure, which can be deduced from their group and/or phase dispersion properties. They allow the sampling of vast areas of the globe that are otherwise devoid of seismic stations, such as the oceans.

Many early studies documented the correlation of seismic velocity variations with surface tectonic features, using regional measurements of phase and group velocities of fundamental mode Love and Rayleigh waves in the period range 20–100 s (e.g., Knopoff, 1972) or at longer periods, reaching deeper into the mantle (e.g., Toksöz and Anderson, 1966). Since the early 1970s, the computation of group velocity has relied on the multiple filtering technique introduced by Dziewonski et al. (1969). This approach, later perfected as the FTAN method (e.g., Lander, 1989), involves two steps. In the first step, an "energy diagram" is formed by windowing the seismogram over group arrival time and filtering over an array of specified center frequencies. The resulting amplitudes are then plotted as a function of time and frequency and their values contoured. The group velocity curve is

obtained by tracing the loci of maximum amplitude as a function of period. In a second step, the time domain seismogram is filtered using multiple filters centered on the group velocity curve (e.g., Figure 4).

Phase velocity is obtained from the phase Φ of the Fourier spectrum of a dispersed wave train that has been corrected for the contribution of the source and the instrument:

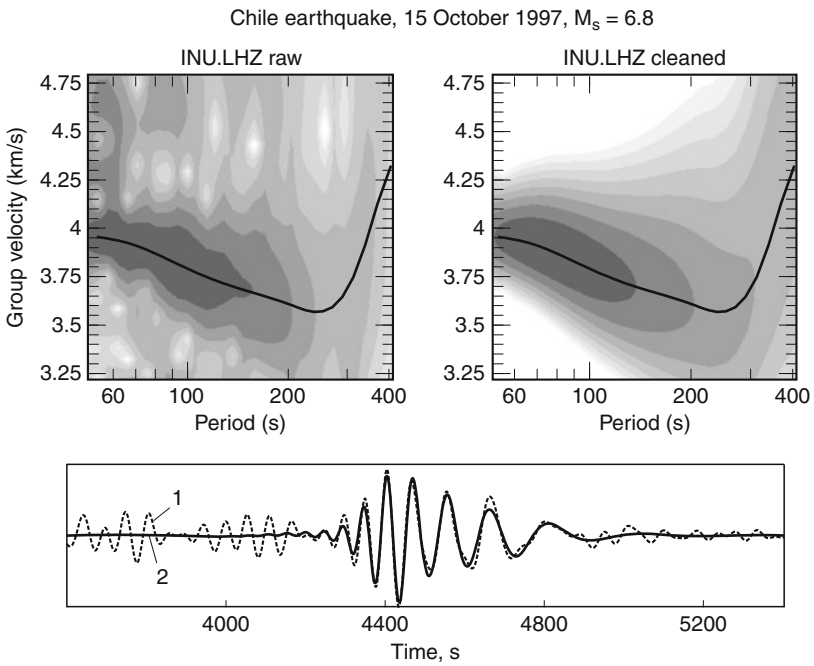
$$C(\omega) = \frac{X}{t_0 - [\Phi - N - (m/4) - 1/8]/\omega} \qquad (9)$$

where t_0 is the start time of the Fourier window with respect to the event's origin time, m is the number of polar passages, and N is an integer arising from the 2π indeterminacy of the phase. This integer is determined first at long periods to obtain reasonable values of phase velocity compatible with well-constrained global earth models. The phase velocity curve is then successively continued to shorter periods at fixed N, so as to obtain a smooth curve. This can become a problem at periods shorter than 30 s, where small variations in phase velocity correspond to rapid cycling of the phase.

The contribution of the earthquake source to the phase needs to be known accurately for the computation of phase velocity, less so for group velocity. This can be circumvented by making measurements using the "two-station method," in which dispersion is measured between two stations approximately aligned with the epicenter on a great circle, thus eliminating the common source phase. If, in addition, the two stations are located within a relatively homogeneous geological province, such measurements are called "pure path" and lead directly to the determination of elastic velocity structure beneath that province. This method has been extended to "many stations" to infer structure beneath an array of stations spanning a geologically homogeneous region.

Noise cross-correlation methodology

Recently, a radically different methodology has been introduced in seismology. The medium's "Green's function" between two seismic stations can be extracted from cross-correlations of records at both stations over long time periods, without the need for using earthquake data (see *Seismic, Ambient Noise Correlation*). These "noise cross-correlations" have been particularly effective for the measurement of the fundamental mode dispersion between two stations in and around the microseismic frequency band (5–30 s), where the background seismic noise is the most energetic. It has been shown that this approach leads to results that are as good as those obtained using standard methods, in regions where seismicity is strong and provides good illumination of the structure using "standard" approaches (e.g., Shapiro et al., 2005).



Surface Waves, Figure 4 Example of group velocity dispersion diagrams obtained for the fundamental Rayleigh wave mode on the vertical record of the Chile Ms 6.8 earthquake of October 15, 1997, at Geoscope station INU, using the FTAN multiple filtering approach. (**a**) Dispersion diagram before filtering; (**b**) same after filtering. The group velocity dispersion curve obtained follows the maxima of energy as delineated by the gray scale contours. (**c**) Corresponding time domain seismogram before (*broken line*) and after (*solid line*) variable filtering. The bandpass is 50–400 s. (Reprinted from Romanowicz 2002.)

This has opened up new horizons for the study of regional crustal structure, especially in seismically quiet regions. There remain some theoretical issues to be resolved, in particular regarding biases introduced by the nonuniform distribution of noise sources around the study region, and the possibility of extracting the overtone part of the Green's function. This is because most of the noise sources that contribute to the reconstruction are located near the earth's surface (see Sect. The earth's background noise spectrum – hum and microseisms) and thus preferentially excite the fundamental mode. Nevertheless, the methodology is developing at a rapid pace.

Global studies of structure using surface waves

With the advent of digital recording in the mid-1970s and the expansion of global digital long-period and later broadband networks (see *Seismological Networks*), the processing of the relatively long time series needed to measure surface waves became much easier and opened the way, in the 1980s to large-scale and global studies of upper mantle structure.

Global studies first proceeded according to a regionalization scheme, in which it was assumed that the depth variation of seismic velocities is the same across each tectonic province. These studies confirmed and extended to longer periods (and hence larger depths) early results on the age dependence of structure in the oceans (e.g., Romanowicz, 2002; see also *Earth's Structure, Upper Mantle*). The constraint of regionalization was soon relaxed, replaced by expansion of lateral heterogeneity into a global basis of spherical harmonics. This revealed, in particular, that the correlation of structure with tectonics disappears below depths of 200–300 km (e.g., Ekström et al., 1997). Dispersion measurements have focused primarily on the fundamental mode, generally in the period range 35–150 s, and thus are generally limited in resolution to depths shallower than ~300–400 km. This approach has led to several generations of global phase velocity maps at discrete frequencies, with increasing spatial resolution (e.g., Figure 5). In these studies, lateral variations of dispersive properties are now well resolved down to wavelengths of ~1,000–2,000 km. At the long period end, the period range is limited by the difficulty of separating consecutive wave trains, and at the short period end, by the increased complexity of surface wave propagation in the strongly heterogeneous crust and uppermost mantle, resulting in lateral refractions and multipathing. The latter are not taken into account in the simple high frequency, great circle propagation assumptions underlying the construction of dispersion maps.

Inversion of surface wave dispersion data

Inversion of surface wave dispersion data generally involves two steps. By combining measurements at a given frequency for many different paths crossing a particular region, or, at longer periods ($T >\sim 40$ s) over the entire globe (e.g., Figure 5), dispersion maps can be obtained by a standard linear inversion procedure, yielding point by point dispersion curves over the region considered.

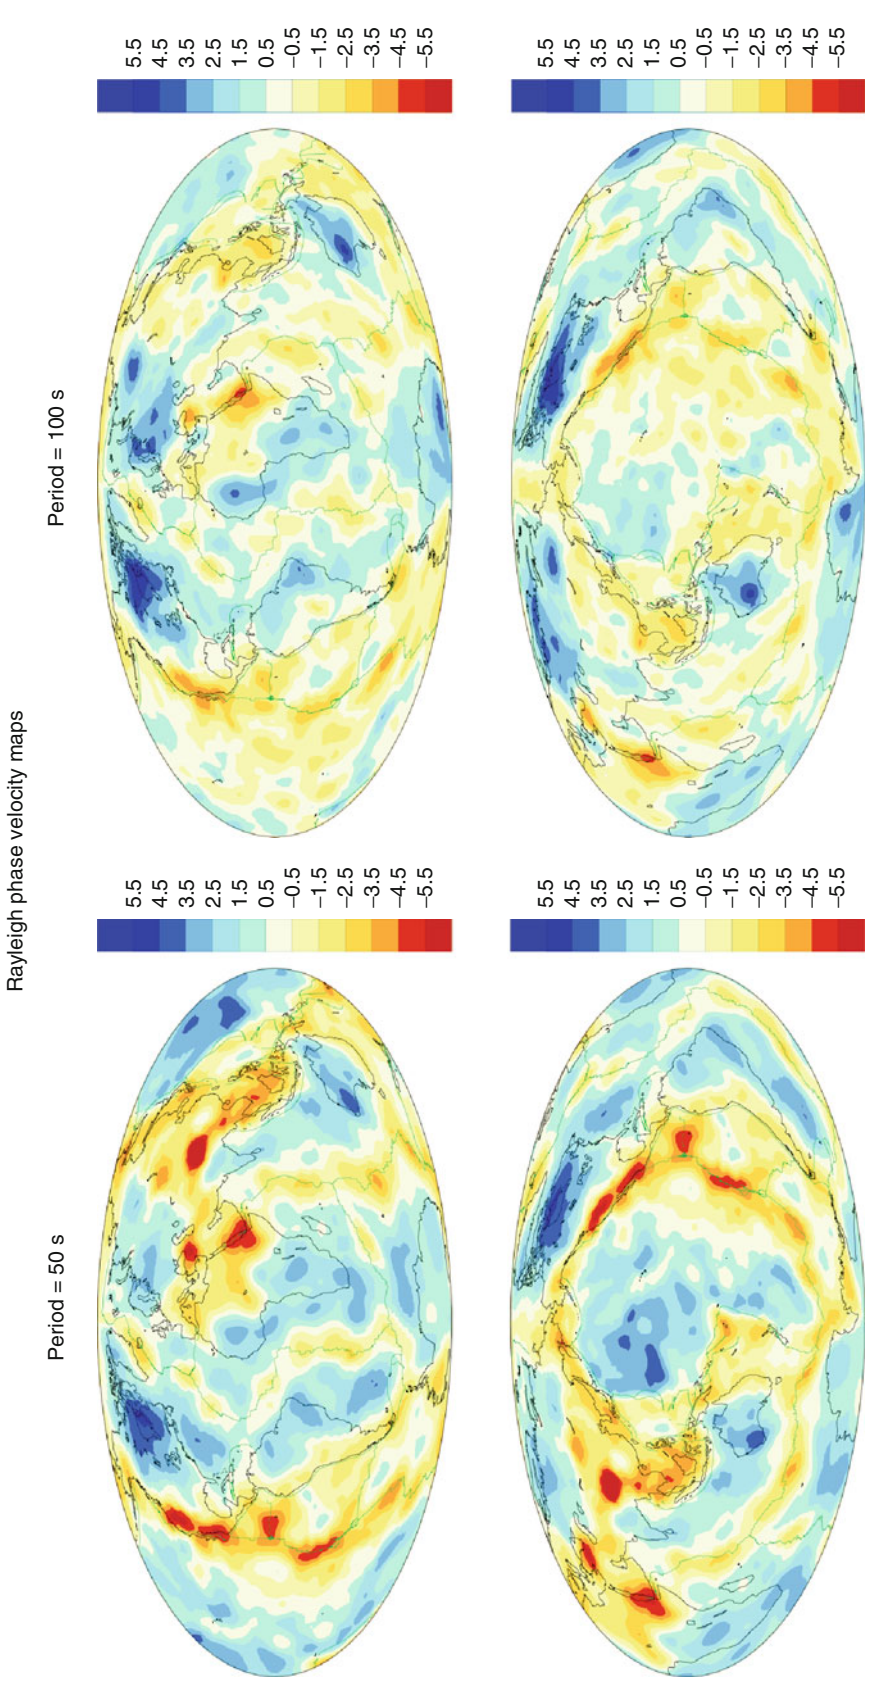
These dispersion curves can then be inverted to obtain the local variation of elastic parameters with depth, by matching observed dispersion curves to theoretical curves calculated for layered earth models, using inverse theory (e.g., Thurber and Ritsema, 2007; see also *Inverse Theory, Linear*). The models thus obtained suffer from some degree of nonuniqueness, as the problem is under-determined. In particular, surface waves cannot by themselves resolve strong gradients of velocity with depth, so that, in general, some a priori constraints are applied, such as fixing the depth of the Moho, or limiting the extent of low velocity layers. A major advance was the theoretical contribution of Backus and Gilbert (1970), which made it possible to calculate the resolving kernels and errors associated with the various least squares solutions of the inverse problem. Surface wave dispersion is most sensitive to shear velocities, so that, in general, a priori conversion factors between shear velocity and compressional velocity, on the one hand, and density, on the other, are assumed.

Crustal corrections

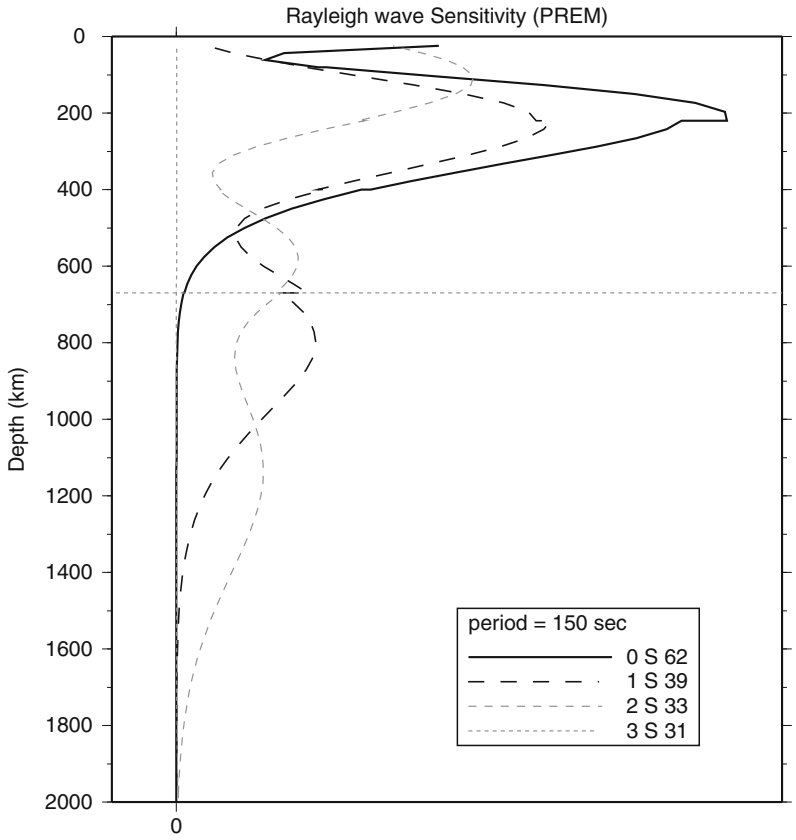
A significant issue regarding the inversion of long period fundamental mode surface waves (40–200 s) for upper mantle structure is that of crustal corrections. Indeed, surface waves are sensitive to shallow structure even at long periods, but not sensitive enough for inversion, unless more difficult to measure short periods (down to ~10 s) are included. Until recently, most studies simply performed crustal corrections in the framework of linear perturbation theory. However, Montagner and Jobert (1988) showed that the effect of the large variations in crustal thickness is nonlinear, and proposed a more accurate correction procedure based on a tectonic regionalization. Developing accurate crustal models worldwide (see *Earth's Structure, Continental Crust*) remains a challenge for large-scale surface wave inversions for structure of the upper mantle, especially in the era of numerical computation of waveforms.

Inversion using overtones

While they are well separated in the time domain from other mode branches, and therefore well suited for frequency domain single mode analysis techniques, fundamental mode surface waves have several shortcomings: at intermediate periods (~20–150 s) their sensitivity to structure below about 200 km is poor, whereas longer period mantle waves, which reach down to the top of the upper mantle transition zone, have poor spatial resolution. In any case, resolving structure in the transition zone, which is also poorly sampled by body waves, requires the inclusion of higher-mode surface waves, whose sensitivity is larger at these depths (e.g., Figure 6). They are also a powerful tool for investigating structures where low velocity zones may be present (e.g., Kovach



Surface Waves, Figure 5 Examples of global Rayleigh wave phase velocity maps at periods of 50 s (*left*) and 100 s (*right*), highlighting the diminishing lateral variations of structure with period (i.e., with depth). These maps were obtained using the dataset of Ekström et al. (1997). (Courtesy of Guy Masters.)



Surface Waves, Figure 6 Sensitivity with depth of Rayleigh wave fundamental mode (*solid line*) and first two overtones (*broken lines*) at a period of 100 s, computed in the PREM model (Dziewonski and Anderson, 1981). The fundamental mode sensitivity peaks around 200 km whereas the overtones have significant sensitivity down to the top of the lower mantle. Courtesy of Yuancheng Gung.

and Anderson, 1964). In general, however, higher-mode surface waves overlap in the time-frequency domain, and single mode dispersion methods therefore cannot be applied.

In the 1970s, array methods were developed independently by Nolet (1975) and Cara (1978) to extract information from overtones, and applied in the period range 20–100 s to paths across Eurasia and the Pacific Ocean, respectively. These methods require a linear regional array of stations approximately aligned with the epicenter (and not in a nodal direction of the source radiation pattern), in order to separate modes in the (ω,k) domain, where k is the wavenumber. They are limited in application to a few regions of the world with relatively dense, linear arrays. A waveform-based method involving the comparison of observed and synthetic seismograms at a single station was proposed by Lerner-Lam and Jordan (1983). In this approach, branch cross-correlation functions (bccf's) are formed between a particular single-mode synthetic and the observed seismograms and used to invert for an average structure along each source-station path. This approach lends itself to the derivation of secondary observables such as group or phase velocity. The main drawback of this methodology is the contamination of the single mode objective function by interference from other mode branches. More recently, van Heijst and Woodhouse (1997) proposed a "mode-branch stripping" method based on a bccf approach combined with a frequency-stepping procedure, yielding single mode dispersion and amplitudes. A global multimode dispersion dataset assembled in this fashion has been used in the construction of several generations of global shear velocity models (e.g., Ritsema et al., 2004). See also *Earth's Structure, Upper Mantle*.

Full waveform inversions

Extracting single mode dispersion information directly from spectra of windowed wave trains is only effective for the fundamental mode, which is well separated on the seismogram, and even in this case, overlapping with overtone wave trains or, at long periods, other orbits of the fundamental mode, can be a problem. A waveform matching approach is therefore desirable, where observed seismograms are compared to synthetics computed for a given reference earth model, and the model is perturbed to improve the fits of the observed and synthetics in the target time window of observation, which can be

optimized. In particular, such an approach is suitable both for fundamental mode and overtone surface waves.

For many years, the computation of long period synthetic seismograms relied on asymptotic approximations to normal mode first order perturbation theory, as developed in the 1970s. The most widely used approximation is the "path average approximation," introduced for waveform modeling by Woodhouse and Dziewonski (1984). The key steps that led to the various formalisms routinely used today are described in Romanowicz et al. (2008). See also *Seismic, Waveform Modeling and Tomography*.

Working under the assumption of PAVA, Nolet (1990) introduced "the partitioned waveform inversion" (PWI), in which inversion for elastic structure proceeds in two steps, more closely related to the two-step inversion using dispersion data. Path integral parameters are defined and retrieved by nonlinear waveform fitting over each path, and in a second step, inverted linearly for elastic structure. The advantage of this approach is that it reduces the number of parameters to be fit in the nonlinear part of the inversion. The PWI also includes progressive filtering of data starting at the longest periods (see *Seismic Tomography*).

Because it includes only coupling of modes along single dispersion branches, the PAVA is rigorously only suitable for single-mode wave trains such as the fundamental mode. The corresponding sensitivity kernels to structure are 1D kernels, that is, they only depend on the laterally averaged structure in the vertical plane between the source and the receiver. When applied to overtones and body waves, coupling across mode branches needs to be included. For a review of these methodologies, see Romanowicz et al. (2008) and Thurber and Ritsema (2007).

Upper mantle anisotropy from surface wave studies

Early studies of surface wave dispersion showed that, in many regions, it is not possible to find a single isotropic model that satisfies both fundamental mode Love and Rayleigh wave dispersion simultaneously. This provided some of the earliest evidence for the presence of anisotropy in the crust and upper mantle (e.g., Anderson, 1961). This discrepancy can be explained by introducing a transversely isotropic medium with a vertical symmetry axis (radial anisotropy), down to at least 200 km depth. It is in this context that the still widely used Preliminary Reference Earth Model (PREM) was constructed (Dziewonski and Anderson, 1981). Gung et al. (2003) showed that radial anisotropy is also present at depths greater than 200 km beneath the lithospheric roots of stable continents and cratons, and explains discrepancies in lithospheric thickness obtained using surface waves of different polarization, thus reconciling lithospheric thickness obtained from seismology with estimates from other geophysical and xenolith data.

Surface wave dispersion also varies with azimuth of propagation, an indication of "azimuthal anisotropy" (e.g., Forsyth, 1975). The global azimuthal variations of Rayleigh and Love wave dispersion at long periods (100–250 s) were first mapped by Tanimoto and Anderson (1985), who showed that the fast direction appears to correlate with flow directions in the mantle. Montagner and Tanimoto (1991) developed the first global model of radial and azimuthal anisotropy in the upper mantle based on fundamental mode surface wave data. While some questions remain about trade-offs between lateral heterogeneity and anisotropy in this type of inversion, Montagner and collaborators have shown that they can explain their datasets with fewer parameters when azimuthal anisotropy is considered than when it is ignored.

To first order, asymptotically, the azimuthal variation of phase velocity (Love or Rayleigh waves) is of the form (Smith and Dahlen, 1973):

$$C(\omega,\theta) = A_0 + A_1\cos(2\theta) + A_2\sin(2\theta) + A_3\cos(4\theta) + A_4\sin(4\theta) \tag{10}$$

where θ is the azimuth of the wavenumber vector defined clockwise from north. The coefficients $A_i(\omega)$ depend linearly on the elastic tensor at every point in the medium. Theoretical expressions and how they can be applied for crust and upper mantle studies are reviewed in Romanowicz (2002) and Montagner (2007). Because Rayleigh waves are sensitive both to shallow crustal and deeper mantle anisotropy, it is important to use a wide frequency range to resolve the depth dependence of anisotropy using surface waves. Montagner and Nataf (1988) introduced "vectorial tomography." By combining radial and azimuthal dispersion terms, under the assumption that the material possesses a symmetry axis (orthotropic medium), they showed that the 3D model can be described using seven elastic parameters (plus density): the five parameters describing transverse isotropy, and two angles describing the orientation in space of the axis of symmetry. Combining long period waveforms and SKS splitting measurements, Yuan and Romanowicz (2010) showed that azimuthal anisotropy provides a powerful tool to detect layering in the continental lithosphere.

Using different seismological tools, including surface wave overtones (e.g., Trampert and van Heijst, 2002), it has also been suggested that azimuthal anisotropy is present in the transition zone. To date, these results are not consistent with each other and still controversial.

Other diagnostic effects of anisotropy in long period surface waves are waveform anomalies caused by Rayleigh-Love coupling, which generates "quasi-Love" waves on vertical components and "quasi-Rayleigh" waves on transverse (e.g., Park and Maupin, 2007). See also *Seismic Anisotropy*.

Effects of scattering and the Born approximation

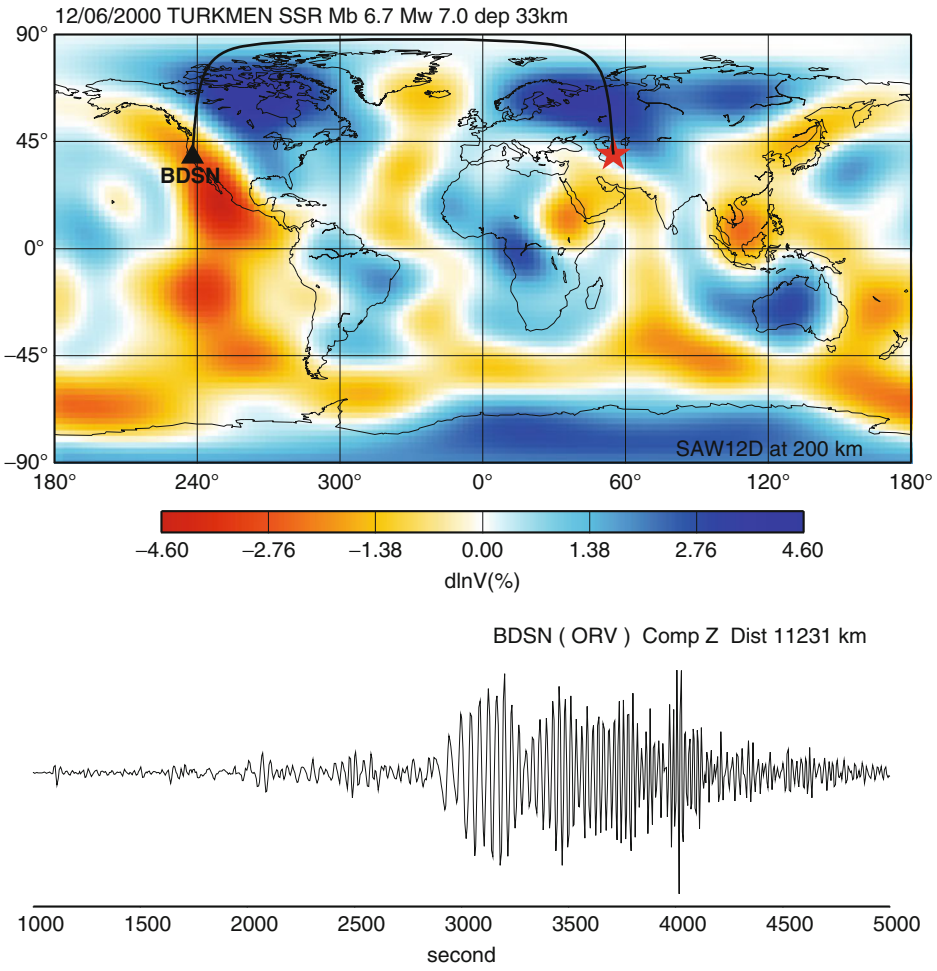
Until recently, most regional and global models of upper mantle structure derived from surface waves were based

on the standard "path average" approximation (PAVA). This is valid only if the wavelength of lateral variations of structure is long with respect to that of the surface waves considered. And it is not strictly appropriate for overtones.

Many observations indicate that lateral heterogeneity is strong enough to cause departures from PAVA. For example, 20 s surface waves sensitive to shallow crustal structure consistently show multipathing (e.g., Capon, 1970 or Figure 7). At longer periods ($T > 100$ s), later arriving trains often show larger amplitudes than the ones preceding them which cannot be explained by lateral variations of attenuation.

Several approaches have been developed to account for these effects and exploit them to obtain better constraints on lateral variations of structure. Woodhouse (1974) introduced the concept of local modes. These are the surface wave modes of a laterally homogeneous model, which locally has the depth distribution of the laterally varying model. If the medium is laterally smooth, the local mode branches propagate as independent wave trains, and their dispersion is modified according to the evolution of the local modes. However, if lateral variations are sharp (e.g., in the presence of a structural discontinuity such as an ocean-continent boundary), the coupling of the local modes cannot be neglected and its strength depends on the width of the structural transition zone (Kennett, 1972). For a recent review see Romanowicz (2002). Kennett (1992) derived a formalism for mode-coupling in 2D slowly laterally varying structures, which was extended to the 3D scattering case, in Cartesian coordinates (e.g., Bostock and Kennett, 1992).

In the framework of scattering theory, the use of tools based on the single-scattering Born approximation has gained popularity in the last 5 years. Born scattering is well suited for inversion since the scattered wavefield



Surface Waves, Figure 7 Example of vertical component record at BDSN station ORV for an *Mw* 7.0 earthquake in Turkmenistan showing multipathing of 20–30 s surface waves. The record has been bandpass filtered between 0.001 and 0.03 Hz. The great circle path is shown on the top plot with a shear wave tomographic model in the background. It arrives to the station from the north, following the coast and along major structural boundaries in the crust that are likely the cause of the multipathing. (Courtesy of Yuancheng Gung.)

depends linearly on structural perturbations (e.g., Snieder, 1988). The use of Born kernels is widely advocated to take into account the effects on dispersion of off-great circle sensitivity of surface waves (e.g., Zhou et al., 2006). However, the relative merits of single-scattering Born sensitivity kernels versus simpler averaging kernels, such as "fat rays" is still debated (e.g., Boschi et al., 2006).

Born is also a poor approximation in the case of strong heterogeneity, or when the region of scattering is large (e.g., Friederich et al., 1993).

Most recently, the introduction to global seismology of the Spectral Element Method (Komatitsch and Vilotte, 1998), which provides an accurate representation of the teleseismic wavefield in arbitrary 3D media up to the second surface wave orbit, has provided a new powerful tool for the study of Earth structure, and is progressively being implemented for waveform modeling of crust and upper mantle structure at the local (e.g., Tape et al., 2010), regional (Fichtner et al., 2010), and global scale (Lekic and Romanowicz, 2010), focusing, so far, on the relatively long period surface waves. These studies show that the use of a more accurate wave propagation theory results in the improved retrieval of amplitudes of lateral variations of shear wave velocity, and in particular, significantly lower values in low velocity zones. For applications at the global scale, this promising new tool presents several challenges: a considerable computational cost, and the necessity of accurate representation of the 3D structure in the crust, a topic that undoubtedly will be addressed in the coming years.

Surface wave attenuation

Surface wave measurements provide the primary constraints on attenuation structure in the crust and uppermost mantle. In the absence of perturbing effects due to scattering and focusing, the amplitude spectrum of a single mode wave train can be written as:

$$A(\omega) = A_0(\omega)\exp(-\eta(\omega)X) \tag{11}$$

where X is the epicentral distance in kilometers and $A_0(\omega)$ represents the amplitude at the source. The attenuation coefficient $\eta(\omega)$ is related to the quality factor Q through (e.g., Aki and Richards, 1980):

$$\eta(\omega) = \frac{\omega}{2C(\omega)Q(\omega)}$$

where C is the phase velocity.

Regional studies of amplitudes of fundamental mode surface waves in the period range 5–100 s and of Lg waves have long established the presence of large variations of Q correlated with tectonic provinces and in particular with the age of the oceans, and with time elapsed since the latest tectonic activity on continents. For recent reviews, see Mitchell (1995) and Romanowicz and Mitchell (2007). Recently, attenuation structure in the vicinity of the East Pacific Rise and in the back-arcs and wedges of subduction zones obtained from a combination of surface wave and body wave data have revealed highly attenuating zones underlying volcanic arcs, down to the slab surface. See also *Seismic, Viscoelastic Attenuation*.

Lateral variations in attenuation at long periods can be an order of magnitude larger than those in elastic velocity. Progress in constraining global 3D anelastic structure of the upper mantle has been slow because of the inherent difficulty of measuring attenuation in the presence of focusing and scattering effects that can be as large as anelastic ones and depend strongly on the short-wavelength details of the elastic structure. The long wavelength 3D attenuation models obtained thus far indicate that lateral variations in attenuation in the first 200–250 km of the mantle are correlated with tectonics. In the transition zone, the long wavelength pattern shifts to one correlated with hotspots and with the structure at the base of the mantle, with high attenuation overlying the two large low shear velocity provinces under Africa and in the Pacific (e.g., Romanowicz and Mitchell, 2007). Progress in resolving finer details of attenuation structure awaits the routine implementation of numerical methods for the computation of long period seismograms to fully account for focusing effects.

Source studies using surface waves

Fundamental mode surface wave spectra contain information about the source moment tensor, source depth (centroid), source process time, and, under favorable circumstances for very large earthquakes, source directivity. Tsai and Aki (1971) first showed that the amplitude spectrum of Rayleigh waves contained the signature of source depth, in the form of a "hole" in the spectrum in the period range 10–100 s, which appears at a period depending on depth, and which also depends on the source mechanism.

In order to correct for propagation, different approaches need to be taken depending on the size of the earthquake and the period range considered. At very long periods ($T > 180$ s) and for large earthquakes ($M > 6.5$), propagation effects can be accounted for approximately using a spherically symmetric reference earth model and ellipticity corrections. At shorter periods, and for smaller earthquakes, corrections on individual source-station paths need to be known much more accurately (for a review, see Romanowicz, 2002). In the last 15 years, the availability of increasingly accurate global 3D tomographic models of the upper mantle has made it possible to extend the period range to shorter periods (down to ~120 s) and to efficiently make use of methodologies, based on time-domain waveform inversion, that are no longer restricted to the fundamental mode, thus providing more accurate estimation of the source depth. Such a waveform approach was first introduced by Dziewonski et al. (1981), who combined waveforms of mantle waves at periods greater than 120 s with overtone waveforms at periods greater than 80 s. This forms the basis of a now routine procedure that serves to construct the widely used Harvard centroid moment tensor (CMT) catalog (Now "global CMT catalog").

The earth's background noise spectrum: hum and microseisms

The presence of background peaks in the frequency range 2–7 mHz, corresponding to the fundamental spheroidal free oscillations of the earth, in the absence of large earthquakes, was discovered recently by Japanese scientists (e.g., Kobayashi and Nishida, 1998). It was later determined that the vertical component long period seismic noise spectrum was made up of Rayleigh waves (Nishida et al., 2002) and that the main source of the "hum" was located in the oceans (Rhie and Romanowicz, 2004), resulting from nonlinear interactions between the atmosphere (oceanic storms), the oceans, and the solid earth. The "hum" has also been detected on the horizontal components, corresponding to Love waves.

The largest background seismic noise is found in the period range 2–20 s and corresponds to the so-called microseismic peak. Microseisms were studied extensively in the 1950s and determined to be surface waves generated in the oceans. There are two types of microseisms: "primary" and "secondary." Secondary microseisms are the strongest. Also called "double-frequency microseisms," they are generated at frequency f by a nonlinear mechanism involving two opposing ocean waves of frequency $f/2$ (Longuet-Higgins, 1950). In the last decade, there has been renewed interest in the study of microseisms, in the context of the use of noise cross-correlations for the study of Earth structure, as seen above. While it has been proposed that the earth's low frequency hum generation mechanism is related to that of microseisms, no common explanation has yet been found for the vertical and horizontal hum generation. See also *Seismic Noise*.

Summary

Surface waves propagate along the surface of the earth with exponentially decreasing energy with depth, with waves of longer period reaching greater depths. They contain most of the elastic energy generated by earthquakes at periods greater than 20 s and are dispersive. There are two types of surface waves, Rayleigh and Love waves, with different polarization properties. The fundamental mode surface waves are well separated from other energy arrivals in the time domain and provide the best constraints to date on continental scale and global scale structure. They play a particularly important role in constraining the upper mantle structure in the ocean basins where few seismic stations have been installed. While the dispersion of fundamental mode surface waves is a classical tool for the investigation of upper mantle structure, higher modes, or overtones provide constraints at transition zone depths (400–700 km) and deeper. They require more sophisticated analysis tools because they cannot be distinguished from each other readily on the seismogram. Waveform inversion approaches are increasingly favored to handle both fundamental mode and overtone interpretation, and hold increasing promise as numerical methods for the computation of the seismic wavefield in arbitrary 3D structures are being implemented, and can account for complex scattering and focusing effects accurately. In addition to isotropic shear velocity, surface waves provide constraints on the distribution of polarization and azimuthal anisotropy in the upper mantle, as well as on anelastic attenuation. When path effects have been corrected for, surface waves provide robust constraints on the source depth and radiation pattern, as expressed by its moment tensor.

The earth's continuous background noise consists primarily of surface waves, at least at periods longer than 5 s. Notable is the microseismic noise peak around 6–7 s. Most of this energy is generated in the oceans by nonlinear interactions involving wind-driven ocean waves, and the seafloor. Recently, a method based on the cross-correlation of noise records has gained popularity and has been applied successfully to resolve crust and uppermost mantle structure. It is particularly useful in seismically quiet regions.

Definition and introduction

T phases are defined as seismic recordings of signals having traveled an extended path as acoustic waves in the water body of the oceans. This is made possible by the "Sound Fixing and Ranging" (SOFAR) channel, a layer of minimum sound velocity acting as a wave guide at average depths of 1,000 m (Okal, 2007). It allows the efficient propagation of extremely small signals over extremely long distances, in practice limited only by the finite size of the ocean basins. The existence of the SOFAR channel results from the dependence of the velocity of sound in water on temperature, pressure and salinity. As a result, the detailed structure of the channel (including the value of the minimum velocity) varies both geographically (mainly with latitude) and seasonally, but at first order, the SOFAR channel can be regarded as a quasi-universal feature of the world's oceans.

At the shoreline of a continent or island, the acoustic wave is converted into a seismic wave which can be recorded by a seismometer or, occasionally, felt by humans. Efficient propagation inside the waveguide requires short wavelengths, in practice frequencies above 3 Hz, and thus T phases generally attenuate fast once converted, although in exceptional geometries they have been detected up to 1,000 km inside stable continental shields. Even though records of T waves were reported as early as 1927, they were not identified as hydroacoustic signals until the late 1940s, when results from antisubmarine warfare during World War II were declassified.

Sources of T waves

T waves can be generated by a diversity of underwater sources, as long as their energy becomes trapped in the SOFAR channel. Most earthquakes in oceanic margins generate strong T phases, since in the presence of a sloping ocean floor, multiple downslope reflections can lead to efficient penetration of the SOFAR (Johnson et al., 1963). However, their generation by earthquakes in abyssal plains deprived of large-scale bathymetry defies the laws of geometrical optics, and remains to this day a major theoretical challenge; it is generally thought that abyssal T phases result from scattering along small random heterogeneities of the ocean floor (Yang and Forsyth, 2003). Also, T waves are occasionally generated by non-shallow earthquakes, even the deepest ones, even though their source is de facto distant from the ocean column. This excitation is made possible by travel through the subducting oceanic slabs which, being cold, propagate high frequencies with limited attenuation and can deliver them to the water interface for conversion to acoustic waves (Okal, 2001a).

Underwater landslides are also T-wave generators. As compared with earthquakes, such sources, which move generally smaller segments of ocean floor over much larger distances, have a considerably longer duration, a lower-frequency spectrum, and thus result in T waves of longer duration but smaller amplitudes (Okal, 2003).

By contrast, explosions at sea, which are intrinsically high-frequency, are particularly efficient sources of T waves; in most instances, they involve a shallow source located inside the SOFAR channel, thus providing optimal feeding of acoustic energy into the channel. In particular, seismic reflection experiments are routinely recorded thousands of kilometers away.

Underwater volcanic eruptions are also regular generators of T waves. Because of the diversity of processes involved during a volcanic sequence, these signals may

Harsh K. Gupta (ed.), *Encyclopedia of Solid Earth Geophysics*, DOI 10.1007/978-90-481-8702-7,

feature a wide variety of characteristics. The opening of cracks during the formation of magmatic plumbing systems is essentially in the nature of an earthquake, while magmatophreatic explosions at the contact between a lava conduit and the oceanic column are reminiscent of chemical explosions. The steady output of lava into the ocean takes the form of a prolonged noise of low amplitude which may be compared to underwater slumping (Caplan-Auerbach et al., 2001). Finally, the oscillation of magma inside the plumbing system, known to cause volcanic tremor long recorded seismically on subaerial volcanoes, generates harmonic T-wave signals. Supercritical hydrothermal venting during volcanic events has also been documented as the source of monochromatic hydroacoustic signals (Talandier and Okal, 1996).

Among the most remarkable T waves ever reported, signals from the eruption of Macdonald Volcano (29°S; 140°W) on 29 May 1967 led to the eventual discovery of this unchartered underwater seamount, and its interpretation as the active member of the Cook-Austral hotspot chain (Johnson, 1970).

The collision of large icebergs, during which their masses can rub against each other, has also been documented as a source of T waves, which can exhibit a harmonic character during episodes of stick-and-slip friction between tabular icebergs (MacAyeal et al., 2008). Hydroacoustic waves are also generated during the disintegration of large icebergs, and thus could be used to monitor and assess any possible change in climatic conditions (Li and Gavrilov, 2006).

Finally, marine mammals can talk into the SOFAR channel and correspond across hundreds of kilometers, using signals in the range of a few tens of hertz, but specific to each species.

Human perception

T waves of sufficient amplitude can be felt by shoreline populations. For example, the underwater nuclear test WIGWAM on 14 May 1955 off the coast of Southern California was felt in Hawaii and even in Japan, 8,000 km away. Large events such as the Alaskan earthquake of 10 July 1958 and the deep Bolivian shock of 9 June 1994 were felt in Hawaii, and T waves from the 2004 Sumatra earthquake were felt in the Maldives and possibly on Zanzibar; they could have provided a warning of the impending tsunami in these otherwise aseismic areas, but their populations were unprepared.

Use in comprehensive nuclear-test ban treaty monitoring

Because hydroacoustic waves can detect small sources (especially intra-oceanic ones) at great distances, they have been included as one of the four technologies used by the International Monitoring System (IMS) of the Comprehensive Nuclear-Test Ban Treaty. Their spectacular efficiency in propagation allows a full coverage of the all the Earth's oceans using only 11 receiver sites, six of which are hydrophones deployed within the SOFAR channels, and five special seismic stations close to shorelines ("T-phase stations"), instrumented for high-frequency seismic recording in the 50−100 Hz range (Okal, 2001b).

Acoustic thermometry of ocean climate

This project consisted of using acoustic sources in the 57 Hz range fired in the vicinity of Heard Island, South Indian Ocean, a location allowing the illumination of all three major oceans (Munk et al., 1994). Detection at extreme ranges of up to 17,000 km allowed precise measurement of acoustic velocities, and it was envisioned to repeat these experiments over several decades, to monitor any evolution of sound velocities, as a proxy to changes in temperature, possibly in the context of global warming. Unfortunately, the project had to be halted in the late 1990s under pressure from the environmental lobby.

Quantification

Like other seismic phases, quantitative measurements of T waves can provide information on source parameters. However, absolute measurements (especially of amplitudes) at seismic receivers are difficult to interpret due to the complexity and site specificity of the conversion processes. In addition, the high-frequency nature of the phase results in amplitude saturation at relatively low magnitudes. In this context, quantification of T waves has emphasized duration of wavetrains over amplitude, and relative measurements under common or comparable receiver conditions. *Okal et al*. (2003) have introduced the concept of *T*−phase energy flux, *TPEF*, reminiscent of the evaluation of seismic energy from body waves, and which should scale with seismic moment M_0 for regular seismic sources. Any deviation in the ratio $\Gamma = TPEF/M_0$ identifies anomalous source properties; in particular, slow earthquakes exhibit deficient Γ, a property with some potential in tsunami warning.

The comparison of duration and amplitude of T wavetrains can efficiently discriminate between earthquakes and explosions at sea, based on the strong differences in the scaling of their source processes (Talandier and Okal, 2001), although small earthquakes located inside steep volcanic edifices remain a challenge in this respect.

A few geophysical applications

As most of their path is hydroacoustic, T phases propagate at a velocity close to that of sound in water, 1.5 km/s; that gives them late arrivals on seismic records, hence their name "T" for "third". Such slow velocities allow a remarkable resolving power for source locations, after accounting for small geographic and seasonal variations in SOFAR velocities, and for the contribution of the converted [seismic] segments of the phase.

In this context, the superior detection capabilities of T phases have been used to improve considerably our coverage of low-magnitude seismicity in the oceanic

environment, and especially our understanding of small-scale processes at mid-oceanic ridges, notably in conjunction with swarms of volcanic activity (Dziak et al., 1995).

The slowness of T waves also allows to very precisely beam a receiving array (e.g., triangles of hydrophones at sites of the International Monitoring System [IMS]) to back-track the source of T phases, or even of individual fragments of their wavetrains; this procedure was used to obtain a detailed source tomography of the great 2004 Sumatra-Andaman event (e.g., Tolstoy and Bohnenstiehl, 2005).

Conclusion

Because of their high-frequency character, T waves provide a valuable complement to more traditional phases in the field of body-wave seismology. Their incorporation into the IMS allows their more systematic recording and opens up a number of new research opportunities.

THERMAL STORAGE AND TRANSPORT PROPERTIES OF ROCKS, I: HEAT CAPACITY AND LATENT HEAT

Christoph Clauser
Institute for Applied Geophysics and Geothermal Energy, E.ON Energy Research Center, RWTH Aachen University, Aachen, Germany

Synonyms

Specific heat capacity; Thermal capacity; Volumetric heat capacity

Definition

Specific heat capacity c. Physical property defining the amount of sensible heat that can be stored in or extracted from a unit mass of rock per unit temperature increase or decrease, respectively. Isobaric and isochoric specific heat capacities are defined at constant pressure and volume, respectively; dimension: J kg^{-1} K^{-1}.

Thermal capacity (*also: volumetric heat capacity*) ρ c. The product of isobaric specific heat capacity and density. Physical property defining the amount of sensible heat that can be stored in or extracted from a unit volume of rock per unit temperature increase or decrease, respectively; dimension: J m^{-3} K^{-1}.

Thermal storage properties

The thermal regime of the Earth is defined by its heat sources and sinks, the heat storage and transport processes, and their corresponding physical properties. The storage properties are discussed below. The transport properties, thermal conductivity and thermal diffusivity, are dealt with in this volume in the companion chapter "*Thermal Storage and Transport Properties of Rocks, II: Thermal conductivity and diffusivity*."

Heat can be stored as sensible heat and enthalpy of transformation. In the Earth, sensible heat is defined by the heat capacity of rocks, and the enthalpy of transformation by their latent heat of fusion.

Heat is transmitted within the Earth mainly by diffusion (in the steady state: conduction), advection, and radiation. Generally, heat diffusion dominates heat radiation within the lithosphere of the Earth, at temperatures below

about 1 000 K. For sufficiently large flow rates, convection-driven heat advection, however, can be equally or even more efficient than diffusion. The heat diffusion–advection equation for a porous medium is:

$$\frac{\partial(\rho c_P T)}{\partial t} = \nabla \cdot \left(\underbrace{\lambda \nabla T}_{q_{dif}} - \underbrace{(\rho c_P)_f T \mathbf{v}}_{q_{adv}} \right) + \underbrace{A}_{\text{generation}}, \quad (1)$$

where T is temperature in K, t time in s, ρ density in kg m^{-3}, c isobaric specific heat capacity in J kg^{-1} K^{-1}, λ thermal conductivity in W m^{-1} K^{-1}, **v** specific fluid discharge (volume flow rate per unit cross section) in m s^{-1}, A (radiogenic) heat generation rate in W m^{-3}; subscript "f" refers to fluid properties. Diffusive bulk storage and transport properties for heat in rocks governing this equation are thermal capacity ρ c_P, also referred to as volumetric heat capacity, and thermal conductivity λ. Advection is governed by the thermal capacity and specific discharge of the flowing fluid, $(\rho\ c_P)_f$ and **v**, respectively.

Heat advection does not require very large flows for becoming as or more efficient than heat diffusion. This is often the case in sedimentary basins (see, e.g., Clauser et al. (2002) for a literature review). But fluid-driven heat advection may be also important in crystalline rocks and on a crustal scale (e.g., Clauser, 1992). The non-dimensional Péclet and Nusselt numbers, Pe and Nu, are ratios of specific heat flows q_{adv} and q_{dif} (Equation 1) indicating the efficiency of (fluid flow driven) advective heat transport versus heat conduction for given flow geometries. For instance, assuming flow of magnitude v over a distance L and a temperature difference $T_1 - T_0$ one obtains:

$$\begin{aligned} Pe &= \frac{q_{adv}}{q_{dif}} = \frac{(\rho c)_f v (T_1 - T_0)}{\lambda (T_1 - T_0)/L} = \frac{(\rho c)_f v L}{\lambda}; \\ Nu &= \frac{q_{adv} + q_{dif}}{q_{dif}} = \frac{q_{adv}}{q_{dif}} + 1 = Pe + 1. \end{aligned} \quad (2)$$

Thus advection or diffusion (in the steady state: conduction) dominate for Pe > 1 or Pe < 1, respectively (in terms of the Nusselt number for Nu > 2 or Nu < 2, respectively). At temperatures above 1 000 K, heat is propagated increasingly as radiated electromagnetic waves, and heat radiation begins to dominate diffusion (see *Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity*, this volume).

Heat capacity

Heat can be stored and delivered as sensible heat or as latent heat required or liberated by phase changes. This and the next two paragraphs are concerned with sensible heat. Following this, latent heat will be discussed.

Sensible heat capacity C is defined as the ratio of heat ΔQ required to raise the temperature of a mass M of rock by ΔT. For each molecule of mass m, this temperature increase requires an energy of (f/2) k ΔT, where f is the number of degrees of freedom of the molecule and k = 1.380 650 4(24) × 10^{-23} J K^{-1} is Boltzmann's constant. For a body of mass M, a temperature increase of ΔT requires an energy of ΔQ = (M/m) (f/2) k ΔT. Thus the heat capacity of the body at constant volume is:

$$C_V = \frac{\Delta Q}{\Delta T} = \frac{f}{2} k \frac{M}{m} = \frac{f}{2} k N_A = \frac{f}{2} R \ (JK^{-1}), \quad (3)$$

where Avogadro's number N_A = 6.022 141 79(30) × 10^{23} mol^{-1} equals the number of molecules or atoms in an amount of substance of 1 mol and R = k N_A = 8 314 472(15) J mol^{-1} K^{-1} is the molar Gas constant (numerical values for N_A, R, k, and all other physical constants used in this chapter are from CODATA, 2006). For solids, f = 6, corresponding to the three degrees of freedom of potential and kinetic lattice vibration energy in each space direction. Accordingly, the heat capacity of one mole of substance, the molar heat capacity at constant volume is constant:

$$C_{V,mol} = 3kN_A = 3R = 24.94 \ (J\ mol^{-1} K^{-1}) \quad (4)$$

where N_A = 6.022 141 79(30) × 10^{23} mol^{-1} is Avogadro's number, the number of molecules in one mole of substance, and R = k N_A the molar gas constant. Isobaric heat capacity $C_{P,mol}$ is larger than isochoric heat capacity $C_{V,mol}$ because additional work is required for volume expansion. Both are related by:

$$C_{P,mol} = C_{V,mol} + R = \frac{f+2}{2} R \ (J\ mol^{-1} K^{-1}). \quad (5)$$

With $C_{V,mol}$ from Equation 4 and assuming, as above, f = 6 this yields:

$$\begin{aligned} C_{P,mol} &= 3R + R = 4R \\ &= 33.26 \ (J\ mol^{-1} K^{-1}), \text{or:} \\ C_{P,mol} &- C_{V,mol} = R. \end{aligned} \quad (6)$$

Equation 4, the *Dulong–Petit law*, is satisfied well for heavy elements. In contrast, molar heat capacities of lighter elements remain below this limiting value, the lower the temperature the smaller $C_{V,mol}$.

Below the Debye temperature, Θ_D, heat capacity varies with temperature. Θ_D tends to zero as T^3 as absolute temperature approaches zero. Θ_D falls in the range 85 K and 450 K for most substances and 200 K and 1 000 K for most minerals (Stacey and Davis, 2008; Table 1). Therefore, heat capacity in the Earth can be well explained by classical Debye theory, in particular in the mantle and except for a thin crustal layer near the Earth's surface. There are, however, exceptions such as beryllium (Θ_D = 1 440 K) and diamond ($\Theta_D \approx$ 1 800 K). These are caused by the so-called freezing of vibrational or rotational degrees of freedom, which cannot absorb heat any more at low temperature. Therefore heat capacity tends to zero close to absolute zero.

Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat, Table 1 Debye temperature Θ_D and mass number A of selected elements (Kittel, 2004)

Element	Mass number A	Θ_D (K)
Carbon	6	2 230
Aluminum	13	428
Silica	14	645
Titanium	22	420
Chromium	24	630
Manganese	25	410
Iron	26	470
Nickel	28	450
Copper	29	343
Zinc	30	327
Silver	47	215
Cadmium	48	209
Tin	50	200
Tantalum	73	240
Tungsten	74	400
Platinum	78	240
Gold	79	165
Lead	82	105

Isobaric and isochoric specific heat capacity

Specific heat capacity c of a substance is defined as heat capacity C related to unit mass:

$$c = \frac{\Delta Q}{M\,\Delta T} = \frac{f}{2}\frac{k}{m} = \frac{f}{2}\frac{k}{A_r\,m_u}\left(J\,kg^{-1}K^{-1}\right), \tag{7}$$

where $m_u = 1.660\,538\,782(83) \times 10^{-27}$ kg is the atomic mass constant, defined as $^1/_{12}$ of the atomic mass of the carbon isotope ^{12}C, and A_r the atomic mass of a substance relative to m_u. Isobaric specific heat capacity c_P is larger than isochoric specific heat capacity c_V because additional work is required for volume expansion. Their ratio, the adiabatic exponent, is:

$$c_P/c_V = (f+2)/f. \tag{8}$$

Alternatively, isobaric specific heat capacity c_P can be expressed by enthalpy H(T,P) = E + P V, a state function of temperature and pressure, where E, P, and V are internal energy, pressure, and volume, respectively. In a closed system, the change in internal energy dE is the sum of the change in heat dQ and the work dW delivered: dE = dQ + dW. If we only consider volume expansion work, dW = −P dV, the change in enthalpy dH becomes:

$$\begin{aligned} dH(T,P) &= dE + pdV + VdP = dQ + VdP \\ &= \left(\frac{\partial H}{T}\right)_P dT + \left(\frac{\partial H}{P}\right)_T dP. \end{aligned} \tag{9}$$

Comparing coefficients, we obtain:

$$\frac{dQ}{dT} = \left(\frac{\partial H}{\partial T}\right)_P \doteq c_P. \tag{10}$$

Thus, Equation 10 defines isobaric specific heat capacity c_P as the first derivative of enthalpy with respect to temperature. Comparison of Equations 7 and 10 shows that both expressions are equivalent for dQ = ΔQ/M, and the isobaric enthalpy change ΔH is equal to the specific heat content ΔQ/M.

Isobaric and isochoric specific heat capacity are related to compressibility β = ΔV/(VΔP) and its inverse, incompressibility or bulk modulus K = VΔP/ΔV, by $c_P/c_V = \beta_T/\beta_S = K_S/K_T$ (e.g., Stacey and Davis, 2008), where subscripts T and S refer to isothermal and adiabatic conditions, respectively. Inserting the thermodynamic relation $\beta_T = \beta_S + \alpha^2\,T/(\rho\,c_P)$ (e.g., Birch, 1966) between isothermal and adiabatic compressibility yields the relative difference between isobaric and isochoric specific heat capacity:

$$c_P/c_v = 1 + \alpha\gamma T, \tag{11}$$

where α = ΔV/(VΔT) is the volume expansion coefficient,

$$\gamma = \frac{\alpha K_S}{\rho c_P} = \frac{\alpha K_T}{\rho c_V}, \tag{12}$$

the dimensionless Grüneisen parameter, and ρ density. Inserting the expressions for α and K into Equation 12 yields:

$$\gamma = \frac{1}{\rho c_P}\frac{\Delta V}{V\,\Delta T}\frac{V\Delta P}{\Delta V} = \frac{\Delta P}{\rho c_P \Delta T}. \tag{13}$$

Thus the Grüneisen parameter γ is the relative pressure change in a material heated at constant volume.

For solids, i.e., f = 6, the absolute difference between isobaric and isochoric specific heat capacity follows from Equations 11 and 8:

$$c_P - c_V = \frac{K_T\alpha^2 T}{\rho} = \frac{3K_S\alpha^2 T}{4\rho}. \tag{14}$$

For crustal rocks (γ = 0.5; α = 20 μK^{-1}; T < 10^3 K; ρ = 2 600 kg m^{-3}; K_S < 75 GPa (Dziewonski and Anderson, 1981; Stacey and Davis, 2008)), the difference between isobaric and isochoric specific heat capacity is less than 9 J kg^{-1} K^{-1} or 1% according to Equations 14 and 11, respectively. Thus, the distinction between isobaric and isochoric specific heat capacity is negligible for crustal rocks at temperatures below 1 000 K. However, it need be made for mantle rocks. From here on, "specific heat capacity" will always refer to isobaric specific heat capacity, denoted simply by the letter c without the subscript "P."

This classical treatment of heat capacity is sufficient for temperatures above the Debye temperature. In the Earth, temperature exceeds the Debye temperature everywhere except in the crust (Stacey and Davis, 2008). Therefore, in experiments at room temperature and atmospheric pressure, we observe deviations from the values predicted by Equations 3–14, which are based on the classical Dulong–Petit theory. The lower the temperature, lighter the element, and stronger the lattice bonding become, the larger are these deviations. Clearly, interpretation of heat

capacity below the Debye temperature is beyond classical mechanics and requires quantum mechanical treatment. This is, however, beyond the scope of this text and interested readers are referred to standard physics textbooks (e.g., Tipler and Mosca, 2007). Therefore heat capacity at crustal temperatures should not be calculated from Equations 3 and 14 but rather be measured or calculated from appropriate, quantum mechanical equations.

Čermák and Rybach (1982) compiled data on isobaric specific heat capacity for different rock-forming minerals and different igneous, metamorphic, volcanic, and sedimentary rocks as well as the corresponding variations with temperature.

Measuring techniques

Specific heat capacity c can be measured directly or derived as the isobaric derivative of enthalpy H with respect to temperature. Specific heat capacity of rocks varies with temperature, pressure, porosity, and saturants. Accordingly, in situ values may deviate from laboratory data according to temperature, pressure, and type and content of pore fluid.

Numerous steady-state and transient calorimetric methods are available for measuring specific heat capacity. The most popular are mixing or drop calorimeters and heat flux differential scanning (DSC) calorimeters. The first method yields an absolute value; the second one is a comparative method. All of these methods and their details are discussed in the literature (e.g., Hemminger and Cammenga, 1989; Brown, 2001; Haines, 2002) to which interested readers are referred. The isobaric enthalpy change (or specific heat content) ΔH of solids may be determined by the method of mixtures using a Bunsen-type calorimeter, in which the unknown isobaric enthalpy change of a sample relative to a base temperature, e.g., 25 °C, is compared to the corresponding known isobaric enthalpy change of platinum (Kelley, 1960; Somerton, 1992).

Calculated heat capacity

When no direct measurements can be performed, the isobaric enthalpy change and specific heat capacity of rocks can be calculated according to Kopp's law, Equation 15, as the arithmetic mean of the individual mineralogical and fluid contributions weighted by the volume fractions n_i of the N individual phases relative to total rock volume:

$$\Delta H = \sum_{i=1}^{N} n_i \Delta H_i; \quad c = \sum_{i=1}^{N} n_i c_i; \quad 1 = \sum_{i=1}^{N} n_i. \qquad (15)$$

Based on data for various minerals (e.g., Kelley, 1960; Berman and Brown, 1985; Somerton, 1992; Waples and Waples, 2004), the isobaric enthalpy change ΔH or specific heat capacity c can be computed from Equation 15 for any rock consisting of an arbitrary number of minerals with given volume fractions.

Temperature dependence

Derived from measured variation of isobaric enthalpy change ΔH with temperature of various oxides, Kelley (1960) suggested a second-order polynomial for fitting ΔH from which $c_P = (\partial H/\partial T)_P$ can be easily calculated. Somerton (1992) and Clauser (2006) report ΔH and c values of various rock-forming oxides and pore fluids. An alternative approach is fitting heat capacity measured at different temperatures directly to polynomials of various degrees (e.g., Maier and Kelley, 1932; Berman and Brown, 1985; Fei and Saxena, 1987; Holland and Powell, 1996; Robertson and Hemingway, 1995). Waples and Waples (2004) provide a discussion of the various approaches. The polynomial proposed by Berman and Brown (1985),

$$C_{P,mol} = k_0 + k_1 T^{-0.5} + k_2 T^{-2} + k_3 T^{-3} (T \text{ in K}), \qquad (16)$$

works over a large temperature range and yields no values incompatible with the Dulong–Petit law for high temperatures. Table 2 lists values for the coefficients k_0–k_3 in Equation 16 determined from fits of heat capacity of selected minerals measured at different temperatures.

As an alternative, Waples and Waples (2004) propose a statistical approach describing the general temperature dependence of all rocks and minerals, which can be rescaled easily for individual rocks and minerals. To this end, measured specific heat capacity c_P was normalized by the corresponding normalizing value $c_{P,n}$ at 200 °C (473.15 K), a temperature at or near which data was available. The resulting polynomial regressions yielded much better coefficients of determination R^2 for data measured on nonporous rock ($R^2 = 0.93$) than for those measured on minerals ($R^2 = 0.62$) while the trends were similar. The regression on the combined data for minerals and nonporous rocks yields an expression for the normalized specific heat capacity of a mineral or nonporous rock at arbitrary temperature T with a coefficient of determination $R^2 = 0.65$:

$$c_{P,n}(T) = 0.716 + 1.72 \times 10^{-3} T - 2.13 \times 10^{-6} T^2 + 8.95 \times 10^{-10} T^3, (T \text{ in } ^\circ\text{C}). \qquad (17)$$

Equation 17 can be rescaled for any mineral or nonporous rock at any temperature T_2 provided a value $C_P(T_1)$ measured at temperature T_1 is available, for instance from any of the compilations of Berman and Brown (1985), Fei and Saxena (1987), Berman (1988), Holland and Powell (1996), or Robertson and Hemingway (1995):

$$c_P(T_2) = c_P(T_1) \frac{c_{P,n}(T_2)}{c_{P,n}(T_1)}. \qquad (18)$$

Additionally, Waples and Waples (2004) consider the variation of specific heat capacity with lithology, where interested readers find a specific discussion regarding coals of different carbon content or maturity.

Mottaghy et al. (2005) used a second-order polynomial in temperature to fit the variation of isobaric specific heat

Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat, Table 2 Coefficients for calculating isobaric molar heat capacity $C_{P,mol}$ (J mol^{-1} K^{-1}) (From Equation 16, Berman, 1988)

Mineral	Chemical composition	k_0 (J mol^{-1} K^{-1})	$k_1 \times 10^{-2}$ (J mol^{-1} K$^{-½}$)	$k_2 \times 10^{-5}$ (J mol^{-1} K^{1})	$k_3 \times 10^{-7}$ (J mol^{-1} K^{2})	T (K)
Albite	$NaAlSi_3O_8$	393.64	−24.155	−78.928	107.064	250–1 373

capacity with temperature measured on a suite of metasedimentary, volcanic, magmatic, and metamorphic rocks:

$$c_P(T) = A_0 + A_1 T^1 + A_2 T^2 (c_p \text{ in J kg}^{-1}\text{K}^{-1}, 1\,^\circ\text{C} \le T \le 100\,^\circ\text{C}). \quad (19)$$

The average values for the coefficients A_0–A_2 determined from a regression of $c_P(T)$ measured over a temperature range of 1 °C–100 °C on 26 samples from seven boreholes are: $\bar{A}_0 = 0.074717725$ J kg^{-1} K^{-1}; $\bar{A}_1 = 1.862585346$ J kg^{-1} K^{-2}; $\bar{A}_2 = -2510.632231$ J kg^{-1} K^{-3}.

Based on a composition of 30 % quartz, 60 % feldspar (albite), and 10 % phyllosilicates (5% phlogopite, and 5 % annite), Whittington et al. (2009) suggest average "bulk crustal" molar specific heat capacity equations based on end-member mineral data for two temperature ranges, separated by the transition at 846 K (~573 °C) between α- and β-quartz:

$$C_{P,mol}(T) = \begin{cases} 199.50 + 0.0857T - 5.0 \times 10^6 T^2; & T \le 846\text{K} \\ 229.32 + 0.0323T - 47.9 \times 10^{-6} T^2; & T > 846\text{K} \end{cases}; \quad (C_{P,mol} \text{ in J mol}^{-1}\text{K}^{-1}). \quad (20)$$

Assuming an average molar mass of 0.22178 kg mol^{-1}, this yields the variation of isobaric specific heat capacity c_P with temperature shown in Figure 1.

Volumetric heat capacity: thermal capacity

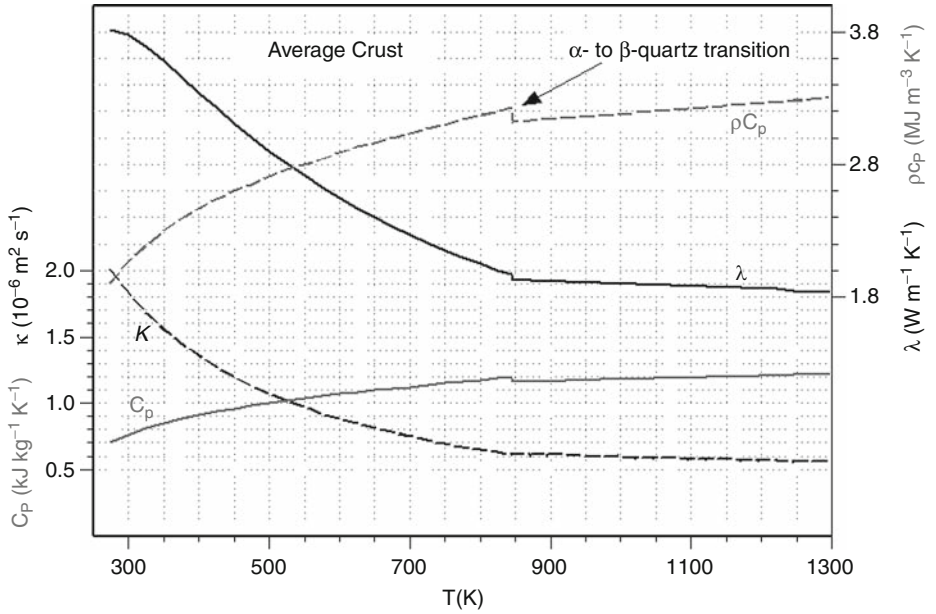
When heat capacity is related to unit volume rather than to unit mass or unit amount of substance, it is referred to as volumetric heat capacity or thermal capacity. It can be calculated as the product of specific heat capacity c and density ρ or as the ratio of thermal conductivity λ and thermal diffusivity κ by

$$\rho c = \lambda/\kappa. \quad (21)$$

Again, Kopp's law yields the rock's bulk thermal capacity $(\rho\, c)_b$ as:

$$(\rho\, c)_b = (1-\phi)\,(\rho\, c)_s + \phi \sum_{i=1}^{N} S_i\,(\rho c)_i, \quad (22)$$

where ϕ is porosity, $(\rho\, c)_s$ thermal capacity of the rock skeleton, S_i fractional saturation, and $(\rho\, c)_i$ thermal capacity of the i^{th} fluid phase in the pore space. The skeleton thermal capacity itself may be calculated again from Kopp's law for a given mineral assemblage and the corresponding volume fractions of the solid phase from Equation 15. Because of the low density of air and gas – about three orders of magnitude lower than that of water



Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat, Figure 1 Variation of specific heat capacity c_P, the phonon components of thermal diffusivity and thermal conductivity κ_p and λ_p, respectively, and thermal capacity $\rho c_P = \lambda_p/\kappa_p$ with temperature in an average crust according to Equation 20.

and rock – the contribution of the gas phase to thermal capacity can often be ignored. In this case, N = 2 for the fluid phases water and oil or N = 1 for water only. Expressions for the density of various fluids are reported in Clauser (2006). Data on density of various minerals and rocks are listed, e.g., in Wohlenberg (1982a,b) or Olhoeft and Johnson (1989). Using Equations 17 and 18, Waples and Waples (2004) analyzed a substantial collection of density and specific heat capacity data from various authors and transformed specific heat capacity and thermal capacity to a uniform reference temperature of 20 °C (Table 3).

The mean thermal capacity of "impervious" rocks was found at 2.300(46) MJ m^{-3} K^{-1} by Roy et al. (1981). This is acceptably close to the mean of 2.460(65) MJ m^{-3} K^{-1} found by Waples and Waples (2004) for inorganic minerals.

Based on density, specific heat capacity, and thermal conductivity measured at room temperature, Mottaghy et al. (2005) determined thermal capacity as inverse slope of a regression of diffusivity on thermal conductivity according to Equation 21. All values fell well within ±20 % of the average of 2.3 MJ m^{-3} K^{-1} recommended by Beck (1988).

Mottaghy et al. (2008) determined average values for thermal capacity according to Equation 21 for metamorphic and magmatic crystalline rocks as the inverse slope of a linear regression of values of thermal diffusivity versus thermal conductivity measured at temperatures in the range 20 °C–300 °C:

$$\kappa(T) = \frac{\lambda(T)}{m + nT}, (T \text{ in } ^\circ C), \quad (23)$$

Regression of data measured on seven samples collected along a profile crossing the Eastern Alps from north to south and on nine samples from the northern rim of the Fennoscandian Shield near the Kola ultra-deep borehole SG-3 yielded m = 20 66(70) kJ m^{-3} K^{-1}, n = 2.2 (4) kJ m^{-3} K^{-2}, R^2 = 0.97 and m = 2404(91) kJ m^{-3} K^{-1}, n = 3.6(5) kJ m^{-3} K^{-2}, R^2 = 0.92, respectively. This yields a range of thermal capacity for the Alpine and Fennoscandian data of about 2.1 MJ m^{-1} K^{-1}–2.7 MJ m^{-1} K^{-1} and 2.4 MJ m^{-1} K^{-1}–3.5 MJ m^{-1} K^{-1}, respectively, in the temperature range 20 °C–300 °C.

The product of an average density of 2 700 kg m^{-3} for the crust and isobaric specific heat capacity calculated for an average molar mass of 0.22178 kg mol^{-1} according to Equation 20 (Whittington et al., 2009) yields the variation of thermal capacity ρc_P (Equation 21) with temperature shown in Figure 1. Its increase with temperature by about a factor of 1.7 in a temperature interval of 1 000 K demonstrates that the effect of temperature is stronger for the phonon component of thermal diffusivity κ than for phonon thermal conductivity λ_p due to the increase of specific heat capacity. Assuming a constant density throughout the crust implies that the increase and decrease in density due to the increase in pressure and temperature, respectively, partly cancel each other and that these changes are small compared to those of specific heat capacity and thermal diffusivity.

Latent heat

Solidification of magma and melting of rocks as well as freezing and thawing of water in soils or rocks liberates or consumes heat, respectively. The like applies to mineral

phase changes such as those associated with the seismic discontinuities at 410 km, 520 km, and 660 km in the transition zone from 400 km–600 km between the upper and lower mantle. These mineral phases are chemically identical but differ with respect to crystal structure and therefore elastic properties. This is why this transition is seen in the seismic wave field. Phase transitions require a certain pressure P and temperature T, but also a specific relation between these two state variables expressed by the so-called Clapeyron slope $dP/dT = \Delta S(P,T)/\Delta V(P,T)$ (the inverse of the Clausius–Clapeyron equation), where S and V are entropy and volume, respectively. This means that the depth where a certain phase transition occurs varies with the ambient temperature in the crust. Positive and negative values for the Clapeyron slope are associated with exothermic and endothermic reactions, respectively.

Phase changes generally consume or deliver much more latent heat than can be stored or delivered as sensible heat: It requires a temperature increase of more than 500 K to equal by sensible heat the amount of latent heat required to melt 1 kg of granite, and still an increase of more than 80 K to equal by sensible heat the amount of latent heat required to melt 1 kg of sea ice (Table 4).

The *discontinuity at 410 km* is generally associated with the transition in olivine from α-olivine to β-spinel, also named wadsleyite (e.g., Stacey and Davis, 2008). At expected pressure and temperature of 14 GPa and 1,600 K, respectively, corresponding values for the Clapeyron slope vary between 2.9 MPa K^{-1} and 4.8 MPa K^{-1} (Bina and Helffrich, 1994; Katsura et al., 2004; Stacey and Davis, 2008). The *discontinuity at 520 km* is associated with the transition from β-spinel (wadsleyite) into γ-spinel, also named ringwoodite (e.g., Stacey and Davis, 2008). At an expected pressure of 18 GPa, a temperature increase, such as by an ascending plume, would require a higher pressure for this transition according to inferred Clapeyron slopes of 4.0 MPa K^{-1}–5.3 MPa K^{-1} (Helffrich, 2000; Deuss and Woodhouse, 2001). A second transition occurs between garnet and calcium-perovskite ($CaSiO_3$), where the iron in garnet goes into Ilmenite, and its $CaSiO_3$-component into calcium-perovskite. This reaction has a negative Clapeyron slope. The two slopes of different sign may shift the depth for two transitions into opposite directions, which is observed as a splitting of the 520 km discontinuity. The *discontinuity at 660 km* defines the transition into the lower mantle. It is caused by the transition of γ-spinel (ringwoodite) into magnesium-perovskite ($MgSiO_3$) and ferrous periclase (magnesiowüstite, (Fe,Mg)O). At an expected pressure of 23.5 MPa, this endothermic transition is associated with a Clapeyron slope of − 2.8 MPa K^{-1} (Stacey and Davis, 2008).

The latent heat L that corresponds to these additional heat sources and sinks can be elegantly combined with the specific sensible heat capacities of the liquid and solid rock, c_l and c_s, respectively, into an effective bulk specific heat capacity c_{eff}. This effective specific heat capacity then accounts for the entire enthalpy change, including latent heat. In this approach, the latent heat effects are assumed to occur between the solidus and liquidus temperatures T_1 and T_2, respectively. The heat liberated by a solidifying

Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat, Table 3 Typical values or ranges for density ρ, isobaric specific heat capacity c_P, and thermal capacity ρ c_P of selected rocks at 20°C (Waples and Waples, 2004; Petrunin et al., 2004)

Rock	ρ (kg m^{-3})	c_P (J kg^{-1} K^{-1})	ρ c_P (kJ m^{-3} K^{-1})
Albite	2 540–2 560	755–780	1 922–1 991

Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat, Table 4 Comparison of isobaric specific heat capacity c_P and latent heat of melting L of granite, basalt, seawater, and freshwater (Stacey and Davis, 2008, supplemented)

	Granite	Basalt	Seawater	Freshwater	Dry air (15°C, 1 atm)
c_P (kJ kg^{-1} K^{-1})	0.83	0.88	3.99	4.18	1.006
L (kJ kg^{-1})	420	420	335	333.55	196

("freezing") liquid phase is obtained by weighting by the volume fractions of liquid and solid phases, ϕ_l and ϕ_s, respectively. The enthalpy change of the rock volume then becomes $dH_{freezing} = (\phi_l\, c_l + \phi_s\, c_s)\, dT + L\, d\phi_l$, and the effective heat capacity c_{eff} is:

$$c_{eff}^{freezing} = \frac{dH}{dT} = \phi_l\, c_l + \phi_s\, c_s + L\, \frac{d\phi_l}{dT}. \quad (24)$$

Conversely, when considering melting the solid phase, the enthalpy change of the rock volume is $dH_{melting} = (\phi_l\, c_l + \phi_s\, c_s)\, dT + L\, d\phi_s$, and the effective heat capacity in this case c_{eff} is:

$$c_{eff}^{melting} = \frac{dH}{dT} = \phi_l\, c_l + \phi_s\, c_s + L\, \frac{d\phi_s}{dT}. \quad (25)$$

Heat conductivity; Thermal conductivity; Thermal diffusivity

Definition

Thermal conductivity (also: heat conductivity) λ: Physical property governing heat diffusion in the steady state. It defines how much heat flows across a unit cross section of rock along a unit distance per unit temperature decrease per unit time; dimension: $W\,m^{-1}\,K^{-1}$.
Thermal diffusivity κ: Physical property governing transient heat diffusion. It is defined by the ratio of thermal conductivity and thermal capacity, i.e., by the ratio of heat flowing across the face of a unit volume and the heat stored in the unit volume per unit time; dimension: $m^2\,s^{-1}$.

Thermal conductivity

Fourier's law of heat conduction defines the vector of specific heat flow q_i, i.e., heat flow normalized by area, as the product of the thermal conductivity tensor λ_{ij} and the temperature gradient vector $\partial T/\partial x_j$:

$$q_i = -\lambda_{ij}\,\frac{\partial T}{\partial x_j}. \quad (1)$$

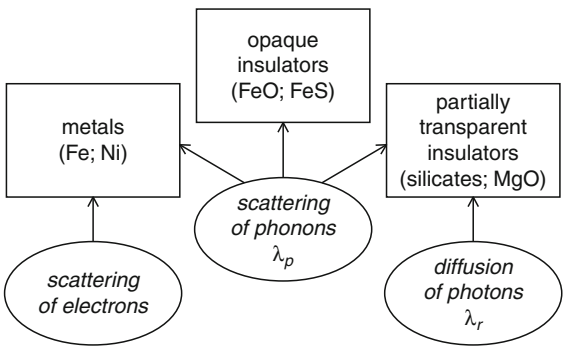
Temperature measurements are usually performed along vertical profiles in boreholes, yielding only the vertical component of the temperature gradient. Thermal conductivity in some rocks is, to a good approximation, isotropic, particularly in volcanic and plutonic rocks. Then heat will flow predominantly vertically, and it is sufficient to consider only the vertical component of Equation 1. In contrast, thermal conductivity of many sedimentary and metamorphic rocks is strongly anisotropic, and lateral heat flow may be significant. Hence, information on anisotropy is often required, demanding laboratory measurements in different directions. Anisotropy occurs over a wide range of scales, from microscopic, over laboratory and macroscopic, to tectonic.

Heat transport in most of the Earth's crust and mantle is diffusive and caused by (1) scattering of quantized lattice vibrations, the phonons, and (2) by diffusive (as opposed to ballistic) radiation of photons. These two processes are described by phonon thermal conductivity λ_p and radiative thermal conductivity, λ_r, respectively, the sum of which is often termed effective thermal conductivity, λ_{eff}. In most polycrystalline material heat radiation starts to dominate at temperatures above 2 500 K. In single crystals and glasses with little or no scattering (e.g., obsidian), however, radiation may become important at much lower temperatures of 500 k–1 000 K. In the metallic core, scattering of electrons provides a third heat transfer mechanism (Figure 1).

The following text deals mostly with phonon thermal conductivity. Radiative heat transfer is discussed in the paragraph on radiative thermal conductivity and in the chapter on thermal diffusivity.

Measuring techniques

Thermal conductivity can be measured in the laboratory on rock samples, i.e., cores or cuttings or in situ either in boreholes or with shallow penetration (3 m–20 m) marine



Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Figure 1 Different types of material in the Earth and associated mechanisms of heat transport (Redrawn after Hofmeister et al., 2009).

heat flow probes. There are numerous steady-state and transient techniques available for measuring thermal conductivity, the most prominent being the "divided bar," "needle probe," "optical scanning," and "(laser) flash," all of which are suitable to determine also the anisotropy of thermal conductivity. These methods are described in, for instance, Parker et al. (1961), Kappelmeyer and Haenel (1974), Beck (1988), Davis (1988), Somerton (1992), Schilling (1999), Popov et al. (1999b), Beardsmore and Cull (2001), and Blumm and Lemarchand (2002). Among these techniques, the transient ones are also suitable for determining thermal diffusivity.

As with most other petrophysical properties, in situ thermal conductivity may deviate significantly from laboratory values, even if the effects of temperature, pressure, and pore fluid are accounted for. This scale dependence involves different aspects: In situ measurements represent an average over a much larger rock volume than laboratory measurements performed on small samples, and cannot resolve small-scale variations. A subsequent upscaling may be necessary to identify the appropriate representative elementary volume (REV) for which reasonable transport parameter averages can be defined.

Indirect methods

When no data are available or no direct measurements can be performed, thermal conductivity can be inferred indirectly, either from mineralogical composition and saturating fluids or from correlations with other physical properties. While some of these methods are based on well-defined physical models, others are purely empirical.

Estimation from mineralogical composition and saturating fluids: Thermal conductivity of rocks may be estimated from their mineral and fluid content. Thermal conductivity of minerals varies much less than in rocks, due to their well-defined composition. As the bulk thermal conductivity of porous rocks varies with different saturants, it may be also of interest to know rock thermal conductivity for other saturants than those used in the laboratory measurement. Numerous models based on volume fractions of the individual mineral and fluid phases have been proposed, all with specific advantages and disadvantages: Some overestimate while others underestimate systematically the true bulk thermal conductivity. Most of them are valid only within a specific range of volume fractions (or porosities) and yield unreasonable results outside. To overcome this problem, additional parameters may be introduced in order to incorporate rock structure into a mixing law (see below).

The parallel and series models for thermal resistance of layered media are easy to understand, but have the disadvantage of being rather special cases, applicable mostly to bedded sediments. They correspond to the well-known weighted arithmetic and harmonic means, λ_{ari} and λ_{har}, Equations 2a and b, and are related to heat flowing parallel or perpendicular to bedding, respectively. They define upper and lower limits for all other models, sometimes also referred to as the Voigt upper bound and Reuss lower bound, respectively. Thus they constrain the maximum variance of possible predictions. The arithmetic mean between the two is known as the Voigt-Reuss-Hill average, λ_{VRH} (Equation 2c). It is useful for estimating an effective thermal conductivity, while the arithmetic and harmonic means are used to define a range for possible values.

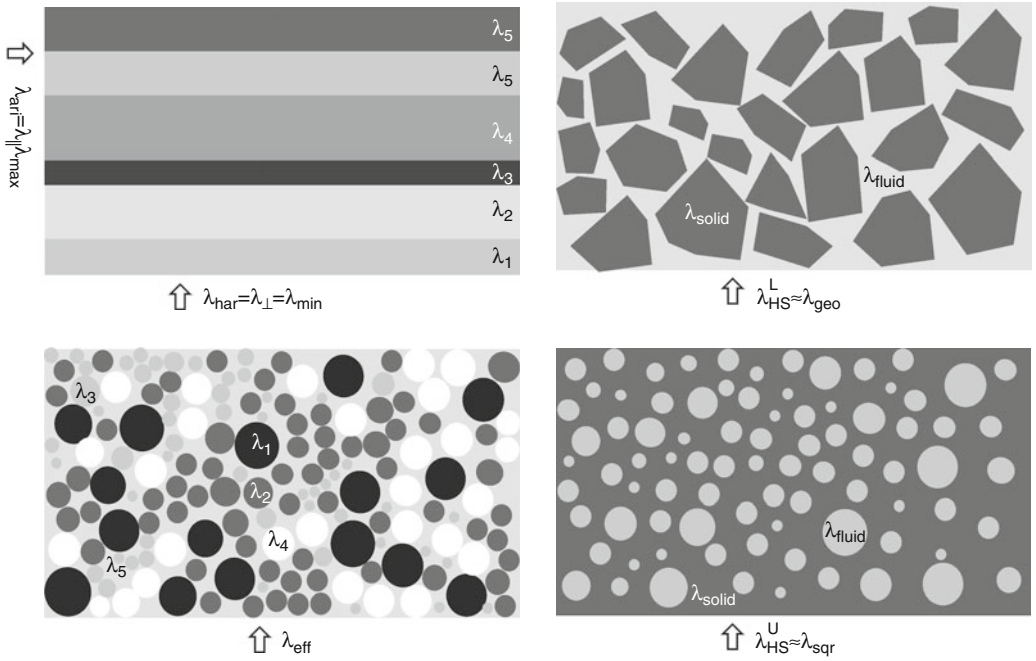
The weighted geometric and square root means λ_{geo} and λ_{sqr} (Equations 2d and e; e.g., Beardsmore and Cull, 2001), respectively, are associated with a mixture of different fluid and mineral phases of unspecified geometry. In many cases, both means successfully explain the data and are therefore widely used for lack of more specific information on the geometric arrangement of the individual volume fractions. In the special case where $N = 2$ and $n_1 = n_2 = 0.5$, the arithmetic, harmonic, and geometric means are related by $\lambda_{geo} = \sqrt{\lambda_{ari}\,\lambda_{har}}$.

Effective medium theory (Bruggeman, 1935) provides the effective medium mean λ_{eff} (Equation 2f) which is useful for macroscopically homogeneous and isotropic rocks consisting of randomly distributed grains and pores.

The upper and lower Hashin-Shtrikman bounds λ^U_{HS} and λ^L_{HS} (Equation 3, Hashin and Shtrikman, 1962), respectively, provide tighter constraints for the predictions of different models other than the arithmetic and harmonic means. The arithmetic average of both defines the Hashin-Shtrikman mean (Equation 2g). Geometrically, the lower Hashin-Shtrikman bound λ^L_{HS} corresponds to a rock model consisting of grains suspended in a fluid and is closely followed by the geometric mixing law. In contrast, the square root law is very close to the upper Hashin-Shtrikman bound λ^U_{HS} and could be related to a well-lithified rock with spherical, fluid-filled pores. Figure 2 illustrates the geometries corresponding to all of these models.

If λ_i denotes the thermal conductivity and n_i the volume fraction of the ith phase relative to the total volume ($1 = \sum n_i$), these seven weighted means are defined by:

$$
\begin{aligned}
&(a)\ \lambda_{\max} = \lambda_{ari} = \lambda_{||} = \sum_{i=1}^{N} n_i\ \lambda_i;\\
&(b)\ \lambda_{\min} = \lambda_{har} = \lambda_{\perp} = \left(\sum_{i=1}^{N} \frac{n_i}{\lambda_i}\right)^{-1};\\
&(c)\ \lambda_{VRH} = \frac{1}{2}\left(\lambda_{||} + \lambda_{\perp}\right);\ (d)\ \lambda_{geo} = \prod_{i=1}^{N} \lambda_i^{n_i};\\
&(e)\ \sqrt{\lambda_{sqr}} = \sum_{i=1}^{N} n_i\ \sqrt{\lambda_i};\ (f)\ \lambda_{eff}^{-1} = \sum_{i=1}^{N} \frac{3\ n_i}{2\ \lambda + \lambda_i};\\
&(g)\ \lambda_{HS} = \frac{1}{2}\left(\lambda^U_{HS} + \lambda^L_{HS}\right);
\end{aligned}
\tag{2}
$$



Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Figure 2 Geometrical arrangement of layers, mineral grains, and pores assumed in different models for calculating mean bulk thermal conductivity of a composite medium: arithmetic (λ_{ari}), harmonic (λ_{har}), geometric (λ_{geo}), square root (λ_{sqr}), Hashin-Shtrikman upper (λ^U_{HS}) and lower (λ^L_{HS}) bounds, and effective medium (λ_{eff}).

where:

$$\begin{aligned}
\lambda^U_{HS} &= \lambda_{\max} + \frac{A_{\max}}{1-\alpha_{\max} A_{\max}},\\
\text{with: } A_{\max} &= \sum_{i=1;\ \lambda_i \neq \lambda_{\max}}^{N} \frac{n_i}{\alpha_{\max} + 1/(\lambda_i - \lambda_{\max})};\\
\lambda_{\max} &= \max(\lambda_1, \ldots, \lambda_N);\ \alpha_{\max} = \frac{1}{3\,\lambda_{\max}}\\
\lambda^L_{HS} &= \lambda_{\min} + \frac{A_{\min}}{1-\alpha_{\min} A_{\min}},\\
\text{with: } A_{\min} &= \sum_{i=1;\ \lambda_i \neq \lambda_{\min}}^{N} \frac{n_i}{\alpha_{\min} + 1/(\lambda_i - \lambda_{\min})};\\
\lambda_{\min} &= \min(\lambda_1, \ldots, \lambda_N);\ \alpha_{\min} = \frac{1}{3\,\lambda_{\min}}.
\end{aligned} \tag{3}$$

For a two-component system consisting of pore fluid and solid rock with thermal conductivities λ_f and λ_s, respectively, Equation 3 simplifies to (Hashin and Shtrikman, 1962; Horai, 1971):

$$\lambda^U_{HS} = \lambda_s + \frac{\phi}{\frac{1}{\lambda_f - \lambda_s} + \frac{1-\phi}{3\,\lambda_s}};\ \lambda^L_{HS} = \lambda_f + \frac{1-\phi}{\frac{1}{\lambda_s - \lambda_f} + \frac{\phi}{3\,\lambda_f}}. \tag{4}$$

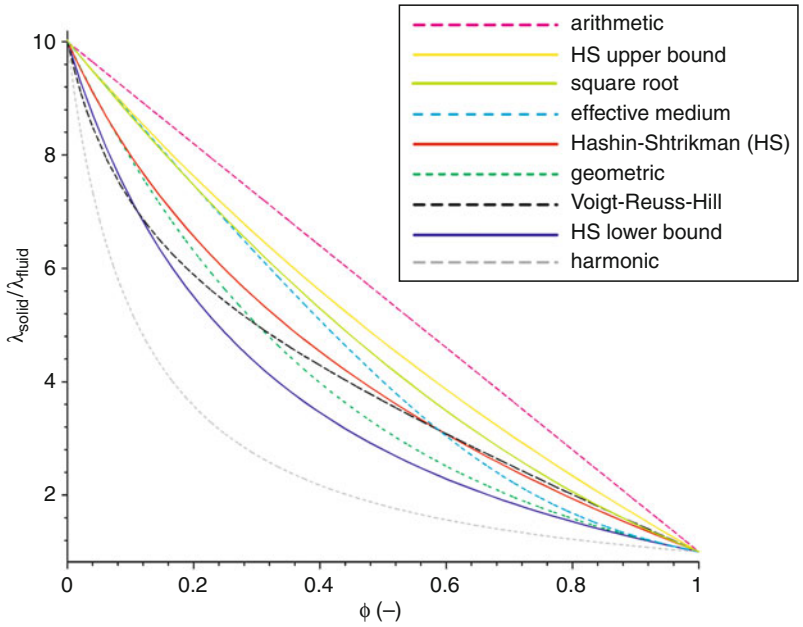
Generally, for a two-component system consisting of pore fluid and solid rock with thermal conductivities λ_f and λ_s, respectively, the implicit definition of λ_{eff} in Equation 2f can be resolved:

$$\lambda_{eff} = \frac{1}{4}\left\{ 3\,\phi(\lambda_f - \lambda_s) + 2\,\lambda_s - \lambda_f + \sqrt{\begin{array}{l} 9\,\phi^2\,\lambda_s^2 + 18\,\phi\,\lambda_s\,\lambda_f - 18\,\phi^2\,\lambda_s\,\lambda_f - 12\,\phi\,\lambda_s^2 \\ + \lambda_f^2 - 6\,\phi\,\lambda_f^2 + 4\,\lambda_s\,\lambda_f + 9\,\phi^2\,\lambda_f^2 + 4\,\lambda_s^2. \end{array}} \right\}. \tag{5}$$

Figure 3 compares the variation of thermal conductivity of a two-component system with volume fraction for these different mixing laws defined by Equations 2–5. By and large, and in particular for such a two-component system, thermal conductivity of a multiphase rock determined according to these models can be ordered as:

$$\begin{aligned}
\lambda_\perp = \lambda_{har} < \lambda^L_{HS} < \lambda_{VRH} < \lambda_{geo} < \lambda_{HS} < \lambda_{eff} \\
< \lambda_{sqr} < \lambda^U_{HS} < \lambda_{ari} = \lambda_{||}.
\end{aligned} \tag{6}$$

While only these nine models are presented and discussed here, various other mixing models are available which take into account additional factors, such as the shape of grains and voids. Several models assume spheroidal pores specifying the aspect ratio of the spheroids (Korvin, 1978, 1982; Schulz, 1981; Zimmerman, 1984, 1989; Buntebarth and Schopper, 1998; Popov et al.,



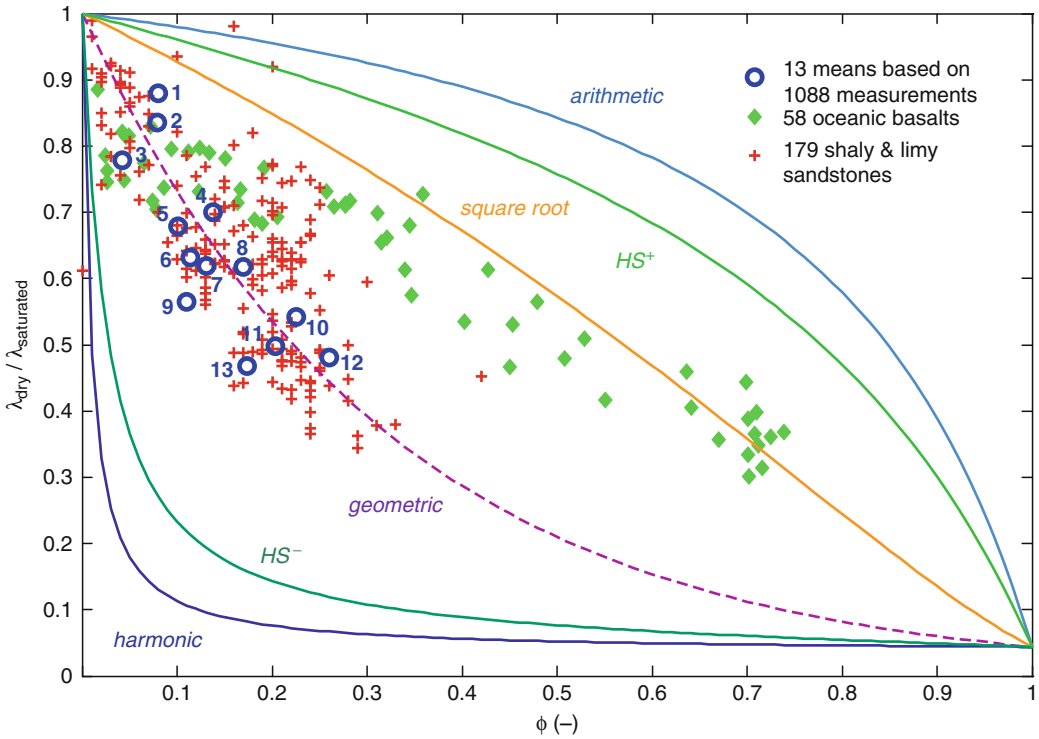
Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Figure 3 Variation of thermal conductivity λ of a two-phase rock with porosity ϕ according to the means in Equations 2–5 for solid and fluid thermal conductivities of $\lambda_{solid} = 6\,W\,m^{-1}\,K^{-1}$ and $\lambda_{fluid} = 0.6\,W\,m^{-1}\,K^{-1}$, respectively: arithmetic (λ_{ari}); Hashin-Shtrikman upper bound (λ^{U}_{HS}); square root (λ_{sqr}); effective medium (λ_{eff}); Hashin-Shtrikman (λ_{HS}); geometric (λ_{geo}); Voigt-Reuss-Hill average (λ_{VRH}); Hashin-Shtrikman lower bound (λ^{L}_{HS}); harmonic (λ_{har}).

2003). These models require information on the geometry of the internal rock structure and differ in the way of averaging over a representative elementary volume. Horai (1991) tested the results of predictions from several different mixing models on a remarkable data set in which porosity virtually varies from 0 % to 100 %. As can be expected, most of the models tested were valid only for certain porosity ranges. Only the two-phase models of Fricke-Zimmerman (Fricke, 1924; Zimmerman, 1989) and Schulz (1981) treating pores as spheroidal inclusions in a homogeneous and isotropic material are valid over the entire range of porosity. However, they require additional information on the spheroids' aspect ratio or orientation. Given the typical ratios of rock and fluid conductivities we observe in nature, i.e. less than 10, most of the conductivity models tested work to within an accuracy of 10 %–15 %.

Based on 1 325 individual measurements on sedimentary rocks and oceanic basalts in dry and saturated condition (λ_{dry}, λ_{sat}), Figure 4 compares the variation of the ratio $\lambda_{dry}/\lambda_{sat}$ with porosity measured with that predicted by the arithmetic, upper Hashin-Shtrikman, square root, geometric, lower Hashin-Shtrikman, and harmonic mixing laws, λ_{ari}, λ^{U}_{HS}, λ_{sqr}, λ_{geo}, λ^{U}_{HS}, and λ_{har}, respectively (Equations 2–4). It is evident that no single mixing law applies equally well to all rock types. But it appears that the geometric and square root model, on average, provide the best general fits to the data. It is also clear that the upper and lower Hashin-Shtrikman means, $\lambda^{L}_{HS}$and λ^{U}_{HS}, provide much tighter bounds than the arithmetic and harmonic means, λ_{ari} and λ_{har}, respectively.

Correlations with other physical properties: Physical properties measured in well-logs can be used to infer estimates for in situ thermal conductivity. The approach is based on an extension of the mixing-model approach to the borehole scale: The volume fractions n_i of the N different mineral (or fluid) phases are either taken directly from induced gamma ray spectroscopy logs (Williams and Anderson, 1990) or determined from a joint analysis of a suitable number J of geophysical logs, such as gamma ray (GR), sonic slowness (DT, the inverse of velocity), gamma density (DEN), and neutron porosity (NPHI) (e.g., Hartmann et al., 2005; Goutorbe et al., 2006). Let $\mathbf{x}$ and $\mathbf{b}$ be vectors composed of the N volume fractions n_i and the J theoretical log responses R^j with respect to the N different phases, respectively. Then, each element R^j of vector $\mathbf{b}$ is the cumulative response of the *j*th log to all phases weighted by their volume fractions:

$$R^j = \sum_i^N n_i R_i^j, \text{ where: } \sum_i^N n_i = 1, \text{and}$$
$$\mathbf{x} = [n_1, \ldots, n_N]^T, \mathbf{b} = [R^1, \ldots, R^J]^T. \quad (7)$$



Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Figure 4 Variation of thermal conductivity ratio $\lambda_{dry}/\lambda_{sat}$ (measured in dry and saturated condition) with porosity ϕ for different rock types. Numbered open circles represent means based on measurements on 1 058 sedimentary rock samples (Kobolev et al., 1990; Popov et al., 1995, 1999a; see also Clauser, 2006): (1) 21 limestones; (2) 54 limestones; (3) 13 quartz sandstones; (4) 44 quartz silt-stones; (5) 35 conglomerates; (6) 141 quartz sandstones; (7) 33 claystones; (8) 99 polymictic sandstones; (9) 30 quartz sandstones; (10) 22 claystones; (11) 65 quartz silt-stones; (12) 99 quartz silt-stones; (13) 241 quartz silt-stones. Shown for comparison are data measured on 58 oceanic basalts (diamonds) and 179 shaly and limy sandstones (crosses). Curves labeled arithmetic, HS^+, square root, geometric, HS^-, and harmonic, correspond to the arithmetic, upper Hashin-Shtrikman, square root, geometric, lower Hashin-Shtrikman, and harmonic mixing laws, λ_{ari}, λ^U_{HS}, λ_{sqr}, λ_{geo}, λ^L_{HS}, and λ_{har}, respectively (Equations 27–29) (Clauser, 2006).

The rows of matrix $\mathbf{A}$ contain the specific responses of each log to the N rock phases:

$$\mathbf{A} = \begin{bmatrix} R_1^1 & \cdots & R_N^1 \\ \vdots & \ddots & \vdots \\ R_1^J & \cdots & R_N^J \end{bmatrix}, \tag{8}$$

and the direct and inverse problems can then be written as

$$\mathbf{Ax} = \mathbf{b} \text{ and } \mathbf{x} = \mathbf{A}^{-1}\,\mathbf{b}, \tag{9}$$

respectively. Thus, in the direct problem, the log response vector $\mathbf{b}$ is computed from the volume fraction vector $\mathbf{x}$ and the specific log response matrix $\mathbf{A}$. In contrast, in the inverse problem, the volume fractions $\mathbf{x}$ are computed from the log responses $\mathbf{b}$ and the inverse of the specific log response matrix, $\mathbf{A}^{-1}$. Thus, for N solid rock constituents, solving the inverse requires $N - 1$ logs. Porosity does not count here, because it follows as the difference of one and the sum of the solid rock volume fractions. If more logs are available, making the problem over-determined, the inverse problem can also be solved in a least-squares sense. Once the volume fractions are known and assigned appropriate thermal conductivities, an appropriate mixing model can applied to compute rock thermal conductivity. Generally, the geometric and square root means, Equations 2d and e, often have turned out useful, but other mixing models may be appropriate in specific cases.

Assigning representative thermal conductivities to the solid rock constituents is not trivial. Tabulated values of rock thermal conductivity should be used only if they characterize specimens from the logged formations. In all other cases, these formations or their outcrops need to be sampled and these specimens tested in the laboratory. If measurements are performed at ambient conditions, the values need to be corrected for the effect of temperature, and in some cases for pressure as well.

In general, the effect of temperature is more pronounced than that of pressure. However, for greater depth

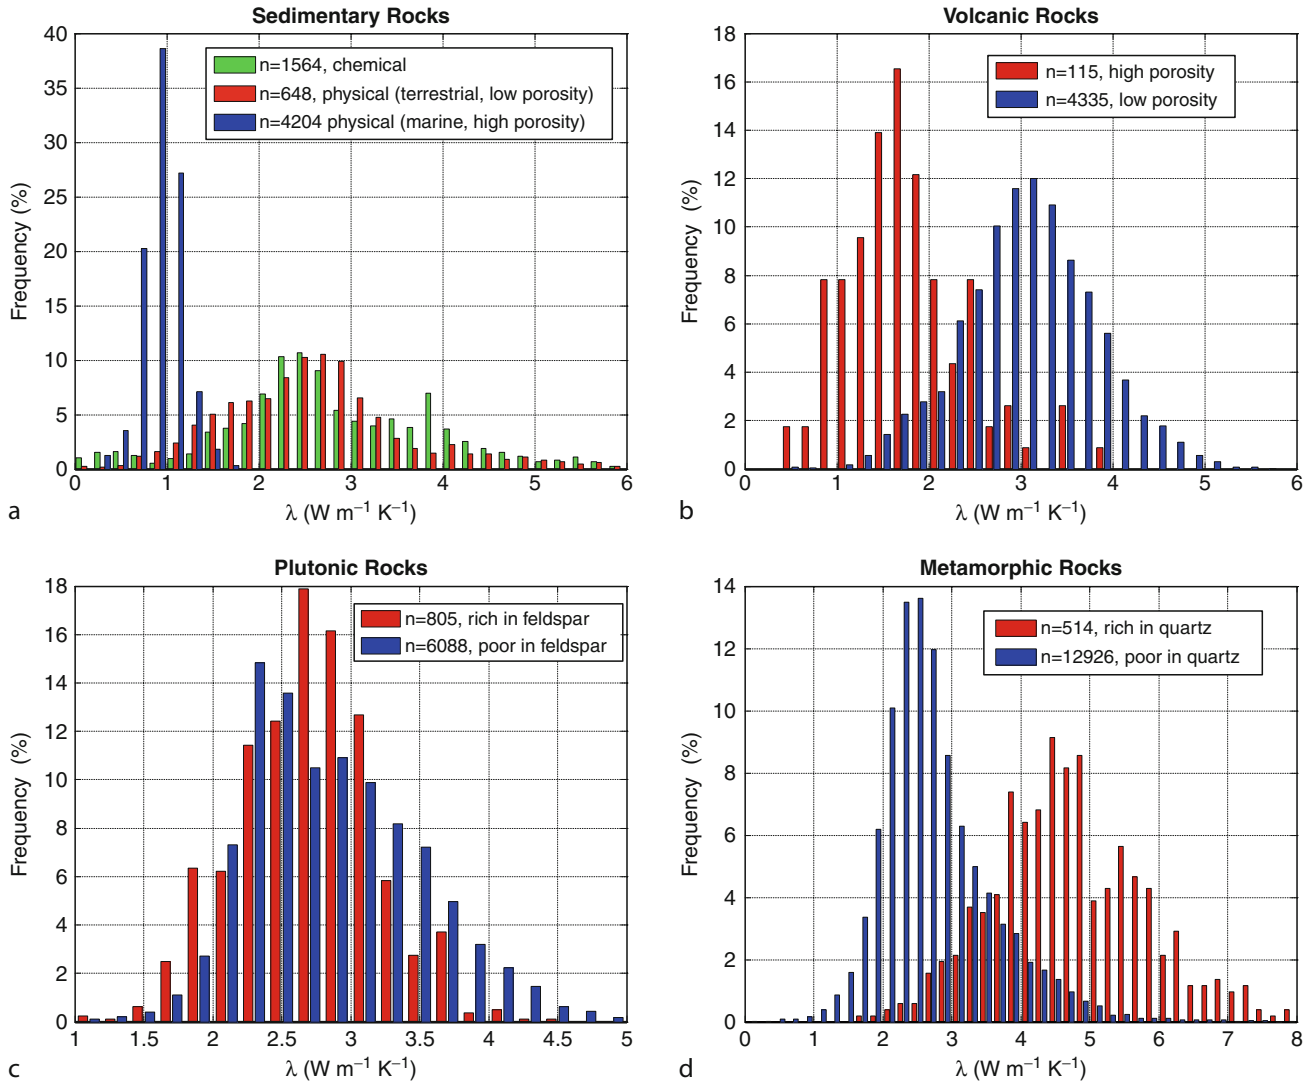
and little or less consolidated rocks it also needs to be accounted for. If commercial log interpretation software is used to perform the inversion, the theoretical log responses R_i^j with respect to the different rock constituents are usually supplied by the software. Alternatively, values for the theoretical log responses R^j can be obtained from the literature (e.g., Crain, 1986).

Thermal conductivity of minerals and rocks

Thermal conductivity of minerals is much better constrained than that of rocks, due to the well-defined crystal structure and chemical formula for each mineral. Substantial collections of mineral thermal conductivities were compiled by Birch (1942), Clark (1966), Horai and Simmons (1969), Dreyer (1974); Roy et al. (1981), Čermák and Rybach (1982), Carmichael (1984), Popov et al. (1987), Diment and Pratt (1988); Somerton (1992), Clauser and Huenges (1995), and Clauser (2006).

Rocks are less well defined. In fact, rock type is a rather poor descriptor for physical properties as it rarely characterizes the dominating factors for any given property. With respect to thermal conductivity, these comprise mineral content, porosity, pore fluid, saturation, and anisotropy for each rock type. As these factors are variable for each rock, the variation of rock thermal conductivity was characterized in a statistical manner in Clauser (2006, 2009) according to the four main diagenetic classes of rocks: sedimentary, volcanic, plutonic, and metamorphic. This discussion is summarized here.

For *sedimentary rocks* (Figure 5a), thermal conductivity is mainly controlled by porosity and sediment type.



Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Figure 5 Histograms of thermal conductivity for (**a**) sedimentary, (**b**) volcanic, (**c**) plutonic, and (**d**) metamorphic rocks (Clauser, 2009).

For *volcanic rocks* (Figure 5b), porosity is the controlling factor on thermal conductivity: Both mean and median of the high- and low-porosity histograms differ by nearly a factor of two, and the high-porosity distribution is skewed toward low conductivities. Plutonic and metamorphic rocks are generally much less porous. Here, the controlling factor is the dominant mineral phase. For *plutonic rocks* (Figure 5c), the feldspar content determines the shape of the histogram: Rocks with a high feldspar content (i.e., >60 %) display a nearly symmetrical conductivity distribution about a lower mean conductivity than rocks with low feldspar content. In spite of these differences, the means and medians for both distributions are nearly identical. For *metamorphic rocks* (Figure 5d), it is the quartz content which controls thermal conductivity: Both mean and median of the distributions for high and low quartz content differ by nearly a factor of two, similar as for *volcanic rocks* (Figure 5b) with regard to porosity. While the histogram for high quartz content rocks (mostly quartzites) is nearly symmetrical, the low quartz content histogram is strongly skewed toward low conductivities.

Radiative thermal conductivity

In addition to heat conduction, heat radiation emitted from hot bodies propagates through a sufficiently transparent and little absorbing medium as electromagnetic waves with velocity

$$c_m = c_0/n = \Lambda_m \nu_m, \tag{10}$$

where Λ_m and ν_m are radiation frequency and wavelength in the medium, and $n = c_0/c_m$ is the ratio of the speed of light in vacuum and in the medium, i.e., the real part of the index of refraction (Table 1).

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Table 1 Refractive index n of selected substances

Substance	$n = c_0/c_m$ (at 589 nm)
Air	1.0003
Water(H_2O)	1.33
Magnesium fluoride (MgF_2)	1.38
Calcium fluoride (CaF_2)	1.43
Rock salt (NaCl)	1.54
Quartz (SiO_2)	1.54
Glass	1.5–1.6
Carbon disulfide (CS_2)	1.63
Corundum (Al_2O_3)	1.76
Zircon ($ZrSiO_4$)	1.92
Sulfur (S)	2.00
Sinc sulfide (ZnS)	2.37
Diamond	2.42
Carborundum (SiC)	2.55
Rutile (TiO_2)	3.10
Galena (PbS) (@ 590 nm)	3.90

Radiation theory is based on Planck's distribution law defining the spectral radiance L_Λ or L_ν of a black body in the wavelength or frequency interval $d\Lambda_m$ or $d\nu_m$ in the medium in terms of the corresponding wavelength or frequency in vacuum, respectively:

$$L_\Lambda(\Lambda_m, T)\, d\Lambda_m = \frac{2hc_0^2 n^2(\Lambda, T)}{\Lambda^5 \left(e^{hc_0/(\Lambda kT)} - 1\right)} d\Lambda \quad (\mathrm{W\,m^{-2}\,sr^{-1}\,m^{-1}} = \mathrm{W\,m^{-3}\,sr^{-1}}),$$

$$L_\nu(\nu_m, T)\, d\nu_m = \frac{2h\nu^3 n^2(\nu, T)}{c_0^2 \left(e^{h\nu/(kT)} - 1\right)} d\nu \quad (\mathrm{W\,m^{-2}\,sr^{-1}\,Hz^{-1}} = \mathrm{W\,s\,m^{-2}\,sr^{-1}}), \tag{11}$$

where, $h = 6.626\,068\,96(33) \times 10^{-34}$ J s is the Planck constant, $k = 1.380\,6504(24) \times 10^{-23}$ J K^{-1} the Boltzmann constant, and $d\Lambda = n\, d\Lambda_m$. Radiance is the radiant energy flux emitted per unit solid angle in a given direction per unit projected area of a source. According to Wien's displacement law, the maximum of spectral radiance increases with temperature and decreases with wavelength (or increases with frequency) of radiation. Hofmeister (2005) estimated the variation of n(ν,T) with temperature and frequency and found both to be very small suggesting that n is approximately constant in the visible frequency range.

The intensity of radiation, I, is related to the incident intensity, I_0, radiation path, x, and opacity, ε, by $I = I_0 \exp(-\varepsilon\, x)$, where opacity $\varepsilon = 1/\ell$ is the reciprocal mean free path ℓ of radiation. It defines the average travel distance of photons before being absorbed or scattered. In general, opacity is a function of the radiation wavelength. Opacity in an absorbing and scattering medium comprises contributions from both of these processes:

$$\varepsilon = \alpha + \varsigma, \tag{12}$$

where α and ς are absorption and scattering coefficients, respectively. The scattering coefficient ς is usually identified with the inverse grain size, suggesting orders of magnitude ranging from 10^2 m to 10^6 m^{-1}. The absorption coefficient α may be as large as $\alpha = 7{,}000\,\mathrm{m^{-1}}$, but values below $\alpha = 1\,500\,\mathrm{m^{-1}}$ are reported for absorption coefficients in single crystal olivines with different proportions of forsterite (Mg_2SiO_4) and fayalite ($Fe_2^{2+}SiO_4$) ($Fo_{94}Fa_6$ – $Fo_{86}Fa_{14}$) in the two pass bands at 0.5 µm and 0.5 µm–6.0 µm (e.g., Shankland et al., 1979; Clauser, 1988; Hofmeister, 2005). The width and level of these pass bands depend critically on the iron content in the minerals. The complex index of refraction of all materials, m, is defined by $m = \sqrt{\varepsilon_r \mu_r} = n - i \cdot k$, where ε_r and μ_r are (complex) relative electrical permittivity and relative magnetic permeability, respectively, $n = c_0/c_m$ is the real and k the imaginary part of the index (sometimes also called extinction coefficient), and

$i = \sqrt{-1}$ is the imaginary unit. The absorption coefficient α is related to the complex index of refraction k by

$$\alpha = 4\,\pi\,k/\Lambda, \tag{13}$$

where Λ is the radiation wavelength (Aronsson et al., 1970).

Radiation therefore becomes important for rocks with a larger free mean path of radiation corresponding to smaller values of opacity or absorption coefficient and scattering coefficient. This holds in particular at larger wavelength, in the infrared part of the absorption spectrum's transmission window between about 0.5 μm–6.0 μm.

Radiated heat is diffused if photons emitted by mineral grains are scattered or absorbed by neighboring grains. If the mean free path of radiation, ℓ, is small compared to the distance to material discontinuities (such as grain boundaries) and for moderate temperature gradients, i.e., no large anisotropy in the intensity of radiation, an effective thermal conductivity

$$\lambda_{\mathrm{eff,ij}} = \lambda_{\mathrm{p,ij}} + \lambda_{\mathrm{r,ij}} \tag{14}$$

replaces λ_{ij} in Equation 1, where $\lambda_{p,ij}$ and $\lambda_{r,ij}$ are phonon and radiative thermal conductivities, respectively.

Rosseland (1930) and Clark (1957) defined the radiative thermal conductivity based on the temperature derivative of the spectral radiance of a blackbody. Following practice in engineering, Hofmeister (2005) accounts in this expression additionally for the emissivity $\eta \leq 1$ of a grainy material by applying the temperature derivative and the subsequent integration to the product of emissivity η and spectral radiance L_ν, yielding

$$\lambda_{\mathrm{r}} = \frac{4\,\pi}{3}\int_0^\infty \frac{1}{\varepsilon(\nu,T)}\,\frac{\partial(\eta(\nu,T)\;L_\nu(\nu,T))}{\partial T}\,\mathrm{d}\nu. \tag{15}$$

Different practical expressions were derived depending on which parameters can be assumed as independent of temperature or frequency (see, e.g., Clark (1957); Shankland et al. (1979); Schärmeli, 1982; Clauser, 1988; Hofmeister, 1999, 2005; Hofmeister et al., 2009). Based on grain size δ and attenuation

$$\mathrm{A} = (\ln \mathrm{I}_0 - \ln \mathrm{I}_\mathrm{t})/\delta \approx \alpha, \tag{16}$$

where α is the absorption coefficient and I_0 and I_t are incident and transmitted intensities, respectively, Hofmeister (2005) suggests the following expressions for emissivity and opacity:

$$\eta = 1 - e^{-\delta\,\alpha(\nu)} = 1 - e^{-(\ln \mathrm{I}_0 - \ln \mathrm{I}_\mathrm{t})}, \quad \varepsilon = \frac{1+\delta\,\alpha}{\delta}, \tag{17}$$

and estimates values for the product $\delta\,\alpha$ based on the interface reflectivity R (%) between two neighboring grains. Values for $\delta\,\alpha$ considered realistic for the mantle range between 5 and 10 (corresponding to a range for R between 0.07 % and 0.05 %) with a preferred value of 7 (R = 0.01 %).

The "gray body" approximation assumes opacity and emissivity as finite, constant, and independent of radiation wavelength. If the real part of the refractive index, n, and the spectral radiance, L_Λ or L_ν, are also independent of temperature and wavelength, Equation 15 simplifies into:

$$\lambda_{\mathrm{r}} = \frac{16\,\eta\,\sigma\,n^2\,T^3}{3\,\varepsilon}, \tag{18}$$

where σ = 5.670 400(40) × $10^{-8}\,\mathrm{W\,m^{-2}\,K^{-4}}$ is the Stefan-Boltzmann constant. An example of magnitude is obtained when emissivity η = 0.99 and opacity ε is identified with the olivine ($Fo_{92}Fa_8$) absorption coefficient α at 1 700 K (Equation 12, neglecting contributions from scattering), with $1\,000\,\mathrm{m^{-1}} < \alpha < 1\,500\,\mathrm{m^{-1}}$. Additionally, a typical silicate value is assumed for the index of refraction, n = 1.6 (Table 1). This yields a range for radiative thermal conductivity at 1 700 K of $3.8\,\mathrm{W\,m^{-1}\,K^{-1}} > \lambda_\mathrm{r} > 2.5\,\mathrm{W\,m^{-1}\,K^{-1}}$.

Inserting Equations 16 and 17, and the temperature derivative of the spectral radiance (11) as provided by Shankland et al. (1979) into (15) yields radiative thermal conductivity as:

$$\begin{aligned}\lambda_\mathrm{r} &= \frac{4\,\pi\,\delta}{3}\int_0^\infty \frac{1-e^{-\delta\,\alpha(\nu)}}{1+\delta\,\alpha(\nu)}\,\frac{\partial(L_\nu(\nu,T))}{\partial T}\,\mathrm{d}\nu \\ &= \frac{8\,\pi\,\delta\,\mathrm{n\,T^3\,k^4}}{3\,c_0^2\,h^3}\sum\int_{lower}^{upper}\frac{1-e^{-\delta\,\alpha(\nu)}}{1+\delta\,\alpha(\nu)} \\ &\times\left[\frac{n\,e^x\,x^4+}{e^x-1}+\frac{2\,T\,x^3}{e^x-1}\,\frac{\partial n}{\partial T}\right]dx\;(\mathrm{W\,m^{-1}\,K^{-1}}),\end{aligned} \tag{19}$$

where x = hν/(k T) and dx = h dν/(k T), and the summation allows for the transparent regions above and below the strong absorption bands in the visible part of the spectrum. The second term of the sum in the integrand vanishes if $\partial n/\partial T \approx 0$ as suggested by Hofmeister (2005). Because α varies nonlinearly with frequency or wavelength, and the cutoff frequencies in the integral in (19) depend on δ and α, Hofmeister (2005) evaluated the integral numerically for polynomials in T whose exponents ranged from 0 to 6, thus yielding other than a purely cubic relationship between radiative thermal conductivity and temperature.

Variation with temperature

Since the pioneering experiments of Eucken (1911), thermal conductivity of minerals and rocks is known to decrease with temperature, generally with its inverse. Eucken's empirical result was corroborated theoretically by Peierls (1929) based on Debye's (1914) theory of phonon scattering. Eucken (1911) observed in his experiments

in contrast to crystals an increase in thermal conductivity of amorphous siliceous glass, a clear indication of radiative heat transfer.

The decrease is primarily due to the decrease of phonon (or lattice) thermal conductivity λ_p with temperature and to a smaller degree to thermal cracking. Since the thermal expansion coefficient increases with temperature (but differently for all minerals) differential expansion may create contact resistances between mineral grains. The effect of contact resistance is less pronounced in water-saturated than in dry rocks, the condition in which most rocks are tested at elevated temperatures. For single-mineral aggregates, a linear relationship between temperature and thermal resistivity, λ^{-1}, discriminates between contributions which depend on temperature T and others which do not, such as micro-cracks, grain boundaries, shape, and orientation of crystals and their fragments:

$$\lambda^{-1}(T) = c_1 + c_2\ T, \tag{20}$$

where λ is in $W\,m^{-1}\,K^{-1}$ and T is in K. By measuring thermal conductivity λ and plotting its inverse, thermal resistivity, λ^{-1}, versus temperature, constants c_1 and c_2 are obtained from intercept and slope of a linear regression. Table 2 provides values for the constants c_1 and c_2 in Equation 20 which may be used to infer the temperature dependence of thermal resistivity for some single-mineral aggregates (Clark, 1969).

Based on measurements on 113 samples of metamorphic rocks from the KTB research borehole in Germany in the temperature range 50 °C–200 °C, Buntebarth (1991) determined mean values for the constants c_1 and c_2 in Equation 20 for gneissic and metabasitic rocks. The arithmetic means determined from measurements on 66 gneiss samples are $\bar{c}_1 = 0.16(3)\,W^{-1}\,m\,K$ and $\bar{c}_2 = 0.37(14) \times 10^{-3}\,W^{-1}\,m$. The corresponding means determined from measurements on 36 metabasite samples are $\bar{c}_1 = 0.33(3)\,W^{-1}\,m\,K$ and $\bar{c}_2 = 0.22(14) \times 10^{-3}\,W^{-1}\,m$.

In contrast to phonon conductivity λ_p, the radiative contribution to thermal conductivity, λ_r, generally increases with the cube of temperature (see above). Thus, measurements of thermal conductivity as function of temperature generally first exhibit a decrease with temperature until, from about 1 000 °C–1 200 °C onward, the radiative component balances and sometimes even reverses the decreasing trend.

The temperature dependence of rock thermal conductivity was characterized in a statistical manner in Clauser (2006, 2009) according to the four main diagenetic classes of rocks: sedimentary, volcanic, plutonic, and metamorphic. This discussion is summarized here (Figure 6).

For *sedimentary rocks* (Figure 6a) up to 300 °C there is a reduction by nearly a factor of two, both for physical and chemical sediments. Above 300 °C, the decrease in thermal conductivity is less, but it is stronger for chemical sediments than for physical sediments. However, there are very few data for this temperature range, which makes this last observation statistically weak. Above 300 °C, the mean thermal conductivity of sediments varies between $1.0\,W\,m^{-1}\,K^{-1}$ – $1.5\,W\,m^{-1}\,K^{-1}$.

Volcanic rocks (Figure 6b) vary quite differently with temperature depending on their opacity, i.e., on how well they transmit thermal energy by radiation. Due to this additional "radiative thermal conductivity," volcanic glasses and rocks with small iron content experience an increase in thermal conductivity for temperatures above 800 °C–1 000 °C (e.g., Clauser, 1988; Hofmeister et al., 2009). In contrast, thermal conductivity of conduction dominated rocks, such as rocks with high iron content, decreases with temperature. An inversion of this trend is indicated by few available high-temperature measurements (above 1 300 °C) but with too few measurements for a statistical appraisal. At about 1 000 °C thermal conductivity for these rocks is at about 50 % of the room-temperature value. Again, there are few data points above 700 °C.

P*lutonic rocks* (Figure 6c) show no strong radiative contribution. At temperatures above 600 °C, thermal conductivity decreases only very little. However, in these rocks the variation of thermal conductivity with temperature depends on their feldspar content. For rocks enriched in feldspar, thermal conductivity decreases little up to 300 °C, while for those poor in feldspar the decrease is stronger, becoming more gentle above 300 °C, and spreading an additional 20 % over the next 1 000 K. The different behavior of rocks with high feldspar content is due to the increase in thermal conductivity with temperature of some plagioclase feldspars (e.g., Höfer and Schilling, 2002; Petrunin et al., 2004) which compensates the decrease in thermal conductivity with temperature observed for most other minerals and rocks. Other notable exceptions are fused silica as well as volcanic and silica glasses.

For *metamorphic rocks* (Figure 6d), the decrease of thermal conductivity with temperature depends on the content in a dominant mineral phase, similar as for plutonic rocks. For quartzites, the decrease is strong, by nearly a factor of three up to a temperature of about 500 °C with only a very mild further decrease beyond this

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Table 2 Values of c_1 and c_2 in Equation 20 for single-mineral aggregates; data: Clark (1969)

Mineral	T (°C)	$c_1 \times 10^3$ ($W^{-1}\,m\,K$)	$c_2 \times 10^3$ ($W^{-1}\,m$)
Halite, NaCl	0–400	−52.55	0.788

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Figure 6 Variation of thermal conductivity with temperature for (**a**) sedimentary, (**b**) volcanic, (**c**) plutonic, and (**d**) metamorphic rocks. Color shading indicates a range defined by plus and minus one standard deviation and N is the number of data at each temperature (Clauser, 2009).

temperature. For rocks poor in quartz the decrease in conductivity is not quite as strong, amounting to about one third of the room-temperature value up to 300 °C. Then it remains roughly constant up to 500 °C and decreases again to about one third of the room-temperature value up to 750 °C.

In summary, for moderate temperatures thermal conductivity of rocks is well described by a linear relationship with inverse temperature, similar as in Equation 20. For this temperature range several approaches are available for inferring thermal conductivity at elevated temperatures. Based on the analysis of available tabulated data of thermal conductivity as function of temperature Zoth and Hänel (1988) suggested the following form:

$$\lambda(T) = A + \frac{B}{350 + T} (0\,^{\circ}C \le T \le 800\,^{\circ}C), \qquad (21)$$

where average values of the coefficients A and B for different rock types are given in Table 3.

Linear relationships between temperature and thermal resistivity, such as Equations 20 and 21, discriminate between temperature-dependent contributions and other factors, which are independent of temperature, such as micro-cracks, grain boundaries, pore volume, mineralogical composition, shape, and orientation of crystals and their fragments.

Sass et al. (1992) and Vosteen and Schellschmidt (2003) distinguish between the effects of composition

and temperature. They propose a general empirical relation for $\lambda(T)$, the thermal conductivity in W m^{-1} K^{-1} at temperature T in °C, as a function of λ_0, the thermal conductivity at 0 °C:

$$\lambda(T) = \frac{\lambda_0}{a + T\left(b - \frac{c}{\lambda_0}\right)} \text{ or } \frac{\lambda_0}{\lambda(T)} = \underbrace{a}_{\text{intercept}} + \underbrace{(b - \frac{c}{\lambda_0})}_{\text{slope}}\ T \quad (22)$$

For different rock types, the slopes and intercepts of this equation can be determined from linear regressions of Equation 22 yielding a mean intercept ā and its uncertainty Δa. Coefficients b and c and associated uncertainties σ_b and σ_c are determined from a second linear regression of the different slopes ($b - c/\lambda_0$) as a function of $1/\lambda_0$ (Table 4).

Since thermal conductivity is usually measured at room temperature, λ_0 is expressed as a function of λ_{25}, the room temperature thermal conductivity, by Sass et al. (1992) for crystalline rocks (felsic gneiss to amphibolite) as:

$$\lambda_0 = \lambda_{25}\left(1.007 + 25\left(0.0037 - \frac{0.0074}{\lambda_{25}}\right)\right). \quad (23)$$

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Table 3 Values for constants A and B in Equation 21 for different rock types (Zoth and Hänel, 1988)

Rock type	T (°C)	A (W m^{-1} K^{-1})	B (W m^{-1})
1. Rock salt	−20 to 0	−2.11	2 960
2. Limestones	0–500	0.13	1 073
3. Metamorphic rocks	0–1 200	0.75	705
4. Acidic rocks	0–1 400	0.64	807
5. Basic rocks	50–1 100	1.18	474
6. Ultra-basic rocks	20–1 400	0.73	1 293
7. Rock types (2)–(5)	0–800	0.70	770

Vosteen and Schellschmidt (2003) find for magmatic and metamorphic rocks:

$$\lambda_0 = 0.53\ \lambda_{25} + 0.5\ \sqrt{1.13\ \lambda_{25}^2 - 0.42\ \lambda_{25}}, \quad (24)$$

and for sedimentary rocks:

$$\lambda_0 = 0.54\ \lambda_{25} + 0.5\ \sqrt{1.16\ \lambda_{25}^2 - 0.39\ \lambda_{25}}. \quad (25)$$

Hofmeister (1999) provided a detailed analysis of heat transport based on an analysis of phonon lifetimes obtained from infrared reflectivity. It accounts for the variation of the phonon contribution λ_p to thermal conductivity with both temperature and pressure as well as for the pressure dependent radiative contribution λ_r. It allows approximation of thermal conductivity for mantle conditions if: (1) K'_0, the pressure derivative of the isothermal bulk modulus K_T, is constant: $K'_0 = dK_T/dP$ = const; (2) the variations of the bulk modulus with temperature and pressure are mutually independent; (3) the pressure derivative of the thermodynamic Grüneisen parameter γ (Equation 12 or 13 in *Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat*, this volume) is constant: $d\gamma/dP = f$. For mantle material, γ varies from 1 to1.4, K'_0 from 4 to 5, and $f \approx 0$ vanishes approximately. According to Hofmeister (1999) and within the uncertainty of these parameters, thermal conductivity in the mantle is:

$$\lambda(T,P) = \lambda_{298\,K,\,101.33\,kPa} \times (298/T)^a (1 + K'_0 P/K_T) e^{-(4\gamma+1/3)\int_{298}^{T}\alpha(T')dT'} + \lambda_r, \quad (26)$$

where T is absolute temperature, $\lambda_{298\ K,\ 101.33\ kPa}$ is thermal conductivity at room temperature and atmospheric pressure, α(T) is volume coefficient of thermal expansion as a function of temperature, and the exponent a is the fitting parameter. The radiative contribution λ_r in (26) may be approximated by Equations 15, 18, or 19. Hofmeister (1999) provides alternative expressions for λ_r for ferrous minerals or dense silicates and oxides (Figure 7):

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Table 4 Coefficients a, b, and c in Equation 22 and associated uncertainties Δa and σ_b, σ_c; Δa is the error of the mean intercept ā for all rock types of the linear regressions of the normalized thermal resistance $\lambda_0/\lambda(T)$ as a function of temperature T; σ_b and σ_c are the errors defined by the linear regression of the slopes ($b - c/\lambda_0$) as a function of the thermal resistance $1/\lambda_0$ (see Equation 22)

Rock type	ā (–)	Δa (%)	$b \times 10^3$ (K^{-1})	$\sigma_b \times 10^3$ (K^{-1})	$c \times 10^3$ (W m^{-1} K^{-2})	$\sigma_c \times 10^3$ (W m^{-1} K^{-2})	T (°C)	Reference

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Figure 7 Variation of radiative thermal conductivity λ_r of ferrous minerals, dense silicates, and oxides with temperature according to Equation 27 (Hofmeister, 1999).

ferrous minerals :

$$\lambda_r = 0.01753 - 1.0365 \times 10^{-4} T + 2.2451 \times 10^{-7} T^2 - 3.407 \times 10^{-11} T^3;$$

dense silicates and oxides

$$\lambda_r = 8.5 \times 10^{-11} T^3 \ (\lambda_r \text{ in W m}^{-1}\text{ K}^{-1} \text{ and T in K}). \quad (27)$$

Figure 1 in the companion article in this volume (see *Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat*) shows the variation of phonon thermal conductivity λ_p with temperature in an average crust of density $\rho = 2\,700\,\text{kg m}^{-3}$ molar mass of $0.22178\,\text{kg mol}^{-1}$. It is derived from $\lambda = \kappa\,\rho\,c$ as the product of thermal capacity $\rho\,c_P$ and thermal diffusivity κ calculated according to Equation 20 (in Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat, this volume"; Whittington et al., 2009). Due to the balancing increase of specific heat capacity with temperature, the decrease in thermal conductivity with temperature is less than in thermal diffusivity by a factor of about 1.3. Assuming a constant density throughout the crust, this implies that the increase and decrease in density due to the increase in pressure and temperature, respectively, partly cancel each other and that these changes are small compared to those of specific heat capacity and thermal diffusivity.

For mantle minerals, such as olivine and its high-pressure polymorphs, the β- and γ-spinels wadsleyite and ringwoodite, respectively, Xu et al. (2004) fitted phonon thermal conductivity measured to 1 373 K and 20 GPa to an exponential equation in temperature yielding values for the exponent between −0.406(35) and −0.537(11) suggesting that fitted phonon thermal conductivity varies with $T^{-1/2}$ (Table 5).

Variation with pressure

The effect of pressure on phonon thermal conductivity λ_p is different in two distinct pressure ranges. First, fractures and micro-cracks (developed during stress release after sampling) begin to close with increasing pressure. This reduces thermal contact resistance as well as porosity which is usually filled with a low conductivity fluid. This process ends when a pressure of about 15 MPa is reached. A compilation of measurements on various sedimentary, volcanic, plutonic, and metamorphic rocks (Clauser and Huenges, 1995) indicates that this effect accounts for an increase of about 20 % relative to thermal conductivity at atmospheric pressure. A further pressure increase to 40 MPa does not affect thermal conductivity significantly. If pressure is increased further, however, a second process becomes effective, the reduction of intrinsic porosity, i.e., voids which are not created by stress release. For granite and for metamorphic rocks, data indicate an increase of thermal conductivity by about 10 % within the pressure range 50 MPa–500 MPa.

For mantle minerals, such as olivine and its high-pressure polymorphs, the β- and γ-spinels wadsleyite and ringwoodite, respectively, Xu et al. (2004) determined values for the pressure coefficient between $0.022\,\text{GPa}^{-1}$ and $0.032\,\text{GPa}^{-1}$ for phonon thermal conductivity measured to 1 373 K and 20 GPa (Table 5). A table of numerical values for pressure derivatives of phonon thermal conductivity measured by a variety of authors was compiled by Hofmeister et al. (2009). Most values for $\lambda^{-1}(\partial\lambda/\partial P)$ fall into the range $0.04\,\text{GPa}^{-1}$–$0.36\,\text{GPa}^{-1}$, exceeded only by values of $0.69\,\text{GPa}^{-1}$ and $0.5\,\text{GPa}^{-1}$ for sulfur and quartz$_{\perp c}$ (measured perpendicular to the optical *c*-axis), respectively. Osako et al. (2004) fitted thermal conductivity measured to 1 100 K and 8.3 GPa on isotropic, single-crystal garnet and anisotropic olivine ($Fo_{93}Fa_7$; in three crystallographic directions) as upper and lower mantle constituents, respectively, to a linear equation in pressure (Table 6). A pressure dependence of garnet and olivine was found on the order of $4\,\%\,\text{GPa}^{-1}$–$5\,\%\,\text{GPa}^{-1}$ and $3\,\%\,\text{GPa}^{-1}$–$4\,\%\,\text{GPa}^{-1}$, respectively.

In contrast, radiative thermal conductivity λ_r was found much less variable with pressure than with temperature (Clark, 1957). In particular, this holds once the spectral radiance overlaps the infrared pass band in the absorption spectrum, at temperatures above 1 900 K (Hofmeister, 2005).

Variation with other factors

Apart from temperature and pressure, thermal conductivity also varies with porosity, pore fluid, saturation, dominant

mineral phase, and anisotropy. These effects are summarized here from the detailed discussion in Clauser (2006):

For large *porosity* (i.e., $\phi >> 1\,\%$) thermal conductivity of the saturating fluid affects significantly the bulk rock thermal conductivity. The influence varies with the thermal conductivity of the saturants, e.g., water, oil, natural gas, air. The resulting bulk thermal conductivity can be estimated from a suitable mixing model, e.g., Equations 2–4.

The effect of partial *saturation* is different for porous or fractured rocks. In porous rocks, porosity comprises both bulk pore space and bottlenecks formed by the contact between individual grains. Dry bottlenecks act as thermal contact resistances between grains, while the bulk pore volume contributes proportionally to the effective rock thermal conductivity. In fractured rocks, in contrast, there are no bottlenecks between grains as in porous rocks, and the small void volume in the fractures corresponds to the bulk pores space of porous rocks.

Figure 8 illustrates these two effects for a water-saturated medium-porosity sandstone and a low-porosity granite: Starting completely dry with an unsaturated conductivity of about 60 % of the saturated value, a level of 85 % is reached for the sandstone at about 10 % saturation. The 15 % conductivity residual is then spread almost linearly over the remaining 90 % of saturation. Physically this observation indicates that the filling of inter-granular bottlenecks accounting for only about 10 %−15 % of the total porosity significantly reduces the contact resistances between the individual grains. In contrast, the replacement of low conductivity air by the more conductive fluid in the major part of the pore volume accounts for the second effect. If only fractures contribute to the total porosity, as in the granite, there are no bottlenecks and only the second effect is observed: Starting completely dry with an unsaturated conductivity of about 85 % of the saturated conductivity, a quasi linear increase is observed

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Table 5 Reference values λ_{298} and κ_{298} at 298 K, pressure coefficients a and a′, and fitting functions for thermal conductivity λ and thermal diffusivity κ of lower mantle minerals with absolute temperature T and pressure P (Xu et al., 2004)

due to the replacement of low conductivity air until the 100 % level is reached for complete saturation.

Anisotropy of sedimentary and metamorphic rocks is due to the conditions of their formation. Anisotropy exists on several scales: (1) On the microscopic scale, many minerals are anisotropic; (2) on the laboratory scale, thermal conductivity of many rocks is also anisotropic. However, even if rocks are composed of anisotropic minerals, random orientation of the crystals within the rock may render the rock's bulk thermal conductivity isotropic on a macroscopic scale; (3) on a still larger scale, if rocks are exposed to folding, orogenic or other tectonic processes, thermal conductivity of the resulting rock formation may be anisotropic.

As a result, thermal conductivity parallel to the direction of layering or foliation, $\lambda_{||}$, is greater than thermal conductivity in the perpendicular direction, $\lambda_{\perp}$. The factor of anisotropy, the ratio $\lambda_{||}/\lambda_{\perp}$, generally falls into the range 0.9–3, with most values between 1 and 2 (e.g., Clauser and Huenges, 1995; Popov and Mandel, 1998; Popov et al., 1999a, b; Clauser, 2006; Davis et al., 2007). For sedimentary rocks a general trend has been reported of decreasing $\lambda_{\perp}$ with factor of anisotropy $\lambda_{||}/\lambda_{\perp}$, but no such trend was identified for metamorphic rocks (Clauser, 2006).

Thermal diffusivity

Thermal diffusivity is required in the analysis of transient heat transfer. A sizable compilation of room-temperature data of phonon thermal diffusivity κ_p measured on various mantle minerals is given by Hofmeister et al. (2009) from measurements by various groups.

If both conductivity and thermal capacity are known, thermal diffusivity κ can be calculated from $\kappa = \lambda/(\rho\, c)$. As for steady-state thermal conduction, transient heat diffusion in most of the Earth's crust and mantle is caused by scattering of quantized lattice vibrations, the phonons, and by diffusive (as opposed to ballistic) radiation of photons. These two processes are described by phonon thermal conductivity λ_p and radiative thermal conductivity, λ_r, respectively, the sum of which is often termed effective thermal conductivity, λ_{eff}. As thermal diffusivity is the ratio of thermal conductivity and thermal capacity, it is also influenced by the variation of density and specific heat capacity. This is of particular interest with respect to the variation with temperature.

Measuring techniques

All of the transient laboratory methods used to determine thermal conductivity are useful to determine thermal diffusivity as well. Recently, heat pulse (Schilling, 1999; Höfer and Schilling, 2002; Gibert et al., 2003) and laser flash methods (Parker et al., 1961; Blumm and Lemarchand, 2002; Hofmeister, 2006) have been used for measurements at high temperature. Compared to other methods their advantage lies in a reduction or even complete absence of physical contacts between samples on the one hand and temperature sensors and heat sources on the other hand. While most methods measure the effective diffusivity comprising contributions from phonon conduction and diffused heat radiation, the laser flash method yields the diffusive component without contributions from heat radiation. This difference becomes important particularly at high temperatures (for a critical assessment see e.g., Hofmeister et al., 2009).

Variation with temperature

Thermal diffusivity κ of rocks varies even more strongly with temperature than thermal conductivity λ. This is caused by the opposite behavior of thermal conductivity and thermal capacity (ρ c) with respect to temperature. Because of several self-compensating factors, thermal capacity (ρ c) with few exceptions generally varies within $\pm 20\,\%$ of $2.3\,\mathrm{MJ\,m^{-3}\,K^{-1}}$ for the great majority of minerals and rocks (Beck, 1988). This is confirmed by a linear regression of thermal diffusivity on thermal conductivity which was measured on a suite of metasedimentary, volcanic, magmatic, and metamorphic rocks together with density and specific heat capacity (Mottaghy et al., 2005):

$$\kappa = \frac{\lambda}{\rho\, c} = \frac{\lambda}{2.3} = 0.44\,\lambda\,(\kappa \text{ in } 10^{-6}\,\mathrm{m^2\,s^{-1}}). \qquad (28)$$

A linear regression of thermal capacity as a function of temperature yields also a linear relationship. This allows to determine thermal diffusivity $\kappa(T)$ at any temperature,

based only on the known variation of thermal conductivity λ(T) with temperature (Mottaghy et al., 2005):

$$\kappa(T) = \frac{\lambda(T)}{2.134 + 0.0044\,T} \quad (\kappa \text{ in } 10^{-6}\,\mathrm{m^2\,s^{-1}};\ \mathrm{T\ in\ ^\circ C}). \tag{29}$$

Thus, thermal diffusivity can be derived from thermal conductivity and vice versa. For the suite of rocks studied by Mottaghy et al. (2005), thermal conductivity decreased by 4 %–7 % in the range 1–100 °C while thermal diffusivity decreased by 18 %–22 %.

Thermal diffusivity was measured at temperatures of up to 550 °C by Ray et al. (2006) on a suite of 16 samples comprising Archean granulitic rocks which are considered a major component of the middle and lower continental crust. Phonon scattering was found dominating heat transport with radiative diffusion of photons setting in at 450 °C for most, but not all rocks. Based on their measurements, Ray et al. (2006) propose an equation by which thermal diffusivity κ(T) at elevated temperature below 450 °C can be derived from room temperature values, κ_{rt}:

$$\kappa(T) = 0.7 + 144\,\frac{\kappa_{rt} - 0.7}{T - 150} \quad (\kappa \text{ in } 10^{-6}\,\mathrm{m^2\,s^{-1}};\ \mathrm{T\ in\ K}), \tag{30}$$

They also proposed an additional term in Equation 30, proportional to T^3, by which the radiative contribution above 450 °C is fitted. However, this assumes a similar variation with temperature of thermal conductivity and thermal diffusivity and neglects the additional variation of specific heat capacity. This, in fact, makes thermal diffusivity vary stronger with temperature than thermal conductivity, which is why the T^3-term is omitted here. Whittington et al. (2009) measured the phonon component κ_p of thermal diffusivity at temperatures of up to 1 260 K on garnet schist, leucogranite, and welded rhyolitic ash-flow tuff using laser flash analysis. This characterizes purely the phonon heat transfer component without any radiative contribution, in contrast to the values discussed above. Below and above the transition between α- and β-quartz at 846 K (~573 °C) the data are reasonably fitted by

$$\kappa_p(T) = \begin{cases} -0.062 + \frac{567.3}{T}; & \mathrm{T} > 846\ \mathrm{K} \\ 0.732 - 0.000135\,T; & \mathrm{T} < 846\ \mathrm{K} \end{cases} \quad (\kappa \text{ in } 10^{-6}\,\mathrm{m^2\,s^{-1}};\ \mathrm{T\ in\ K}), \tag{31}$$

assuming an average molar mass of 0.22178 kg mol^{-1} and an average density of 2 700 kg m^{-3} for the crust (see Figure 1 in *Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat*, this volume). The leucogranite and rhyolite samples were homogeneous and isotropic. The schist was anisotropic owing to alternating mica- and quartz-rich layers, requiring testing in the direction parallel and perpendicular to foliation.

For mantle minerals, such as olivine and its high-pressure polymorphs, the β- and γ-spinels wadsleyite and ringwoodite, respectively, Xu et al. (2004) fitted phonon thermal diffusivity measured to 1 373 K and 20 GPa to an exponential equation in temperature yielding values for the exponent between −0.563(35) and −0.793(17) suggesting that fitted phonon thermal conductivity varies with $T^{-½}$–T^{-1} (Table 5).

Pertermann and Hofmeister (2006) measured thermal diffusivity on oriented single crystals and polycrystalline samples of olivine-group minerals with the laser-flash method at temperatures of up to about 1 500 °C. They fitted the data to a second order polynomial in T:

$$\kappa_p(T) = a + b/T + c/T^2 (\mathrm{T\ in\ K}). \tag{32}$$

Values for the coefficients a, b, and c fitted to data measured on single crystal and polycrystalline samples are shown in Table 7.

Osako et al. (2004) fitted thermal diffusivity measured to 1 100 K and 8.3 GPa on isotropic, single-crystal garnet and anisotropic olivine ($Fo_{93}Fa_7$; in three crystallographic directions) as upper and lower mantle constituents, respectively, to a linear equation in inverse temperature (Table 6). They found a strong anisotropy in olivine which they assume to prevail throughout the olivine stability field in the mantle down to 410 km.

Variation with pressure

Tommasi et al. (2001) measured thermal diffusivity in the crystallographic [100] and [010] directions parallel and perpendicular to a strain-induced foliation, respectively, as a function of temperature at atmospheric pressure on spinel lherzolites and spinel harzburgite. These rocks are considered representative for the subcontinental and suboceanic mantle, respectively. They found an anisotropy in thermal diffusivity on the order of 25 % with the maximum aligned in the direction of strain. Support of their experimental findings was provided by corroborating petrophysical modeling.

For mantle minerals, such as olivine and its high-pressure polymorphs, the β- and γ-spinels wadsleyite and ringwoodite, respectively, Xu et al. (2004) fitted phonon thermal diffusivity measured to 1 373 K and 20 GPa to a linear equation in pressure yielding a pressure coefficient of 0.036(4) GPa^{-1} (Table 5).

Osako et al. (2004) fitted thermal diffusivity measured to 1 100 K and 8.3 GPa on isotropic, single-crystal garnet and anisotropic olivine ($Fo_{93}Fa_7$; in three crystallographic directions) as upper and lower mantle constituents, respectively, to an exponential equation in pressure (Table 6). The pressure dependence of garnet and olivine was found to be on the order of 4 % GPa^{-1}–5 % GPa^{-1} and 3 % GPa^{-1}–4 % GPa^{-1}, respectively.

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Table 7 Coefficients for fitting the variation of thermal diffusivity (10^{-6} m^2 s^{-1}) with temperature (K) according to Equation 32 (Pertermann and Hofmeister, 2006)

Variation with other factors

Micro-cracks and grain boundaries give rise to increased thermal resistance and to a reduction of the mean free path of radiation due to scattering of radiation. It is somewhat debated below which grain size the effect is negligible: Based on the agreement between diffusivities measured on minerals and rocks, Gibert et al. (2003) concluded that the effect of grain boundaries, thermal cracking, and secondary phases is negligible. Along the same lines, Seipold (1998) argued that grain size is much larger than the phonon mean free path and therefore grain boundaries should not interfere with heat diffusion. Branlund and Hofmeister (2008) confirm this for quartzites, but find diffusivities measured on chert, agate, and chalcedony to be lowered by grain boundaries. They propose that grain sizes above 1 μm should not affect heat transfer.

Additional advective heat transfer was identified by Seipold and Schilling (2003) due to the release of water adsorbed at the inner surfaces of voids (i.e., pores and cracks) in rocks at about 450 K and by dehydration of serpentinite at 850 K. Both processes create high local overpressures which are relieved by cracking if the overpressure exceeds the tensile strength of the rock. The resulting flow is then accompanied by a corresponding advective heat transfer. This phenomenon was observed and studied in laboratory experiments (Seipold and Schilling, 2003) but has implications for the lower crust and upper mantle with respect to recrystallization processes involving the discharge of fluids. These “crustal burps” provide the only conceivable way how some fluids from the mantle or lower crust my find their way to the Earth’s surface. The example discussed by Seipold and Schilling (2003) involves liberating water of crystallization during the conversion of serpentinite into forsterite and talc, followed by the formation of enstatite. As this involves heat advection as a separate heat transfer mechanism, this process is better addressed separately and not parameterized into some sort of “effective” heat transport property not directly linked to a physical process.

Summary

Understanding the thermal regime of the Earth requires appreciation of properties and mechanisms for storage, transport, and generation of heat with the Earth. Both experimental and indirect methods are available for inferring the corresponding rock properties. Steady-state heat conduction or transient heat diffusion is the dominant transport process in the Earth’s crust, except when appreciable fluid flow provides a mechanism for heat advection. For most crustal and mantle rocks, heat radiation sets in at temperatures above about 450 °C and becomes significant only at temperatures above 1 200 °C. At temperatures above 2 500 °C heat radiation becomes a dominant mechanism.

TIME REVERSAL IN SEISMOLOGY

Carène Larmat[1], Clarence S. Clay[2]
[1]Geophysics Group, EES-17, MS D443, Los Alamos National Laboratory, Los Alamos, NM, USA
[2]Marine Geophysics and Wave Propagation, Department of Geoscience, University of Wisconsin-Madison, Madison, WI, USA

Definition

Time-Reversal – This refers to a collection of techniques that aim to focus wave energy onto a specific point in space and time, implicitly using the *source-receiver reciprocity* and the *invariance* of the wave propagation equation to the transformation $t \rightarrow -t$. The usual way to perform a time-reversal experiment is to simultaneously rebroadcast from a set of receivers the recorded signals read backward. By doing this, an approximate and reverse version of an original wave propagation movie is created, which will display wavefronts converging back onto the source point. A variant of this procedure is *reciprocal Time-Reversal*, where the read backward signals are rebroadcast from the source point instead of from the recording point. Based on the *source-receiver reciprocity*, the wavefield will in this case focus on the receiver.

Invariance of the wave equation – In the absence of loss terms, the wave equation only contains second-order space and time derivatives. This implies that if u(x,t) is a wavefield solution, then u(x,−t), u(−x,t), and u(−x,−t) are also solutions of the equation. This means that the propagation direction of a wavefield may be reversed if it has been measured at any point of space at a given moment. Consideration about the correct boundary conditions to be applied can be found in the subsequent references.

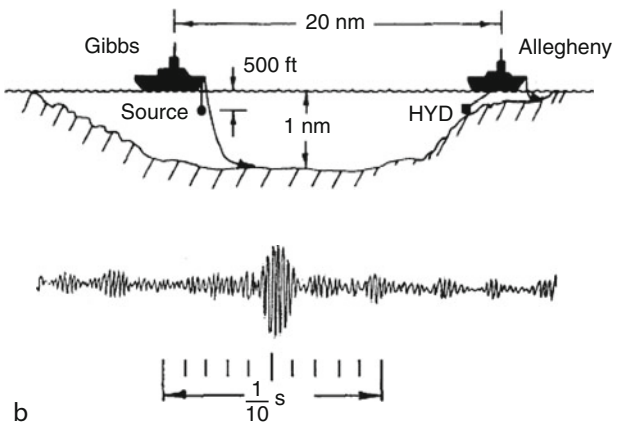
Source-receiver reciprocity – The principle of reciprocity states that a source and receiver may be interchanged and the same waveform will be observed. The conditions required are that the considered signal is transient, nonlinear effects are negligible, and that the medium remains unchanged.

History

Imagine filming the ripples formed when a pebble is dropped into a pond, and playing the movie backward. You will observe the ripples converge back onto the original impact point, indicating its location by a local concentration of wave energy. The history of developing Time-Reversal is strongly related to the ability to physically or numerically realize this thought experiment based on progress in understanding wave propagation and in developing the necessary tools.

The story of Time-Reversal starts in the 1950–1960s in a cluttered room of the Hudson Laboratory of Columbia University where Antares Parvulescu (1923–1998) tested his idea of time-reversed transmissions. A microphone was placed about 25 ft from a loud speaker, from which a series of short impulses were sent 1 s apart. A sequence of the signal due to the room reverberations was received at the microphone and tape-recorded. The tape was removed and played backward. These "time-reversed signals" (called then "matched signals") were played by the loud speaker (notice it is a reciprocal Time-Reversal experiment that was carried out). When an indiscernible rushing noise could be heard over the rest of the room, the scope at the microphone displayed a signal that looked like the autocorrelation of the reverberation signal. When we indeed brought our ears to the microphone, the rushing noise became a simple "click," indicating that localization in space and time of the wave energy did occur! This result was first published in a terse abstract (Parvulescu, 1961) and is further documented in Parvulescu (1995) and in chapter 7 of the book of Tolstoy and Clay (1966 and its revision in 1987).

In 1961–1962, Parvulescu and colleagues decided to take this matched signal experiment to sea. This was a serious logistic and scientific challenge as most of the geophysicists at that time did not believe that transmission in ocean was reproducible. The marine experiment used two oceanographic research ships, the Gibbs and Allegheny, with deep anchoring capability in the Tongue of Ocean, which is an oceanic trench. Figure 1a shows the setting of the experiment. The received signals at the Allegheny, lengthened by multiple reverberations, were radioed back to the Gibbs to be then transmitted from the source (this was again a reciprocal Time-Reversal experiment). Figure 1b shows the peak of pressure created on the hydrophone. The report of this first "field" Time-Reversal experiment is documented in Parvulescu and Clay (1965). Details of further experimentations can be found in chapters 4–8 of Tolstoy and Clay (1966–1987).



Time Reversal in Seismology, Figure 1 **(a)** Ship positions and instruments used for the marine experiment. Gibbs has the source, and Allegheny has the receiver (HYD). **(b)** Signal received at the hydrophone when performing a reciprocal time-reversal between the two ships in an oceanic trench. Figures from Parvulescu and Clay (1965) and Tolstoy and Clay (1966).

In 1980s, Time-Reversal was first used in seismology by George McMechan and colleagues at the University of Texas. They modified techniques developed for exploration geophysics to image the primary source of excitation instead of geologic reflectors and rediscovered the principle of Time-Reversal. They successfully imaged the source of a small 1983 aftershock earthquake in California using a purely acoustical 2D model to numerically rebroadcast signals recorded at a very dense network in a 15 by 12 km vertical slice of the formation (McMechan, 1982).

In the late 1980s, advances in microelectronics, storage capacity, and automated signal processing led to the development of the *Time-Reversal Mirror* (TRM) by Mathias Fink and colleagues at the Laboratoire Ondes et Acoustique (LOA) of the University of Paris VII (Fink, 1992). TRMs are finite-size arrays of transmit-receive transducers that are at the base of active research on theoretical limit of Time-Reversal (Fink et al., 2000; Fink, 2006). TRMs have made possible novel applications of Time-Reversal ranging from nondestructive evaluation (Ulrich et al., 2008a, b) to medical imaging (Fink and Tanter, 2010).

For references and more technical details about Time-Reversal, see the reviews by Fink et al., 2000; Fink, 2006; Anderson et al., 2008; and Larmat et al., 2010.

Time-reversal and complexity

The Earth and oceans are complex environments in which transmitted signals quickly become difficult to interpret, for example, instead of a single pulse for the first arrival, the P-wave is accompanied by a coda train due to the scattering within the crust. Contrary to many location methods based on simple paradigms, Time-Reversal thrives with complexity. In a homogeneous and purely acoustic medium, only one phase will be recorded on a single receiver from a source point. Introduce a reflecting interface and two phases will be recorded: the primary and a copy of the source impulse due to the reflection on the interface. The two combined phases contain more information about the source location than the primary phase alone. All these different phases will converge and add up onto the source point when traveling backward. Several studies (e.g., Dowling and Jackson, 1992; Fink et al., 2000; Blomgren et al., 2002) have actually demonstrated the width of the focus is smaller in randomly heterogeneous media than in the homogeneous case (implying better resolution on the location). This is referred as *super-resolution.* Theoretical discussion about Time-Reversal resolution can be found in Fink et al. (2000). A second important point for complex media is that any arbitrary time-segment will return to the source. Time-Reversal does not need any interpretation of the signals.

These unique facets of Time-Reversal explain the wide use of the method in very different disciplines handling with complex media, for example, target detection method and communication in underwater acoustics, nondestructive evaluation (i.e., location of defects in intact specimens), improved imaging and destruction of stones/tumors in medicine, and source location and imaging techniques in geophysics.

Location of seismic sources

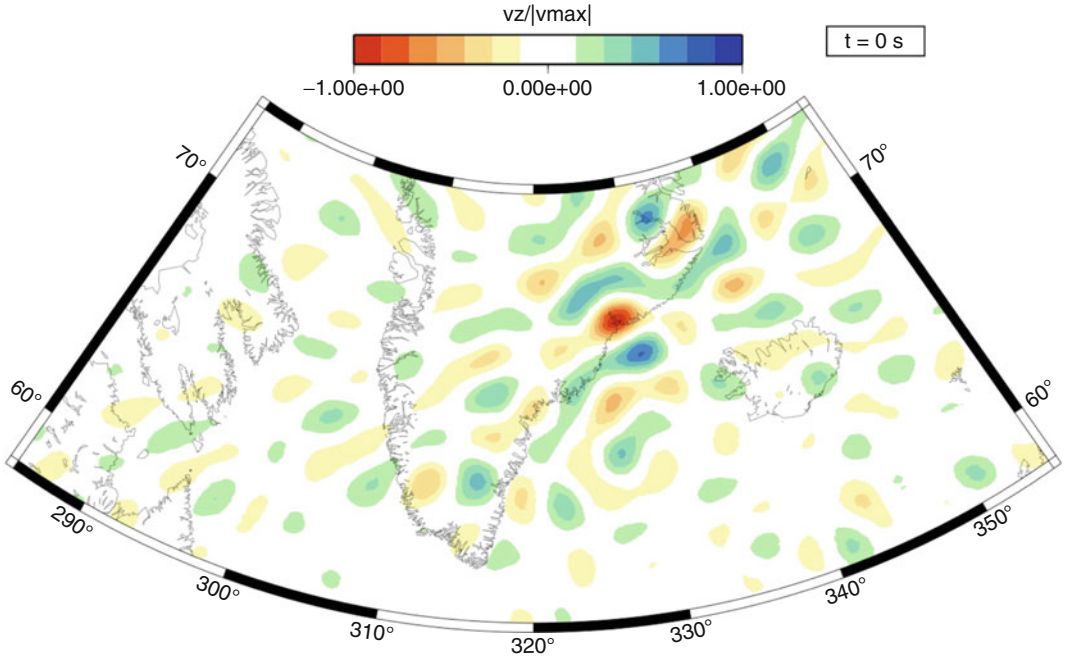
Since the late 1990s, several groups have performed Time-Reversal location of seismic events (for references, see Anderson et al., 2008; Larmat et al., 2010), harnessing the developing computing power. These applications have demonstrated that contrary to what was thought by McMechan, Time-Reversal does work with "sparse" rebroadcasting networks (i.e., with receivers way more than one wavelength apart). Figure 2 shows the time-reversal result from a 2001 magnitude-5 glacial earthquake in Greenland by Larmat et al. (2008). Glacial earthquakes were discovered in 2003 by Ekström et al. (2003) as long-period signal barely above the noise level. The signal from 146 stations in the Northern hemisphere was filtered between 0.01 and 0.02 Hz, time-reversed and rebroadcast into a 3D Earth model. The figure shows the snapshot of the vertical component of the time-reversed displacement at the moment of the focus (actually the vertical component normalized by the maximum value reached on the snapshot). The focus appears as a two-lobe pattern of opposite polarity indicating the origin of the seismic signal. The two-lobe pattern reveals that the nature of the source excitation was a single force vector, which is consistent with recent source analysis by Tsai et al. (2008). Had the source been a simple monopole, the focus would have manifested itself as a single point (see details in Larmat et al., 2008).

In the last 5 years, Time-Reversal application to seismology has evolved into using 3D full-waveform modeling to locate any type of seismic sources (e.g., point source, long lasting, finite) with "no specific interpretation . . . made of the various arrivals" as pointed out by Brian Kennett (1983). One application can be location of the origin of various emergent signals such as tremors (Steiner et al., 2008; Larmat et al., 2009; Lokmer et al., 2009) and weaker microseismicity. It must be noted that several Time-Reversal source location have been carried out of late.

Other location methods are based on the core idea of sending back some recorded signals to a given point in space and time. All back-projection related methods can be seen as simplified Time-Reversal procedures for which the backward propagation is reduced to shifting the time series by predicted arrival times (e.g., Source Scanning Algorithm of Kao et al. (2005).

Location of features in the velocity model

Time-reversed propagation is also used to image the subsurface structure. The exploration methods used by McMechan have evolved into reverse-time migration (e.g., Baysal et al.,1983). Next generation tomography



Time Reversal in Seismology, Figure 2 One hundred and forty-six vertical displacement signals of a glacial earthquake were time-reversed and sent back in a 3D Earth model. The vertical component (vz) of the created time-reversal signal at the moment of the focus displays a two-lobe pattern of opposite polarity consistent with a single force vector as the source mechanism (adapted from Larmat et al., 2008).

models are currently created based on the adjoint method that uses a forward and a backward propagation to locate the source of discrepancies between data and predicted waveforms (Tromp et al., 2005).

Time-reversal and correlation methods

The signal produced at point A from source S can be expressed with the Green function formalism: $S_A(t) = G(x_S, x_A, t) \otimes s(t)$ where $s(t)$ is the source time function and $\otimes$ denotes the convolution operation. If you time-reverse the signal $S_A(t)$, and rebroadcast it from A, the signal produced on point S will be:

$$\begin{aligned} S_S^{TR}(t) &= G(x_A, x_S, t) \otimes S_A(T-t) \\ &= [G(x_S, x_A, T-t) \otimes G(x_S, x_A, -(T-t)] \otimes s(t) \end{aligned} \quad (1)$$

where the reciprocity between A and S of the Green function has been used. The right term of this expression is similar to the expression of the autocorrelation of S_A in terms of Green functions. More generally, the cross-correlation of the signal recorded at a point A and B is:

$$\begin{aligned} C_{AB}(t) = [G(x_S, x_A, t) \otimes G(x_S, x_B, -t)] \otimes [s(T-t) \otimes s(t)] \\ \rightarrow S[G(x_A, x_B, t) + G(x_A, x_B, -t)] \end{aligned} \quad (2)$$

which states that under certain conditions the cross-correlation of two signals is composed of the superposition of the Green function between the two receivers and its time-reversed version. Equation (2) is the basis of what is known as *interferometry* or imaging with ambient noise, as the Green function contains information about the properties of the medium (see *Seismic, Ambient Noise Correlation*, the review by Snieder and Wapenaar, 2010 and the pioneer paper of Claerbout, 1968).

To come back to Time-Reversal, if the source time function is considered to be a dirac, the time-reversed signal at the original point source S is:

$$S_S^{TR}(t) = [G(x_S, x_A, T-t) \otimes G(x_S, x_A, -(T-t)] \quad (3)$$

This expression is typical of a *matched filter*, whose output is optimal in some sense. Whatever the Green function, the Time-Reversal wavefield is maximal at the focus time and at the source point (Fink et al., 2000, p. 1946). Applications derived from this interpretation of Time-Reversal consist in locating seismic sources, such as trapped miners, by comparing their transmitted distress signals with a database of prerecorded Green functions (created by recording the seismic response for each possible source location) (Hanafi et al., 2009).

Summary

Interest in seismic source study has recently shifted from event-based temporary observation to continuous

monitoring using dense seismic networks. Seismologists now study a wealth of signals due to less energetic sources than earthquakes such as tremors and microseismicity. Glacial earthquakes, landslides, Earth Hum, and meteorological phenomena such as hurricanes belong to a group of events that defines "environmental seismology," a term coined by the French seismologist Jean-Paul Montagner.

Microseismic noise is now used for imaging the Earth. Due to their emergent nature, these signals represent a challenge to classical location methods based on triangulation. Time-Reversal as a method and Time-Reversal ideas are emerging as a promising framework to foster future location and imaging methods. The success of Time-Reversal as a source location method shall rely on the coverage of seismic networks, the accuracy of high-resolution velocity models, and the performance of numerical schemes to be used for the backward propagation. Still unclear are the convergence and resolution power of Time-Reversal under various conditions. Our ability to reliably observe and model scattering phenomena is expected to be an important part of the answer.

TRAVELTIME TOMOGRAPHY USING CONTROLLED-SOURCE SEISMIC DATA

Colin A. Zelt
Department of Earth Science, Rice University, Houston, TX, USA

Synonyms

Active-source data; Traveltime inversion

Definition

Traveltime. The total time for a particular wave to travel from a source to a receiver.
Tomography. Determination of model structure by back projection of the data along a path connecting a source and a receiver.
Controlled-source seismology. Determination of earth structure using seismic waves generated by artificial sources such as chemical explosives, mechanical vibrators, weight drops, gun shots, etc.

Background

Traveltime tomography is the main method by which the Earth's seismic velocity structure is determined on all scales, from the upper few meters to the whole mantle. It was adapted from algorithms used in medical imaging in the 1970s (Dziewonski and Anderson, 1984). In seismology, the term tomography refers to the back projection of data along a path connecting a source and receiver using a mathematical inverse method. Ideally, the traveltimes of seismic arrivals corresponding to many criss-crossing rays are used to construct a two-dimensional (2D) or 3D image of the Earth's seismic velocity variations. Tomography is a type of inverse problem, although the terms traveltime inversion and traveltime tomography are used in the seismological community without a well-defined distinction. The latter usually implies a uniform, fine grid model parameterization, in which a smooth model is sought. Any departure from this approach is usually referred to as traveltime inversion, although the distinction is somewhat arbitrary (Levander et al., 2007); this article will discuss both approaches. This article concerns traveltime tomography using controlled-source data and does not discuss other types of tomography that use seismic amplitudes, phases, or waveforms as input data, nor earthquake or surface-wave data.

Data from earthquakes and artificial (controlled) sources are used in traveltime tomography, the former usually for crustal or mantle structure, the latter usually for crustal or near-surface structure. Much of the theory and practice of traveltime tomography is the same or similar for controlled-source and earthquake data. However, earthquake tomography usually uses delay times and includes a determination of the source locations (hypocenters), whereas controlled-source tomography usually uses total times and the source locations are known very accurately. Also, the degree of lateral velocity heterogeneity in the crust, and in particular the near-surface, can be much greater than in the mantle, so there is often no sense of a reference model in controlled-source seismology as there is in earthquake seismology, and this in turn means that a nonlinear tomographic method must be applied to controlled-source data in which the rays must be determined along with the unknown velocity structure as part of the inverse problem. Finally, controlled-source data are often acquired using sources and receivers distributed along a straight or nearly straight line, yielding a so-called 2D dataset. In this case, 2D modeling is used in which lateral homogeneity perpendicular to the line is assumed. Earthquake tomography is almost always 3D given the typical distribution of earthquakes and stations. Today, 3D controlled-source data is not uncommon, but it is expensive to acquire, especially for crustal-scale studies. In some studies, both earthquake and controlled-source data have been inverted simultaneously (e.g., Ramachandran et al., 2005).

Controlled-source seismology can be divided into two main approaches: (1) near-vertical reflection methods, and (2) refraction/wide-angle reflection methods. Traveltime tomography is applied to data from both experiments, although it is more common for refraction data. The most common applications of traveltime tomography using controlled-source data are (1) tectonic studies of the crust and uppermost mantle, (2) earthquake risk studies for upper crustal fault and basin geometries, (3) petroleum exploration in crosswell studies, model building to facilitate migration, and for refraction statics, and (4) environmental/engineering studies of the near surface (as shallow as a few meters). The traveltimes utilized are often limited to those of the first arrivals corresponding to direct, refracted (turning) or diffracted waves. Sometimes the traveltimes of primary reflections are included, for example, from the basement overlying sediments or the crust-mantle (Moho) boundary, necessitating the need for layers or interfaces in the model parameterization. Only rarely are later refracted arrivals, multiples or conversions utilized. Traveltimes are picked from the seismograms usually either interactively by eye, or using a semi-automated scheme whereby a few picks are made interactively, and the intervening picks are determined automatically using a cross-correlation scheme (Zelt, 1999). Usually only very high quality, spatially-dense data can be picked using fully automated schemes.

Most controlled-source tomography uses only P-wave traveltimes to constrain the compressional wave-velocity structure because P wave are easiest to generate and therefore the P wave arrivals are usually the strongest and easiest to pick. However, S wave experiments are quite common in environmental/engineering studies (e.g., Chambers et al., 2009). Theoretically, traveltime tomography is the same for P- and S-wave data, and if both data are available in the same study, Poisson's ratio can be estimated. The forward modeling component of traveltime tomography is almost always based on ray theory, an infinite-frequency approximation of wave propagation, although recently a finite-frequency approach for

controlled-source data has been proposed (Zelt, 2009). Almost all applications of traveltime tomography assume isotropic media because it is rarely necessary to invoke anisotropy to model the observed data. Exceptions to this are mainly for crosswell data and in studies of the oceanic crust (e.g., Pratt and Chapman, 1992; Dunn et al., 2000). Traveltime tomography is applied to land and marine data, as well as onshore-offshore data, using the same tomographic methodology. Arrays of airguns are the most common marine source, while on land chemical explosives, mechanical vibrators, weight drops, hammers, shotguns and rifles are common sources.

The ideal dataset for traveltime tomography is one with as dense a spacing of sources and receivers as possible, along a line for a 2D experiment, or areally distributed for a 3D experiment. As a result, a subsurface point will be sampled by rays at as many different angles as possible, which in turn will yield the best possible spatial model resolution as discussed later. There is usually very little processing of seismic data before traveltime picking, only that required to "clean up" the data to make it easier for picking. This may include bandpass filtering, trace editing, velocity filtering, trace mixing or binning, or deconvolution. Picks should not be interpolated to provide uniform spatial coverage if there are significant trace gaps, since this will provide an incorrect sense of model constraint (Zelt, 1999). Uncertainties should be assigned to the pick times to avoid over- or under-fitting the data, and to allow the appropriate up- and down-weighting of less noisy and more noisy data, respectively (Zelt, 1999). Elevation or bathymetric corrections should be avoided as they depend on the unknown velocity structure. Instead, the known surface topography or bathymetry should be incorporated into the 2D or 3D model. For a 2D experiment in which the shot and receiver locations deviate significantly from a straight line, it may be necessary to perform 2.5D modeling, i.e., using a 3D model and 3D ray tracing, and the known topographic or bathymetric surfaces, but keeping the velocity model homogeneous in a direction perpendicular to the main trend of the profile (e.g., Van Avendonk et al., 2004). Given the spatial resolution of most velocity models derived from traveltime tomography, the degree of profile "crookedness" must be substantial to warrant 2.5D modeling (Schmelzbach et al., 2008; Figure 1).

There are several review papers relevant to this article. Nowack and Braile (1993) review traveltime tomography methods in 1D and 2D media. Zelt (1999) focuses on 2D traveltime tomography and inversion, as well as model assessment methods. Rawlinson and Sambridge (2003a) present an overview of traveltime tomography for 2D and 3D structure. Levander et al. (2007) review all aspects of crustal-scale controlled-source seismology, including traveltime tomography.

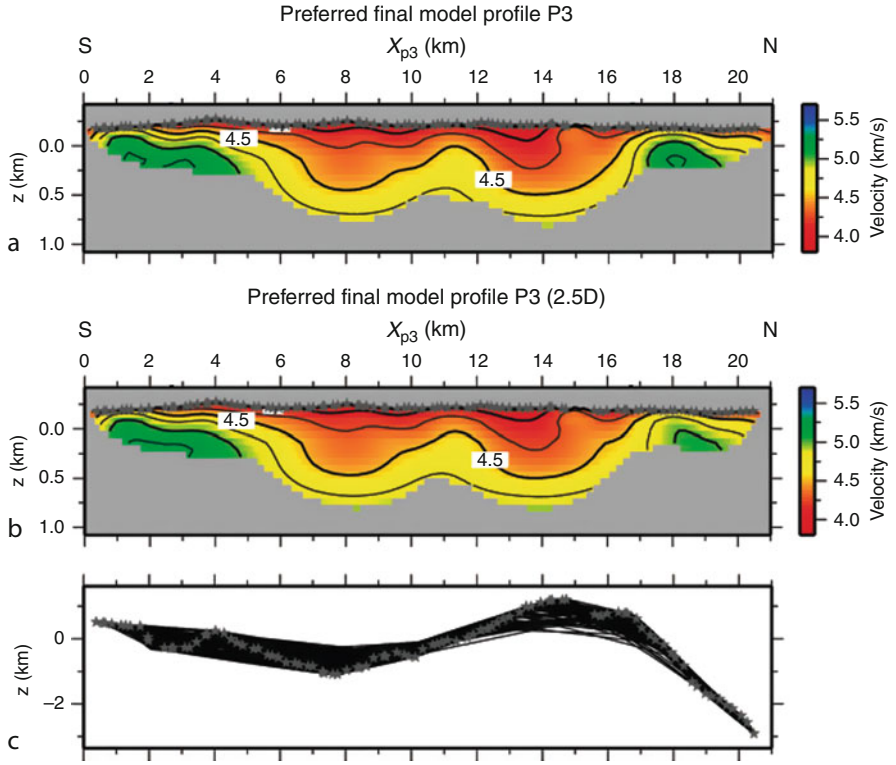
Forward modeling

In the 1970s, ray theory, an infinite-frequency approximation of wave propagation, for laterally heterogeneous media was developed (Cerveny et al., 1977, McMechan and Mooney, 1980). This allows earth models of arbitrary 2D and 3D complexity to be considered, provided the tenants of ray theory are honored, that is, the velocity field varies slowly with respect to the seismic wavelengths. Sharp velocity changes are modeled as velocity discontinuities (layer boundaries) using Snell's law. As a result, ray theory models are typically composed of one or a few layers, bounded by smoothly varying interfaces, within which the velocity varies smoothly. Ray theory forms the basis for the forward modeling used today in almost all traveltime tomography algorithms. There are two main types of infinite-frequency modeling: ray tracing and wavefront tracking.

Two end-member approaches to ray tracing are used: numerical and analytical. In the former case, the velocity field is specified by a regular (e.g., McMechan and Mooney, 1980) or irregular (e.g., Zelt and Ellis, 1988) grid of nodes, together with a scheme for interpolation between nodes, and a ray is traced by specifying a take-off angle from a point source and solving a set of ordinary differential equations, the ray tracing equations (Cerveny et al., 1977). In the analytic case, the velocity field is specified by a regular (e.g., Chapman and Drummond, 1982; White, 1989; Rawlinson et al., 2001) or irregular (e.g., Spence et al., 1984) grid of nodes, but with a form of interpolation, for example linear, such that the rays can be calculated analytically within each cell of the grid. In practice, the numerical and analytical techniques may be about equally efficient if the analytical method uses a fine grid of nodes to represent a sufficiently smooth velocity field as required by ray theory, and if the numerical scheme adjusts the step length according to the velocity gradient (Zelt and Ellis, 1988).

For an arbitrary 2D velocity model, a non-trivial consideration is the determination of ray take-off angle from the source such that an arbitrary receiver location is reached, or such that a particular layer or interface in the model is reached. Today, most 2D ray tracing algorithms offer an automatic determination of take-off angles by shooting trial rays followed by a bisection scheme to sufficiently refine the take-off angles so that the receivers are hit (e.g., Zelt and Smith, 1992). The robustness of the shooting method is crucial because the data from receivers for which it is not possible to find rays will not be used in the inverse step. Also, it is important to be sure that an inability to find rays is because of the velocity model, e.g., a shadow zone, as opposed to a shortcoming of the ray tracing algorithm.

To avoid the limitations of shooting/bisection algorithms, particularly for 3D models, ray bending methods were developed (Um and Thurber, 1987). In this approach, a ray connecting a source and receiver is estimated, typically using a 1D reference model, and the ray's path is iteratively updated using Fermat's principle until the minimum-time path is determined. In practice, shooting methods are more efficient and sufficiently robust for 2D models, whereas bending methods are favored for 3D models.



Traveltime Tomography Using Controlled-Source Seismic Data, Figure 1 Shallow crustal example from the South Portuguese Zone fold-and-thrust belt of first-arrival tomography by Schmelzbach et al. (2008) using the smoothing-regularized Zelt and Barton (1998) algorithm to seek a minimum-structure model. There were 99 shots (grey stars) along the crooked line. (**a**) Velocity model obtained by projecting all the data onto a straight line and performing a 2D inversion. (**b**) Velocity model obtained by performing a 2.5D inversion that preserves the true positions of all shots and receivers. (**c**) Rays projected into the horizontal plane for the 2.5D modeling to illustrate the extreme crookedness of the experiment. Model regions not sampled by rays are grey. The models in (**a**) and (**b**) are very similar, confirming the appropriateness of 2D modeling of traveltime data, even in the case of extreme crooked lines.

In the late 1980s, a new infinite-frequency forward modeling approach was introduced in which first-arrival traveltimes are calculated on a fine grid using a finite-difference solution of the eikonal equation (Vidale, 1988, 1990; Podvin and Lecomte, 1991). Rays are obtained by following the gradient of the time field. These methods are known as wavefront tracking algorithms. Reflected rays can be calculated in a two-step procedure by calculating downgoing and upgoing wavefronts (Hole and Zelt, 1995). Hole and Zelt (1995) also presented a modification to Vidale's approach which otherwise breaks down for velocity contrast of more than ~40%. The advantage of wavefront tracking methods is that they find the ray between any two points with the shortest traveltime, including the diffracted path in the case of a geometrical shadow zone, and they can be very efficient, especially for 3D models. The disadvantages are that they are computationally cumbersome for calculating later arrivals, and they can be inaccurate and/or computationally intensive for high-contrast media. Another type of wavefront tracking scheme that solves the eikonal equation is the fast-marching method, which is computationally efficient and unconditionally stable (Sethian and Popovici, 1999).

Nakanishi and Yamaguchi (1986) and Moser (1991) introduced the shortest path ray-tracing method based on Fermat's principle which uses a fine network of nodes and graph theory. It is capable of handling arbitrarily heterogeneous media and calculating first arrivals, reflections, and multiples. Its advantages over other methods are robustness and the fact that the grid does not have to be rectangular or regular. However, its memory and computation requirements are greater. Van Avendonk et al. (2001) developed a hybrid of the shortest path and ray bending methods that uses the shortest path algorithm to find an initial ray, and then refines it using a bending method. The result is an efficient and robust algorithm to calculate accurate traveltimes and rays for refractions and reflections in 2D and 3D media.

Traveltime tomography and inverison

The traveltime t between a source and receiver along a ray L is given in integral form for a velocity field $v(\mathbf{r})$ as

$$t = \int_L \frac{1}{v(\mathbf{r})} \mathrm{d}l$$

where $\mathbf{r}$ is the position vector in 2D or 3D media. This is a nonlinear inverse problem given the relationship between the measured data (traveltimes) and the unknown model parameters (the velocity field). However, by transforming variables to use slowness $s(\mathbf{r})$, the reciprocal of velocity, instead of velocity as the unknown, a seemingly linear inversion problem is created:

$$t = \int_L s(\mathbf{r}) \mathrm{d}l.$$

However, the ray L is also dependent on the velocity (or slowness) model, thus making the inverse problem nonlinear regardless of what form of model variable or parameterization is used. In global seismology, a 1D (radially-symmetric) earth model is often used to predict the rays given the relatively small velocity heterogeneities in the mantle, and thereby converting the inverse problem into a linear one. In controlled-source seismology, there is no concept of a reference model that is sufficiently accurate to predict the rays in advance given the relatively large velocity heterogeneities that are typically encountered in the crust. This means the controlled-source tomography or inverse problem is always treated as a nonlinear one. This also means the model can be parameterized any number of ways using velocity or slowness, and cells, nodes, or splines, since the problem's nonlinearity must be dealt with regardless of the parameterization. Most often a linearized gradient approach is applied in which a starting model is used and both the model and rays are updated over a series of iterations with the hope that there will be convergence to an acceptable model (the final model).

The model is almost always discretized using cells, nodes, splines, or other interpolating functions; in the latter two cases, the discrete model parameters are the coefficients of the interpolating functions. In the simplest formulation of the tomography problem, the model is parameterized using constant-slowness cells, in which case the equation for the ith data becomes

$$t_i = \sum_j l_{ij} s_j$$

where l_{ij} is the length of the ith ray in the jth model cell and s_j is the slowness in the jth cell. In vector–matrix form this is

$$\mathbf{t} = \mathbf{L}\mathbf{s}.$$

Applying a Taylor series expansion to this equation keeping only the linear term and assuming the rays are independent of slowness yields the perturbation equation

$$\delta\mathbf{t} = \mathbf{G}\delta\mathbf{s}$$

where $\delta\mathbf{t}$ is the data misfit vector equal to the difference between the observed traveltimes and those predicted by a prior model, and $\delta\mathbf{s}$ is the difference between the unknown slowness model and the prior slowness model; the unknown model is also called the estimated model. The partial derivative matrix, $\mathbf{G}$, contains the elements $g_{ij} = \partial t_i / \partial s_j$, and for the constant-slowness cell parameterization, $g_{ij} = l_{ij}$, or $\mathbf{G} = \mathbf{L}$. In the general case, the elements of the partial derivative matrix are $g_{ij} = \partial t_i / \partial m_j$ where m_j is the jth model parameter, which could be the velocity at a node or the coefficient of an interpolating function, or the position of an interface within the velocity model (e.g., Zelt and Smith, 1992). In the general case, the perturbation equation becomes

$$\delta\mathbf{t} = \mathbf{G}\delta\mathbf{m}.$$

The elements of the partial derivative matrix $\mathbf{G}$ are usually calculated analytically to avoid the potential inaccuracy of numerical differencing and the extra computation needed to trace additional rays. The approximations involved in the analytic partial derivatives, e.g., the stationary ray assumption, are typically not a problem since the resultant gradient direction in model space will be improved over a series of iterations.

The perturbation equation is not solved directly because the unknown model parameters are typically under- or mix-determined (Menke, 1989), depending on the model parameterization; with relatively few model parameters, it is possible for the problem to be overdetermined, but even in this case the perturbation equation is not solved directly because it is wise to constrain the magnitude of the model perturbation to avoid violating the linearization assumption. Thus, model constraints, in addition to the observed data, are usually included to stabilize the solution. Also, all observed data contain noise and to avoid over-fitting noisy data, additional model constraints are required to select one model from an infinite number that will statistically predict the observed data at the equivalent desired misfit according to the estimated noise level. This issue points out the non-uniqueness of all inverse problems involving real data, regardless of whether the system of equations is overdetermined or underdetermined.

The additional model constraint is called regularization (e.g., Scales et al., 1990), and in addition to stabilizing a solution, it is an effective way of steering the solution towards models with desirable pre-defined characteristics. The regularization is most often in the form of the zero-, first- or second-order spatial derivatives of the estimated model parameters, or their perturbation from a background model. This is because it is often desirable to seek an estimated model that is as close as possible to another model, and/or a model that has a minimum structure as measured by its spatial derivatives in keeping with Occams's principle (Constable et al., 1987). Regularization is always arbitrary, and the specific form of

regularization that is best for a particular problem depends on the model parameterization, the data, including its coverage and noise level, and the experimental objectives.

The most common forms of regularization in traveltime problems are the minimization of the model's perturbation from a background model, and/or the minimization of the second-order spatial derivative of either the model, or its perturbation from a background model. A model with minimum perturbation is called the smallest model; a model with minimum second-order derivative is called the smoothest model. Any combination of model constraints may be included as a part of the regularization to form the objective function, $\Phi(\mathbf{m})$, where $\mathbf{m}$ is the vector containing the estimated model parameters. The objective function usually measures the square of the data misfit vector and the square of the perturbation or spatial derivative operators comprising the regularization so that minimizing the objective function leads to a linear system of equations that is amenable to efficient algorithms for their exact or approximate solution. One example of an objective function for the traveltime problem is

$$\Phi(\mathbf{m}) = \delta\mathbf{t}^{\mathrm{T}}\mathbf{C}_d^{-1}\delta\mathbf{t} + \lambda\left\{\beta\left[\alpha\left(\mathbf{v}^{\mathrm{T}}\mathbf{W}_h^{\mathrm{T}}\mathbf{W}_h\mathbf{v}+s_z\mathbf{v}^{\mathrm{T}}\mathbf{W}_v^{\mathrm{T}}\mathbf{W}_v\mathbf{v}\right)\right.\right.$$
$$\left.\left.+(1-\alpha)\Delta\mathbf{v}^{\mathrm{T}}\mathbf{W}_p^{\mathrm{T}}\mathbf{W}_p\Delta\mathbf{v}\right]+(1-\beta)\left[\mathbf{z}^{\mathrm{T}}\mathbf{W}_z^{\mathrm{T}}\mathbf{W}_z\mathbf{z}\right]\right\}$$

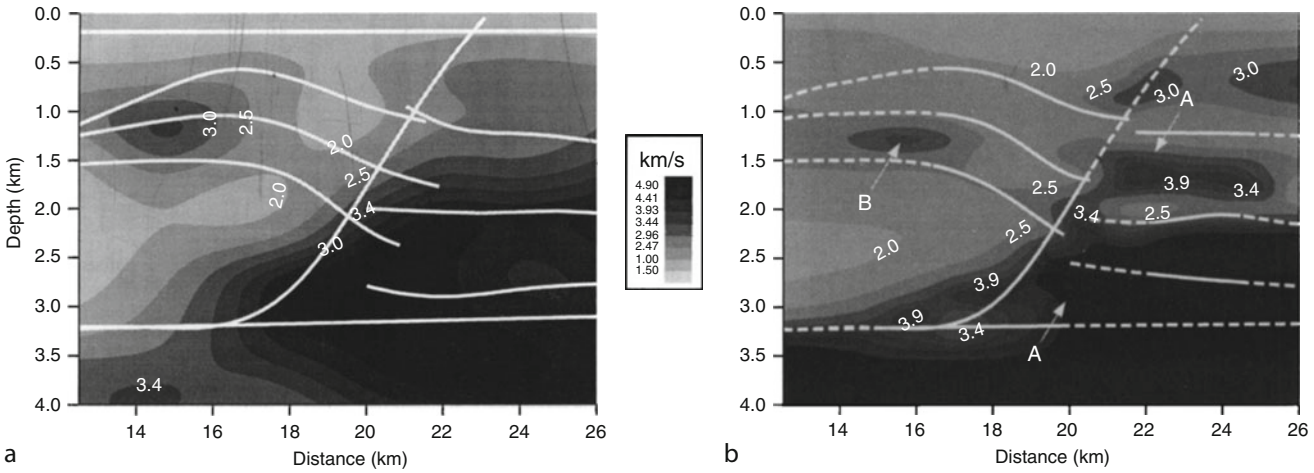
where $\mathbf{m} = \mathbf{v} + \mathbf{z}$; $\mathbf{v}$ and $\mathbf{z}$ are vectors containing the estimated model parameters defining the velocity (or slowness) field and the interfaces (if any); $\Delta\mathbf{v}$ is the velocity perturbation vector equal to $\mathbf{v}$-$\mathbf{v}_{\mathrm{o}}$, and $\mathbf{v}_{\mathrm{o}}$ is the background velocity model vector. $\mathbf{C}_{\mathrm{d}}$ is the data covariance matrix containing the estimated pick uncertainties providing the appropriate up-weighting and down-weighting of the low-noise and high-noise data, respectively. $\mathbf{W}_{\mathrm{h}}$ and $\mathbf{W}_{\mathrm{v}}$ are the horizontal and vertical roughness matrices containing the second-order spatial finite-difference operators that measure the roughness of the velocity field in the horizontal and vertical directions, respectively; $\mathbf{W}_{\mathrm{p}}$ is the velocity perturbation weighting matrix which is a diagonal matrix containing the weights applied to the perturbation between each estimated and background velocity model parameter; $\mathbf{W}_z$ is the interface roughness matrix containing the second-order spatial finite-difference operators that measure the roughness of the interfaces. When applying spatial derivative operators to the velocity field, it is common to use different operators to measure the horizontal and vertical structure, and weight these differently, since one would normally expect the earth to contain more heterogeneity vertically compared to horizontally. Any or all of these operators may be normalized by the reference model values so that relative quantities are penalized as opposed to absolute values (e.g., Toomey et al., 1994). In addition, the operators can be weighted according to their spatial position in the model, e.g., penalize model structure more in the deep portion of the model versus the shallow portion since one would generally expect decreasing resolution with depth.

There are four free parameters in this example objective function to control the relative weight of each term. λ determines the overall amount of regularization, that is, the trade-off between fitting the data and constraining the model; β determines the trade-off between velocity and interface regularization; α determines the trade-off between second derivative and perturbation regularization of the velocity parameters; and s_z specifies the relative weight of vertical versus horizontal smoothing regularization of the velocity parameters. In some algorithms, λ is not a free parameter because it is reduced automatically by the algorithm at each iteration from a free-parameter starting value, λ_{o} (e.g., Zelt and Barton, 1998). The reduction of λ stabilizes the inversion by constraining the long-wavelength structure in the initial iterations and allowing progressively finer model structure to enter in later iterations.

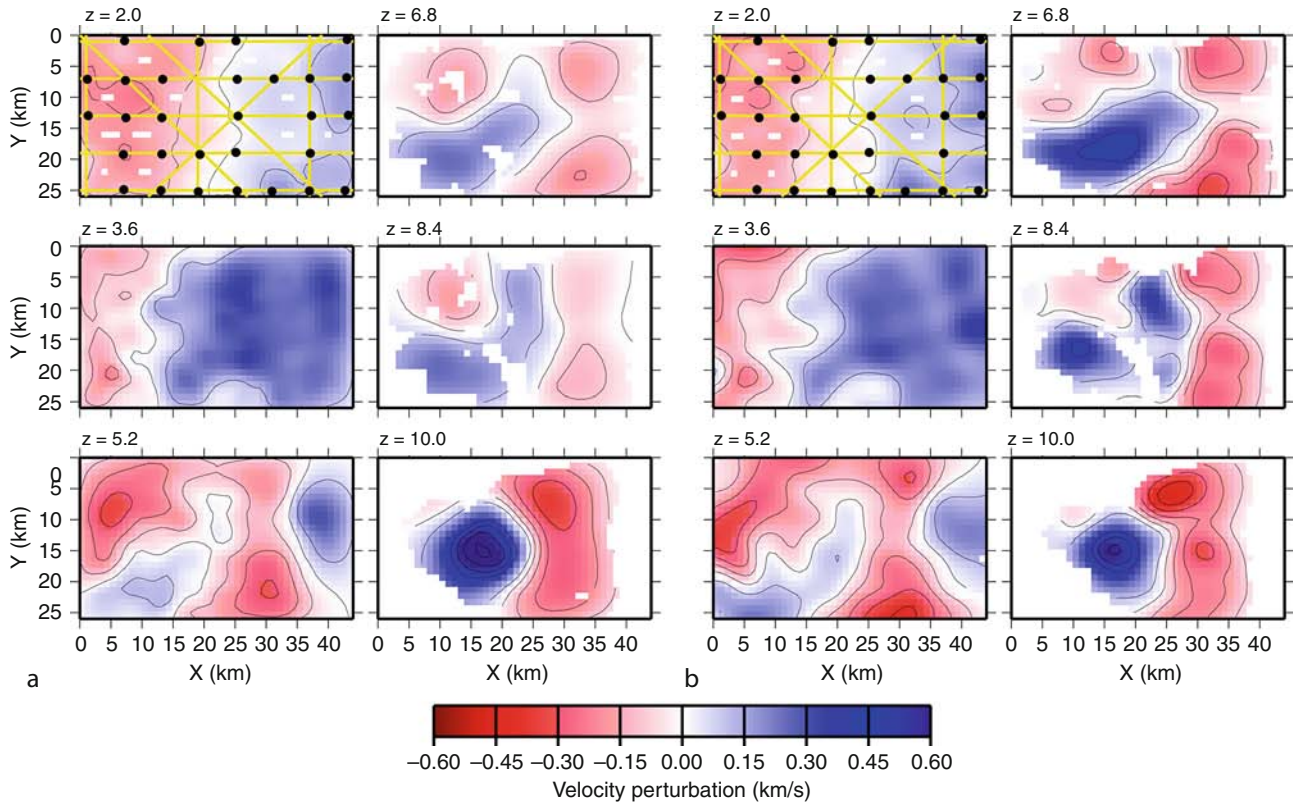
Minimizing the objective function with respect to the unknown model parameters ($\mathbf{v}$ and $\mathbf{z}$) leads to a linear system of equations that may be relatively small or very large, depending on the number of data and model parameters. If the linear system is large, it will also typically be very sparse (at least 99.9%), in which case there are efficient algorithms for their solution (e.g., Paige and Saunders, 1982; Rawlinson et al., 2001). If the linear system is relatively small, it can be solved directly using standard matrix inversion routines, such as LU decomposition (Press et al., 1992).

The objective function presented is designed to illustrate in a single example the different types of regularization that are most commonly applied. In practice, the objective function will typically be simpler depending on the data, model parameterization, and experimental goal. This objective function can be simplified or modified to correspond to those used in most of the popular traveltime inversion and tomography algorithms used today. For example, the Zelt and Smith (1992) inverse method includes only perturbation constraint on the velocity and interface parameters with respect to the model from the previous iteration; the Zelt and Barton (1998) tomographic method includes only smoothness constraints on the velocity field. Thus, together with their very different model parameterizations to be discussed in the next section, these two algorithms can been viewed as end-members of the same regularized inverse approach, and most algorithms in use today fall somewhere in between. In fact, the main differences between the algorithms discussed in the next section lies not in the details of the objective function, but more so in the form of model parameterization, forward calculation, and the types of arrivals considered.

For layered models, including both velocity and interface parameters in a single inversion scheme, as opposed to solving for each parameter separately, either one after the other, or by alternating between the two, makes the



Traveltime Tomography Using Controlled-Source Seismic Data, Figure 2 Synthetic example of reflection tomography for a smooth velocity model by Lailly and Sinoquet (1996) based on real data from a passive margin with a salt structure and a listric fault. (**a**) True model. The reflectors (white curves) are embedded in the smooth velocity field and are allowed to cross each other. (**b**) Estimated model using reflections from the continuous portions of the reflectors (white curves); the parts of the reflectors represented by dashed lines are not illuminated by rays.



Traveltime Tomography Using Controlled-Source Seismic Data, Figure 3 Example of 3D first-arrival tomography applied to ocean-bottom-seismometer (OBS) data from the Faeroe Basin to find the minimum-structure model (Zelt and Barton, 1998). (**a**) Model obtained using smoothing-regularized tomography. (**b**) Model obtained using back-projection tomography method of Hole (1992). Horizontal slices of velocity perturbations with respect to a 1D starting model are shown at the depths labeled from 2 to 10 km. The OBS locations and shot lines are overlaid on the z = 2 km slice. Regions not sampled by rays are blank. Contour interval is 0.1 km/s. Both models provide the same level of fit to the data, but the model from back-projection contains more structure overall. The high-velocity anomaly at z = 10 km likely indicates a basement high.

problem significantly more challenging. There will be more model non-uniqueness because of trade-offs between the two parameter types, and more prior information will be required to deal with the increased ambiguity. Also, more testing will be required to ensure that the trade-offs are fully understood. But solving for both parameter types simultaneously allows one to explore the trade-offs more thoroughly and is the only way to ensure the overall minimum-structure model is obtained, if that is the objective.

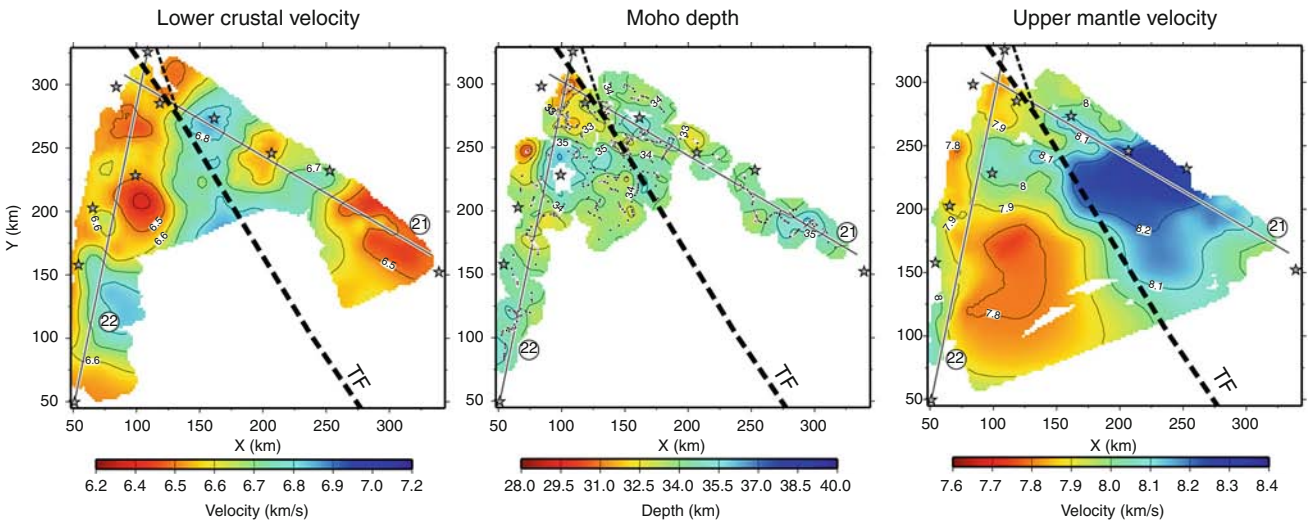
Assuming uncorrelated, Gaussian picking errors, and a model parameterization that does not limit the degree to which the predicted data can match the variability of the observed data, a final model should be chosen that provides a normalized misfit, χ^2, of one (Bevington, 1969).

$$\chi^2 = \frac{1}{N}\left[\delta\mathbf{t}^{\mathrm{T}}\mathbf{C}_d^{-1}\delta\mathbf{t}\right]$$

where N is the number of data. A model that provides a χ^2 value less than one means the observed data are being over-fit, and therefore to some extent, the noise in the data is also being fit. Although the χ^2 criterion is a good rule of thumb, there are several instances in which it should not be followed. First, traveltime picking errors are likely not uncorrelated. Second, for spatially sparse data from a region with strong lateral heterogeneities, it may be necessary to use so many independent model parameters in order to achieve $\chi^2 = 1$ that the constraint on some parameters is unacceptably small, in which case fewer parameters may be preferable and a χ^2 value greater than one is allowed (Zelt, 1999). An inability to achieve $\chi^2 = 1$ may be because of inconsistent picking, for example for reciprocal pairs, in which case the inconsistencies should either be corrected or used as the basis for assigning the pick uncertainties in the first place (e.g., Zelt et al., 2006a).

Algorithms

This section describes many of the algorithms available today, each with its own capabilities and limitations. Some of the earliest 2D traveltime tomography and inversion algorithms were presented by Firbas (1981) and White (1989) which used regular parameterizations and only first arrivals, and Spence et al. (1985) which allowed an irregular model grid and later arrivals. Lutter and Nowack (1990) and Lutter et al. (1990) developed a 2D inversion algorithm using a regular grid of nodes and numerical ray tracing that allows for the independent inversion of first arrivals and reflections for velocity and interface geometry, respectively. The Zelt and Smith (1992) 2D algorithm is the opposite in many respects. An irregular grid of velocity and interface nodes can be used, and any type of refracted or reflected arrival can be inverted simultaneously for velocity and interface geometry. In addition, unique to the Zelt and Smith (1992) algorithm, it allows any subset of the total set of model parameters to be inverted for, holding all others fixed, facilitating an automated forward modeling approach and making it straightforward to incorporate prior information. Clowes et al. (1995) used the Zelt and Smith (1992) algorithm to simultaneously invert refraction and reflection times from

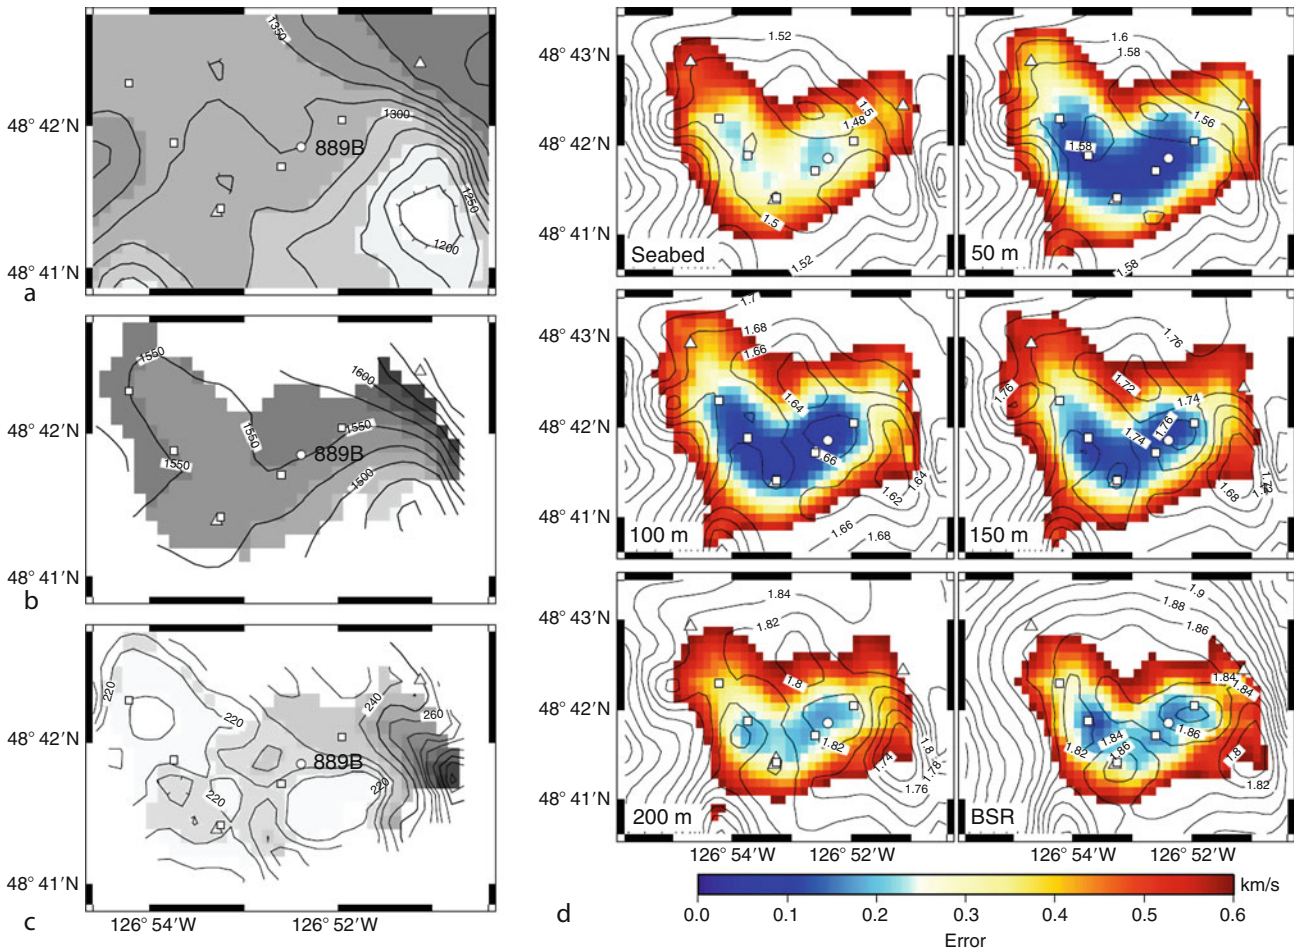


Traveltime Tomography Using Controlled-Source Seismic Data, Figure 4 Example of simultaneous 3D first-arrival and reflection tomography of sparse crustal data across the Tintina strike-slip fault in the northern Canadian Cordillera (Zelt et al., 2006b). Left panel shows the lower crustal velocity averaged vertically between 1 and 15 km above the Moho. Center panel shows depth to Moho; dots show reflection points. Right panel shows the upper mantle velocity averaged vertically between 1 and 15 km below the Moho. Stars are shot locations. The straight lines labeled 21 and 22 indicated the best-fit lines of the crooked profiles containing the receivers locations. Regions not sampled by rays are blank. Dashed line is the surface location of the fault. There is a 0.3–0.4 km/s change in upper mantle velocity across the fault.

a network of 2D profiles such that the model parameters at the intersection points were linked to ensure consistency. This approach can be used to infer 3D structure from 2D data, or develop a starting model for full 3D inversion if offline data is available in addition to inline data (e.g., Zelt et al., 1999).

Hole (1992) developed a 3D first-arrival tomography algorithm using the Vidale (1990) forward modeling scheme and back projection to solve for a smooth velocity field. Hammer et al. (1994) developed a 3D first-arrival tomography algorithm specially suited to sparse data using a spectral, continuous function model parameterization. Toomey et al. (1994) developed a 3D first-arrival tomography algorithm to obtain a smooth velocity field in which the velocity grid is "draped" from an irregular bathymetric surface by vertically shearing the columns of nodes to accurately model seafloor relief. Vertically sheared grids are particularly important for marine data, especially at mid-ocean ridges, where a large velocity discontinuity may exist. Other algorithms with sheared grids have been developed by Van Avendonk et al. (1998) and Korenaga et al. (2000), although they are limited to 2D models, but include reflections. The main difference between these two algorithms is the former uses first arrivals that can turn above or below a reflecting interface at which there is no velocity discontinuity, whereas the latter only uses first arrivals that turn above a reflecting interface.

Lailly and Sinoquet (1996) developed a 2D algorithm for inverting reflection times to estimate a smooth velocity

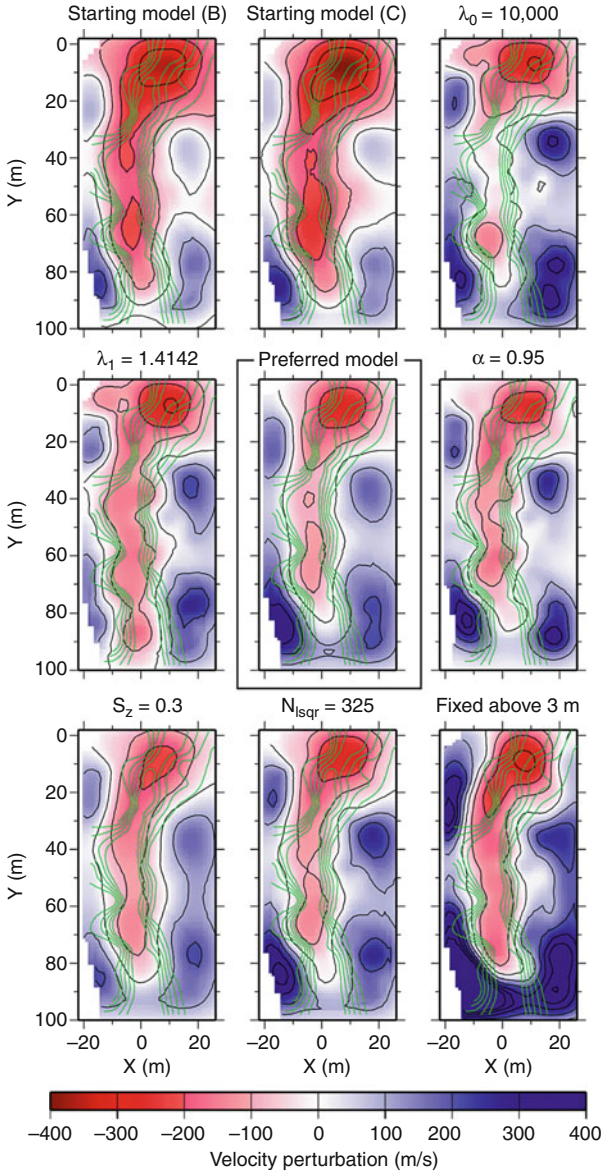


Traveltime Tomography Using Controlled-Source Seismic Data, Figure 5 Example of simultaneous 3D refraction and reflection tomography of OBS data and coincident single channel reflection profiles over a gas hydrate stability zone offshore Vancouver Island (Hobro et al., 2005). (**a**) Seafloor depth. (**b**) Bottom simulating reflector (BSR) depth. (**c**) BSR depth below the seafloor. (**d**) Slices through the velocity model at the seafloor, at 50-m intervals through the hydrate stability zone and immediately above the BSR. Labeled contours indicate velocities (km/s) and color scale marks formal uncertainty estimates. Ten OBS positions and ODP site 889 are marked. Refracted arrivals from above and below the BSR were inverted along with wide-angle and normal-incidence reflections from the BSR.

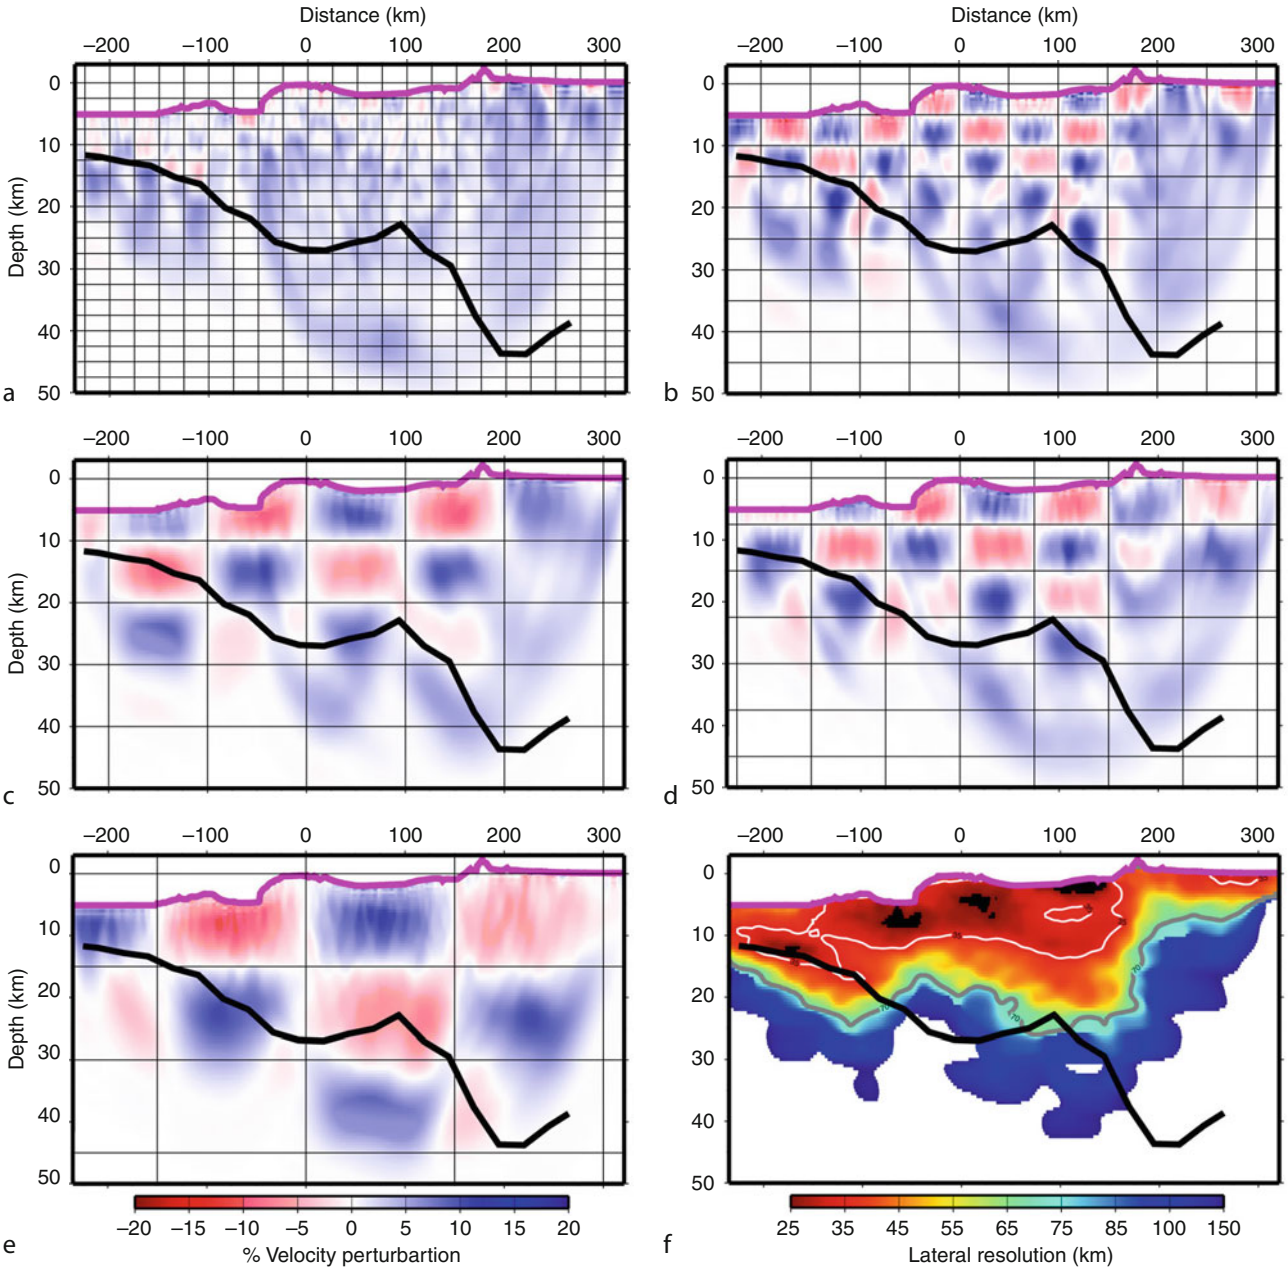
model for pre-stack depth migration of reflection data using the wavefront tracking method of Podvin and Lecomte (1991) for the forward calculation (Figure 2). Zelt and Barton (1998) developed a 3D first-arrival tomography algorithm using smoothing regularization and compared the results with those from the back-projection method of Hole (1992) (Figure 3). The results showed that for the same level of fit to the data, regularized inversion can provide a simpler model. Zelt et al. (2006b) applied 3D simultaneous refraction and reflection tomography to solve for smooth velocities and multiple interfaces using a sparse crustal-scale 3D dataset (Figure 4). McCaughey and Singh (1997) and Hobro et al. (2003) developed related 2D and 3D simultaneous refraction and reflection tomography algorithms that solve for smooth velocities and interfaces with the allowance for discontinuities across the layer boundaries (Figure 5).

Most of the algorithms described above are general purpose in nature and follow more or less from the objective function presented in the previous section. However, more specialized algorithms have been developed and a few are described here to give a sense of what is possible. Hole et al. (1992) developed an algorithm for determining a 3D interface using first arrivals with known velocities above and below the interface. Zhang et al. (1998) inverted traveltime curves instead of points, specifically average slowness and apparent slowness. They claim this balances the contribution from short and long rays, and enhances resolution and convergence speed. Rawlinson and Sambridge (2003b) developed an algorithm for the inversion of refraction and reflection times using a 3D multi-layered model parameterization. Interfaces are defined by a non-uniform node distribution and velocities vary linearly with depth so rays are calculated analytically as piece-wise circular arcs using a shooting method. Trinks et al. (2005) presented a method for simultaneous refraction and reflection inversion using a 2D layered model parameterization which adapts to non-uniform ray coverage such that the cell size is inversely proportional to the local ray density.

Refraction/wide-angle reflection traveltimes can be jointly inverted with coincident near-vertical reflection times in several ways (Zelt, 1999). Arrivals in pre-stack reflection data can be picked and inverted jointly with the wide-angle data, but it is often difficult to pick weak events in pre-stack data. The most common approach is to pick reflections from a stacked reflection section and invert these data simultaneously with the wide-angle data by modeling zero-offset reflections (e.g., McCaughey and Singh, 1997; Zelt et al., 2003). One potential pitfall when using coincident reflection data is incorrectly correlating the near-vertical reflection event with the corresponding wide-angle event or layer boundary; Jaiswal et al. (2006) present a way to avoid this problem. As an alternative to joint inversion, the reflector geometries and interval velocities from stacked data can be used as prior information in the regularization to constrain a layered velocity model (e.g., Bosch et al., 2005).

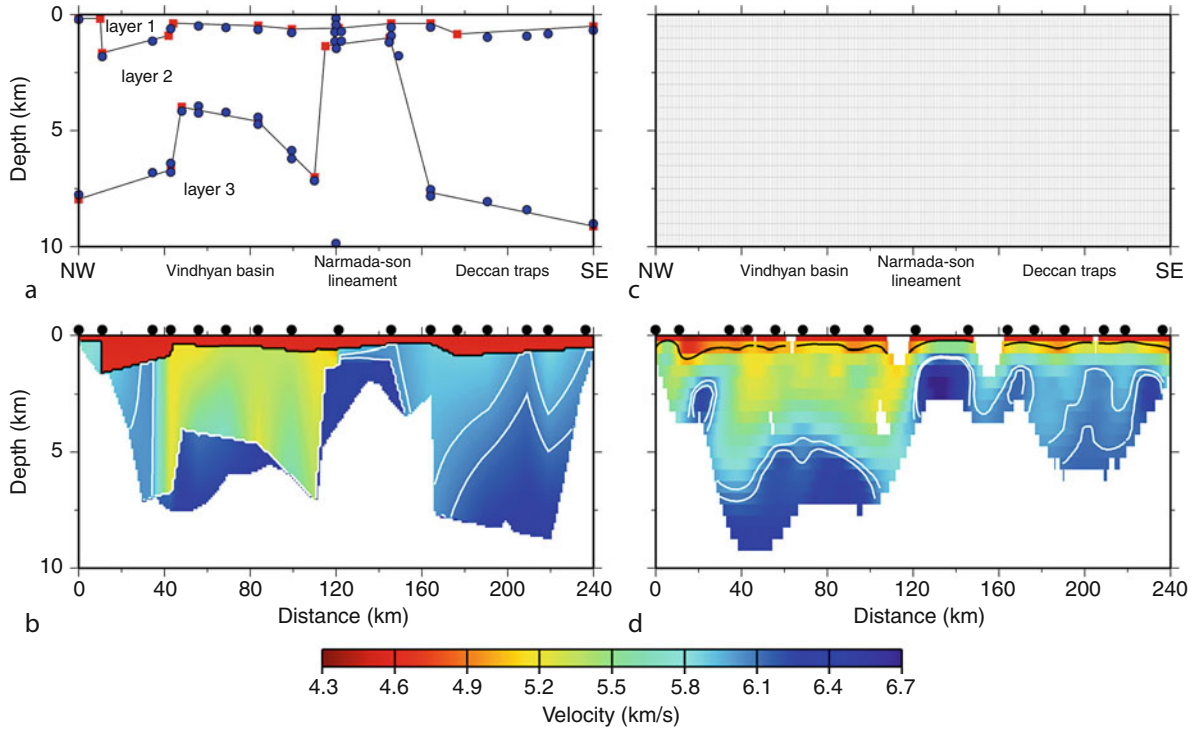


Traveltime Tomography Using Controlled-Source Seismic Data, Figure 6 Example of model assessment for near-surface 3D first-arrival tomography at a groundwater contamination site (Zelt et al., 2006a) using the Zelt and Barton (1998) regularized inversion algorithm seeking a minimum-structure model. Target of the surface was a low-velocity paleochannel cut into a clay layer running roughly north-south through the center of the survey area. The depth to the clay layer was known from extensive well data in the area; depth-to-clay contours (green) from 7 to 11 m overlay the depth slices at 10 m for this comparison of nine different models. Models displayed as perturbations relative to a 1D starting model; the starting velocity at this depth is 1150 ms/s. The preferred final model is in the center. The other models were obtained by trying two different starting models, different values for five free parameters that control the inversion, and by fixing the model above 3 m at the starting model values. Overall, the preferred model has minimum structure; the model in the lower left appears simpler in this depth slice, but it is rougher vertically.



Traveltime Tomography Using Controlled-Source Seismic Data, Figure 7 Example of 2D first-arrival checkerboard test for crustal data from an onshore-offshore experiment across the South American-Caribbean plate boundary at 67°W (Magnani et al., 2009). There were shots and receivers both onshore and offshore. (**a**)–(**e**) show recovered checkerboard anomalies for sizes from 25×2.5 km to 150×15 km. (**f**) Estimated lateral resolution of the velocity model using a 2D version of the method presented by Zelt (1998). Regions with better than 25 km resolution are black; regions with worse than 150 km resolution are white. Pink line indicates the land surface and bathymetry. The coast line is at ~160 km. Black line indicates the Moho from the preferred final model.

The close relationship between seismic velocity and density (Brocher, 2005) lends gravity data to a joint inversion with traveltime data. Nielsen and Jacobsen (2000) used the Zelt and Smith (1992) algorithm as the basis for a simultaneous inversion of refraction and reflection times with gravity data to derive a layered 2D crustal model. Korenaga et al. (2001) carried out a joint inversion of traveltime and gravity data in which error propagation from the velocity model to the predicted gravity anomalies was taken into account.

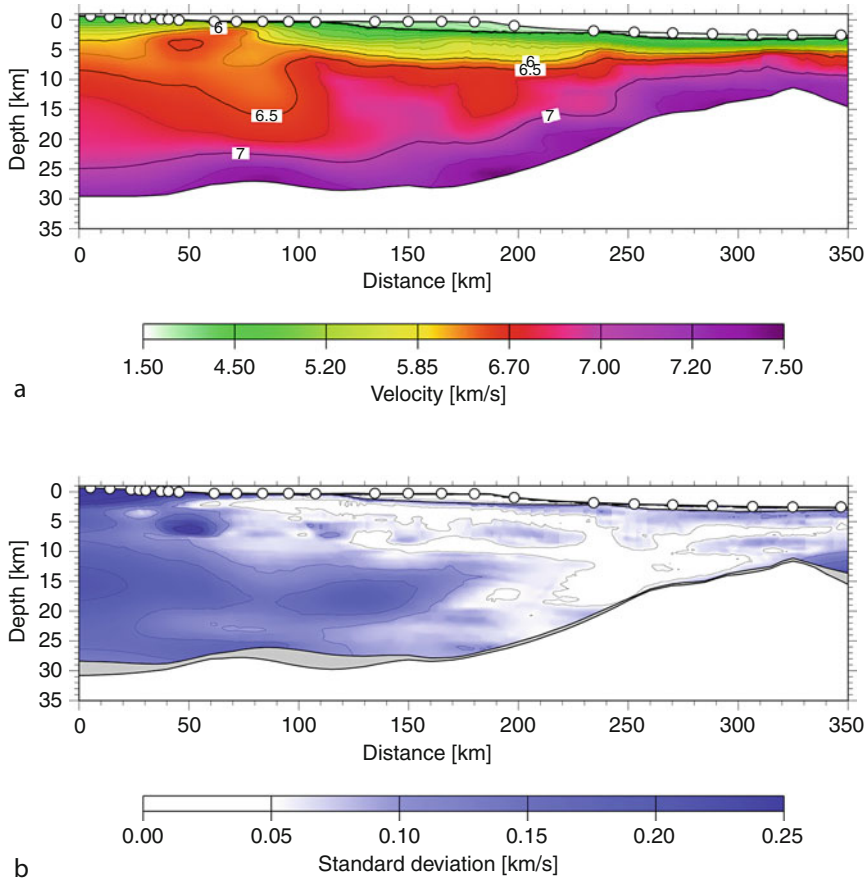


Traveltime Tomography Using Controlled-Source Seismic Data, Figure 8 Example from central India across the Narmada-Son lineament of applying two different traveltime inversion algorithms to the same refraction/wide-angle reflection data (Zelt et al., 2003) to compare the "geological" model with the minimum-structure model. (**a**) Layered model parameterization using the Zelt and Smith (1992) algorithm; there are 43 velocity nodes (blue dots) and 21 interface nodes (red squares). (**b**) Velocity model corresponding to parameterization in (**a**); both first arrivals and reflections from the top of the third layer were used. (**c**) Fine-grid model parameterization using the Zelt and Barton (1998) algorithm to seek a smooth minimum-structure model; there are 7018 slowness cells. (**d**) Velocity model corresponding to parameterization in (**c**); only first arrivals were used. Only those portions of the models sampled by rays are shown. Isovelocity contours of 5.0 km/s (black) and 6.0 and 6.1 km/s (white) indicated. Shot point locations (black dots) and geologic features labeled above the models. An interpretation of the main features of the geological model in (**b**) is supported by the minimum-structure model in (**d**) since it contains the same features.

Model assessment

Once a model to explain a particular set of data is developed, model assessment should be used to explore the non-uniqueness, resolution, and errors associated with the model. This is an attempt to quantify the robustness of the model, a process that is not straightforward for nonlinear inverse problems, and different assessment techniques will be appropriate depending on the data, model parameterization, geologic target, and objectives of the experiment. There are two classes of assessment methods: linear and nonlinear. The former methods assume it is valid to consider only a local neighborhood of the final model within which the model-data relationship is linear. The latter methods involve additional nonlinear inversions of the real data or synthetic data using the true source-receiver geometry of the experiment. Linear methods are quick and easy to apply, although potentially less reliable depending on the nonlinearity of the problem. Nonlinear methods are computational intensive, often more so than what was needed to derive the final model, and may require a specialized inversion algorithm. However, nonlinear methods are the only way to properly estimate the final model's robustness. Zelt (1999) and Rawlinson and Sambridge (2003a) describe many of the assessment techniques in use today, while Zelt et al. (2006a) apply several different techniques to the same 3D dataset (Figure 6).

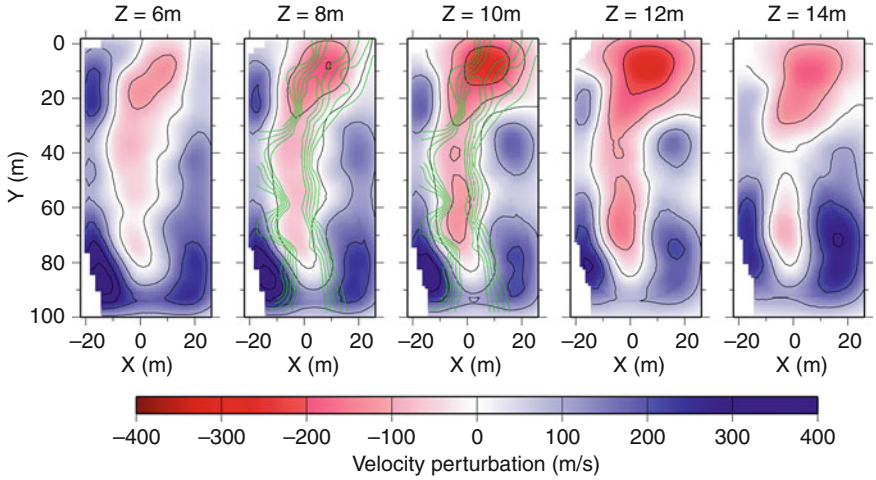
The simplest form of model assessment is to examine the ray coverage in the model using ray plots or "hit counts" (the number of rays sampling each model parameter). These can be misleading since a limited distribution of ray angles may provide less independent model constraint than expected from the number of rays alone. For example, rays in the uppermost mantle will tend to be sub-horizontal, and therefore capable of providing little lateral resolution. Toomey et al. (1994) used a measure called derivative weight sum (DWS) that equals the sum of the partial derivatives for each model parameter. This is somewhat more meaningful than hit count since it weights



Traveltime Tomography Using Controlled-Source Seismic Data, Figure 9 Example of model assessment using a nonlinear Monte Carlo procedure to estimate model variance (Korenaga et al., 2000). (**a**) Velocity model for the southeast Greenland continental margin obtained by joint traveltime inversion of first arrivals and wide-angle Moho reflections recorded at 18 OBS's and eight land stations (white circles). This model was obtained by averaging 100 Monte Carlo ensembles. (**b**) Corresponding standard deviation for velocity and depth nodes; the standard deviation of the Moho is indicated by the width of the grey zone at the base of the crust.

the contribution from each ray according to the parameter's sensitivity to that ray. However, it also fails to account for the degree of independence within the ray set. Other common linear assessment measures include an examination of the diagonals of the posterior resolution and covariance matrices (e.g., Zelt and Smith, 1992). These are more precise measures since they account for the independence of the ray set, but they are best used in a relative as opposed to absolute sense, since they do not account for the nonlinearity of the problem. Rows of the resolution matrix, known as resolution kernels, provide a spatial sense of the averaging of the true structure by the model (Zelt, 1999). Probably the most precise linear assessment method uses singular value decomposition (SVD) since it is able to quantify the nature and degree of model constraint through construction of an orthogonal set of basis vectors that span model space, each with a specified weight in the model reconstruction (e.g., White, 1989; Scales et al., 1990).

A nonlinear assessment of the spatial resolution or uncertainty of a single model parameter, or set of parameters, is possible in which the real data and synthetic data are inverted in the same way that the final model was derived, allowing the full nonlinearity of the problem to be accounted for, including trade-offs between model parameters (Zelt and White, 1995; Zelt, 1999; Christeson et al., 1999). For spatial resolution, the value of a model parameter is perturbed enough to yield a significant traveltime anomaly with respect to the pick uncertainties. Rays are traced through the perturbed model to calculate a set of perturbed traveltimes. The perturbed data are then inverted using the final model as the starting model. The spatial resolution about the selected parameter will be indicated by the amount that the values of adjacent parameters differ from their corresponding value in the original final model. If the model is poorly resolved about the selected parameter, then the parameter's perturbation will be smeared into adjacent parameters, perhaps both



Traveltime Tomography Using Controlled-Source Seismic Data, Figure 10 Example of near-surface 3D first-arrival tomography at a groundwater contamination site (Zelt et al., 2006a) using the Zelt and Barton (1998) regularized inversion seeking a minimum-structure model. The Horizontal depth slices from 6 to 14 m displayed as perturbations relative to a 1D starting model. Black contour interval is 100 m/s. Target of the surface was a low-velocity paleochannel cut into a clay layer running roughly north-south through the center of the survey area. The depth to the clay layer was known from extensive well data in the area; depth-to-clay contours (green) from 7 to 11 m overlay the 8 and 10 m depth slices. This experiment consisted of ~600 shots recorded by ~600 receivers yielding ~360,000 traces, providing 187,877 useable picks for the inversion.

velocities and interface depths if both parameter types are involved, and the extent of the smearing indicates the spatial resolution. Both positive and negative parameter perturbations should be tested, and it will likely be sufficient to examine only one or two representative velocity and interface parameters for each layer or region of the model.

A parameter-selective algorithm such as the Zelt and Smith (1992) approach allows for a nonlinear estimate of a single parameter's absolute uncertainty (Zelt, 1999). The value of the model parameter is slightly perturbed from its value in the final model and held fixed while inverting the observed data involving all other model parameters. The size of the perturbation is increased until the recovered model is unable to fit the observed data as well as the preferred final model based on an F test comparing the traveltime fits of the preferred and perturbed final models. The maximum parameter perturbation that allows a comparable fit to the observed data is an estimate of its absolute uncertainty. Again, both positive and negative parameter perturbations should be tested, and it will likely be sufficient to examine only one or two representative velocity and interface nodes for each layer or region of the model. A fine grid tomographic approach can also be used to perform tests like these. For example, Zelt and Barton (1998) examined one region of a model where there was significant lateral structure even though the constraint from the ray coverage was known to be low in this area. They added regularization to the inversion to force that region to remain laterally homogeneous and thereby establish the required trade-offs elsewhere in the model.

One of the most common forms of nonlinear model assessment to estimate spatial model resolution is the checkerboard test (e.g., Magnani et al., 2009; Figure 7). In these tests an alternating pattern of high and low anomalies is superimposed on the starting model from the inversion of the real data. Synthetic data are calculated for the "checkerboard" model, and then inverted using the same starting model and source-receiver geometry as the real data. The recovered model will closely resemble the checkerboard pattern in regions of good constraint, but will otherwise not resemble the checkerboard model. The resolution at different length scales can be estimated by testing anomaly patterns of different sizes. Anomaly patterns with different polarity, registration, and orientation should be tested to average out the effects of changing ray coverage due to the nonlinearity of the problem (Zelt, 1998).

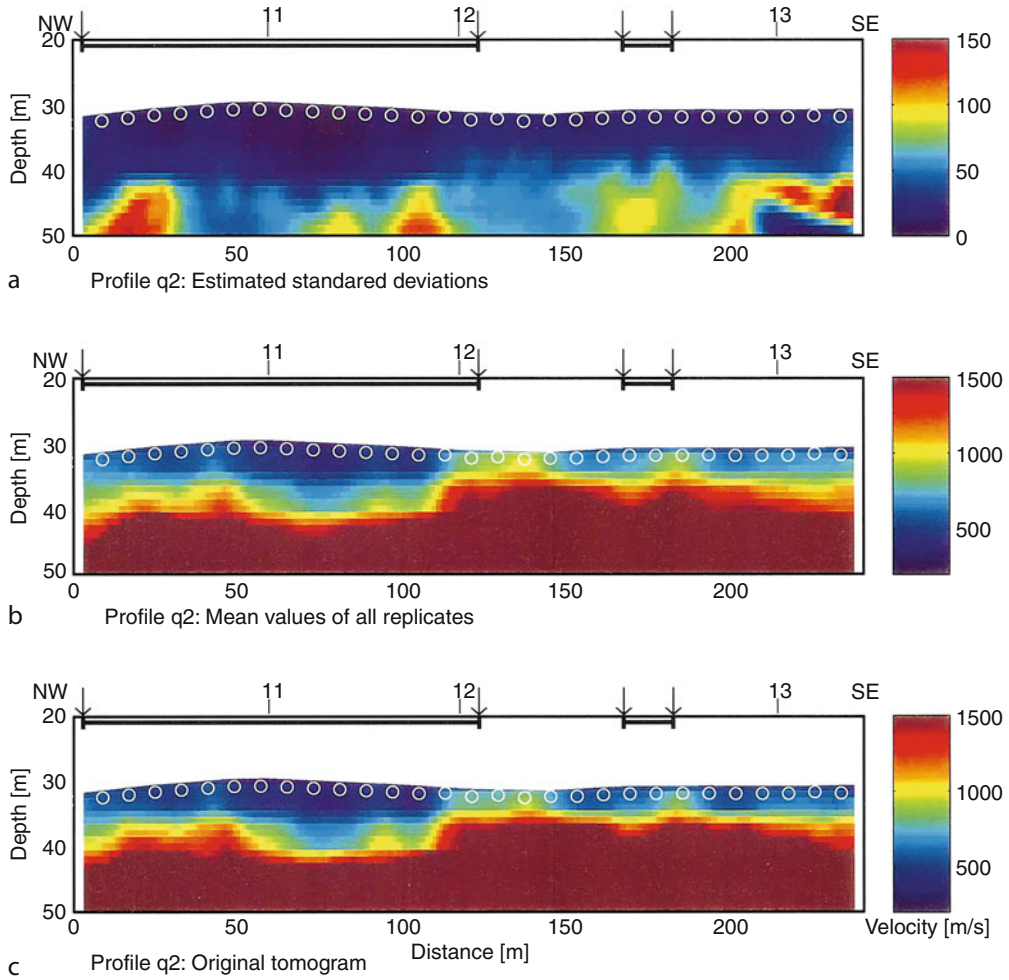
Other nonlinear assessment techniques include trying different starting models, different values of the free parameters in the objective function, and exclusion of subsets of the data considered less reliable (e.g., Zelt et al., 2006a; Figure 6). Using different model parameterizations and different inversion algorithms can be effective, especially when one inversion algorithm seeks a model that satisfies all notions of what is geological reasonable, and one algorithm seeks the minimum-structure model (Figure 8; Zelt et al., 2003). In this way, it is possible to determine what model structure is consistent with the data to facilitate hypothesis testing, while at the same time establishing what model structure is required by the data.

Perhaps the most complete and computationally intensive form of model assessment involves a nonlinear Monte Carlo procedure. Many inversions are performed in which randomized data and/or randomized starting models are used. The resulting models are used to compute posterior model covariance and resolution estimates. Zhang et al. (1998) and Korenaga et al. (2000) applied this approach to 2D inversions of first arrivals and reflections (Figure 9).

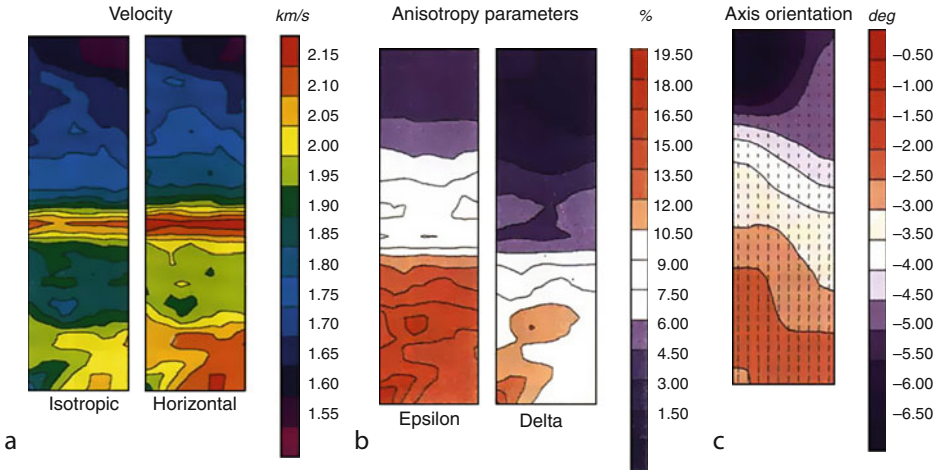
More examples

The examples in Figures 1–9 demonstrate the types of models that can result from a wide range of controlled-source experiments. The remaining examples presented in this section are intended to round out the range of applications to which traveltime tomography and inversion are applied in controlled-source studies, and the types of model structure that can result. The main purpose of the examples is to show what is possible in terms of tomographic imaging of different kinds of geologic features in the near-surface, upper crust, lower crust, and uppermost mantle using traveltime data. All examples shown in this article use only P-wave traveltime data.

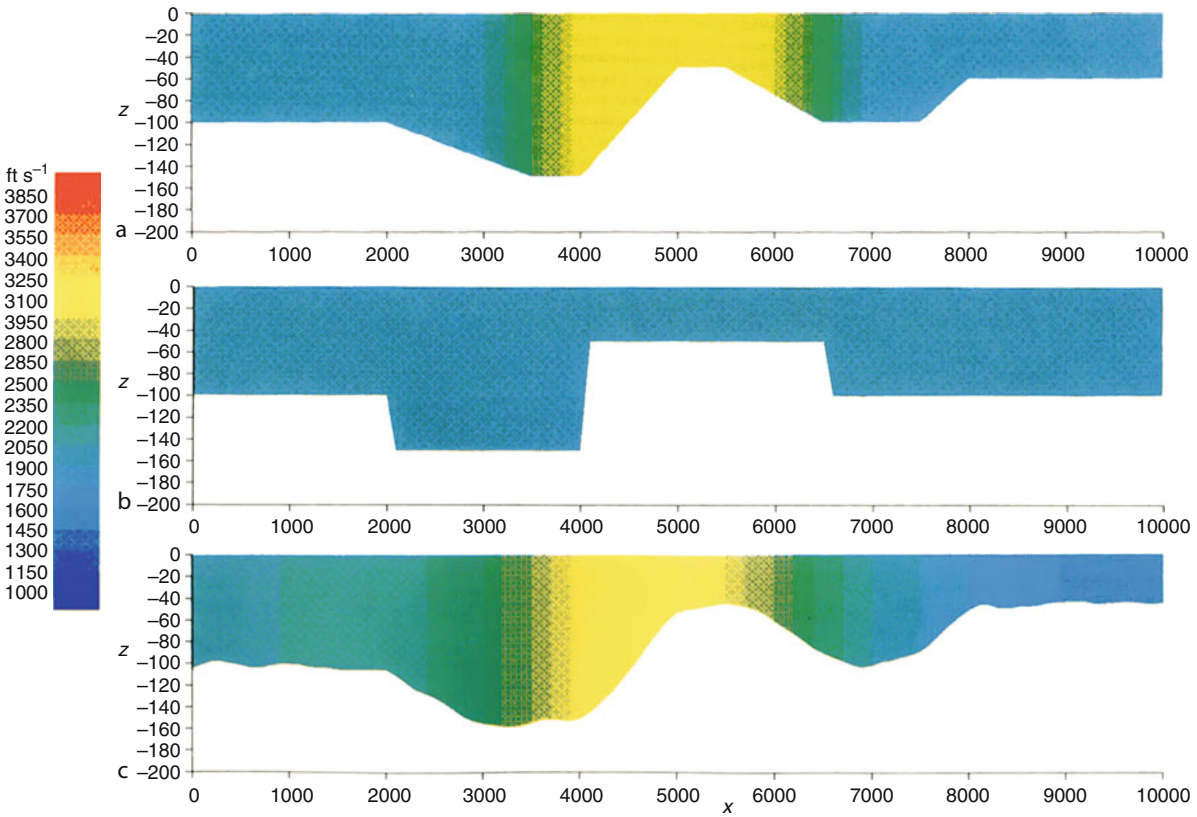
Zelt et al. (2006a) applied the regularized 3D first-arrival tomography algorithm of Zelt and Barton (1998) to a dense 3D dataset from a groundwater contamination site (Figure 10). Lanz et al. (1998) applied 2D first-arrival tomography and a Monte Carlo scheme to estimate a smooth model with standard deviations for a buried waste disposal site (Figure 11). Pratt and Chapman (1992) applied 2D first-arrival tomography to crosswell data to simultaneously determine velocity and anisotropy



Traveltime Tomography Using Controlled-Source Seismic Data, Figure 11 Example of near-surface first-arrival tomography over a buried waste disposal site seeking a smooth model (Lanz et al., 1998). (**a**) Estimated standard deviation of velocities computed using 200 randomized datasets. (**b**) Mean velocity model from 200 randomized datasets. (**c**) Preferred final model from inversion of original picked data. Open circles are shot locations. Arrows indicate landfill borders defined by several other geophysical techniques.



Traveltime Tomography Using Controlled-Source Seismic Data, Figure 12 Example of crosswell tomography in which transverse isotropy is assumed and regularization was used to seek a smooth model (Pratt and Chapman, 1992). The velocity and anisotropic parameters were solved for simultaneously. (**a**) Comparison of isotropic velocity model and horizontal velocity model from anisotropic inversion. The model is 20 m across and 60 m deep. (**b**) Anisotropy parameters. The amount of anisotropy generally increases with depth, reaching nearly 20%. (**c**) Symmetry axis orientation. The length of the markers is proportional to one of the anisotropy parameters (epsilon).

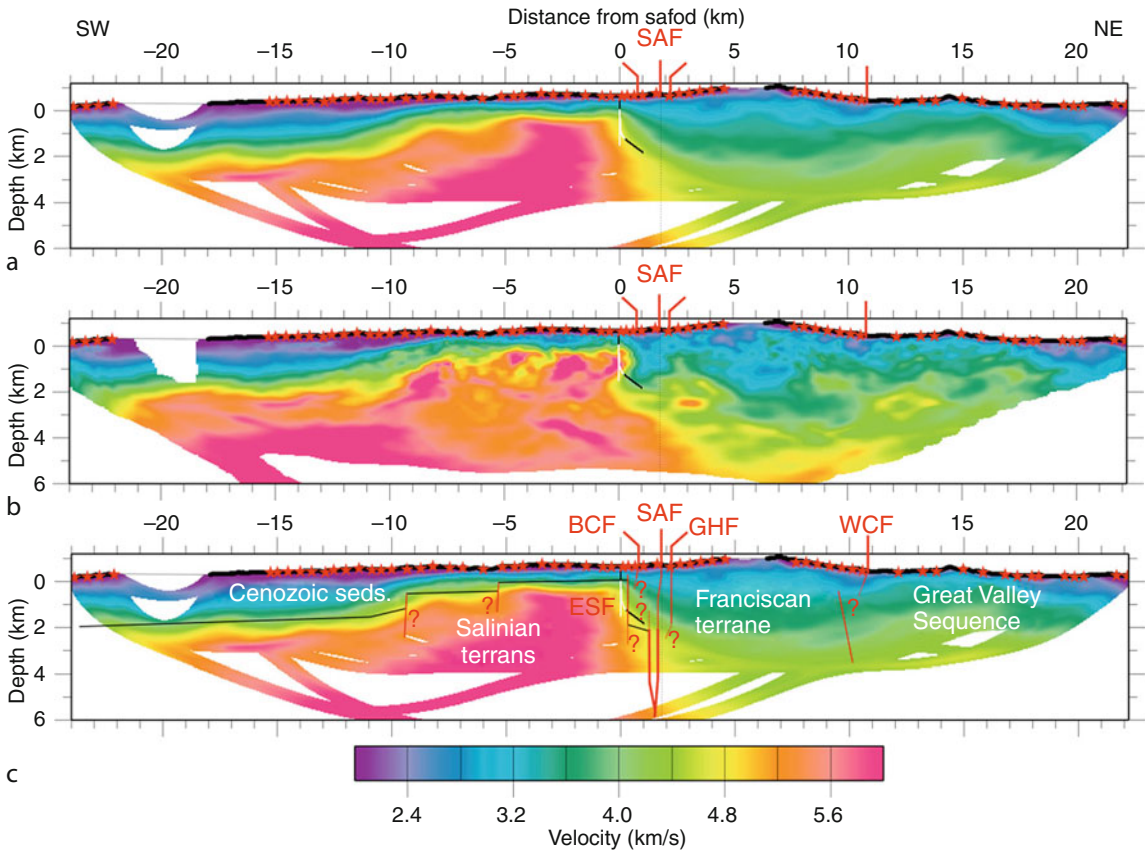


Traveltime Tomography Using Controlled-Source Seismic Data, Figure 13 Example of imaging the near-surface weathering layer (i.e. the refraction statics problem) using smoothing regularization (Scales et al., 1990). Shots were placed at either end of the model and there were 100 receivers between them. (**a**) True model. Refractor velocity is 5000 ft/s. (**b**) Starting model with blocky thickness variations in the weathering layer. Refractor velocity is 4000 ft/s. (**c**) Final model. Refractor velocity is 5001 ft/s. The inversion solved simultaneous for a laterally-varying weathering-layer velocity and refractor, and a constant refractor velocity.

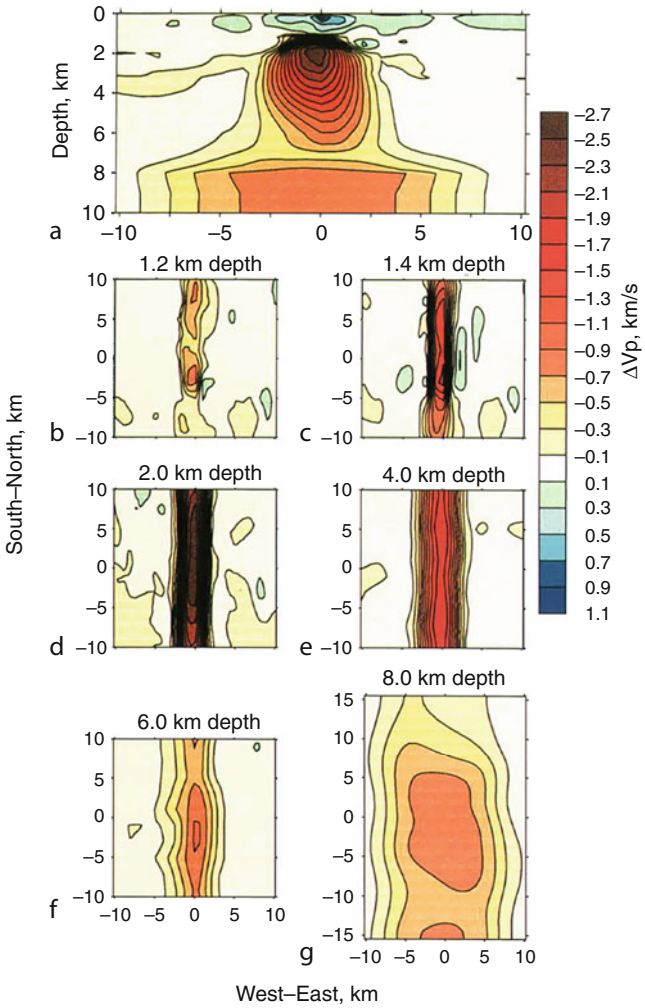
parameters (Figure 12). Scales et al. (1990) imaged a near-surface weathering layer using 2D first-arrival times, solving simultaneously for lateral variations in the velocity and thickness of the layer (Figure 13). Hole et al. (2006) applied 2D first-arrival tomography to data recorded across the San Andreas Fault using two different algorithms (Figure 14). Dunn et al. (2000) applied 3D refraction and reflection tomography incorporating anisotropy to data from the East Pacific Rise (Figure 15). Van Avendonk et al. (1998) inverted refraction and reflection times for a smooth 2D velocity model and an assumed flat Moho across the Clipperton transform fault (Figure 16). Clark et al. (2008) inverted refractions and reflections from an onshore–offshore survey across the South American-Caribbean plate boundary using a smooth tomography approach for the upper crust, and a layer-based inversion for the lower crust, Moho, and upper mantle (Figure 17). Zelt et al. (2003) compared layer-based simultaneous refraction and reflection inversion with independent smooth refraction and reflection tomography for three different 2D crustal datasets (Figure 18).

Future

Full 3D seismic experiments are likely to become more commonplace, necessitating the need for some of the popular 2D tomography and inversion algorithms to be extended to 3D. It is likely that three-component, S-wave, and converted-wave studies will become more widespread, especially for near-surface environmental and engineering studies, necessitating the need for algorithms that can perform coupled P-wave, S-wave, or Poisson's ratio inversions. The desire to incorporate or determine anisotropy will likely become more commonplace in the



Traveltime Tomography Using Controlled-Source Seismic Data, Figure 14 Example of first-arrival tomography across the San Andreas Fault comparing models from two different algorithms (Hole et al., 2006). There were 63 shots (red stars) and 912 receivers (Thick black line). (**a**) Velocity model from application of the Hole (1992) back-projection method. (**b**) Velocity model from application of Zelt and Barton (1998) smoothing-regularized method. Both models provide roughly the same level of fit to the picks. Regions without ray coverage are white. Well-log observations at SAFOD (San Andreas Fault Observatory at Depth) are white for granite and black for sedimentary rock. Note how high velocities (>5 km/s) better match the known position of granite in the well for the model in (**b**) compared to the model (**a**), suggesting that some of the additional structure in the model in (**b**) may be true. (**c**) Geology and fault interpretation overlaid on the model in (**a**). Black lines are top of basement; red lines are faults.

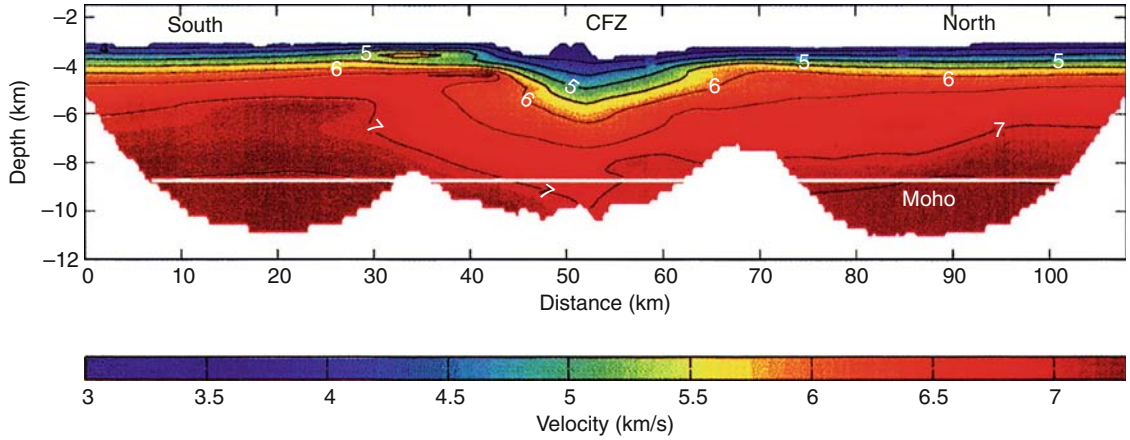


Traveltime Tomography Using Controlled-Source Seismic Data, Figure 15 Example of 3D refraction and reflection tomography across the East pacific Rise at 9°30′N for crust and uppermost mantle structure (Dunn et al., 2000). There were 15 OBS's and 480 explosive sources. Refracted arrivals from the crust and upper mantle and reflections from the Moho were simultaneously inverted. Anisotropy of 4% in the crust and 7% in the upper mantle was included in the modeling. Final velocity model as perturbations relative to a 1D model are shown and are contoured at 0.2 km/s intervals. (**a**) vertical section through the center of the model. (**b**–**g**) Depth slices from 1.2–8.0 km beneath the seafloor. The low-velocity body is interpreted to represent melt distribution within a magmatic system.

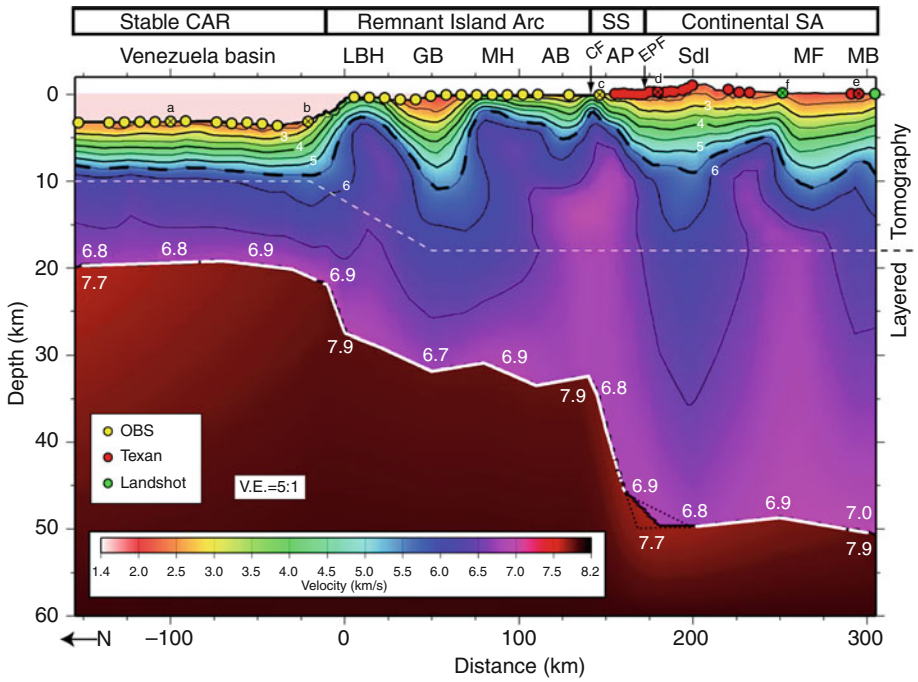
future, and there are currently only a few traveltime algorithms that include any form of anisotropy (e.g., Dunn et al., 2000).

For all scales of seismic experiments, the need for flexible, general-purpose traveltime tomography and inversion algorithms will remain, both as the primary modeling tool and to provide long-wavelength starting models for higher-resolution full waveform inversion techniques (e.g., Brenders and Pratt, 2007). The Zelt and Smith (1992) traveltime inversion algorithm has been widely used for many years for several reasons: (1) an irregular, layered model parameterization adaptable to the data coverage and geologic structures, (2) parameter-selective inversion, (3) any type of body-wave data can be modeled, and (4) it is easy to incorporate prior information. As such it stands apart from most other popular algorithms that use a uniform, fine grid parameterization, and consider only first arrivals, and in some cases reflections. However, the Zelt and Smith (1992) algorithm was primarily intended for relatively sparse 2D data. There will likely be a niche for a new version of the Zelt and Smith algorithm if it maintains all of its current advantages, but is extended to 3D and includes regularization to handle dense data, namely second-order derivatives to seek a smooth, minimum-structure model.

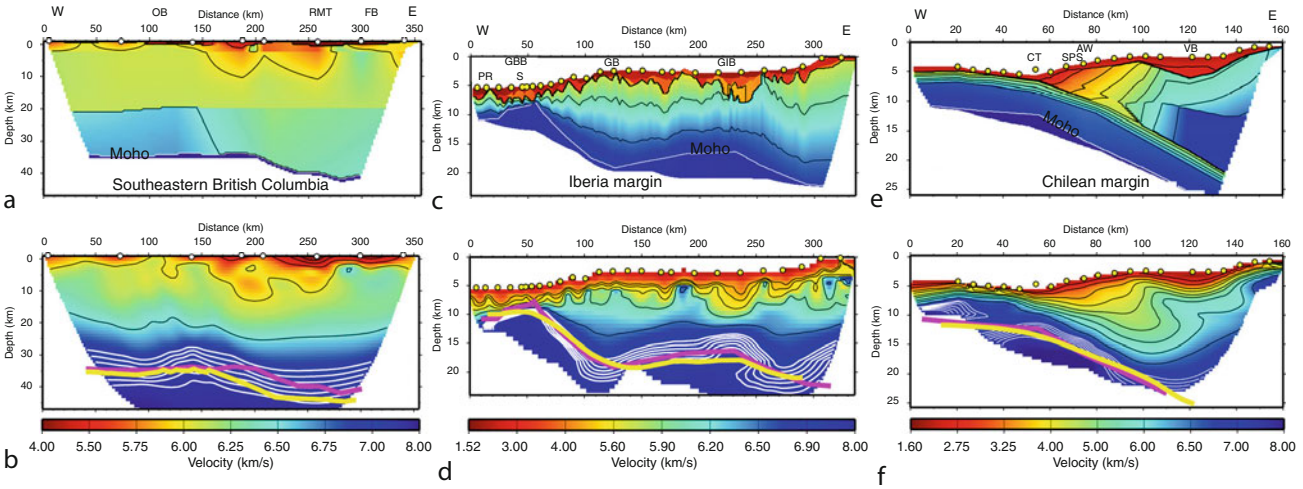
About 10 years ago, a theory for traveltime tomography was developed in global seismology to take into account the finite-frequency nature of seismic data (Dahlen et al., 2000). This method is known as finite-frequency traveltime tomography and it yields what are popularly known as banana-doughnut sensitivity kernels. By taking finite-frequency effects into account, this form of traveltime tomography should, theoretically, yield a more accurate estimation of velocity anomalies in terms of their magnitude and spatial resolution because the physics of wave propagation is treated more accurately. The theory developed for global seismology uses as input data delay times relative to a reference Earth model, and as such the theory is generally not applicable to controlled-source data. This is because for controlled-source data there is no requisite reference velocity model known in advance that is capable of yielding realistic synthetic waveforms that are close enough to the recorded seismograms to yield a meaningful delay time through cross correlation of the waveforms because the crust and near-surface are much more laterally heterogeneous than the mantle. As a result, a nonlinear inverse method must be used, requiring a starting model, an iterative method and recalculated travel paths at each iteration. In addition, the method must be capable of calculating a frequency-dependent traveltime along the total path, as opposed to a delay time. Zelt (2009) presented a finite-frequency traveltime tomography method specifically designed for controlled-source data, that is, a nonlinear inversion of total traveltimes, with frequency taken into account for both the forward calculation of traveltimes, and in the inverse step by calculating the appropriate frequency-dependent sensitivity kernels. The results show it is possible to achieve more accurate velocity estimation than in the equivalent infinite-frequency-derived models. And in addition, applications without any regularization are possible, and therefore finite-frequency traveltime tomography has the potential to allow the data alone to determine the model structure in a robust manner. These characteristics of finite-frequency traveltime tomography



Traveltime Tomography Using Controlled-Source Seismic Data, Figure 16 Example of 2D tomography across the Clipperton transform fault (Van Avendonk et al., 1998). There were only five OBS's. Crust and upper mantle refracted arrivals and Moho reflections were inverted simultaneously for a smooth velocity model. A flat Moho at 8.6 km depth was assumed. The model shows reduced velocities in the upper crust as far as 10 km south and 18 km north of the transform fault (CFZ).



Traveltime Tomography Using Controlled-Source Seismic Data, Figure 17 Example of crustal velocity model from onshore-offshore survey across the South American-Caribbean plate boundary at 64°W (Clark et al., 2008). There were airguns offshore, two shots on land (green dots), OBS's offshore (yellow dots), and seismometers on land (red dots). The model above the dashed white line was obtained by first-arrival tomography using the Zelt and Barton (1998) smoothing-regularized tomography algorithm; the model below the dashed line was derived using the Zelt and Smith (1992) layer-based inversion using upper mantle refractions and Moho reflections to determine a sharp velocity contrast for the Moho. The strike-slip system near the coastline at ~150 km accommodates relative motion between the two plates and from this model is interpreted to extend near vertically through the entire crust and offset the Moho.



Traveltime Tomography Using Controlled-Source Seismic Data, Figure 18 A comparison of three sets of 2D crustal velocity models obtained using two different inversion algorithms (Zelt et al., 2003). The study areas are southeastern British Columbia, the Iberia margin and the Chilean margin. The top row of "geologic" models were obtained using the Zelt and Smith (1992) layer-based algorithm simultaneously inverting crust and upper mantle refractions and Moho reflections. The bottom row of "minimum-structure" models were obtained using the Zelt and Barton (1998) smoothing-regularized first-arrival tomography algorithm. Open circles are shot locations; yellow circles are OBS's. Black contours in the crust have an interval of 0.5 km/s; white contours representing the Moho in the smooth tomographic models have an interval of 0.1 km/s from 7.0–7.6 km/s. Pink lines are the Mohos from the layered models overlain on the tomographic models for comparison. Yellow lines are the Mohos from independent reflection tomography in which the tomographic velocity models were held fixed. Interpretations of the main features of the geological models are supported by the corresponding minimum-structure models since they contain the same features.

suggest that it will play an important role in the future. This is especially true for near-surface studies where infinite-frequency (ray) theory is least likely to be valid because the length scales of heterogeneities are often comparable or smaller than the seismic wavelengths.

Definition

Dispersive. Characteristic of waves whose velocity of propagation depends on wave frequency. The shape of a dispersive wave packet changes as it moves along.
Eigenfunction. Functional shape of the horizontal and vertical components of wave motion versus depth in the ocean for a specific wave frequency.
Geometrical spreading. Process of amplitude reduction resulting from the progressive expansion of a wave from its source.
Run-up. Final phase of tsunami life starting when the wave shoals to a size equal to the water depth and begins to break, and ending when the water runs over land and reaches its highest level.
Shoal. Process of waves coming into shallow water. Shoaling waves slow, shorten their wavelength, and grow in size.
Wavenumber. Wavenumber k equals 2π divided by wavelength λ. Large wavenumbers associate with short waves and small wavenumbers associate with long waves.

Tsunami are gravity-driven water waves. They belong to the same family as common sea waves that we see every day; however, tsunami are distinct in their mode of generation and in their physical traits. Unlike common sea waves that evolve from persistent winds, most tsunami spring from sudden shifts of the ocean floor. These sudden shifts can originate from undersea landslides and volcanoes, but mostly, submarine earthquakes parent tsunami. Compared to wind-driven waves, tsunami waves have periods, velocities, and wavelengths ten or a hundred times larger and present profoundly different shoreline consequences than do their common cousins.

Tsunami = killer wave?

In the years since the 2004 Sumatra earthquake, everyone has seen disturbing videos of tsunami-caused destruction. Certainly the prospect of a "killer wave" born from some far off earthquake is frightening. More so is the thought that after traveling with stealth great distances, that wave might suddenly rise up without warning at your own doorstep. Could it be me desperately floating by in the next tsunami video?

Understandably, worst-case scenarios of natural hazards come to mind, but it is important to keep perspective.

Tsunami over 2 m high are not common. It takes a submarine earthquake greater than magnitude M8 to source a wave of this size. On a global average, only one M8+ earthquake occurs per year. Of these, maybe one in five strikes under the ocean with an orientation favorable for tsunami excitation. True, tsunami decay in transit and have shorter run-up at distant shores, so wave damage tends to localize within 1,000 km of that one in five quakes. On these accounts, tsunami that induce widespread damage and casualties number only about one per decade. Even at that modest recurrence rate, your personal risk is mitigated increasingly through education and technology. Today, ocean bottom pressure sensors detect stealthy tsunami of a few centimeters height in the open sea. Moreover, with advances in understanding, communication, and implementation since the 2004 Sumatra earthquake, scientists are better, quicker, and more specific at prediction than they were just a decade past. There is a good chance now that you will be warned and take action even if that rare wave does come your way.

Tsunami characteristics

Tsunami period, velocity, and wavelength

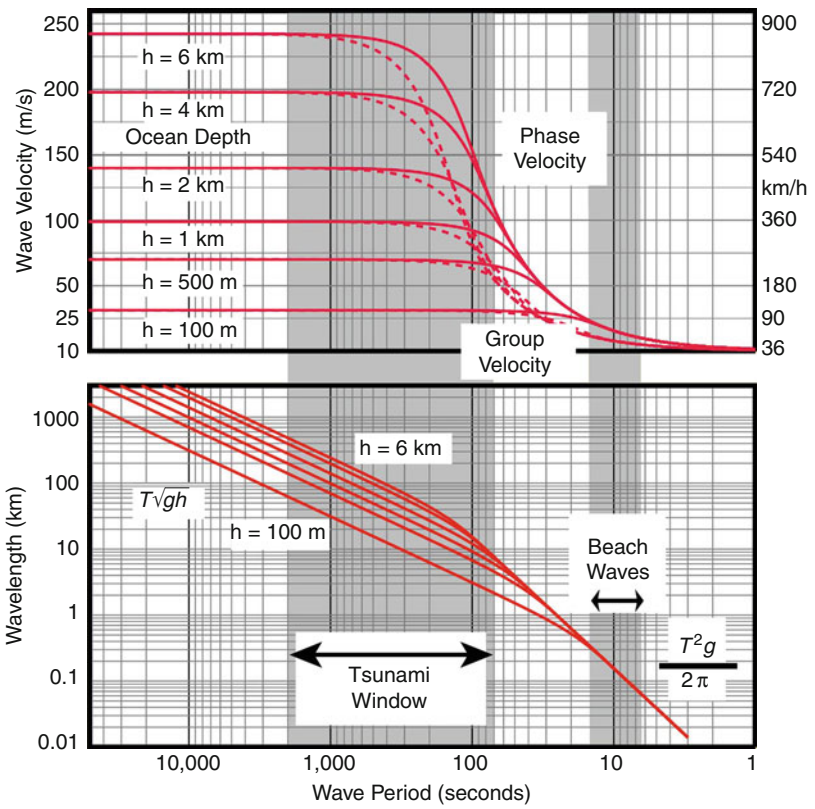
When discussing tsunami, I like to contrast them with something that we all have experienced – waves at the beach. Tsunami belong to the same family as these ordinary ocean waves but with major distinctions: principally tsunami period, tsunami velocity, and tsunami wavelength.

Tsunami period. The period (T) of a wave equals the time elapsed between one passing crest and the next. Common beach waves have a period of about 10 s (darkened column right side Figure 1). The period of tsunami depends upon what creates it (earthquake, landslide, asteroid impact), but I can tell you that tsunami have far greater periods than beach waves. The "tsunami window" in Figure 1 covers waves of 70, 200, 500, or even 2,000 s periods. Unlike "splash and dash" beach waves, tsunami arrive and may continue to flow in for several minutes. I like the description – "The ocean turns into a river." Anyone who has seen those 2004 Sumatra videos can testify that tsunami act more flood-like than wave-like.

Tsunami velocity. Under classical theory, the phase c (ω), and group u(ω) velocity of surface gravity waves on a flat ocean of uniform depth h are:

$$c(\omega) = \sqrt{\frac{gh\ \tanh[k(\omega)h]}{k(\omega)h}} \tag{1}$$

and



Tsunami, Figure 1 Phase velocity c(ω) (*solid lines*) and group velocity u(ω) (*dashed lines*) of tsunami waves on a flat earth covered by oceans of 100 m to 6 km depth (*top*). Wavelength associated with each wave period. The "tsunami window" is marked (*bottom*).

$$u(\omega) = c(\omega)\left[\frac{1}{2} + \frac{k(\omega)h}{\sinh[2k(\omega)h]}\right]. \quad (2)$$

Here, g is the acceleration of gravity (9.8 m/s^2) and $k(\omega)$ is the *wavenumber* associated with a sea wave of frequency $\omega = 2\pi/T$. Wavenumber connects to wavelength as $\lambda(\omega) = 2\pi/k(\omega)$ and to phase velocity as $c(\omega) = \omega/k(\omega)$. Wavenumber also satisfies the relation:

$$\omega^2 = gk(\omega)\tanh[k(\omega)h]. \quad (3)$$

For surface gravity waves spanning 1–50,000 s period, Figure 1 (*top*) plots $c(\omega)$ and $u(\omega)$. These velocities vary widely and increase for waves of longer periods in deeper water. The speed of ordinary sea waves is about 15 m/s (50 km/h) – the speed of a moped. Because of their longer period, waves in the tsunami window travel much more rapidly, reaching 160–250 m/s (600–900 km/h) in the open ocean. It is said that deep-water tsunami travel at the speed of a jet airliner. While true, be aware that wave energy is the quantity that runs ahead at jet speeds. The physical bits of water in a deep-water tsunami move less than a meter per second (see next section). Waves whose velocity varies with frequency are called *dispersive*. During propagation, dispersion "pulls apart" originally pulse-like waves into their component frequencies. Dispersion is strongest for waves whose period falls on the steepest slopes of the group velocity curves in Figure 1.

Tsunami wavelength. Wavelength measures the distance between one wave crest and the next. Wavelength equals the product of wave period times phase velocity $\lambda(\omega) = Tc(\omega)$. Common beach waves have a wavelength of about 100 m – the length of a football field (Figure 1, *bottom*). Tsunami, with their longer period and higher velocity, have much longer wavelengths than beach waves. In the deep ocean, tsunami span 10, 30, even 100 km between crests. If you could stand on one tsunami crest, the next one might be over the horizon. With wavelengths this large, tsunami slopes are very small even if the wave has large amplitude. For ships at sea, tsunami pass completely unnoticed.

Short wave versus long wave: Discussions of waves of length λ in oceans of depth h sometimes include two simplifications: a long wave approximation ($\lambda >> h$, $1/k >> h$) and a short wave approximation ($\lambda << h$, $1/k << h$). Under a long wave approximation [$kh \to 0$, $\tanh(kh) \to$ kh, $\sinh(2kh) \to 2kh$] Equations 1–3 predict nondispersive wave propagation with $c(\omega) = u(\omega) = \sqrt{gh}$. Long wave theory holds for the flat part of the curves in Figure 1 (*top*). Under a short wave approximation, [$kh \to \infty$, $\tanh(kh) \to 1$, $\sinh(kh) \to \infty$] the equations predict dispersive propagation with $c(\omega) = 2u(\omega) = gT/2\pi$. Short wave theory holds to the right in Figure 1 (*top*) where all the curves lie atop each other. Waves in the tsunami window have intermediate character, behaving like shallow water waves at their longest periods and like deep-water waves at their shortest periods. Neither the long nor the short wave simplification serves adequately in tsunami studies. A rigorous treatment requires an approach that works for waves of all lengths.

Tsunami eigenfunctions

Tsunami also differ from waves at the beach in the way they move the ocean. Tsunami *eigenfunctions* describe wave motion in a tsunami mode of a particular frequency. Consider coordinate system (x, y, z) where $\hat{\mathbf{x}}$ points north, $\hat{\mathbf{y}}$ east, and $\hat{\mathbf{z}}$ down. Vertical (u_z) and horizontal (u_x) components of tsunami eigenfunctions normalized to vertical amplitude A_z at the sea surface are:

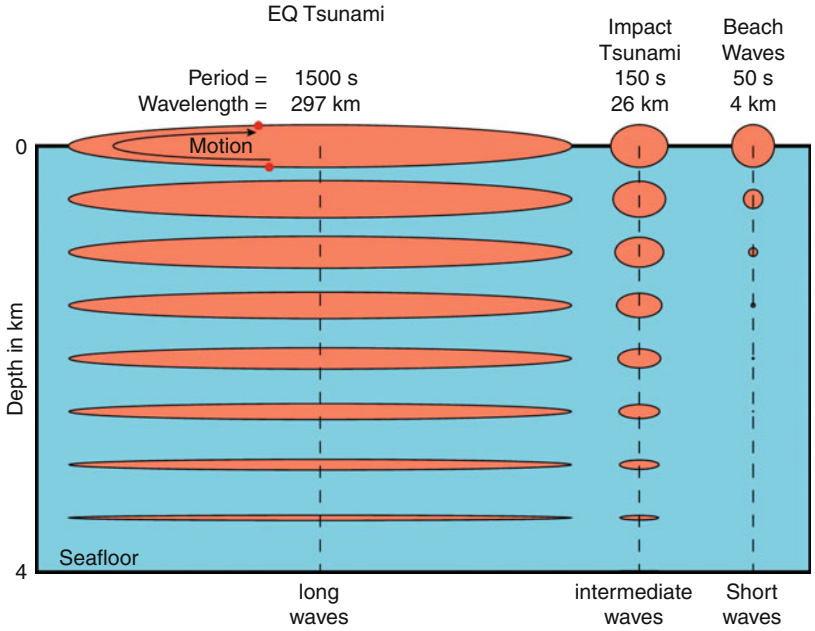
$$u_z(\omega, z) = A_z \frac{k(\omega)g}{\omega^2} \frac{\sinh[k(\omega)(h-z)]}{\cosh[k(\omega)h]} e^{i[k(\omega)x - \omega t]} \quad (4)$$

$$u_x(\omega, z) = A_z \frac{-ik(\omega)g}{\omega^2} \frac{\cosh[k(\omega)(h-z)]}{\cosh[k(\omega)h]} e^{i[k(\omega)x - \omega t]}$$

Figure 2 plots tsunami eigenfunctions versus depth in a 4-km deep ocean at long (1,500 s), intermediate (150 s), and short (50 s) periods. The ellipses trace the path of a water particle as a wave of frequency ω passes. At 50-s period (Figure 2, *right*), ordinary ocean waves have deep-water behavior. Water particles move in circles that decay exponentially from the surface. Sensibly, because the eigenfunctions of short waves do not reach to the seafloor, their velocity is independent of ocean depth [$c(\omega) = 2u(\omega) = gT/2\pi$, Figure 1, *top right*]. The failure of short waves to "feel" the seafloor also means that they cannot be excited by deformations of it. The only means to excite ordinary ocean waves is to disturb the surface.

At 1,500 s period (Figure 2, *left*), the tsunami has a wavelength of λ = 297 km and it acts like a long wave. Although vertical displacement peaks at the ocean surface and drops to zero at the seafloor, horizontal displacement persists undiminished through the ocean column. Unlike ordinary waves that are confined near the sea surface, the energy of a tsunami spreads through the entire depth of the sea. You cannot out dive a tsunami. This fact explains why tsunami can be detected by pressure sensors on the seafloor. A second distinction of tsunami versus ordinary sea waves is that their horizontal motion far exceeds their vertical motion. Every meter of up and down in a 1,500-s tsunami involves ≈10 m of back and forth. If you were to build a shore-based or space-based "tsunami detector," the large horizontal motions might make a better target than the vertical motions. Applications of Doppler radar come to mind.

Toward the short period side of the tsunami window at 150 s (Figure 2, *middle*), λ decreases to 26 km. For these tsunami waves, long wave characteristics begin to break down, and horizontal and vertical motions more closely agree in amplitude.



Tsunami, Figure 2 Tsunami eigenfunctions in a 4-km deep ocean at periods 1,500, 150, and 50 s. Vertical displacements at the ocean surface has been normalized to A_z = 1 m in each case.

From (4), it is easy to deduce the peak velocity of surface water in waves of amplitude A_z as:

$$\left|v_x^{\max}(\omega, z=0)\right| = \frac{A_z k(\omega) g}{\omega} = \frac{A_z g}{c(\omega)}. \tag{5}$$

For long waves $c(\omega)$ equals$\sqrt{gh}$, and peak surface water velocity in a 1-m amplitude tsunami in 4,000 m of waver would be just 4.9 cm/s. Peak water velocity at the sea floor

$$\begin{aligned}\left|v_x^{\max}(\omega, z=h)\right| &= \frac{A_z\, k(\omega) g}{\omega \cosh[k(\omega)h]} \\ &= \frac{A_z g}{c(\omega)\cosh[k(\omega)h]}\end{aligned} \tag{6}$$

is even less. As mentioned, although tsunami travel at several hundred meters per second, the water itself moves at a tiny fraction of this.

Tsunami excitation

Tsunami get started in many ways. Suppose that the seafloor at positions $\mathbf{r}_0$ uplift instantaneously by an amount $u_z^{\text{bot}}(\mathbf{r}_0)$ at time $\tau(\mathbf{r}_0)$. Under classical tsunami theory in a uniform ocean of depth h, this sea bottom disturbance produces surface tsunami waveforms (vertical component) at observation point $\mathbf{r} = x\hat{\mathbf{x}} + y\hat{\mathbf{y}}$ and time t of

$$u_z^{\text{surf}}(\mathbf{r}, t) = \text{Re} \int_{\mathbf{k}} d\mathbf{k}\, \frac{e^{i[\mathbf{k}\cdot\mathbf{r} - \omega(k)t]}}{4\pi^2 \cosh(kh)} F(\mathbf{k}). \tag{7a}$$

with

$$F(\mathbf{k}) = \int_{\mathbf{r}_0} d\mathbf{r}_0\, u_z^{\text{bot}}(\mathbf{r}_0) e^{-i[\mathbf{k}\cdot\mathbf{r}_0 - \omega(k)\tau(\mathbf{r}_0)]} \tag{7b}$$

$k = |\mathbf{k}|$, and $\omega^2(k) = gk\tanh(kh)$. The integrals in (7a, 7b) cover all wavenumber space and locations $\mathbf{r}_0$ where the seafloor disturbance $u_z^{\text{bot}}(\mathbf{r}_0) \neq 0$.

Equation 7a looks scary but it has three identifiable pieces:

(a) The $F(\mathbf{k})$ term is the wavenumber spectrum of the seafloor uplift. This number relates to the amplitude, spatial and time distribution of the uplift. Tsunami trains are dominated by wavenumbers in the span where $F(\mathbf{k})$ is the greatest. The peak of $F(\mathbf{k})$ corresponds to the characteristic dimension of the uplift. Large-dimensioned uplifts produce longer wavelength, lower frequency tsunami than small-dimensioned sources.

(b) The $1/\cosh(kh)$ term comes from the tsunami eigenfunction shapes (4) and it acts to low-pass filter the source spectrum $F(\mathbf{k})$. Because $1/\cosh(kh) \to 1$ when $kh \to 0$, and $1/\cosh(kh) \to 0$ when $kh \to \infty$, the filter favors long waves. Due to the low-pass filter effect of the ocean layer, only wavelengths of the uplift that exceed three times the ocean depth (i.e., $kh = 2\pi h/\lambda <\approx 2$) contribute much to tsunami.

(c) The exponential term in (7a) contains all of the propagation information including travel time, *geometrical spreading*, and frequency dispersion.

By rearranging Equation 7a, 7b, vertical tsunami motions at **r** can also be written as:

$$u_z^{\text{surf}}(\mathbf{r},t) = \text{Re}\int_0^\infty \frac{k\,\text{d}k e^{-i\omega(k)t}}{2\pi\cosh(kh)} \sum_{n=-\infty}^{\infty} \text{J}_n(kr)e^{in\theta} F_n(k)$$

with (8)

$$F_n(k) = \int_{\mathbf{r}_0} \text{d}\mathbf{r}_0\, u_z^{\text{bot}}(\mathbf{r}_0)\, J_n(k\text{r}_0)\, e^{i(\omega(k)\tau(\mathbf{r}_0)-n\theta_0)}$$

Here θ marks azimuth from north (the $\hat{\mathbf{x}}$ direction) of the observation point **r** from the coordinate origin. The $J_n(x)$ are cylindrical Bessel functions. For simply distributed uplift sources, (8) might be easier to evaluate than (7a, 7b).

Tsunami excitation by earthquakes

Earthquakes produce 80–90% of tsunami. Not surprisingly, earthquake features determine many sea wave characteristics. Earthquakes result from slip on faults and three primary parameters describe the process – moment, mechanism, and depth.

Moment measures earthquake strength. Moment M_o is the product of rigidity μ of the source region's rocks, fault area A, and average fault slip Δu. Earthquake moment and earthquake magnitude tie through a number of empirical formulae. One formula defines moment magnitude M_w as $M_w = (2/3)(\log M_o - 9.05)$. Earthquake moment varies by 2×10^4 within the magnitude range $6.5 \le M_w \le 9.5$ (Table 1). Even without a detailed understanding of tsunami generation, it is safe to suppose that the larger the earthquake moment, the larger the tsunami, all else fixed.

Mechanism specifies the orientation of the earthquake fault and the direction of slip on it. Usually, faults are idealized as plane rectangles with normal $\hat{\mathbf{n}}$. Three angles then, summarize earthquake mechanisms – the strike and dip of the fault and the angle of slip vector $\hat{\mathbf{a}}$ measured from the horizontal in the plane of the fault. (Seismologists call this angle the "rake.") The role of fault mechanism on tsunami production is not as obvious as the influence of moment; however, one might suspect that earthquakes that affect large vertical displacements of the seafloor would be more effective than faults that make large horizontal displacements.

Earthquake *depth* needs no explanation. Because seafloor shifts cause tsunami, the distance of the fault from the seafloor should be important. Presumably, deep earthquakes produce less potent tsunami than similar shallow earthquakes.

Numerical, or synthetic waveforms quantify the roles of earthquake parameters on tsunami generation. For illustration, insert into (7a, 7b) the surface uplift pattern $u_z^{\text{bot}}(\mathbf{r}_0)$ of a small earthquake fault (point source really) placed at depth d in a halfspace. Further assume that the uplift occurs instantly with $\tau(\mathbf{r}_0) = 0$. (Actually, real earthquakes uplift the seafloor over several, or several tens of, seconds. This distinction is not a big issue because tsunami waves have periods of many hundreds of seconds. Uplifts taking a few dozen seconds to develop look "instantaneous" to tsunamis.) Equation 7a, 7b becomes

$$u_z^{\text{surf}}(\mathbf{r},t) = \int_0^\infty k\,\text{d}k \frac{\cos\omega(k)t}{2\pi\cosh(kh)}\left[A\Delta u \mathbf{M}_{ij}\varepsilon_{ij}\right], \qquad (9)$$

where

$$\begin{aligned}
\varepsilon_{xx} &= -\frac{1}{4}\left(\frac{\mu}{\lambda+\mu} - kd\right)[J_0(kr) - J_2(kr)\cos 2\theta]e^{-kd}\\
\varepsilon_{yy} &= -\frac{1}{4}\left(\frac{\mu}{\lambda+\mu} - kd\right)[J_0(kr) + J_2(kr)\cos 2\theta]e^{-kd}\\
\varepsilon_{xy} = \varepsilon_{yx} &= \frac{1}{4}\left(\frac{\mu}{\lambda+\mu} - kd\right)[J_2(kr)\sin 2\theta]e^{-kd}\\
\varepsilon_{zz} &= -\frac{1}{2}\left(\frac{\mu}{\lambda+\mu} + kd\right)[J_0(kr)]e^{-kd}\\
\varepsilon_{xz} = \varepsilon_{xz} &= \frac{kd}{2}[J_1(kr)\cos\theta]e^{-kd}\\
\varepsilon_{yz} = \varepsilon_{zy} &= \frac{kd}{2}[\text{J}_1(kr)\sin\theta]e^{-kd}
\end{aligned} \qquad (10)$$

The six elements of symmetric tensor

$$M_{jk} = \left(\hat{a}_j\hat{n}_k + \hat{n}_j\hat{a}_k\right) \qquad (11)$$

capsulize the mechanism of the earthquake. In (11), $\hat{\mathbf{n}}$, $\hat{\mathbf{a}}$ are the fault normal and slip vectors introduced above. A pure dip slip earthquake on a vertical north–south

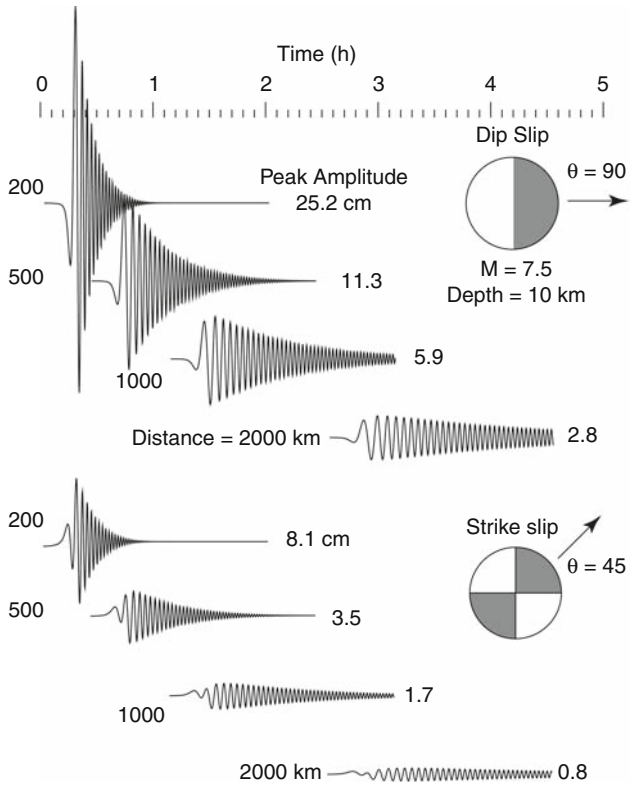
Tsunami, Table 1 Relationship between earthquake magnitude and moment with values of fault area, length, and mean slip for typical tsunami-generating earthquakes. This paper assumes $\log(L) = 0.5\,M_w - 1.8$, $\Delta u = 2 \times 10^{-5}\,L$, and $\lambda = \mu = 5 \times 10^{10}$ Pa

Magnitude M_w	Moment M_0 (Nm)	Area A (km^2)	Length L (km)	Width W (km)	Slip Δu (m)
6.5	6.3×10^{18}	224	28	8	0.56
7.0	3.5×10^{19}	708	50	14	1.00
7.5	2.0×10^{20}	2,239	89	25	1.78
8.0	1.1×10^{21}	7,079	158	45	3.17
8.5	6.3×10^{21}	22,387	282	79	5.66
9.0	3.5×10^{22}	70,794	501	141	10.0
9.5	2.0×10^{23}	223,872	891	251	17.8

trending fault for instance, has $\hat{\mathbf{n}} = \hat{\mathbf{y}}$ and $\hat{\mathbf{a}} = \hat{\mathbf{z}}$, so $M_{yz} = M_{zy} = 1$ and $M_{xx} = M_{yy} = M_{zz} = M_{xz} = M_{zx} = M_{xy} = M_{yx} = 0$.

The bracketed terms in (9) contain all of the relationships between earthquake parameters and tsunami features. Some relationships are easy to spot: tsunami amplitudes from earthquakes are proportional to the product of fault area and average slip ($A\Delta u$); tsunami amplitudes decrease with earthquake depth via the e^{-kd} terms. The ε_{ij} provide the dependence of tsunami amplitude and azimuthal radiation pattern on source type. Equation 10 says that tsunami from point sources radiate in azimuthal patterns no more intricate than $\sin 2\theta$ or $\cos 2\theta$.

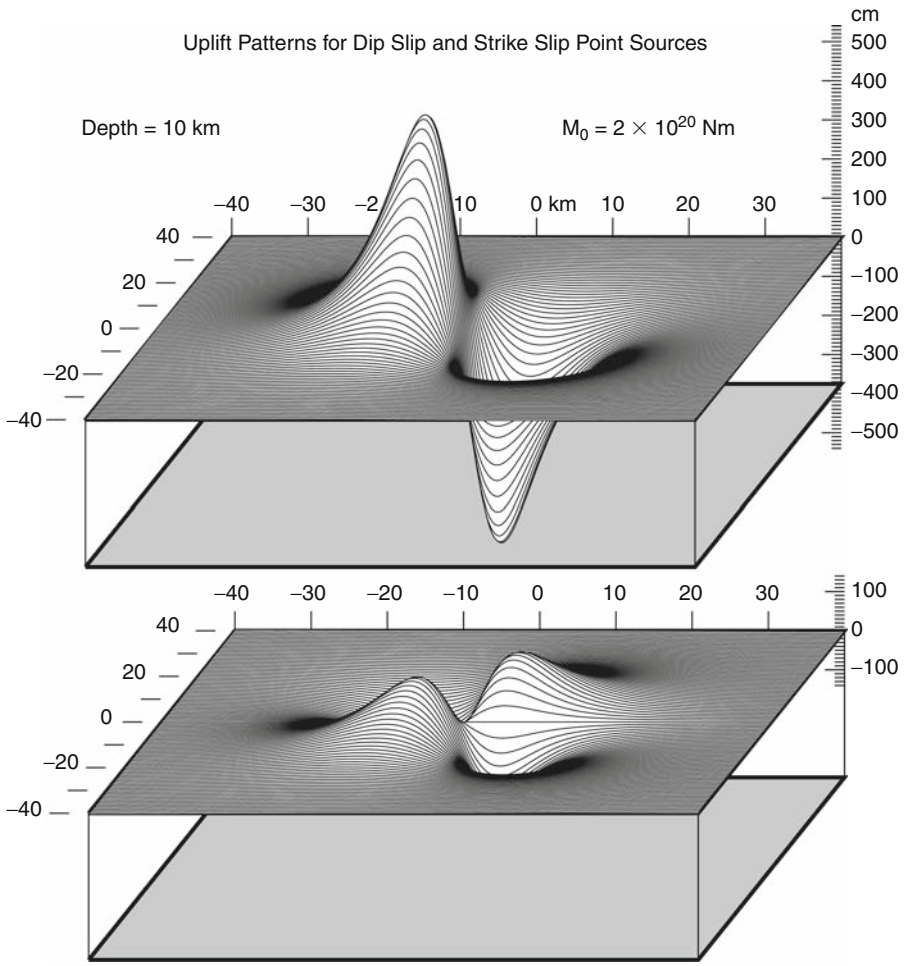
Figure 3 shows 5 h of tsunami waveforms calculated from (9) at distances of r = 200, 500, 1,000, 2,000 km from dip slip ($M_{yz} = M_{zy} = 1$) and strike slip ($M_{xy} = M_{yx} = 1$) point sources of magnitude $M_w = 7.5$ ($\Delta uA = 3.98 \times 10^6$ m^3. See Table 1) buried at 10 km depth. Sea waves from these sources have radiation patterns of $\sin\theta$ and $\sin 2\theta$, respectively. I compute the waveforms in Figure 3 at the azimuth of maximum strength, $\theta = 90°$ and $\theta = 45°$. Frequency dispersion, with the long periods arriving first, is the most conspicuous feature of the waveforms. Tsunami onset rapidly. They reach maximum height in the first few cycles and then decay slowly over an hour or more. Even for this large earthquake, tsunami beyond 500 km distance reach just a few centimeters – hardly killer waves. Note that if the observation direction was west versus east (Figure 3, *top*), or northwest versus northeast (Figure 3, *bottom*), the tsunami waveforms would be inverted. Whether tsunami onset in a withdrawal or an inundation at a particular shoreline strictly depends on the style of faulting and the relative positions of the shore and the fault.



Tsunami, Figure 3 Synthetic record sections of vertical tsunami motions at distances of 200, 500, 1,000, and 2,000 km from point dip slip (*top*) and strike slip (*bottom*) earthquakes of magnitude $M_w = 7.5$ and depth 10 km. Time runs for 5 h and the peak amplitude of each trace is given in centimeters at the right. The lower half of the focal sphere and azimuth of observation θ are shown toward the right. For other directions, the waveforms should be scaled by $\sin\theta$ and $\sin 2\theta$, respectively.

Figure 3 demonstrates that for point sources, dip slip earthquakes produce three or four times larger tsunami than strike slip earthquakes of equal moment. The differences in generation efficiency are understood most easily by considering directly the seafloor deformation patterns $u_z^{\text{bot}}(\mathbf{r}_0)$. I find these by setting $t = 0$ and $h = 0$ in (9) so $\cos\omega(k)t/\cosh(kh) = 1$. Figure 4 pictures the uplift patterns for the two faults of Figure 3 where two ($\sin\theta$) and four-lobed ($\sin 2\theta$) deformations spread over a region 40 km wide. The most striking contrast in the fields is maximum vertical displacement – 1.4 m for the strike slip versus 5.4 m for the dip slip. It is no coincidence that the ratio of maximum uplift for these two faults replicates the ratio of tsunami heights in Figure 3. After all, vertical seafloor deformation drives tsunami and vertical deformation is controlled largely by the rake of the slip vector $\hat{\mathbf{a}}$. Strike slip faults have a rake of 0° or 180°. Dip slip faults have rake equal ±90°. Further simulations show that, excepting very shallow, nearly horizontal faults, dip is not a terribly significant factor in tsunami production.

The sea surface cross sections in Figure 5 (*left* and *middle*) chronicle the birth and early life of a sea wave spawned by M7.5 thrust earthquakes on 45° dipping planes. In these figures, I replace the idealized point sources of Figure 3 with faults of typical dimension (L = 89 km, W = 25 km, and Δu = 1.78 m; see Table 1). In Figure 5 (*left*) the fault reaches to the sea floor. In Figure 5 (*middle*) the fault stops 30 km down. Soon after the earthquake, the sea surface forms "dimples" similar to those on the deformed sea floor. The sea surface dimples, however, are smoother and a bit lower in amplitude because of the $1/\cosh(kh)$ low-pass filtering effect of the ocean layer. After a time roughly equal to the dimension of the uplift divided by tsunami speed $\sqrt{gh}$, the leading edges of the wave organize and begin to propagate outward as expanding rings (Figure 5, *right*). Early on, the wave appears as a single pulse. Characteristic tsunami dispersion begins to be seen only after 10 or 20 min. Consequently, for shorelines close to tsunami sources, seismic sea waves arrive mostly as a single pulse. For distant shorelines, sea waves arrive with many oscillations, dispersion having spread out the initial pulse.



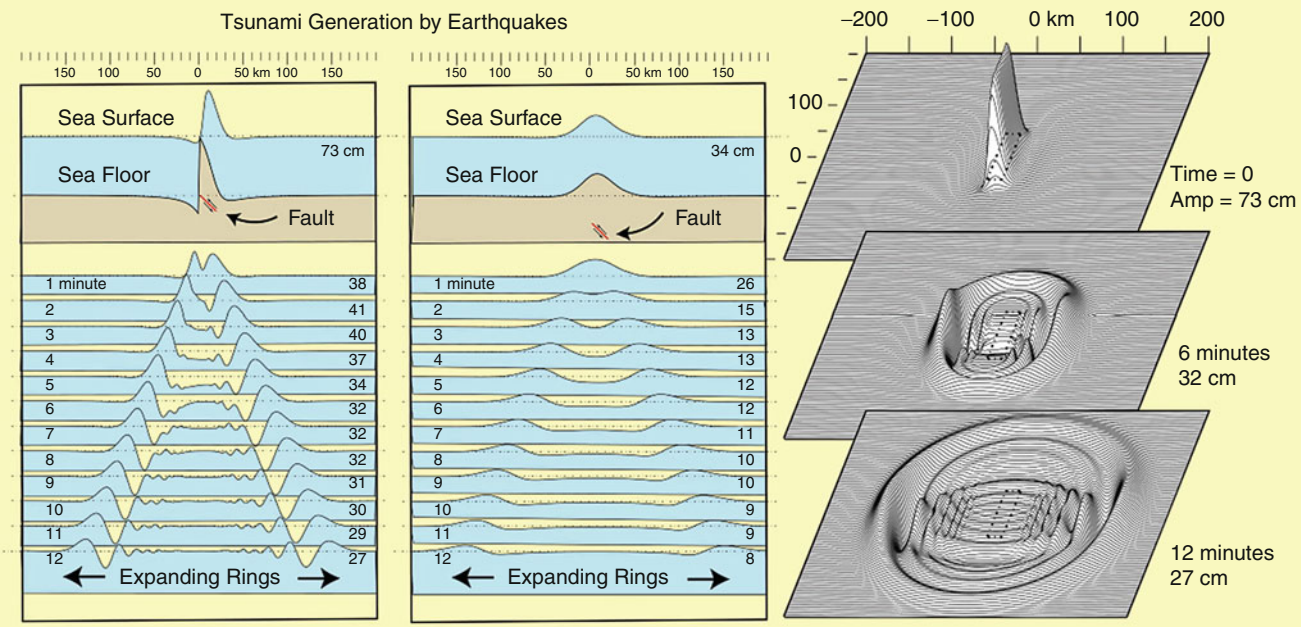
Tsunami, Figure 4 Static vertical displacements of the seafloor for the dip slip (*top*) and strike slip (*bottom*) earthquake point sources that generated the tsunami of Figure 3. Maximum excursions of the seafloor are 5.4 and 1.4 m, respectively.

The e^{-kd} terms in the tsunami excitation functions (10) let shallow earthquakes excite higher frequency tsunami than deep earthquakes (compare Figure 5 *left*, with Figure 5 *middle*). Higher frequency waves travel more slowly than longer period waves, so high frequency waves contribute to peak tsunami height only while it propagates as a single pulse. After a few hundred kilometers of travel, high frequency waves drift to the back of the wave train (Figure 5, *left*) and no longer add to the tsunami maximum. At 200 km distance, the shallow earthquake generates a wave about 3 times larger than the 30-km deep event. If you track the waves out to 2,000 km, however, you would find that the extra high frequencies in the shallow event will have fallen behind and that the maximum wave heights for the two events would be nearly equal. Beyond 2,000 km distance, any earthquake depth less than 30 km appears to be equally efficient in tsunami genesis.

Faults of finite size, like those in Figure 5, radiate tsunami in distributions more complex than the $\sin\theta$ and $\sin 2\theta$ patterns from point sources. The largest earthquakes have fault lengths of several hundred kilometers. Simulations show that long earthquake faults preferentially emit tsunami in a tight beam perpendicular to the fault strike, regardless of the focal mechanism. This preferential beaming simplifies tsunami forecasting because it tells us which direction to look for the biggest waves.

Tsunami excitation from submarine landslides

Earthquakes parent most tsunami, but other things do too. For instance, earthquake shaking often triggers landslides. If the slide happens under the sea, then tsunami may form. Consider a seafloor landslide confined in a rectangle of length L and width W. Let a constant uplift u_0 start along one width of the rectangle and run down its length ($\hat{\mathbf{x}}$ direction, say) at velocity v_r, that is, $\tau(\mathbf{r}_0) = x/v_r$. Placing this $u_z^{\text{bot}}(\mathbf{r}_0)$ and $\tau(\mathbf{r}_0)$ into (7a, 7b), I find the tsunami from this uplift source at observation point $\mathbf{r}$ and time t to be



Tsunami, Figure 5 *Left*. Cross sections of expanding tsunami rings from a M7.5 thrust earthquake. The fault strikes north–south (into the page) and the sections are taken east–west. Elapsed time in minutes and maximum amplitude in centimeters are given at the left and right sides. *Middle*. Cross sections of expanding tsunami rings from the same M7.5 thrust earthquake now buried 30 km. Deeper earthquakes make smaller and longer wavelength tsunami. *Right*. Views of the expanding tsunami rings from the shallow earthquake case at t = 6 and 12 min. The dashed rectangle in the center traces the surface projection of the fault. For large earthquakes, nearly all tsunami energy beams perpendicular to the strike of the fault (*toward the left and right in this picture*).

$$u_z^{\text{surf}}(\mathbf{r},t) = \frac{u_0 LW}{4\pi^2} \operatorname{Re}\int_k d\mathbf{k}\, \frac{e^{i(\mathbf{k}\cdot\mathbf{r}-\omega(k)t)}e^{-iX(\mathbf{k})}}{\cosh(kh)}\,\frac{\sin X(\mathbf{k})}{X(\mathbf{k})}\,\frac{\sin Y(\mathbf{k})}{Y(\mathbf{k})} \tag{12}$$

where

$$X(\mathbf{k}) = \frac{kL}{2}\left(\hat{\mathbf{k}}\cdot\hat{\mathbf{x}} - c(k)/v_r\right) \quad \text{and} \quad \mathrm{Y}(\mathbf{k}) = \frac{\mathrm{kW}}{2}\left(\hat{\mathbf{k}}\cdot\hat{\mathbf{y}}\right).$$

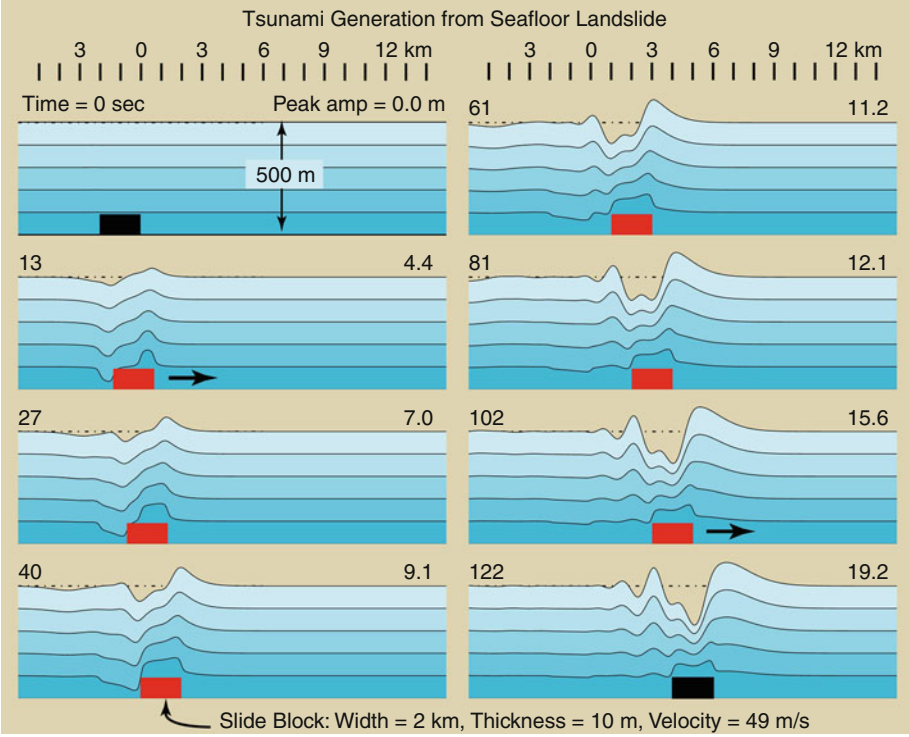
The $X(\mathbf{k})$ and $Y(\mathbf{k})$ factors, because they depend on the relative positions of the observation point and the landslide source, instill radiation patterns to the tsunami much like the ε_{ij} do for earthquakes.

By adding a trailing excavation source to the uplift source (12), I simulate tsunami from a sliding submarine block. Figure 6 pictures in cross section the waves stirred from a 2-km wide block, 10-m thick sliding at 49 m/s for 6 km along the bottom of an ocean 500 m deep. As the block moves, the water must go around the obstruction. Water gets pushed up in front and drawn down behind the slide block. Experiments reveal that, depending on the aspect ratio of the block and the ratio of slide velocity to the tsunami phase velocity, significant beaming and amplification of the tsunami are possible. In particular, when the slide velocity v_r approaches the tsunami speed $c(k) \approx \sqrt{gh}$, $X(\mathbf{k})$ is nearly zero for waves traveling in the slide direction. In this direction, the waves from different parts of the landslide arrive nearly "in phase" and constructively build. Figures 6 and 7 highlight the beaming and amplification effects. In both cases, witness the large tsunami pulse sent off in the direction of the slide. (Quicktime movies of Figures 6 and 7 and many other Figures in this paper are available for viewing; see Table 2.) Submarine landslides are prime suspects in the creation of "surprise tsunami" from small or distant quakes. Surprise landslide tsunami might initiate well outside of the earthquake uplift area or be far larger than expected given the magnitude of the quake. Historical examples of surprise landslide tsunami include the 1929 Grand Banks and the 1998 Papua New Guinea waves.

Tsunami excitation from impacts

In addition to tsunami from earthquakes and landslides, another class holds interest – those generated from surface detonations, explosive volcanoes, and asteroid strikes. I call waves from these sources "impact tsunami." Imagine that the initial stage of cratering by an impact excavates a radially symmetric, parabolic cavity of depth D_C, and radius R_C:

$$u_z^{\text{impact}}(\mathbf{r}) = D_C(1 - r^2/R_C^2) \qquad r \le \sqrt{2}R_C = R_D$$



Tsunami, Figure 6 Tsunami produced by a submarine landslide. The slide block is 10 m thick and 2 km wide. The slide starts to the left and runs to the right at 49 m/s. Note the amplification of the wave in the slide direction.

$$u_z^{\text{impact}}(\mathbf{r}) = 0 \qquad r > \sqrt{2}R_C = R_D$$

Based on Equation 8, the impact tsunami at observation point **r** and time t is

$$u_z^{\text{surf}}(\mathbf{r}, t) = \int_0^\infty \frac{k\,dk}{2\pi} \cos[\omega(k)t] J_0(kr) F_0(k), \qquad (13)$$

where

$$F_0(k) = \int_{\mathbf{r}_0} r\,d\mathbf{r}_0\, u_z^{\text{impact}}(\mathbf{r}_0) J_0(kr_0) = \frac{2\pi D_C R_D}{k} J_3(kR_D).$$

The principal distinction between (8) and (13) is the absence in the latter of the $1/\cosh(kh)$ low-pass ocean filter. Impacts crater the surface of the ocean not the sea floor, so this filter does not come into play.

If we restrict ourselves to asteroid-induced tsunami and suppose that the depth of the impact cavities equals 1/3 their diameter $d_c = 2R_C$, then D_c relates scales with the density, velocity, and radius of the impacting asteroid as

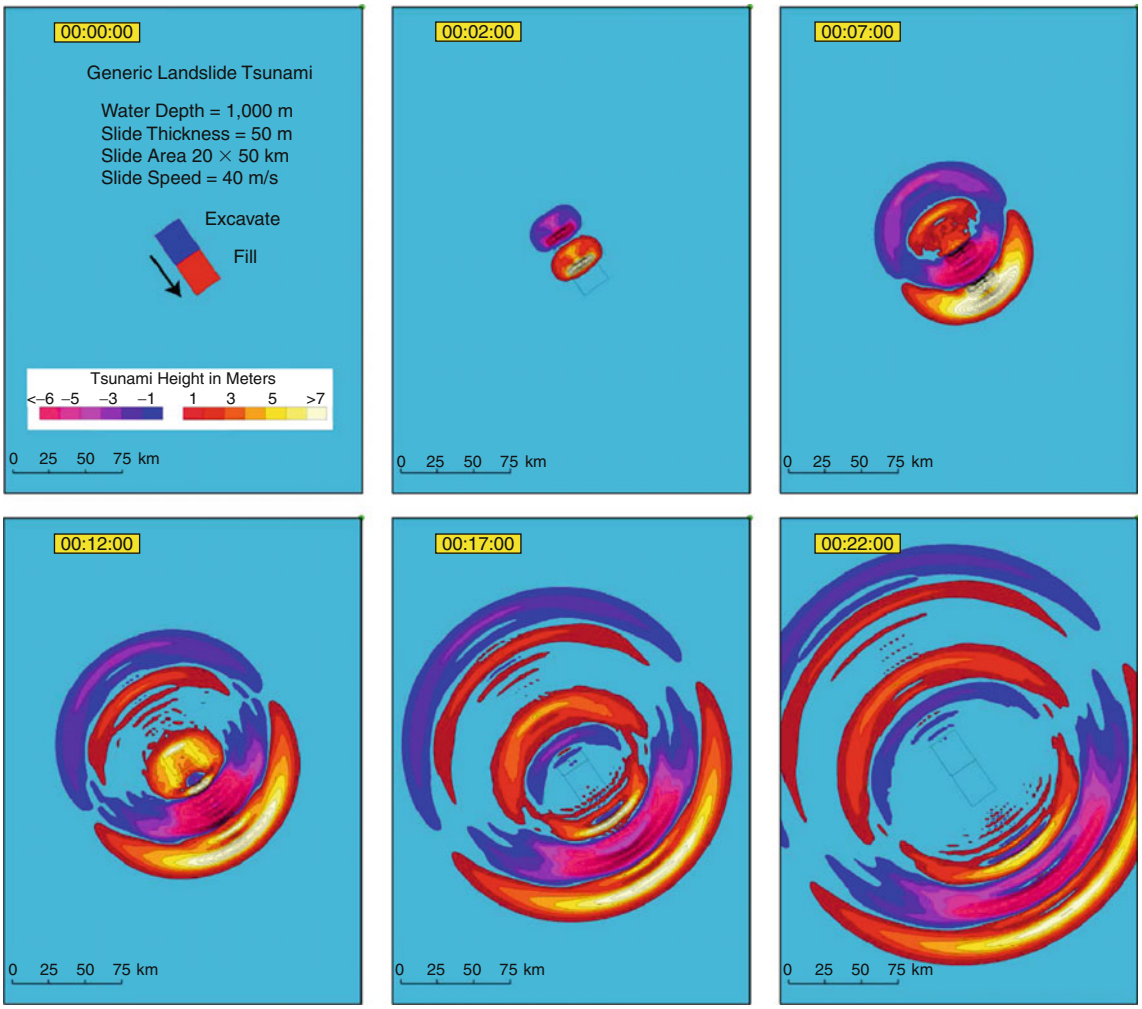
$$D_C = d_c/3 = (8\varepsilon\rho_I V^2{}_I/9\rho_w g)^{1/4} R_I^{3/4} \qquad (14)$$

In (14), ε is the fraction of the kinetic energy of the asteroid that goes into the tsunami wave. High velocity impact experiments suggest that $\varepsilon \approx 0.15$. With $\rho_I = 3$ gm/cm^3, $\rho_w = 1$ gm/cm^3, and $V_I = 20$ km/s, (14) returns crater depths of 1,195, 2,010, and 4,000 m for asteroids of radius $R_I = 50$, 100, and 250 m.

Figure 8 plots cross sections of the expanding rings of tsunami waves induced by the impact of a 200-m diameter asteroid at 20 km/s as computed by Equation 13. Within 100 km of ground zero, tsunami from moderate size (100–250 m) asteroids have heights of many hundreds of meters and dwarf the largest (10–15 m) waves parented by earthquakes. Fortunately, impact tsunami fall on the steep-sloped part of the group velocity curve (Figure 1) so they decay faster with distance than earthquake tsunami (more like r^{-1} versus $r^{-3/4}$ for earthquake tsunami). Figure 9 illustrates how dispersion quickly pulls apart the initial impulse into dozens of waves. At 1,000 and 3,000 km, the tsunami in Figure 8 would decay to 6 and 2 m amplitude, respectively – still a concern, but not catastrophic. For perspective, asteroids with diameters >200 m impact Earth about every 10,000 years, far less frequently than great M9 earthquakes that strike the planet once in 25 years or so.

Tsunami propagation

In uniform depth oceans, tsunami propagate out from their source in circular rings (e.g., Figure 9) with ray paths that look like spokes on a wheel. In real oceans, tsunami



Tsunami, Figure 7 Map view of a tsunami from a landslide block similar to Figure 6. Note the dipole form of the wave in its early stages and the beaming in the southeast direction of the slide.

speeds vary place to place (even at a fixed frequency) so tsunami ray paths refract and become bent. Consequently, in real oceans, both tsunami travel time and amplitude have to be adjusted relative to their values in uniform depth ones. To propagate tsunami in real oceans, I find it best to keep tsunami "mode-like" versus depth but "ray-like" horizontally. I first transform the various integrals over wavenumber (7, 8, 9, etc.) to integrals over frequency because wave frequency, not wave number, is conserved throughout. Using the relations $u(\omega) = \mathrm{d}\omega/\mathrm{d}k$ and $c(\omega) = \omega/k(\omega)$, I find that tsunami vertical motions from (13) for instance, are to a good approximation:

$$u_z^{\mathrm{surf}}(\mathbf{r},t) = \int_0^\infty \frac{\cos(\omega t)\mathrm{d}\omega}{2\pi k(\omega)u(\omega)} J_0(\omega T(\mathbf{r},\omega))F_0(k(\omega)) G(\mathbf{r})S_{\mathrm{L}}(\omega,\mathbf{r}) \quad (15)$$

In (15) the travel time of waves of frequency ω has been changed from $r/c(\omega)$ to

$$T(\mathbf{r},\omega) = \int_{\mathrm{raypath}} \mathrm{d}r/c(\omega,h(\mathbf{r})), \quad (16)$$

where the integral path traces the tsunami ray from the source to the observation point. Equation 15 also incorporates a new shoaling factor $S_{\mathrm{L}}(\omega,\mathbf{r})$ that accounts for wave height changes due to water depth and new ray geometrical spreading factor $G(\mathbf{r}) \leq 1$ that takes into consideration the reduction of wave amplitudes into shadow zones.

Real geometrical rays for tsunami can be very messy (*top left*, Figure 10). Rather, I employ "network rays" that are simply minimum time paths between source and receiver (*top right*, Figure 10). Unlike geometrical rays, network rays possess neither caustics nor shadow zones.

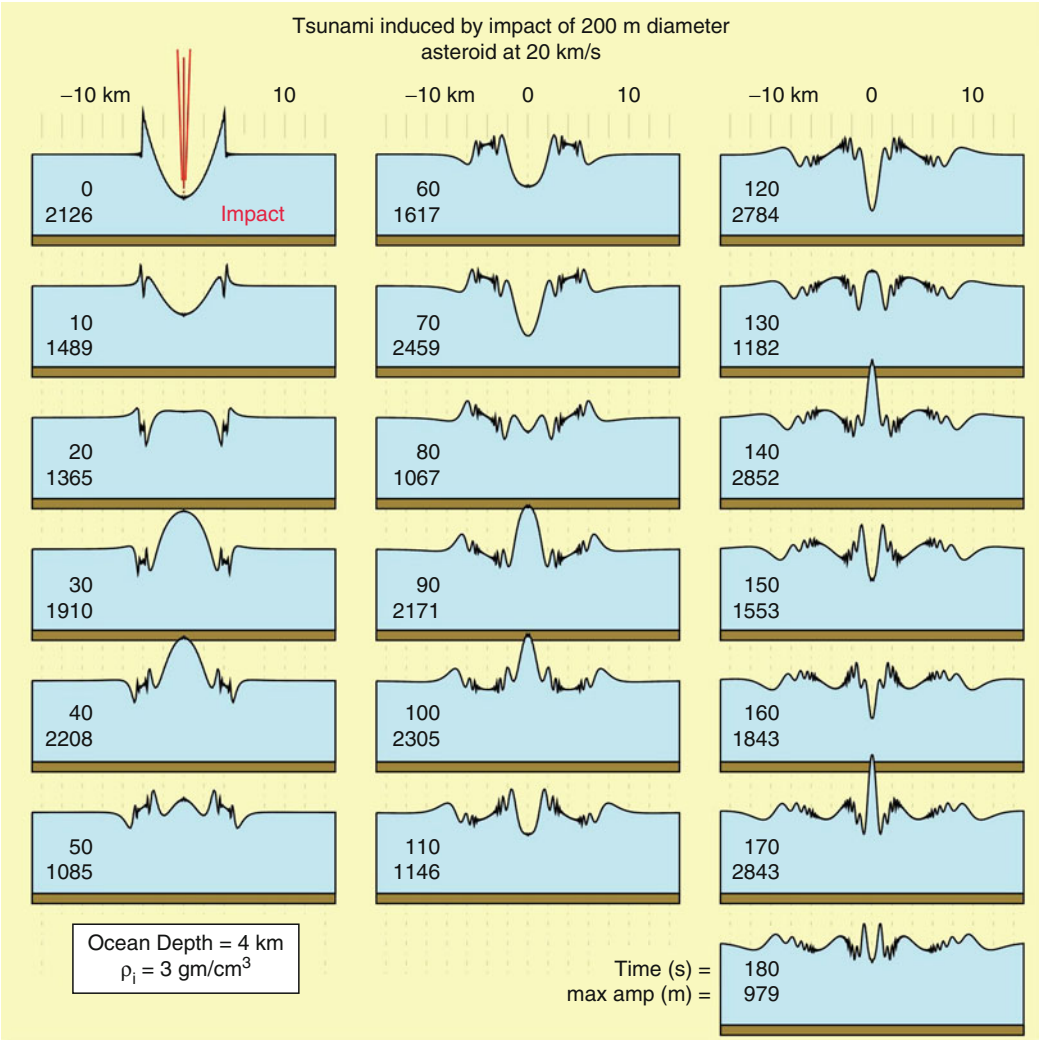
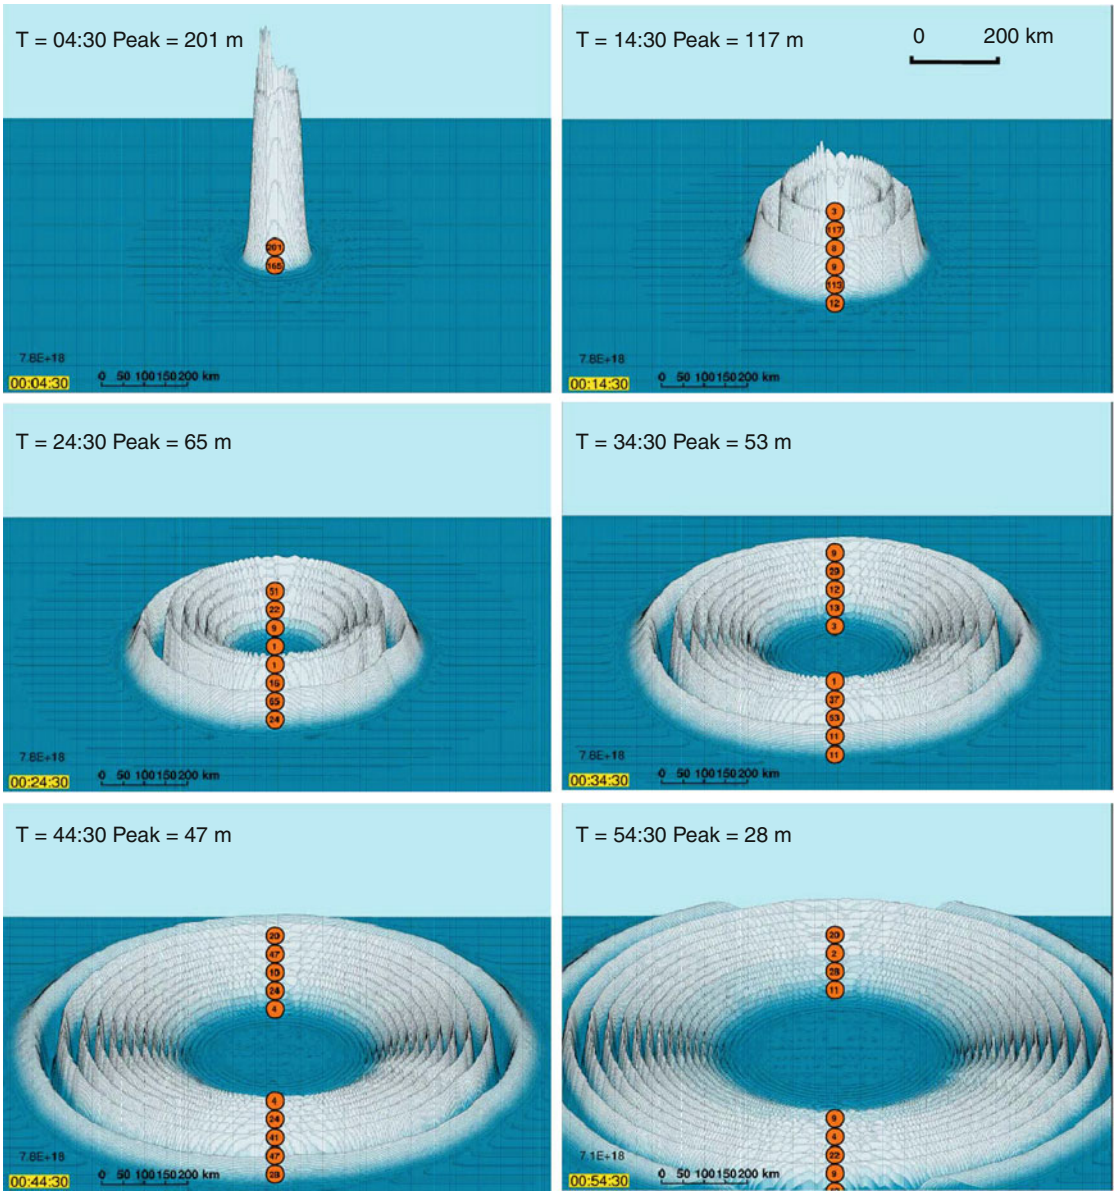
To compute the ray geometrical spreading factor $G(\mathbf{r})$, I replace the curvature of the wave front with curvature of the ray in the path integral (Figure 10, *bottom row*):

$$G(\mathbf{r}) = \exp\left[-\frac{1}{2}\int_{\text{raypath}} \frac{\partial\alpha(s)}{\mathrm{d}w}\mathrm{d}s\right] \Rightarrow \exp\left[-\frac{1}{2}\int_{\text{raypath}} \left[\frac{\partial\theta(s)}{\mathrm{d}s}\right]\mathrm{d}s\right]. \tag{17}$$

In this approach the distinction between wave refraction and diffraction blurs.



Tsunami, Figure 8 Computed tsunami induced by the impact of a 200-m diameter asteroid at 20 km/s. The waveforms (shown at 10 s intervals) trace the surface of the ocean over a 30 km cross section that cuts rings of tsunami waves expanding from the impact site at $x = 0$. Maximum amplitude in meters is listed to the left.



Tsunami, Figure 9 Expanding rings of an impact tsunami in a 3D-like style. Note the strong wave spreading due to dispersion.

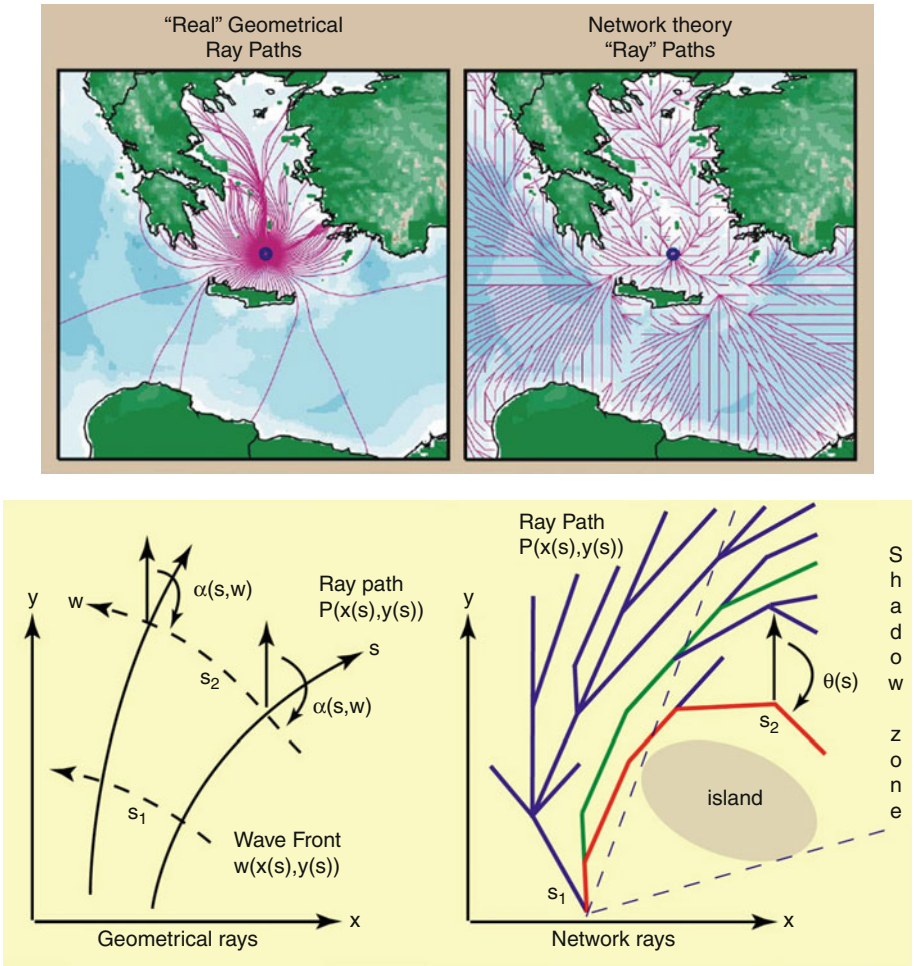
Tsunami shoaling and run-up

Shoaling. Toward shore, real oceans shallow and the waves carried on them amplify in a process called *shoaling*. Shoaling is easy to understand. The tsunami velocity depends on the ocean depth so as water shallows, tsunami waves slow down. Because their frequency is fixed, the wavelength of a slowing tsunami decreases (Figure 11, *inset*) and its energy compresses horizontally. Secondly, because a tsunami occupies the entire water column, as it enters shallow water its energy also gets compressed vertically. The only way for the compressing wave to maintain the same energy flux is for it to grow in amplitude. For the shoaling factor in (15), linear theory gives:

$$S_{\mathrm{L}}(\omega, \mathbf{r}) = \sqrt{\frac{u(\omega,h_0)}{u(\omega,h(\mathbf{r}))}}. \tag{18}$$

Shoaling amplification depends on the ratio of group velocity at the nucleation-site and the coast-site (ocean depths h_0 and $h(\mathbf{r})$, respectively). As does $G(\mathbf{r})$, S_{L} reverts to one in oceans of uniform depth.

Figure 11 pictures a shoaling tsunami wave of 150 s period. Initially, a unit height wave comes ashore from

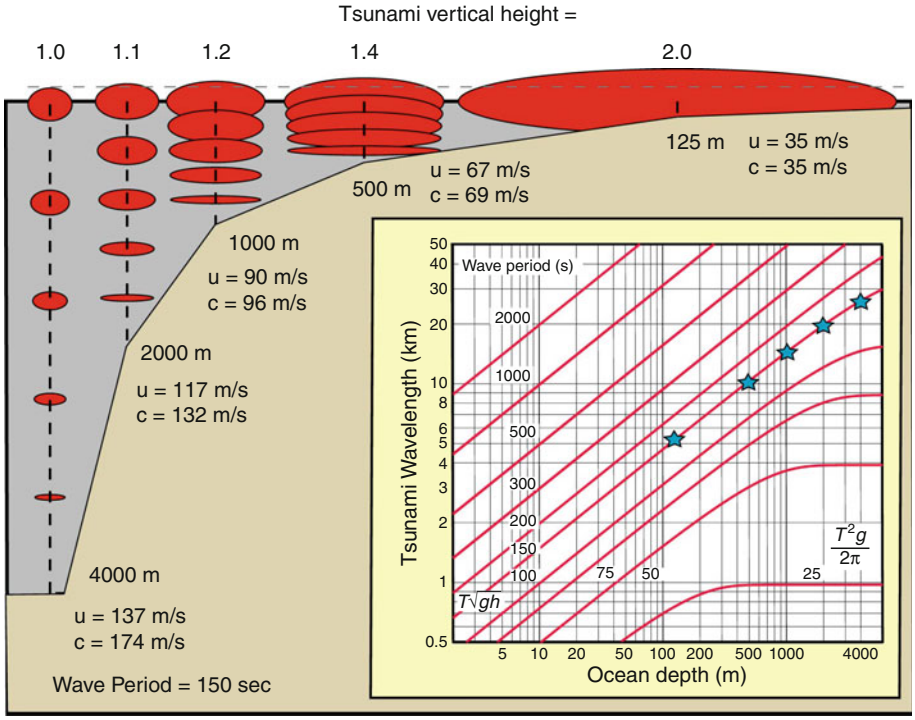


Tsunami, Figure 10 Real tsunami rays (*top left*) versus network rays (*top, right*). I track the curvature of the ray (*right, bottom*) rather than the curvature of the wave front (*left, bottom*) to account for wave size losses as tsunami propagate around obstacles.

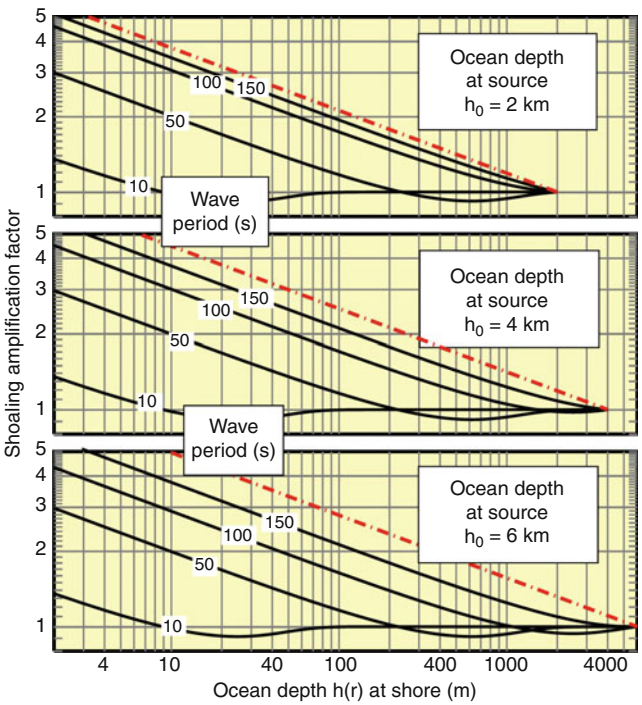
4,000 m of water at the left. As the water shallows, the velocity of the wave decreases and the wave grows in amplitude. By the time it reaches 125 m depth it has slowed from 137 m/s group velocity to 35 m/s and grown in height by a factor of 2. Figure 12 plots (18) as a function of coast-site depth for sea-wave periods from 10 s, and ocean depths of 2, 4, and 6 km. Because their energy does not occupy the entire water column, beach waves at 10 s period do not amplify much (perhaps 50%) in shoaling. Tsunami waves (100–2,000 s period) experience much stronger shoaling amplification – about 3–6 over a wide range of conditions. For waves of period greater than 250 s, $u(\omega,h_0) = (gh_0)^{1/2}$, $u(\omega,h(r)) = (gh(\mathrm{i}))^{1/2}$, and the shoaling factor reduces to Green's Law, $S_L = (h_0/h(r))^{1/4}$ (dashed red line in Figure 12).

Run-Up. Run-up is the final phase of tsunami life. The run-up phase begins when the approaching tsunami shoals to an amplitude roughly equal to the water depth and the wave begins to break. Run-up also covers the inundation phase where the water runs over land and reaches its maximum excursion above sea level. Run-up is the most complicated phase of tsunami life; nevertheless, "Will I get wet?" is the question everyone wants answered, so tsunami scientists have to take their best shot at carrying the waves to the last mile.

One approach to run-up is wave tank or computer experiments like Figures 13 and 14, where waves of various sizes and periods are sent onto model beaches. These experiments reveal a wide range of behaviors depending on wave period, wave size, wave direction, number of waves, beach slope, and beach friction. In real-world situations, this information is not known well, so the direct applications of the experimental results are limited. I follow an alternative approach that takes a broad brush view of run-up, but allows for considerable random uncertainty in the outcome. Using the methods above, I propagate tsunami to a position close to shore in shallow water where it can be considered a long wave, but not so



Tsunami, Figure 11 Effect of shoaling on tsunami eigenfunctions. The shallowing ocean near shore concentrates wave energy into smaller and smaller volumes and tsunami grow in response.



Tsunami, Figure 12 Shoaling amplification factor for ocean waves of various frequencies and source depths. The *dashed red line* is Green's Law.

shallow that its amplitude $A(h)$ exceeds water depth h there. I estimate run-up height η, on shore by:

$$\eta = A(h)^{4/5} h^{1/5} \tag{19}$$

Because $A(h) < h$, run-up always exceeds the offshore wave amplitude. Considering the large uncertainties involved, I view run-up at any field site to be a random variable drawn from a distribution function with (19) being its mean and its spread ranging from 1/2 to 2 times the mean. It does not matter at which depth h is used to evaluate (19), provided the water is shallow enough for the tsunami to act like a long wave. According to Green's Law, a long wave with amplitude $A(h_1)$ in water of depth h_1, has an amplitude $A(h_2) = A(h_1)\,(h_1/h_2)^{1/4}$ in water of depth h_2. Run-up estimate at η_2 at depth h_2

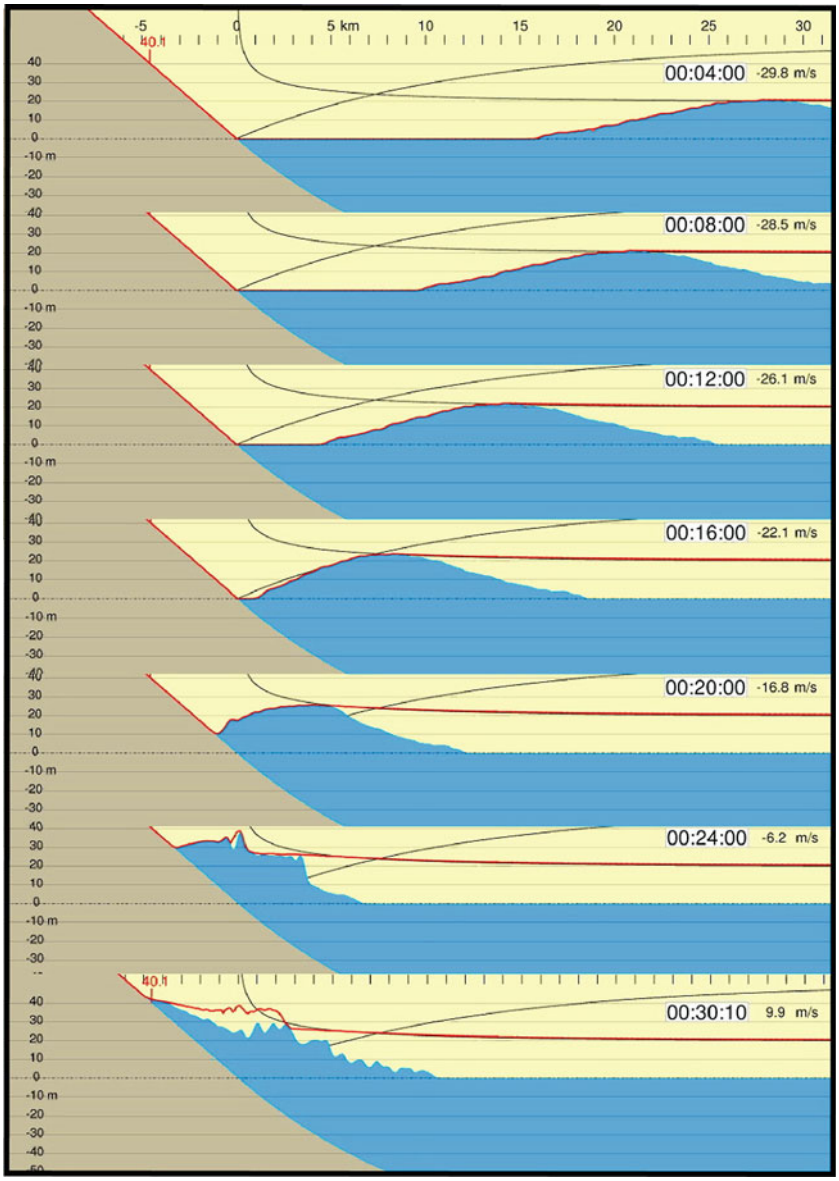
$$\eta_2 = A(h_2)^{4/5} h_2^{1/5} = \left[A(h_1) \left[\frac{h_1}{h_2} \right]^{1/4} \right]^{4/5} h_2^{1/5}$$

$$= A^{4/5}(h_1) {h_1}^{1/5} = \eta_1$$

equals estimate η_1 at depth h_1.

Tsunami samples

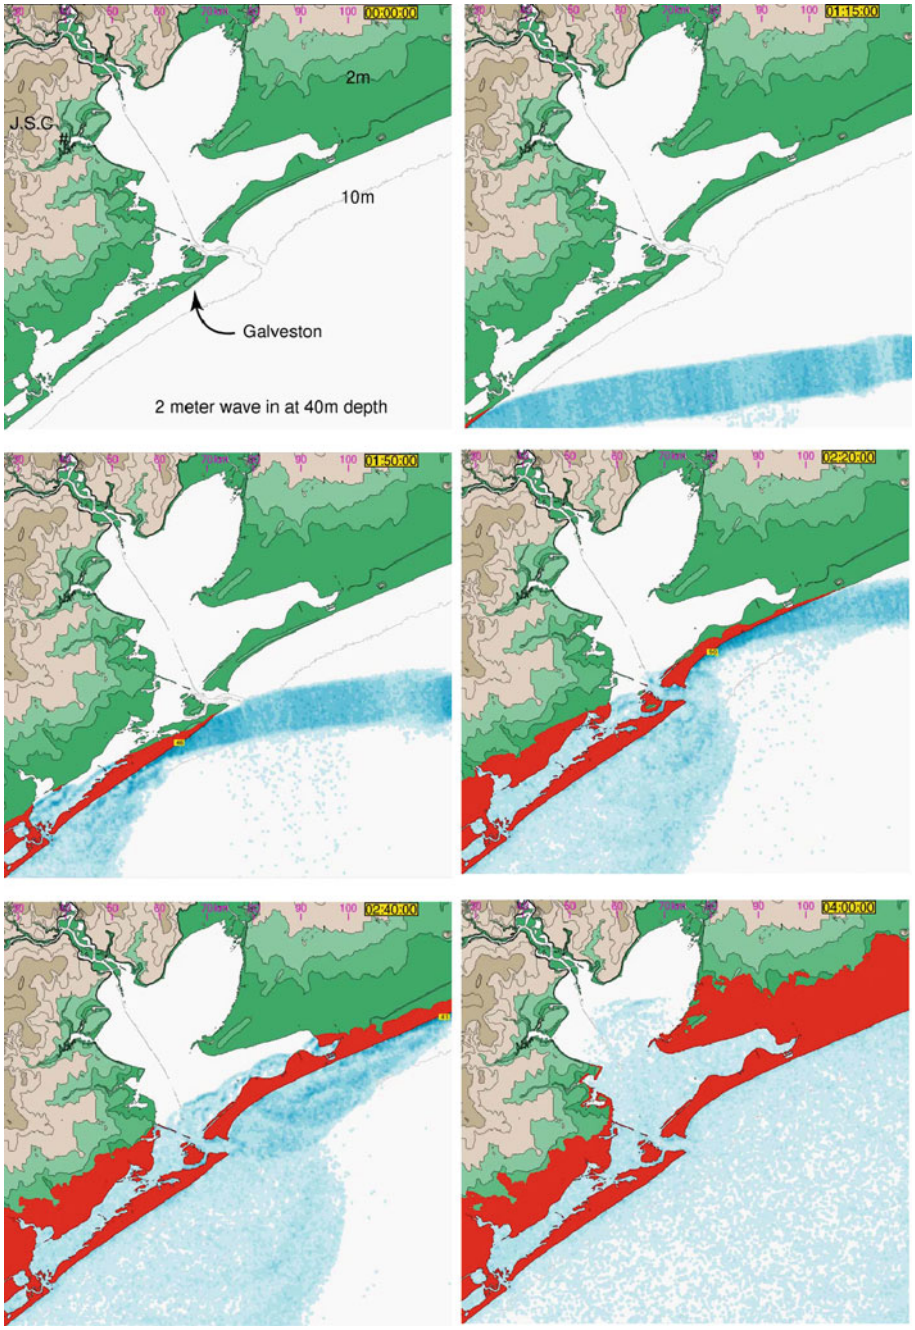
Sumatra earthquake 12/26/2004. Figure 15 snapshots a simulation of the 2004 Sumatra tsunami. As modeled



Tsunami, Figure 13 Run-up and inundation of a 20 m high, 1,200 s duration wave on a steep 0.5° slope. On steep beaches breaking has little time to operate so run-up amplifications are large.

by several rectangular patches, the megathrust fault that sourced the wave trends north–south for several 100 km (Figure 15 *top left*). As the example in Figure 5 predicted, nearly all of the wave energy in the 2004 tsunami emits perpendicular to the fault – Sumatra and Thailand toward the east, and India and Sri Lanka toward the west. Not surprisingly, these locations suffered the lion's share of tsunami damage. I believe that the very large run-up near Banda Aceh was due to concentrated slip on a thrust ramp splaying up from the megathrust just offshore at that latitude.

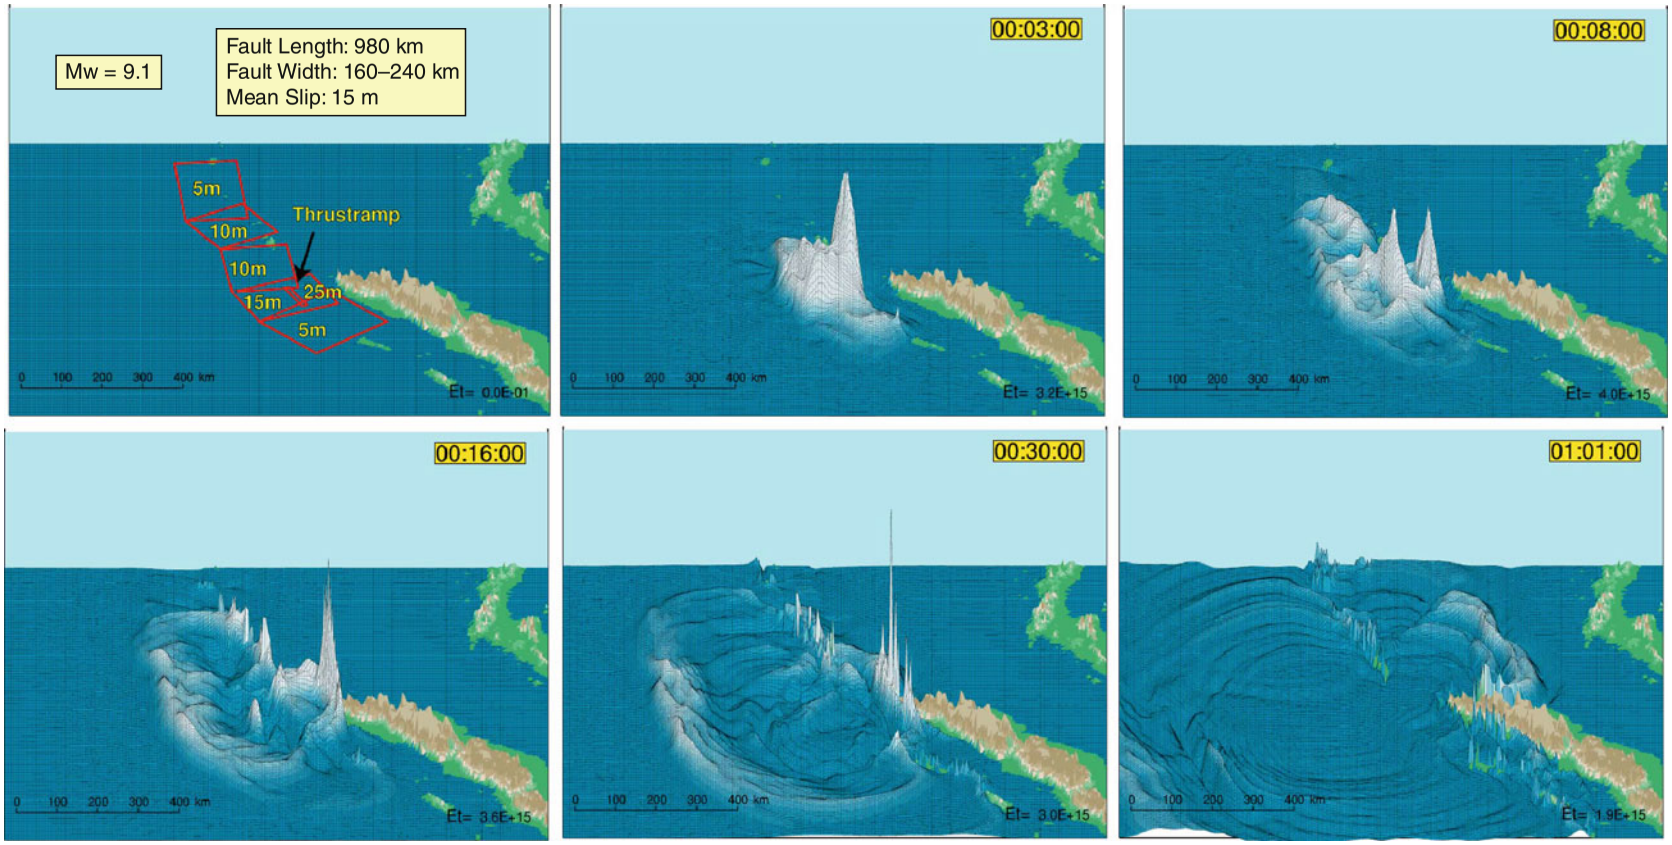
La Palma landslide tsunami. Like its fellows in the Canary Island chain, the volcanic Island of La Palma has experienced cycles of growth and partial collapse. Its flank last failed 550,000 years ago. Since then, new Cumbre Vieja volcano has filled the vacant scar. For the last 125,000 years this volcano grew steadily but in the last 7,000, its structure changed. It now mainly erupts along a north–south trending rift that splits the mountain in half. Moreover, during an eruption in 1949 a fault broke surface along the crest of the volcano and part of its western side slid 5 m down and toward the ocean. The volcano again may be showing initial stages of instability. While certainly collapse is not imminent and it may take many eruptive cycles over the next few thousand years to give it that final shove, the volcano will collapse so it is sensible to consider the consequences (Figure 16). If 500 km^3 of its



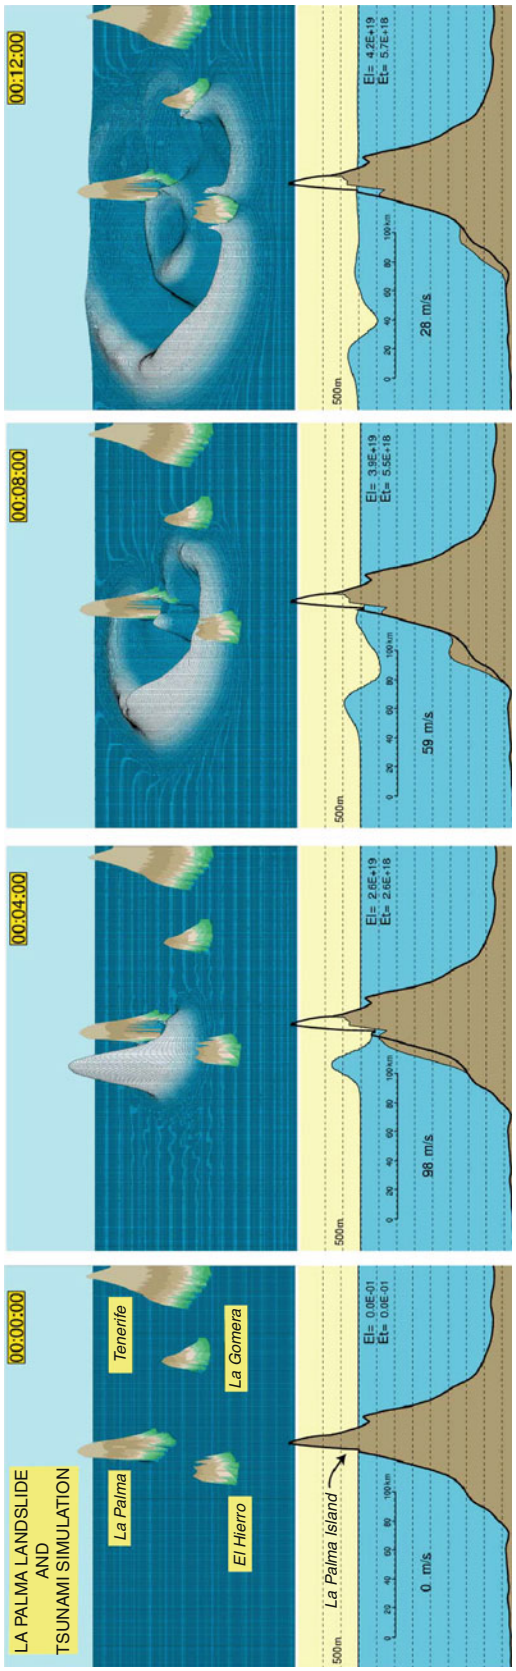
Tsunami, Figure 14 Simulation of 2 m tsunami wave beaching at Galveston Texas. Red area blankets the predicted inundation zone. Note the multiple wave reflections and wave interference that contribute to run-up complexity and randomness.

flank falls into the sea like it did last time, a La Palma collapse will spawn a mega tsunami hundreds of meters high locally that will buffet all coasts of the Atlantic with 10–30 m waves.

Gulf of Guinea impact tsunami. In a 2008 training exercise, the US Air Force considered the consequences of, and response to, an impact of a small comet into the Atlantic Ocean off the coast of Guinea. In this scenario, pictured in Figure 17, tsunami run-ups exceed 10 m along a 1,200 km stretch of coastline. This wave would knock out coastal shipping and oil production facilities for many months and trigger major ripple effects in the global economy. Unlike those Hollywood movies, currently there is no defense against an asteroid impact.



Tsunami, Figure 15 Simulation of the Sumatra Earthquake Tsunami of December 2004. Note the large wave directed toward the northern tip of Sumatra due to the small thrust ramp offshore there (*upper left*).



Tsunami, Figure 16 (*Top row*) First 12 min of the La Palma Tsunami. Initial wave heights exceed 500 m. (*Bottom row*) Landslide and tsunami in cross section. Just like the simple example in Figure 6, water gets pushed up in front of the slide and drawn down behind.

Tsunami forecasting

Official approach: Perhaps the ultimate goal of tsunami research is forecasting. A forecast predicts the size of a particular tsunami given the knowledge that a potentially dangerous earthquake has occurred already. Tsunami travel at jet speeds, but for many places there may be several hours between the earthquake and the arrival of the sea waves. This time can be spent analyzing seismograms, estimating earthquake parameters, and forecasting the expected height of the oncoming wave with the aid of computer models and initial field reports. This is precisely the mission of the various warning centers like NOAA's Pacific Tsunami Warning Center (PTWC). The past decade has witnessed considerable progress in tsunami forecasting coupled with faster and more geographically selective warnings. By and large, the current tsunami prediction system functions well. Figure 18 pictures a nearly real-time prediction of tsunami run-up from the M8.1 Samoa Earthquake of September 29, 2009. Based on rapid calculations like these, the PTWC issued accurate advanced warnings and watches for this tsunami – at least for locations greater than 2,000 km distance from the quake where sufficient delay time existed.

The biggest uncertainty in the current procedures lay in fixing earthquake parameters quickly. For instance, in the first hours after a quake, it is not uncommon for estimates of earthquake magnitude to vary 0.3 or 0.4 units as more extensive seismic data arrive. Because earthquake magnitude or earthquake moment is the prime driver for tsunami (Equation 9), a 0.4 unit uncertainly makes for a factor of 2 or 3 uncertainly in tsunami height all else aside. Partly on this concern, the DART buoy network that provides real-time measurements of passing tsunami was expanded from 6 to 24 sites after the Sumatra earthquake. Information from the DART sensors provides a real-time "reality check" on computer simulations run rapidly on uncertain earthquake parameters.

Do-it-yourself approach: Apart from official predictions, readers of this article have enough information to produce a Do-It-Yourself tsunami forecast. The three step recipe needs: earthquake magnitude M, the ocean depth at source H_o, distance to the quake R, and mean ocean depth $\overline{H}$ between the earthquake and you.

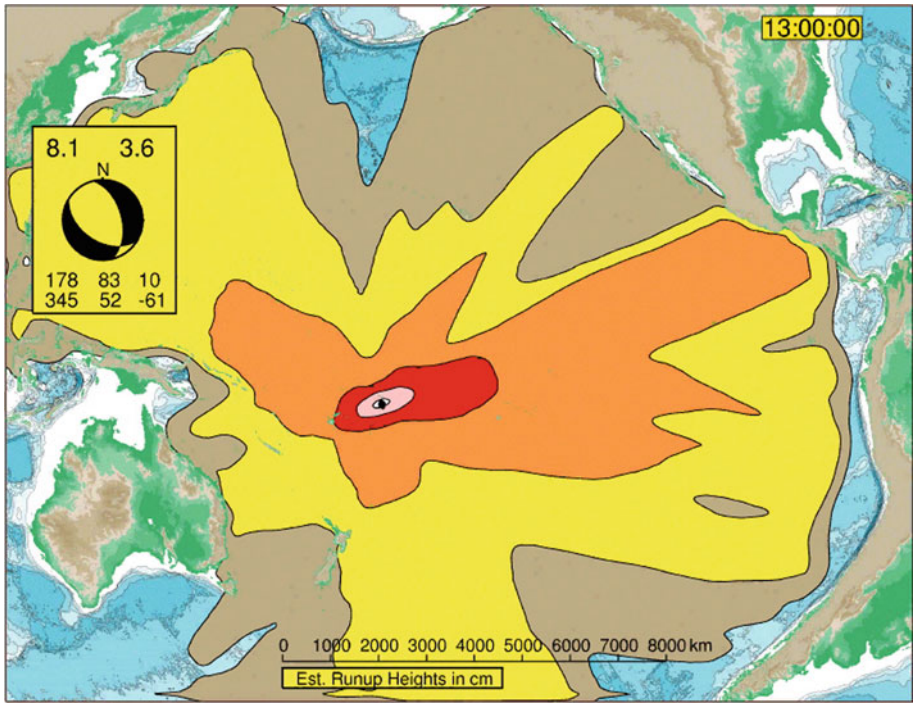
Step 1 – Find Initial Tsunami Amplitude A_0. Let us approximate initial tsunami height by:

$$A_0 = \frac{\alpha \Delta u(M)}{\cosh\left[\frac{4\pi H_0}{W(M)+L(M)}\right]}, \tag{20}$$

where α is the fraction of earthquake slip that transforms into tsunami-making uplift:

$$\alpha = (1 - \theta/180)\sin\theta|\sin\phi|,$$

with θ and ϕ being the fault dip and rake angles in degrees. Fault slip $\Delta u(M)$, width $W(M)$, and length $L(M)$ are functions of magnitude and can be read from Table 1 or computed from the formulas in its caption.



Tsunami, Figure 18 Nearly real-time prediction of run-up height from the 9/29/09 M8.1 Samoa Earthquake. Colors correspond to run-up heights: *Brown* 10–25 cm; *Yellow* 25–50 cm; *Orange* 50–100 cm; *Red* 1–2 m; *Pink* >2 m.

You recognize the 1/cosh as the low-pass filter due to the ocean layer. Unlike Equation 9, Equation 20 makes no assumption about radiation pattern, so in this sense it represents the worst case. The most efficient mechanism (surface breaking, pure dip slip on planes dipping near 45°) for tsunami generation gives $\alpha = 0.55$.

Step 2 – Correct for Propagation Loss *P*.

Tsunami waves decay as they travel due to geometrical spreading and frequency dispersion. For an ocean of constant depth $\overline{H}$, the propagation loss is roughly

$$P = \left(1 + \frac{2R}{L(M)}\right)^{-\psi}, \tag{21}$$

where

$$\psi = 0.5 + 0.575 \exp\left(-0.0175 \frac{L(M)}{\overline{H}}\right). \tag{22}$$

The first term in exponent (22) accounts for square root of distance losses due to geometrical spreading. The second term in (22) accounts for additional losses due to frequency dispersion with larger dimensioned tsunami decaying more slowly. Peak deep-water tsunami amplitude $A_d(R)$ at distance R is

$$A_d(R) = A_0 P = \frac{\alpha \Delta u(M)}{\cosh[4\pi H_0/(W(M) + L(M))]} \left(1 + \frac{2R}{L(M)}\right)^{-\psi} \tag{23}$$

Propagation loss (23) supposes an unobstructed wave path to the observation location. If the waves pass around headlands, squeeze through narrows, or cut into shadow zones, then (23) again overestimates tsunami size.

Step 3 – Correct for Shoaling and Run-Up.

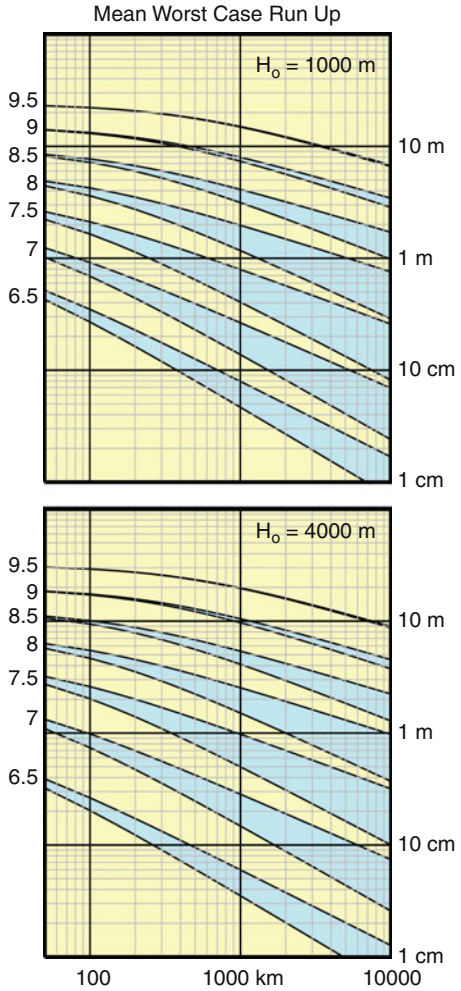
For long waves, the shoaling correction S_L (18) reduces to Green's Law $S_L = (H_0/H)^{1/4}$ and the shoaled tsunami amplitude $A_S(R)$ at distance R is

$$A_S(R) = A_0 P S_L = \frac{\alpha \Delta u(M)}{\cosh\left[\frac{4\pi H_0}{W(M)+L(M)}\right]} \left(1 + \frac{2R}{L(M)}\right)^{-\psi} \left[\frac{H_0}{H}\right]^{1/4}. \tag{24}$$

Applying (19) on (24) returns peak wave run-up height $\eta(R)$

$$\eta(R) = [A_0 P S_L]^{4/5} H^{1/5} = \left[\frac{\alpha \Delta u(M)}{\cosh\left[\frac{4\pi H_0}{W(M)+L(M)}\right]} \left(1 + \frac{2R}{L(M)}\right)^{-\psi}\right]^{4/5} H_0^{1/5}. \tag{25}$$

Figure 19 plots Do-It-Yourself prediction (25) for earthquake magnitudes 6.5–9.5, at distances R to 10,000 km, for $\overline{H}$ between 1,000 and 4,000 m, and $H_0 = 1{,}000$ m (*top*



Tsunami, Figure 19 Mean worst-case tsunami run-up height versus distance from earthquakes of magnitude 6.5–9.5. The blue areas include an allowance for mean ocean depth between 1,000 (*upper limit*) and 4,000 m (*lower limit*). Top and Bottom panels assume 1,000 and 4,000 m water depth at the source.

panel) and H_0 = 4,000 m (*bottom panel*). Because several steps above selected extreme assumptions, these curves represent a mean worst case. The worst worst case might be twice as large still. For $M = 8$, $H_0 = \overline{H} = 4{,}000$ m, Figure 19 (*bottom*) predicts run-ups of 3 m at 300 km distance, 2 m at 600 km distance, 1 m at 2,000 km distance, and 0.5 m at 5,000 km distance. These numbers compare well with the more rigorous calculations in Figure 18.

Summary

Tsunami are gravity-driven water waves caused mostly by undersea earthquakes, but sometimes they are sourced by submarine landslides, surface detonations, explosive volcanoes, and asteroid strikes. Tsunami differ from ordinary beach waves in that they have longer period, larger wavelength, and higher velocity. Because of shoaling effects, these characteristics make tsunami especially damaging because they grow in height proportionally more in approaching shore than do ordinary waves of equal size. This article provides mathematical expressions for tsunami excitation, propagation, and simplified steps to compute wave run-up height from tsunamigenic earthquakes.

Tsunami: Bay of Bengal

TSUNAMI: BAY OF BENGAL

Vineet Gahalaut
National Geophysical Research Institute (CSIR), Hyderabad, India

Definition

Bay of Bengal: Northeastern part of the Indian Ocean, which is about 2,000 km long and about 1,500 km wide, and is bordered on the west by India and Sri Lanka, on the north by Bangladesh, and on the east by Myanmar and Thailand; the Andaman and Nicobar Islands separate it from the Andaman Sea.
Tsunami: Gravity-driven water waves in the sea caused by submarine earthquakes, landslides, volcanic eruption, and impact meteorites.

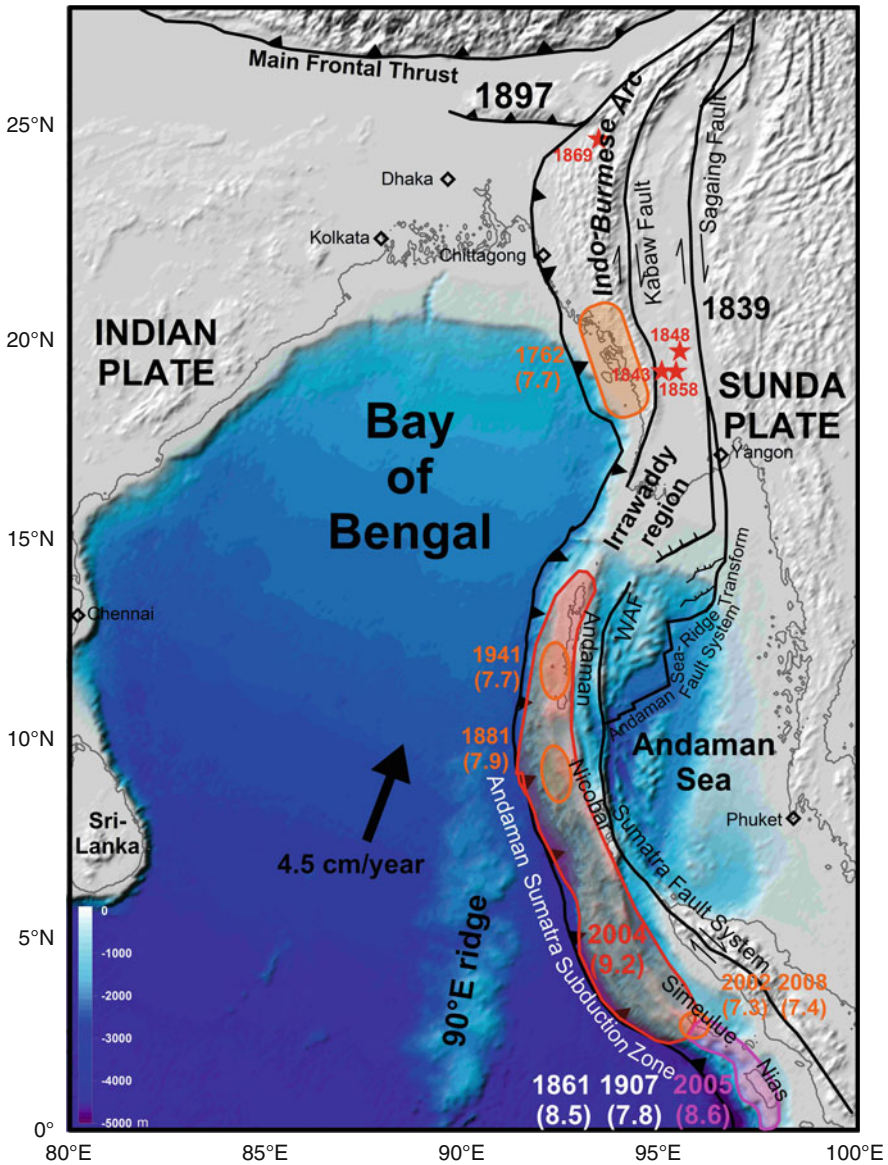
Introduction

The coastal region around the Bay of Bengal is one of the most populated regions of the world with population density of more than 1,000 people/km^2 in Bangladesh and region around it. Natural hazards in this region, namely, floods and cyclones, have turned into disasters making this region very vulnerable. The occurrence of the December 26, 2004, Sumatra-Andaman earthquake (Mw 9.2) and the tsunami caused by it (Lay et al., 2005), which devastated the coastal regions around the Bay of Bengal and killed more than 200,000 people, further exposed the vulnerability of this region due to earthquakes and tsunami. For an objective assessment of the tsunami hazard in this region, it is necessary to understand the tectonics and the mechanism of earthquake occurrence in this region. Other than earthquakes, submarine landslide in the several-kilometer-thick sediments of the Ganga and Brahmaputra rivers deposited in the northern Bay of Bengal may also pose tsunami hazard in the region. There are no historical records to suggest occurrence of such submarine landslides and no studies have been carried out to assess the tsunami hazard due to this. However, some

attempts have been made to assess tsunami hazard due to earthquakes in the region (Okal and Synolakis, 2008; Cummins, 2007).

Tsunami hazard in the Bay of Bengal

The tsunami hazard in the Bay of Bengal region is mainly due to the great and major earthquakes along the northern Sunda arc where the eastern margin of the Indian plate interacts with the Sunda plate (Figure 1). Tsunami caused by great earthquakes in the far-field regions, namely, the Banda arc which is to the east of Sunda arc (i.e., southeast of the equator), the Makran region which is along the southern coast of Pakistan and Iran, and the circum pacific belt, may not affect the Bay of Bengal region due to directivity effect and the presence of intervening land masses during their propagation. The frontal arc of the northern Sunda arc consists of the Indo-Burmese arc in the north, and the Sumatra- Andaman arc in the south with the



Tsunami: Bay of Bengal, Figure 1 Bay of Bengal, general tectonics of the northern Sunda arc and locations of major and great earthquakes along the arc. Stars denote major earthquakes that occurred in the Indo-Burmese arc. These earthquakes were not associated with any tsunami. The great 1897 Shillong Plateau earthquake and the great 1839 earthquake on Sagaing fault are also shown for reference. The 1897 intraplate earthquake is associated with the tectonics of the Indian plate and its interaction with the Himalaya, rather than the tectonics of the Indo-Burmese arc. Major earthquakes of Sagaing fault are not shown here, as they do not pose any tsunami hazard. The 1861 and 1907 earthquakes occurred in the source region of the 2005 Nias earthquake. However, none of the tsunami caused by of these earthquakes, including that of the 2005 Nias earthquake, affected the Bay of Bengal region.

intervening Irrawaddy delta region. In the back arc, the Sagaing fault which runs through Myanmar on the land and is characterized by strike slip motion, the Sumatra Fault system which is characterized by the earthquakes with strike slip motion, and the Andaman Sea ridge transform fault system which is characterized by the normal and strike slip earthquakes of low magnitude ($M < 6.5$), do not pose tsunami hazard to the Bay of Bengal region. The tsunami hazard in the Bay of Bengal due to low-level seismicity in the diffused plate boundary region between India and Australia in the Indian Ocean may be very low.

Plate motion along the northern Sunda arc

In the northern Sunda arc, relative motion between the India and Sunda plates is about 3.7 cm/year toward N15° in the northern part (i.e., Indo-Burmese arc region) and about 4.5 cm/year toward N25° in the southern part (i.e., the Sumatra region). The oblique motion between the India and Sunda plates is accommodated along the arc through slip partitioning in the frontal and back arc (Gahalaut and Gahalaut, 2007; McCaffrey 2009). In the north, the north–south trending Indo-Burmese arc accommodates slip of about 1.6 cm/year through dextral motion (Gahalaut et al., 2010a) and the remaining motion of about 2.0 cm/year is accommodated across the dextral strike slip Sagaing fault in the Myanmar (Maurin et al., 2010). Thus, at present, the underlying gently east dipping Indian plate beneath the accretionary wedge of the Indo-Burmese arc moves toward north. Further south in the Irrawaddy and Andaman region, the motion in the frontal arc becomes oblique. In the back arc, the dextral strike slip motion occurs along the north–south planes and normal motion occurs along the Andaman Sea ridge transform fault system which is consistent with the Andaman sea opening. In the Sumatra region, the motion in the frontal arc is arc normal, leading to thrust motion on the plate boundary interface. The strike slip motion in the back arc is accommodated through dextral motion along the Sumatra Fault System. The Sumatra Fault System joins the Sagaing fault in the north through the Andaman Sea ridge transform fault system.

Seismicity of the northern Sunda arc region and tsunami hazard

For the convenience of discussion, the seismicity of the Indo-Burmese arc, Irrawaddy, and Sumatra-Andaman region is described separately.

Indo-Burmese arc

The plate reconstruction models suggest that subduction probably occurred along the Indo-Burmese arc in the geological past (prior to about 50 Ma) when the arc was predominantly southeast–northwest trending. However, after the collision of the Indian plate with the Eurasian plate, the northern Sunda arc rotated clockwise to become predominantly north–south trending. Several geological and geophysical studies confirm that the subduction occurred across the Indo-Burmese arc between India and Burma plates and there is evidence of the subducted Indian slab, but presently the subduction does not appear to be active (Hall, 1997; Guzman-Speziale and Ni, 1996; Rao and Kumar, 1999; Pesicek et al., 2010). This is further confirmed from the earthquake occurrence and the crustal deformation studies.

The historical records of earthquakes and tsunami in the Indo-Burmese arc are generally very poor. Although there are a few unverifiable reports of earthquake occurrence as early as 1548 in Tripura, Assam (two states in northeastern India), or Bangladesh, there are large uncertainties in the location of historical earthquakes. The catalogue is probably reliable only after 1762. The most notable earthquakes are the April 2, 1762, the August 24, 1858, Arakan earthquakes, and the January 10, 1869, Cachar earthquake (Richter, 1958). Other than these earthquakes, several instances of damage due to earthquakes are reported from Chittagong, Sylhet, Manipur valley, and Cachar regions. However, it is possible that the high damage in these sediment-filled valleys was due to relatively large population and local site effects. The April 2, 1762, Arakan earthquake has been considered as a great tsunamigenic earthquake (Cummins, 2007). It caused extensive damage in the Chittagong region through shaking, liquefaction, damming of channels, seiches, etc. (Gulston, 1763). The reported uplift of Cheduba Island due to this earthquake was not found to be singularly due to this earthquake (Oldham, 1883; Martin and Szeliga, 2010). Halsted (1843) reported the effects of the earthquakes which were mostly found to be highly exaggerated by Gupta and Gahalaut (2009). They found that the highly qualitative observations of the coseismic elevation changes are consistent with a predominant strike slip motion on the earthquake rupture which was located under the land and/or under very shallow water, and it was only a major earthquake (Martin and Szeliga, 2010) which probably did not cause any major tsunami (Gupta and Gahalaut, 2009). The August 24, 1858, Arakan earthquake was felt in many parts of Burma and was severely felt at Kyauk Pyu, Ramree Island, Myanmar. It caused liquefaction and damage to buildings and Pagodas. In this region, the distance between the Sagaing fault and the structurally mapped Arakan trench is less than 200 km, and, hence, based on the scanty reports of damage, it is difficult to judge whether this one and the 1843 and 1848 earthquakes are linked with the Indo-Burmese arc or with the Sagaing fault. But none of these three earthquakes is associated with tsunami. The January 10, 1869, Cachar-Manipur earthquake is referred to as the most severe earthquake in the available 2,000 years of written historical records of Manipur state of India. However, recent examinations of the historical records suggest that even this earthquake was not a great one and the damage was very much confined to the sediment-filled valleys of Imphal and Cachar (Kundu and Gahalaut, 2010b). As this earthquake occurred

on the land, far from the sea, there is no question of tsunami being generated by this earthquake.

Although precise motion on rupture during these major earthquakes is not known, the current seismicity and the results from crustal deformation studies suggest that the historical earthquakes in the Indo-Burmese arc might have occurred through predominant strike slip motion on steep planes, which dips away from the coast. This severely limits the possibility of a tsunamigenic earthquake in the coastal Indo-Burmese arc region. Lack of paleo-tsunami deposits in the coastal Myanmar region (Aung et al., 2008) further supports this argument.

Irrawaddy region

Seismicity in the Irrawaddy frontal arc is extremely low as compared to that in the Andaman Nicobar arc in the south and the Indo-Burmese arc in the north. Earthquakes in the Irrawaddy region occur at depths less than 50 km, whereas in the Indo-Burmese arc and the Andaman Nicobar region, earthquakes occur down to a depth of up to 150–200 km (Guzman-Speziale and Ni, 1996). From the limited earthquake focal mechanisms, it is not possible to constrain sense of motion along this part; however, the regional plate motion models suggest that very oblique motion occurs along the frontal arc (Gahalaut and Gahalaut, 2007). The reason for very low seismicity of the frontal arc at shallow depth (>50 km) could be that the region is either aseismic or accumulating strain. However, absence of seismicity even at depths greater than 50 km suggests that the subducting slab might not be continuing to that depth at all. In the Andaman and Indo-Burmese arc regions, occurrence of earthquakes at intermediate depths confirms the continuity of the Indian plate slab in those regions. The absence of seismicity at intermediate depth level of the Irrawaddy region is possibly due to the presence of tear in the subducting Indian slab, which is has been confirmed from the tomographic studies of the region (Richards et al., 2007). Thus, it is the tear in the slab which is responsible for very low seismicity at shallow depth and no seismicity at deeper depth (Kundu and Gahalaut, 2010a). Presence of a tear and lack of slab in the region may substantially reduce the potential of occurrence of a future great earthquake in the region. Accordingly, it may also reduce tsunami hazard in the nearby regions due to major and great earthquakes in this region. It is possible that this tear hindered the northward rupture propagation of the 2004 Sumatra-Andaman earthquake. However, it is necessary to further confirm the presence of such a tear using marine deep seismic surveys, detailed tomographic studies, and analysis of earthquakes with the deployment of ocean bottom and land seismometers in the region.

Sumatra-Andaman arc region

The state of knowledge about the Sumatra-Andaman region was very poor until the occurrence of the December 26, 2004, Sumatra-Andaman (M 9.2), March 28, 2005, Nias (M 8.6), and several other earthquakes since then. These earthquakes have provided immense information about the tectonics and seismogenesis of this region. These earthquakes suggest that Indian plate subducts obliquely beneath the Andaman arc while the subduction becomes arc normal in the Sumatra arc. Precise hypocentral locations of these earthquakes and their aftershocks have helped in mapping the subsurface plate boundary interface in the frontal arc region and its seismogenic width. The 2004 Sumatra-Andaman earthquake occurred on a 1,400 km long and 100–150 km wide rupture between the northern Sumatra and north Andaman Islands. The large coseismic displacement in the source region (Gahalaut et al., 2006) caused a devastating tsunami which propagated through the Indian Ocean and caused heavy destruction in the countries surrounding the Bay of Bengal, namely, Indonesia, India, Thailand, and Sri Lanka. There were a few remarkable aspects of this earthquake and tsunami caused by it. It is learnt that the rupture in the northern part, i.e., under the Andaman Islands, was slower (Lay et al., 2005) and that it did not reach the surface. Thus this part of the rupture did not contribute in tsunami generation. It has been suggested that the subducting 90°E ridge probably slowed down the rupture under the Andaman Islands (Gahalaut et al., 2010b) and the subducted unconsolidated sediments of Bay of Bengal probably did not allow the rupture to propagate to the surface. These aspects need to be explored further. Earlier, another earthquake occurred here on June 26, 1941, with M 7.7 (Pacheco and Sykes, 1992), for which no seismological data exist to suggest whether slow rupture occurred during that earthquake as well. Though the reports are scanty, it appears that even that earthquake did not generate a tsunami (Rajendran et al., 2007). There may be various reasons for that earthquake for not being tsunamigenic, including slow rupture speed and rupture on blind fault. It may be possible that the Andaman segment may not generate major tsunami during future great earthquakes as well. However, it needs to be explored further by analyzing the frontal arc characteristics through deep seismic imaging and modeling.

An earthquake occurred on December 31, 1881 (M 7.9), in the Nicobar region. It caused a tsunami with less than 1 m height in the Andaman Islands and the coastal region of India. Unfortunately, the history of the Andaman and Nicobar Islands is very poor. The intermittent colonial occupation of the Islands started in the middle of the eighteenth century by the Danish, followed by the British, and continuous colonial occupation started only after 1869 until the independence of India in 1947. Prior to the nineteenth century, we do not know much about the history of the Andaman Nicobar region as the indigenous tribes did not maintain any written records. Thus, prior to the occurrence of earthquakes on October 31, 1847, possibly near Nicobar Islands (Bilham et al., 2005), and the two earthquakes mentioned above, we have no knowledge of historical earthquakes or tsunami in the region. However, it is certain that the great and major earthquakes under the Nicobar and northern Sumatra arc

have produced tsunami and are capable of generating tsunami during future great and major earthquakes.

In the northern Sumatra region, after the occurrence of the 2004 Sumatra-Andaman earthquake, another great earthquake occurred to the south on March 28, 2005, which is referred as the Nias earthquake. Despite its large magnitude and normal rupture speed, the earthquake could not generate a major tsunami. Majority of the slip on the rupture occurred under the shallow and no water and hence it could not displace large amount of water, causing only a localized tsunami whose amplitude faltered quickly as it moved in the open ocean. Nevertheless, this region has the potential to generate a tsunami during great earthquakes, though it may not affect the Bay of Bengal region due to rupture directivity. The arc region located further southeast, though capable of causing tsunami during great earthquakes, may not affect the Bay of Bengal region.

Summary

The Arakan coast of the Indo-Burmese arc can produce a major earthquake. However, it is unlikely that a major tsunami would be generated by the earthquake in this segment due to predominant strike slip motion on the plate boundary interface which is mostly located on the land and under very shallow water, and dips eastward, away from the sea. The Irrawaddy frontal arc region may not produce great or even major earthquakes and hence the tsunami threat from this region is low. The Andaman arc which did not contribute in tsunami generation during the 2004 Sumatra-Andaman earthquake needs to be studied in great detail in view of the slow and blind rupture. The real and definite threat is from the Nicobar and northern Sumatra arc region, which has produced tsunami in the past and is capable of generating tsunami during future great earthquakes.

Definition

Tsunami. Japanese word literally meaning harbor wave (*tsu+nami*). Tsunamis are series of ocean gravity waves caused mainly due to undersea earthquakes and undersea volcanic activity, rarely due to submarine landslides and very infrequently due to meteor impacts.
Tsunamigenic earthquake. Large earthquakes occurring mostly in subduction zones capable of generating tsunami.
Tsunami warning center (TWC). A 24 × 7 operational center with a mission to advise and warn coastal populace on tsunami.
Tsunami Bulletin. A real-time situation report of the event.
National tsunami warning center (NTWC). An early warning system responsible for collating and disseminating tsunami warning advisories information within a country.
Regional tsunami watch provider (RTWP). A NTWC capable of detecting and analyzing tsunami events and informing other NTWC within an oceanic region.
Service level. Level of operational capability in accurately advising/warning target populace.

Introduction

The 2004 Sumatra-Andaman earthquake and subsequent tsunami in the Indian Ocean were a grim reminder of nature's fury. The event prompted many countries in the region to set up tsunami warning centers (TWC), which were further integrated into a collaborative network of regional tsunami watch providers (RTWP) (UNESCO-IOC, 2007). Within India, an interim warning center was established in 2005 (Gupta, 2005; and Nayak and Kumar, 2008a) at Indian National Center for Ocean Information Services (INCOIS) and by the end of 2007, it became a full-fledged operational warning center.

An important fact that is well known about tsunami is that they travel very fast in open ocean (velocity of the order of several hundreds of kilometers per hour) and cannot be discernible easily by wave heights (of the order of a few centimeters), but slow down as they approach the coast (of the order of several tens of kilometers per hour) with wave heights increasing to disastrous proportions (of the order of several meters). Hence, to forewarn ourselves, we need to have a seismic network to detect tsunamigenic earthquakes and a network of sea-level observations to detect any water level changes. A forewarning system is essential to mitigate the effects of tsunami. Few centuries ago, traditional knowledge indicated that as soon the water withdraws from the beach, there is an impending tsunami. However, with the advancement of science (especially modeling, geospatial technologies, and communication infrastructure) and rapid increase in coastal population, the inherent risk in terms of loss of lives and economic damages (socioeconomic parameters) too has increased many fold, but now it is possible to mitigate damage by scientifically confirming/canceling such warnings derived from traditional knowledge and recommending the right advice to the populace at the right time. Such a scientific establishment is known as TWC. The mission of a TWC is to provide early warnings (known as tsunami advisories) on potentially destructive tsunamis to emergency/disaster management officials, and as appropriate, directly to the public to prevent loss of life and property. This article briefly describes TWC, its components, the advisory products that are generated, and level of operational service that these centers are designed for.

Types of tsunamis

Broadly, the Intergovernmental Oceanographic Commission (IOC) of United Nations Educational, Scientific, and Cultural Organization (UNESCO) has classified tsunamis into nine types: Historical tsunami, Local tsunami, Maremoto, Meteorological tsunami (meteotsunami), Microtsunami, Ocean-wide tsunami, Paleotsunami, Regional tsunami, and Teletsunami (Distant tsunami). However, from the early warning perspective, three types are considered most relevant, based on the distance from the source and the tsunami travel time (UNESCO-IOC, 2006). They are:

1. *Local Tsunami* originates from a nearby source for which its destructive effects are confined to coasts within 100 km or less than 1 h tsunami travel time from its source. These can often be the most dangerous because there is often little warning between the causing event and the arrival of the tsunami.

2. *Regional Tsunami* is capable of creating destruction in a particular geographic region, generally within 1,000 km or 1–3 h tsunami travel time from its source.
3. *Distant Tsunami* (also called an ocean-wide, distant, tele or far-field tsunami) is a tsunami that originates from a far away source, which is generally more than 1,000 km away from the area of interest or more than 3 h tsunami travel time from its source. A distant tsunami is capable of causing widespread destruction, not only in the immediate region of its generation, but across an entire ocean. All ocean-wide tsunamis have been generated by major earthquakes in the subduction regions.

Tsunami warning centers in the world

There are seven major tsunami warning centers operating in the world today in terms of independent services. They are: National Oceanic and Atmospheric Administration's (NOAA) Pacific Tsunami Warning Center (PTWC), Japan Meteorological Agency (JMA), NOAA's West Coast and Alaska Tsunami Warning Center, Sakhalin Tsunami Warning Center (STWC), German Indonesian Tsunami Early Warning System (GITEWS), Joint Australian Tsunami Warning Centre (JATWC), and the Indian National Tsunami Early Warning System (INTEWS). Each of these systems is conceptualized as the National Tsunami Warning Centres (NTWC), where they are the sole advisors in terms of area of responsibility regarding tsunami warning. In the event of distant tsunamis, they will act as regional tsunami watch providers (RTWP) to those regions that could be immediately affected and do not have their own NTWC or to other NTWCs operating in the region, as "heads-up" information. In addition to the above, few systems have been conceived as system of systems like International Tsunami Information Center (ITIC) and Indian Ocean Tsunami Warning System (IOTWS), where information from different major tsunami advisory providers is integrated as shown in Figure 1. The latter, IOTWS, has been an initiative from the US and UNESCO to enhance the warning capability in the region. In addition, critical seismic data providers like USGS (Earthworm seismic data processing system) and Global Seismic Network (GSN) are few of the specialized information providers essential for tsunami early warning.

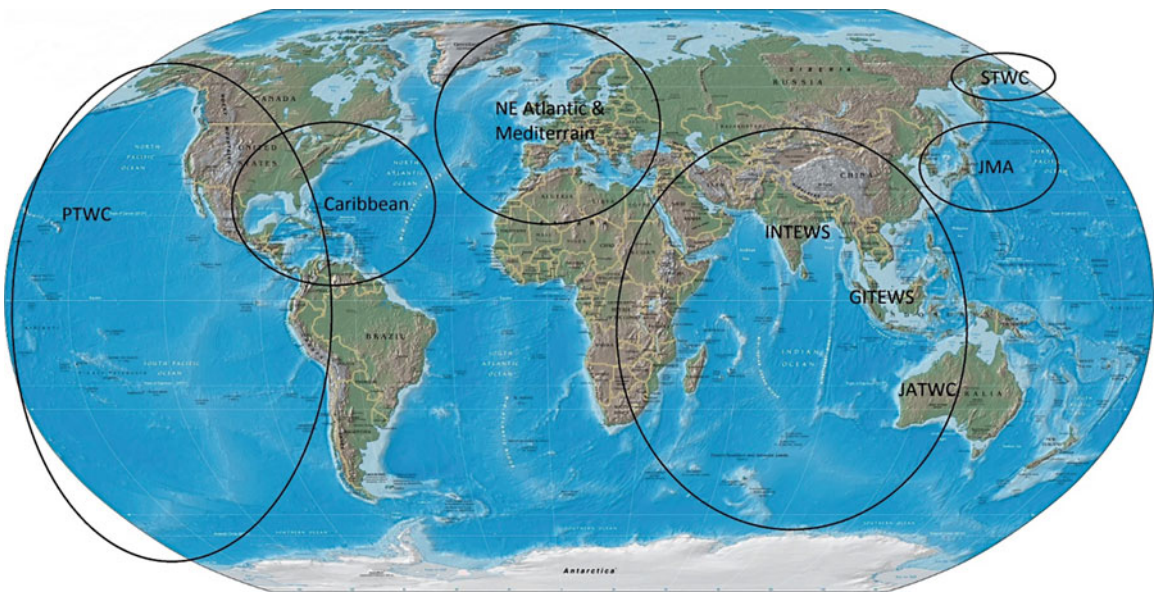
Key components

In order to carry out its mission, the TWC must at least consist of five important components: a network of sensors (seismic and sea level) to detect earthquakes and evaluate its potential for tsunamis, tsunami modeling capability (generation, propagation, and inundation models), high-resolution database on bathymetry and coastal topography, communication infrastructure to issue timely alarms to permit evacuation of coastal areas, and a 24 × 7 operational facility housing the infrastructure, decision support system (DSS) based on standard operating procedures (SOP), and experienced staff (Nayak and Kumar, 2008a). A typical outlay of TWC is shown in Figure 2.

Network of sensors

Seismic network

TWCs use local and global seismographic networks transmitting seismograms in real time to continuously monitor seismicity, in order to locate and estimate the size of potentially tsunamigenic earthquakes. To produce accurate



Tsunami Watch and Warning Centers, Figure 1 Tsunami warning systems presently operating in the world.

moment magnitude, NTWCs and RTWPs require reliable, broad-frequency, low-noise, high dynamic-range, digital seismic data in real time. The timeliness of the data is crucial in issuing an initial bulletin within 5 min of an earthquake. This is especially important for centers with local tsunami sources. In terms of network density, it is recommended that at least eight stations must be operating in a radius of 900 km, with data latency not exceeding 30 s.

Sea-level network

In order to confirm whether the earthquake has actually caused a tsunami, it is essential to measure the change in water level as near to the fault zone as possible with high accuracy. A TWC uses sea-level networks (tide gauge, bottom pressure recorders, and coastal ocean dynamics applications radar, CODAR) reporting data in real and near real time to verify the generation and evaluate the severity of a tsunami. Numerous international sea-level monitoring networks provide essential real-time data that can be accessed by NTWCs and RTWPs. Many of these networks are coordinated by the IOC of the UNESCO. The most extensive and notable is the Global Sea Level Observing System (GLOSS), conducted under the auspices of the Joint Technical Commission for Oceanography and Marine Meteorology (JCOMM) of the World Meteorological Organization (WMO) and the IOC. A tsunami creates a signal component that is not normally present in the observed sea level in usual times. Fortunately, the signature of tsunami waves at sea-level gages

Tsunami Watch and Warning Centers, Figure 3 Typical tsunami signal found in tide gauge sea-level data. (UNESCO Manual of Sea Level Interpretation Vol. 4, 2006.)

is generally quite distinctive and thus recognizable (see Figure 3) and can be differentiated from a signal due to storm surge (UNESCO-IOC Manual and Guides, 2006).

Modeling capability

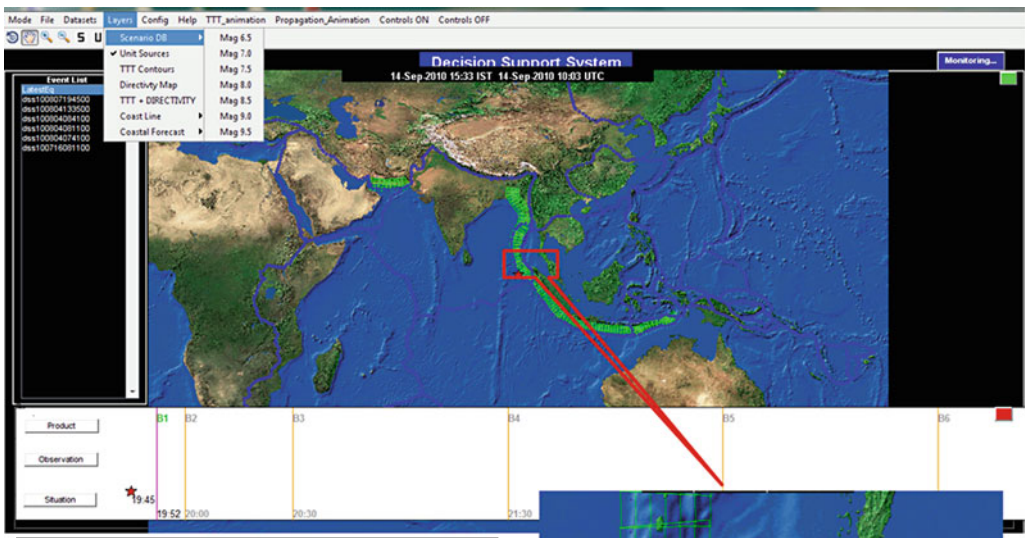
Guesstimating the generation mechanism of tsunami from the earthquake information, identifying the wave propagation scheme, forecasting the travel time, and mapping inundation zones are critical requirements in tsunami early warning, which can be accomplished using numerical models.

Tsunami modeling

Two of the most commonly used tsunami models presently are: the Method of Splitting Tsunami (MOST) developed by Titov and Gonzalez (1997) and the Tohoku University's Numerical Analysis Model (TUNAMI) developed by Imamura et al. (1995). Both these models are capable of simulating the three processes of a tsunami: earthquake generation, transoceanic propagation, and inundation of land. These models basically take the seismic deformation as input to predict the run-up heights and inundation levels at coastal regions for a given tsunamigenic earthquake (Imamura et al., 1995). The seismic deformation for an earthquake is computed using Mansinha and Smylie (1971) formulation using the earthquake parameters like epicenter, focal depth, strike, dip and rake of the rupture plane, length, width of the rupture, and slip magnitude on the rupture plane.

Scenario database

The above models cannot be run in real-time situations because of the computational overheads and resources. Hence, a pre-run scenario database or look-up-table (LUT) approach is most suitable in operational conditions. The forecast strategy is based on a unit-source function methodology, whereby the model runs are individually scaled and combined to produce arbitrary tsunami scenarios. Each unit-source function is equivalent to a tsunami generated by a Mw 7.5 earthquake with a rectangular fault 100 km by 50 km in size and 1 m slip (Gica et al., 2008; Greenslade and Titov, 2008; and Nayak and Kumar, 2008b, c). The faults of the unit functions are placed abutting each other. When the functions are linearly combined, the resultant source function is equivalent to a tsunami generated by a combined fault rupture with assigned slip at each sub-fault. These unit sources are located along the known fault zones for the entire Pacific Basin, Caribbean for the Atlantic region, and Indian Ocean. Figure 4 shows how the unit sources are set up in the Indian Ocean. A database of pre-run scenarios has been created for 1,000 unit sources covering all the tsunamigenic sources in the



Magnitude (M_w)	Width (W) (km)	Length (L) (km)	Slip (u_0) (m)
7.5	50	100	1
8.0	75	150	2.5
8.5	100	300	5
9.0	150	600	10
9.5	300	1200	20

Tsunami Watch and Warning Centers, Figure 4 Modeling using "unit-source" approach and the resulting scenario database. (Courtesy: INCOIS.)

Indian Ocean region (Kuwayama, 2006). At the time of earthquake occurrence, based on the location and magnitude, the basic unit-source open-ocean propagation scenarios are selected from the pre-run scenario database. These scenarios are then merged and scaled up/down using scaling relations (Nayak and Kumar, 2008c) to reconstruct a scenario representing the actual magnitude.

Geospatial integration: inundation modeling and mapping

The resulting open-ocean wave from the scenario database, described in previous section, has to be extended over to the shallow waters and to the coastal area to simulate inundation over land. Knowing the coastal inundation zone is the first step in disaster management and mitigation, as it directly tells us the extent of population to be evacuated and the estimated economic loss due to an event. To perform accurate modeling of tsunami inundation and run-up, a detailed model of near-shore bathymetry and coastal topography is necessary. This is crucial as the accuracy of model predictions is directly related to the quality of the data used to create the bathymetry and topography of the model area. Coastal Bathymetry is the prime determinant of the height of the tsunami wave or storm surge as it approaches the coast. Within the Indian Ocean context, topography of the region at 1:25,000-scale with contours at intervals of 0.5–2 m up to 20 m has been acquired. Preliminary maps have been prepared of coastal topography using satellite stereo data (CARTOSAT-1) for the Indian coast. These datasets, along with airborne **Li**ght **D**etection and **R**anging (LIDAR) data, were further used to create coastal vulnerability index (CVI) maps and multi-hazard vulnerability maps (MHVM) of coastline of India (Nayak and Kumar, 2008b). Similar high-resolution geospatial database is being leveraged in the Atlantic and Pacific Oceans (Gica et al., 2008).

Inundation mapping is not the only area where geospatial technologies are used, the inundation levels estimated and the subsequent threat status has to be accurately linked and conveyed to the respective administrative block within the coastal zones or within a province or a country. To implement such mechanism, the concept of coastal forecast points (CFP) and coastal forecast boxes (CFB) was developed (ICG/IOTWS) and implemented within the Indian Ocean region. Another major application of evolving geospatial trends is the application of 3D modeling or "videogrammetric" approach to visualize inundation and to identify evacuation routes and safe houses during inundation.

Communication infrastructure

Communication infrastructure is the most crucial and tangible aspect of any warning system for tsunami or any hazard. The ability to report and warn of an event is what makes and defines the warning system. Communication in terms of receiving all scientific data and disseminating information to the target audience within the required time needs a reliable communication infrastructure. During this process, TWC must respond fast, be as accurate as possible, and be reliable in order to be effective. All tsunami warning systems feature multiple lines of communications (such as SMS, email, fax, radio, texting, and telex, often using hardened dedicated systems), enabling emergency messages to be sent to the emergency services and armed forces, as well as to population alerting systems.

Decision support system and 24 × 7 operational center

In simple words, when the standard operating procedures are coded into a program that can support organizational decision making, then such a program can be called as a decision support system. It helps decision makers to compile useful information from a combination of raw real-time data, documents, personal knowledge, and tsunami scenarios models to accurately disseminate warning advisories to the needed area at the right time. The DSS encapsulates and foresees all the operations from the beginning of the event till the passage of threat by issuing timely advisories (Figure 2). The set of currently practiced advisories are earthquake information, warning, watch, and alert, which are described in detail in the following sections. All the information gathering, decision-making process, and infrastructure are part of the operational monitoring center.

Types of tsunami advisories

Based on the earthquake information, the tsunami modeling scenarios and operational capability, different types of advisory products are issued to the disaster management officials and to the general public. Each advisory has a distinct meaning and clearly suggests the action to be taken. The earthquake information bulletin issued solely on the earthquake information is a qualitative advisory while all others are quantitative advisories (Figure 5) issued taking into consideration the modeling results, and real-time sea-level observations, along with the earthquake information.

1. *Earthquake information bulletin* is issued to inform the occurrence of an earthquake and to advise its potential to generate a tsunami based on the magnitude. The bulletin contains information about the earthquake parameters (origin time, latitude, longitude, focal depth, and magnitude) and the name of the geographical area where it has occurred.
2. *Warning* is the highest level of advisory where immediate action has to be taken. This advisory is issued when a potential tsunami with significant widespread inundation is imminent or expected. Warnings alert the public that widespread, dangerous coastal flooding accompanied by powerful currents is possible and may continue for several hours after arrival of the initial wave. Warnings also alert emergency management

officials to take action for the entire tsunami hazard zone. Warnings may be updated, adjusted geographically, downgraded, or canceled.

3. *Watch* is issued to alert emergency management officials and the public of an event which may later impact the watch area. Immediate public evacuation is not required, Local officials should be prepared for evacuation if it is upgraded to warning status. The watch area may be upgraded to a warning or canceled based on updated information and analysis. Watches are normally issued based on seismic information without confirmation that a destructive tsunami is underway.
4. *Alert* contains information about the earthquake and a qualitative tsunami evaluation message indicating that a tsunami is expected. As conditions warrant, the advisory will either be continued, upgraded to a watch or warning, or canceled. Alert implies public should avoid beaches since strong currents are expected. Local officials should be prepared for evacuation if it is upgraded to warning status.
5. *Cancelation* indicates the end of the threat due to tsunami. A cancelation is usually issued after an evaluation of sea-level data confirms that a destructive tsunami will not impact the warned area anymore. A cancelation will also be issued following a destructive tsunami when sea-level readings indicate that the tsunami is below destructive levels and is subsiding in most locations.

Service levels

Based on the level of integration of key component into the TWC, each TWC has the capability to deliver advisory products at certain operational level. Each higher service level represents much more detailed threat evaluation and will be directed to more specific agencies/population group for disaster mitigation with increased confidence levels. Presently, the implementation plan of IOTWS (UNESCO-IOC, 2007) classifies these product levels into three groups, based on incremental capacity development:

Service Level I: At this level of operation, the TWC disseminates only the earthquake information and a qualitative tsunami threat evaluation to other national warning centers.

Service Level II: This is a more robust service level that includes all of the elements of Service Level I but adds modeling and forecast elements so that Watches and Advisory products include: Estimated wave height(s) (EWH) and Estimated time(s) of arrival (ETA) for offshore forecast points, potential threat zones, advanced warning and notification products of threat status and zones in image format. At this service level of operation, real-time observations are included in the decision making and in advisory products from Bulletin – 3 onward.

Service Level III: This is the most advanced level of operational service. At this level, the advisory products include local risk and hazard assessment using inundation models, and they are more specifically directed to communities at risk. Service Level III operations take into account real-time inundation forecast in evaluating the threat status. A TWC operating at this service level indicates a mature early warning system capable of detecting and evaluating tsunamigenic earthquakes occurring anywhere in the global oceans.

Conclusion

Although tsunamis are known to occur rarely, the key elements integrated in a TWC become the essential and minimum requirements in dealing with other ocean-related hazards like: cyclone related storm surges, cloud bursts, and impacts of long-term coastal erosion and sea-level rise. Geospatial technology has immensely helped in the design of early warning system for tsunami, and the GIS base layers and survey data make a TWC capable of dealing with coastal threats due to multiple hazards.

Acknowledgments

The authors would like to thank the Tsunami Early Warning Team at the Indian National Centre for Ocean Information Services (INCOIS) for their support in the preparation of graphics for this manuscript, especially Dr. Uma Devi, Mr. Ch. Patanjali Kumar, and Mr. Raghavendra S. Mupparthy. The authors are thankful to the Director of INCOIS for his active cooperation and encouragement during this process.

Definition
Vertical Seismic Profiling A geophysical technology for measuring the *seismic* properties in a *profile* of the earth using a set of sources and receivers, either of which are placed along the depth (*vertical*) axis.

Introduction
Vertical seismic profiling (commonly abbreviated to the name VSP) is a major technique in geophysical exploration, which involves measuring downgoing and upgoing seismic wavefields through a stratigraphic sequence. Shortly after the first attempts of developing surface reflection seismology, where both sources and receivers were at the surface, the line of research set out with the idea of burying either sources or receivers in boreholes. McCollum and LaRue (1931) proposed that local geologic structure could be determined from measuring the arrival of seismic energy from surface sources with buried receivers. This geometry forms the basic principle of determining seismic wave propagation velocities from VSP measurements even today. The technology of VSP acquisition and processing was initially developed by researchers in the former Soviet Union in the 1950s through the 1970s. It was only later, in the mid 1970s, that non-Soviet geophysicists became systematically engaged in the advance of VSP technology for exploration applications. Today, the fruits of these efforts have served not only in the improvement of velocity analysis, but have materialized numerous other applications ranging from structural imaging of complex 3D structures such as faults and salt domes in exploration studies, to directing drill operations, monitoring secondary recovery processes, and hydraulic fracturing.

Acquisition techniques
A variety of data acquisition techniques are currently employed, depending on the survey's application and financial budget. Figure 1 shows the main geometric configurations, which include (1) zero-offset VSP (ZVSP), where the source is near the well-head above the vertical receiver array, (2) offset VSP, where the source is located a distance away from the vertical borehole, (3) multi-offset VSP, for multiple distances of the source to the borehole, (4) walk-away VSP, where multiple sources are located on a line at the surface and the receivers in a vertical array, (5) walk-above VSP, where the sources are located over receivers buried in a deviated or horizontal well, and (6) drill-bit SWD (seismic while drilling) VSP, where the drill-bit acts as the seismic source and the receivers are on the surface. 3D VSP uses borehole receivers, and a 2D surface source geometry (i.e., multi-azimuth multi-offset, or walk-away VSP).

The common active seismic sources used in VSP include those used in land and marine surface studies (see *Seismic Data Acquisition and Processing*) as well as the noise of the drill-bit in the case of SWD-VSP. There is a variety of geophone tools available for use in cased or uncased boreholes, which combine three orthogonal geophones, a hydrophone and other borehole seismic tools at each recording level. The receiver spacing is set by the depth-sampling interval to avoid spatial aliasing.

Vertical Seismic Profiling, Figure 1 Common acquisition geometries for vertical seismic profiling (VSP): (1) zero-offset VSP (ZVSP), (2) offset VSP, (3) multi-offset VSP, (4) walk-away VSP, (5) walk-above VSP, and (6) drill-bit SWD (seismic while drilling) VSP.

To limit field acquisition time, most commonly multilevel receiver arrays are employed. The main source of noise in VSP studies are tube waves, which are generated when the fluid in the well is displaced by a seismic source, such as ground roll. Tube waves propagate up and down a well and create secondary tube waves in borehole anomalies, which may interfere with primary reflections. As a coherent noise mode, tube waves cannot be attenuated by stacking, therefore, both field procedures, such as use of attenuating heavy mud and construction of ditches to attenuate the ground roll, as well as processing techniques, such as filtering and tube wave modeling, are commonly used to minimize their effect.

VSP applications

The primary use of VSP is the integration of VSP and downhole logging to surface reflection surveys (Hardage, 1985). Contrary to surface studies, which infer subsurface conditions from measurement of the reflected wavefields with the source and receiver at the surface, a VSP configuration involves closely spaced direct physical measurements of the wavefield between the source position and the reflector.

Zero-offset VSP measurements can be correlated with sonic logs and check-shot surveys in the borehole and improve the depth positioning of reflections recorded in surface data. From a velocity perspective, zero-offset VSP measurements are denser than check-shot surveys; hence, they provide a finer interval velocity profile. On the other hand, VSP samples a larger velocity body around the well than the high frequency sonic log, which may be subject to cycle skipping and the effects of the washed-out zones. VSP also contains the signature of the near-surface, which is often absent in logging. Hence, synthetic seismograms computed from sonic logs may not accurately represent reflections recorded from surface measurements. Reflections from zero-offset VSP, however, can be matched to those from surface measurements via an appropriate static time-shift to account for the differential travel times of the two recording geometries.

Concerning seismic imaging, the recorded wavefield in a buried VSP array has higher signal to noise ratio across a larger seismic bandwidth than surface measurements for two reasons. First, surface cultural noise is suppressed in the borehole, and second, upgoing reflections do not propagate through the near-surface material, which is highly *attenuating* (see *Seismic, Viscoelastic Attenuation*). In addition, the reflections recorded in a VSP suffer less attenuation as the distance to the target is shorter. This shorter distance also implies that the *Fresnel zone* (see *Seismic, Waveform Modeling and Tomography*) is smaller in the case of a VSP, leading to higher resolution compared to surface seismic studies. Given that downgoing and upgoing wave modes are separated in the f-k space, either an f-k filter, or a trace by trace arithmetic subtraction of the estimated wave mode can isolate downgoing from upgoing waves. Estimation of the downgoing wavefield from VSP data is used in the design of deconvolution operators, which can be thereafter applied to surface data to improve the vertical resolution. On the other hand, upgoing reflections can be mapped to their origin position via either a CDP-VSP mapping, or *Seismic, Migration* algorithm, or a combination of the two. A migration step is strongly advisable in the case of

complex geologies. In recent years, VSP seismic imaging has transformed from an analysis of acoustic reflections to migrating converted-wave reflections (Grech et al., 2001), which may be more sensitive to imaging tight-sand reservoirs compared to P-P reflections (O'Brien and Harris, 2006), as well as to applications of free-surface multiples, which can increase the narrow cone of coverage of a VSP to that of a 3D CDP survey (Jiang et al., 2005). Another promising technique for seismic imaging applications is interferometric imaging, which through the creation of virtual sources (VS) in the location of the receivers eliminates the need for any knowledge of the complex overburden (Bakulin and Calvert, 2004). In addition, unlike traditional migration schemes, interferometric imaging circumvents a priori knowledge of the velocity structure in the vicinity of targets, such as salt flanks, and can be applied to imaging complex structures above or below a receiver array (Xiao et al., 2006; Vasconcelos et al., 2008).

Through the separation of downgoing and upgoing wavefields and their relative amplitudes, it is possible to extract the true *reflection coefficients* (see *Energy Partitioning of Seismic Waves*) used for lithological interpretation. Moreover, from multi-offset 3-component VSP data it is possible to determine the *AVO response* (see *Energy Partitioning of Seismic Waves*) with no assumptions to the path of the propagating wavefield, which is required in surface seismic AVO analysis.

Another benefit of using VSP measurements is their robustness in estimating *Seismic Anisotropy*, which improves lithologic interpretations as well as increases the quality of seismic imaging. Given the seismic velocity response to changes in reservoir porosity and fluid content, velocity *Seismic Anisotropy* can also be applied in monitoring of fluid-drainage patterns during production. Fracturing will also affect seismic velocity; hence, VSP velocity measurements can also be used in monitoring hydraulic fracturing.

With *attenuation* (see *Seismic, Viscoelastic Attenuation*) gaining increasing importance as a seismic parameter linked to lithological properties, VSP has proven to be a powerful tool for Q (see *Seismic, Viscoelastic Attenuation*) estimation. Aside from true amplitude processing required in stratigraphic interpretation, VSP-derived Q profiles are also used in the design of inverse Q-filters to enhance seismic resolution. Recent studies also suggest a link between anisotropic attenuation and fracturing (Maultzsch et al., 2007); hence, VSP azimuthal measurements of attenuation may potentially be applied in monitoring hydraulic fracturing in hydrocarbon and geothermal applications.

Summary

In recent years, VSP surveys are becoming increasingly popular for reducing risk in well placement and improving reservoir monitoring. Intrinsic to the complex geometry of the VSP, which poses several data acquisition and processing challenges, is the ability of the VSP to expand the spatial and time-lapse subsurface characterization potential of conventional downhole logging and surface reflection studies. Henceforth, following the success of VSP surveys and their increased benefits over their financial cost, the VSP technique is a rapidly developing area of geophysical research and may soon become a standard logging service.

Definition

Very Long Baseline Interferometry (VLBI). correlation interferometry of celestial objects with separately

operating radio antennas equipped with frequency standards, off-line data reduction remotely by a digital correlator.
e-VLBI. VLBI with transmission of data by a high-speed network instead of storage media.

Introduction

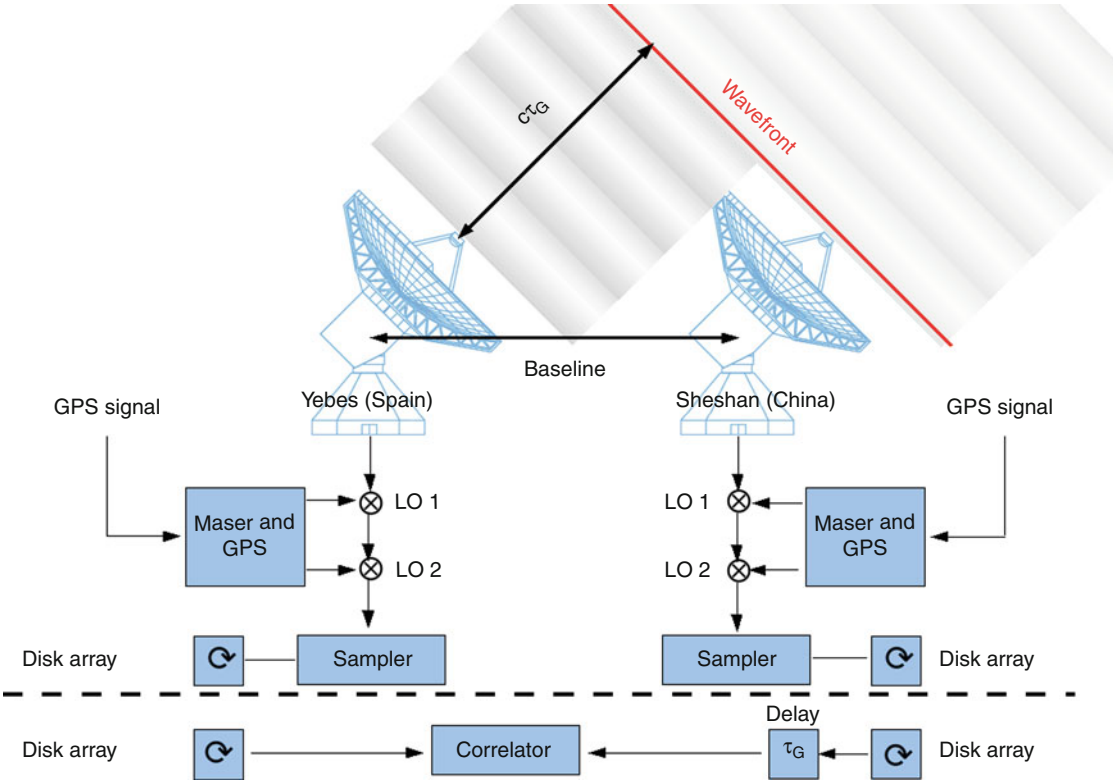
Very long baseline interferometry (VLBI) is a radio-astronomical technique to achieve high spatial resolution in astronomical imaging (of the order of milliarcseconds), involving antennas separated by thousands of kilometers (a "VLBI network"). Because the reconstruction of the image depends on the precise knowledge of the vector (hereafter: baseline) connecting the two antennas of a station pair, the a priori knowledge of the image can be used to determine the baseline vector by inverting the measurement equation, with a precision corresponding to a fraction of the wavelength. Such an a priori knowledge is naturally given if the astronomical source on the sky is spatially unresolved and therefore a "point source." Such sources – usually quasars, that is, the nuclei of bright radio galaxies – are spread over the entire sky and regularly observed in radio astronomy. Whereas VLBI in radio astronomy aims at resolving these active galactic nuclei, improper assumptions about source structure limit the accuracy of the determinations of antenna stations. This can be avoided by using appropriate source structure models (Tornatore and Charlot, 2007). The importance of VLBI techniques in Geophysics is evident if the two antennas of a baseline are located on different tectonic plates, whose relative motion and deformation can therefore be determined with high accuracy (qv *Geoid*).

A VLBI array can be thought as a fictive giant single-dish telescope whose aperture is synthesized while the baseline vector sweeps the sky thanks to the rotation of the Earth. The resulting image therefore depends on the angular momentum vector of the Earth. This dependency implies applications of VLBI in the measurements of the Earth's spin axis in space and with respect to the solid crust as well as irregularities of the *Earth Rotation*. Other, less precise methods are position determinations with the Global Positioning System (qv *GPS, Tectonic Geodesy*) and synthetic aperture radar measurements (qv *SAR Interferometry*), the latter being an interferometric method, like VLBI.

Methods and techniques in very long baseline interferometry

The idea of connecting several telescopes to an array in order to synthesize part of the surface of a single, large telescope dates back to 1946, when Ryle and Vonberg (1946) used for the first time a multi-element radio telescope for solar observations. In both optical and radio astronomy, the idea turned out to be extremely fruitful for achieving the highest spatial resolutions. For a single telescope, the resolution (in radians) is given by the ratio of wavelength to aperture diameter (up to a factor of order unity). By consequence, a radio telescope working at a wavelength of 21 cm needs an aperture of about 50 km in order to achieve the same angular resolution as, for example, an optical telescope limited by atmospheric seeing. The largest, fully steerable radio telescopes have apertures of the order of 100 m and reach, at that wavelength, an angular resolution of 9 arc minutes. As an alternative to even larger single-dish radio telescopes, several telescopes can be connected by microwave or fiber optics cables in order to form a connected-element interferometer. If the telescopes of such an interferometer are suitably distributed, a sufficiently long observation of a celestial source can be reconstructed to form an image whose angular resolution is of the order of the ratio of the wavelength to the longest among the distance vectors ("baseline," see Figure 1) between telescope pairs. The advantage of connected-element interferometers is that the signals can be correlated in real time, such that the phase of the electromagnetic wave when it arrives at the different telescopes is preserved. This is achieved by mixing the incoming signal with that from a local oscillator. In a connected-element interferometer, the local oscillators in all antennas are driven with a common phase reference. The Very Large Array (VLA, New Mexico) and the British e-Merlin array have elements connected by optical fiber cables, with baselines of up to 50 km (VLA) and 200 km (e-Merlin). Despite modern communication technology sometimes used (e.g., satellite links), the physical connection of array elements becomes impractical beyond a certain limit.

The step from a connected-element interferometer to a VLBI experiment consists of abandoning (for practical and economical reasons) the microwave or optical fiber links, registering the data, together with time marks, on a suitable storage medium, and analyzing the data later with a digital correlator. While local oscillators are necessary to convert the observed frequency band pass to one at a lower frequency (for recording the data), they cannot be locked to a common phase reference because of the large separation between the antennas. Time marks are therefore necessary. This technique became feasible with the availability of reliable frequency standards for the time marks, and magnetic tapes of sufficient storage capacity. The first VLBI observation correlated the data of a single baseline between the Hat Creek (California) and Green Bank (West Virginia) observatories (Bare et al., 1967). Since then, the major improvements in VLBI were mainly due to the increase of baseline length (i.e., spatial resolution) and collecting area (i.e., sensitivity), and due to the availability of more reliable clocks and faster digital samplers, leading to larger spectral bandwidth and thus sensitivity. Nowadays, hydrogen masers are used as frequency standards, while arrays of hard disks replace the tapes. The distinction between a connected-element interferometer and a VLBI network is somewhat imprecise. Using network connections of large bandwidth, VLBI data can now be transmitted in real time to the central correlator, while the local oscillators of the antennas participating in the



Very Long Baseline Interferometry, Figure 1 Schematic representation of an antenna pair on a baseline between Spain and China (distances not to scale). The electromagnetic wave from a distant point source (a quasar) is shown together with the position of the wave front when arriving in China (red line). The signal path corresponding to the time delay τ_G is shown, as well as the correction for the latter in the data reduction. There is no physical connection between both antennas, each operating with an independent local oscillator (labeled LO). The dashed line separates the measurement from the off-line data processing. Credits: Greve/IRAM/Rebus.

network are not synchronized. This technique has been demonstrated in 2005 with the European VLBI Network (EVN), involving a transatlantic baseline.

Physical principles

Interferometric experiments detect both amplitude and phase of electromagnetic waves (conveniently described by complex functions) and combine them in a suitable way to provide images, spectra, and polarization information. Phase-sensitive detection is possible by measuring correlations (or coherence functions) in the incoming electromagnetic field. It has been shown (Sudarshan, 1963) that for the case of two-point correlation functions, classical and quantum electrodynamics lead to equivalent results if nonlinear effects are ignored. We therefore limit our discussion to the case of ensembles of incoherent packets of quasi-monochromatic electromagnetic waves from different directions but confined to a small field of view.

The starting point of any interferometric imaging experiment is the van Cittert-Zernicke theorem (van Cittert, 1934; Zernike, 1938), stating that the correlation of the electromagnetic field at two points (two-point or mutual coherence function) is, up to a complex scaling factor, given by the Fourier transform (also called "visibility function") of the spatial intensity distribution (example: the interference pattern observed on a screen behind an illuminated slit or a grid). The complex scaling factor involves a correction due to the fact that the antenna baselines are not parallel to the plane of the sky (and, for the case of VLBI, not coplanar among them). This so-called delay correction τ_G needs to be applied because of the lag between the arrival times of the front of the electromagnetic wave at the antennas of a given baseline (Figure 1), and is equivalent to steering the fictive large single-dish telescope mentioned above to the source. The applied delay correction will differ from the theoretical one, owing to the clock error and to the inaccuracy of the assumed baseline length. In the absence of an error-free, absolute time scale, the data streams from an antenna pair rather have to be synchronized by maximizing the correlated signal, applying reasonably guessed delay corrections. A first synchronization is done by using the GPS time signal (qv *GPS, Data Acquisition and Analysis*) to which the local oscillators in the antennas are locked. A refinement needs to be applied later when the data are cross-correlated. There are actually two free parameters

per baseline pair, not only the delay correction, but also the frequency of the oscillations, due to the Earth's rotation, in the interference pattern ("fringes"). This frequency has to be fitted, too, because it depends on the clock rate. For hydrogen masers, whose radio signal at a frequency of 1.4 MHz is now commonly used as a frequency standard for VLBI experiments, the fractional frequency drift (e.g., due to temperature drifts) after 100 s is of the order of 10^{-14}. Such a high precision is required if phase information is to be extracted once the signals are correlated. There is yet another difference between a connected-element interferometer with baselines of up to 10^6 wavelengths, and a VLBI experiment: in the former case, the field of view of the interferometer is limited by the central lobe of the antenna reception pattern ("main beam"), whereas in VLBI the field of view is limited by the largest delay τ_G within which the signal from a given direction is coherent. This delay depends on the baseline length with respect to the wavelength, on the spectral bandwidth across which these signals are averaged, and on the accuracy required (e.g., astrometry or precise baseline determinations need a higher degree of coherence). Therefore, the field of view of VLBI observations is much smaller than that of observations with connected-element interferometers. However, nowadays more evolved data analysis techniques exist that permit to overcome this limitation (Garrett et al., 1999).

For each telescope of the VLBI network, the data from the receiving system are recorded on an array of hard disks, together with the time marks from the clock. Later these data are correlated with a digital correlator. Modern correlators currently used are the Mark IV and Mark V or K4 and K5 systems. They allow us to analyze VLBI data for large frequency bands (for high sensitivity to continuum signals) or high-frequency resolution (for observing spectral lines).

Data calibration and imaging

After applying the aforementioned delay and fringe rate corrections, the phases of the complex data need to be recovered. The visibility functions are first smoothed to an integration time interval, which depends on the tolerated "visibility smearing": owing to the rotation of the Earth during this time span, different spatial frequencies are measured at different times, even for a single baseline. Furthermore, at the highest frequencies, where atmospheric fluctuations become important (mm VLBI), the elementary integration times are kept below 20 s, which allows one to apply atmospheric phase corrections. Another upper limit to the integration time interval is given by the stability of the clock. However, the time constant of a hydrogen maser is longer than the two previous limitations.

Unlike connected-element interferometers, where the phase of the front of the incident electromagnetic wave is not too much distorted by atmospheric effects, the phase difference between signals received by different VLBI stations is completely lost. This is because the atmospheric fluctuations at the different antenna sites are uncorrelated, and because the local oscillators in the antennas are not locked by a common phase reference. Fortunately, only phase differences with respect to a reference antenna are important. For a triangle of VLBI antennas, the phase errors due to atmospheric and instrumental fluctuations cancel out in the sum of the phase differences between the antennas of the three baselines involved ("phase closure"). Since the number of baselines scales roughly with the square of the number of antennas, whereas the number of phase errors increases only linearly with it, a considerable part of the phase information can be recovered (e.g., 89 % for the 18 antennas of the EVN). This recovery of phase information can be improved by a "self-calibration" initially assuming a point source as model, calibrating the measured phases under this assumption, and then creating a new source model using an imaging algorithm. In the underlying theory, complex antenna gains are used, and closure relations also exist for their amplitudes.

Such imaging algorithms are needed because the VLBI stations cannot sample the visibility functions on a regular grid of spatial frequencies. Therefore, the brightness distribution resulting from a Fourier transform is convolved with the "synthesized beam," which is the Fourier transform of the sampling of spatial frequencies. Iterative algorithms exist to deconvolve the image such that the result is the brightness distribution as observed with a fictive single dish telescope whose diameter corresponds to the longest available baseline. The CLEAN algorithm (Högbom, 1974) considers the brightness distribution as a collection of spatially unresolved sources. Other deconvolution algorithms have been proposed and applied since then, depending on the nature of the observed brightness distributions. The combination of CLEAN and phase closure is known as hybrid mapping (e.g., Readhead et al., 1980). Global fringe fitting (Schwab and Cotton, 1983) extends the closure relations to time delays and fringe rates and is iteratively used together with a deconvolution algorithm like CLEAN.

For high-precision work (e.g., measurements of the Earth rotation parameters, see below), general relativistic effects need to be considered. As an indication, the gravitational time delay due to the Earth's gravity amounts to up to ~0.02 ns on a 6,000 km long baseline, and the positions of the celestial sources have to be corrected for light bending in the gravitational field of the sun (4 milliarcsecond for an incidence orthogonal to the direction from Earth to Sun, for a summary and further references, see Heinkelmann and Schuh, 2010; Fomalont et al., 2010).

VLBI networks

VLBI networks now extend all over the world. The most sensitive network is the European VLBI Network (EVN), connecting 18 radio telescopes in Europe, Puerto Rico, and South Africa, operating together for more than

3 months per year. The American Very Large Baseline Array (VLBA) works for the whole year. Other national VLBI facilities exist in the UK (the Merlin array), Japan (Japanese VLBI network JVN), and Australia (long baseline array, LBA). Occasionally, some of these networks work together to form global VLBI networks (e.g., the EVN with the VLBA or Merlin, and the Asia-Pacific telescope APT with observatories in Australia, China, New Zealand and Japan). Currently, the best angular resolutions (down to 0.1 milliarcsecond) are achieved with global VLBI at 3 mm wavelength. Future improvements of the spatial resolution scale are to be expected from VLBI below 3 mm wavelength, and from networks including satellite stations (with the Japanese HALCA antenna, in operation from 1997 to 2005, to be replaced by the VSOP 2 mission). These VLBI networks are mainly used for astrophysical research. However, VLBI is also used extensively for geodetic and geophysical applications (see below). Owing to the importance of the VLBI techniques for these disciplines, the International VLBI Service for Geodesy and Astrometry (IVS, Schlüter and Behrend, 2007) coordinates the observations of a dedicated network of VLBI stations on all continents (Figure 2), operated by national research agencies.

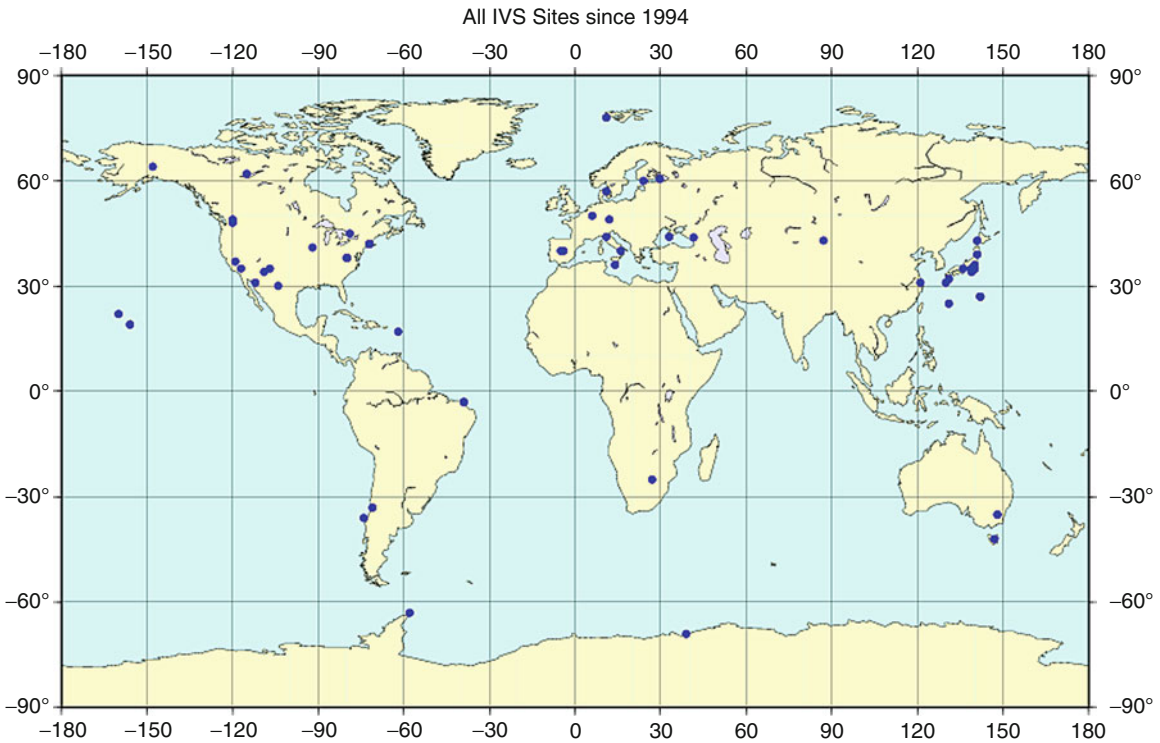
Geodetic and geophysical applications

The technique of VLBI is also used for geodetic and geophysical applications. In this context, the positions of compact extragalactic radio sources, like quasars, are considered to be known to sufficient accuracy and the relative telescope coordinates are inferred from time delay observations which reflect the baseline-source geometry. In most cases, networks of six to eight telescopes (Figure 2) are employed in series of weekly sessions organized by the IVS for the determination of Earth orientation parameters (qv *Earth Rotation*) and radio telescope coordinates. Observing between 50 and 60 radio sources in a repeated sequence of scans of 50–100 s duration over a 24-h period provides enough redundancy and geometric stability to determine telescope coordinates and Earth orientation parameters.

Reference systems and tectonics

Geodetic and geophysical applications of VLBI have to do a lot with coordinates of the radio telescopes on Earth and in space. Through sophisticated engineering and constant developments in the theoretical models, the coordinates of radio telescopes around the world can be determined with a relative accuracy of a few millimeters today. These coordinates are always referred to a very specific point of the telescope structure which lies at or close to the intersection of the axes about which the telescope is rotated to aim at the quasars.

The coordinates of geodetically used radio telescopes are determined repeatedly over the years and are fed into the database of the International Earth Rotation and



Very Long Baseline Interferometry, Figure 2 Locations of the VLBI antennas of the IVS network participating in the period of 1994 to 2009.

Reference Systems Service (IERS, qv *Earth Rotation*, see also http://www.iers.org). Together with observations of other space-geodetic techniques like the Global Navigation Satellite Systems (GNSS) or Satellite Laser Ranging (SLR, qv *Satellite Laser Ranging*), the VLBI results are merged into the International Terrestrial Reference Frame (ITRF, qv *Geodesy, Networks and Reference Systems*). The last version of the ITRF, ITRF2008, contains about 700 points on Earth which are all accurate to sub-centimeter. The importance of VLBI for this endeavor is that VLBI is the technique which is used to determine the scale of the ITRF. Here, VLBI benefits from the fact that the geodetic VLBI measurements link radio telescopes over intercontinental distances with extreme accuracy. The observations of the other techniques are then used to densify the global reference frame.

Closely linked to the coordinates of the radio telescopes are the changes of the positions which are caused by global tectonics better known as continental drift (qv *Geoid*). Geodetic VLBI was the first technique to verify Alfred Wegener's theory of continental drift through real measurements across the North Atlantic between 1979 and 1984 (Carter et al., 1985; Herring et al., 1986). Today, a full global scenario of several plates and deformation zones exists for which geodetic VLBI has helped to determine the magnitude and direction of the tectonic movements. While the distance between North America and Europe extends by about 20 mm per year, the changes in the Pacific region reach 80 mm per year (Kondo et al., 1987).

Likewise, the positions in space of the Earth and of the quasars observed by VLBI are defined in the International Celestial Reference System (ICRS). The ICRS has been realized through the International Celestial Reference Frame (ICRF, Ma et al., 1998) and its successor, the ICRF2 (Ma et al., 2009), which rely on the VLBI positions of many hundred extragalactic radio sources. Due to the large distances of the latter, the ICRF can be considered as definition of a local inertial system (or quasi-inertial system). The origin of the ICRF is the barycenter of the solar system. Systematic effects and additional random errors of the ICRF2 do not exceed 50–100 microarcseconds (Ma et al., 2009). The accuracy of the ICRF is expected to further improve in the future, thanks to the aforementioned space VLBI (Charlot, 2009).

Earth rotation

Polar motion and irregularities in the Earth's rotation: Geodetic VLBI is one of the few main techniques for the determination and monitoring of the Earth's variable rotation (qv *Earth Rotation*). Through the direct link between the terrestrial and the celestial reference frames, VLBI is the only technique which permits to determine all components of Earth rotation without any input from other techniques. While today polar motion is regularly determined precisely with GPS observations (qv *GPS, Tectonic Geodesy*) on a routine basis, VLBI uniquely contributes the Earth's phase of rotation represented through the time UT1 (Universal Time 1). UT1 is quite variable, due to movements of the atmosphere and of the oceans, and information on UT1 is needed for a number of applications including orbit transformations of Global Navigation Satellite Systems. For this purpose, the International VLBI Service for Geodesy and Astrometry (IVS) runs daily observations providing UT1 with an accuracy of about 5–10 μs.

Precession and Nutation: Looking at the Earth's axis of rotation in space, one can see that it describes a cone with an opening angle of 23.45°, which needs about 25,700 years to complete. This phenomenon is called precession. Superimposed on the precession cone are periodic movements of the Earth's axis of rotation which have a magnitude of a few arcseconds and are called nutation. For historical reasons, precession and nutation are handled independently although they are caused by the same phenomenon: The astronomical bodies of Sun, Moon, and planets exert a torque on the equatorial bulge of the Earth trying to pull it toward the ecliptic. Through its desire to conserve angular momentum, the Earth reacts with a precession effect. Through the periodic rotations of the attracting bodies, superimposed periodicities result and more than a 1,000 nutation periods can be identified covering a spectrum from 13.6 years down to a few days.

General relativistic effects in Earth Rotation: Owing to the orbital motion of the Earth, spin-orbit coupling leads to a "geodetic precession" of about 2 arcseconds per century (qv *Earth Rotation*, Klioner et al., 2010) that are measured by VLBI, which lends itself also to other tests of general relativity (Fomalont et al., 2010).

Today, geodetic VLBI is the only technique that is used to determine precession and nutation. The accuracy of the nutation offsets determined from 24 h of VLBI observations is on the order of 80–100 microarcseconds which correspond to about 3 mm when transformed to a metric displacement at the Earth's surface. The agreement between these observations and a model which is derived geophysically using an elastic Earth model is on the order of 1 milliarcsecond. The main cause of the deviations is the effect of the so-called free core nutation (FCN). This phenomenon results from the fact that the Earth's core has a slightly different ellipticity than the rest of the body resulting in different torques.

WAVELET ANALYSIS

Mikhail Kulesh
Information Technology, DIS AG, Mahlow, Germany

Synonyms

Time-frequency analysis; Wavelet transform; Wavelets

Definition

Time-frequency representation (TFR). A view of a time series represented over time and frequency.
Wavelet. A special function that is well localized in both time and frequency domains.
Continuous wavelet transform (CWT). TFR of the analyzed signal obtained as a set of scalar products of all dilated and translated wavelets with this signal.
Discrete wavelet transform (DWT). A wavelet transform for which the wavelet is dilated and translated discretely.

Introduction

Spectral analysis methods of the time series based on the Fourier transform are significantly limited in their ability to distinguish the waves with similar frequency content but having the different time of arrival. This limitation can be overcome using different time-frequency analysis techniques that allow us to examine how the frequency content of a given signal changes as a function of time.

A view of a time series represented over both time and frequency is called the time-frequency representation (TFR). Time-frequency analysis means analysis into a TFR. There are different TFR methods each suitable for different applications:

1. The short-time (alternatively short-term or windowed) Fourier transform that is used to determine the sinusoidal frequency and phase content of local sections of a signal as it changes over time (Allen and Mills, 2004).
2. The Gabor transform is a special case of the short-time Fourier transform that uses a Gaussian function to create a window of time from which the spectrum of the local signal values is computed (Allen and Mills, 2004).
3. The Wigner (alternatively Wigner–Ville) distribution (Wahl and Bolton, 1993) and the pseudo-Wigner–Ville distribution (Prosser et al., 1999; Andria and Savino, 1996) that can be formulated by the multiplicative comparison of a signal with itself, expanded in different directions about each point in time.
4. The S-transform (Stockwell et al., 1996; Pinnegar and Mansinha, 2003) that is similar to the short-time Fourier transform, but with a Gaussian window whose width scales inversely, and whose height scales linearly, with the frequency.
5. The continuous wavelet transform (CWT) of a real or complex signal with respect to a real or a complex analyzing wavelet that is a set of scalar products of all dilated and translated wavelets with this signal (Grossmann and Morlet, 1984; Heil and Walnut, 1989; Chui, 1992; Daubechies, 1992; Holschneider, 1995; Mallat, 1999; Antoine, 2004). A wavelet is a special function that is well localized in both time and frequency domains.
6. The discrete wavelet transform (DWT) that is a wavelet transform for which the analyzing wavelet is dilated and translated discretely (Heil and Walnut, 1989; Holschneider, 1995).

The short-time Fourier transform has a fixed resolution dependent on the windowing function width. A wide window gives better frequency resolution (frequency components close to each other can be separated), but poor time resolution. A narrower window gives good time resolution

Harsh K. Gupta (ed.), *Encyclopedia of Solid Earth Geophysics*, DOI 10.1007/978-90-481-8702-7,

(the time at which frequencies change), but poor frequency resolution. Among all possible window functions, there is one signal in particular that shows the best performance regarding time and frequency localization: the Gaussian. Thus, the Gabor transform and the S-transform are the short-time Fourier transforms with the best joint time-frequency resolution.

Since the Wigner distribution is a correlation of the signal with a time and frequency translation of itself, there is no limitation in the time-frequency resolution. However, its distribution may show negative energy levels and exhibit interferences that do not have any physical meaning. To minimize the effect of these interferences, the smoothed pseudo-Wigner–Ville distribution can be used. Unfortunately, the use of the smoothing operator introduces time-frequency smearing in the resulting TFR and therefore downgrades its advantage over the Gabor or wavelet transform, namely, the exact localization over time and frequency.

The CWT and DWT are computed by correlating the signal with families of time-frequency atoms (wavelets). Therefore, the time-frequency resolution of this method is limited by the uncertainty relation bound to the simultaneous time-frequency resolution of the analyzing wavelet.

All of these above-mentioned methods are widely used in the geophysical applications. However, the wavelet transform gives a more general framework for the time-frequency analysis of geophysical data; this approach is powerful and elegant and has several remarkable properties that can be directly applied to the polarization and dispersion analysis of seismic waves in the time-frequency domain.

In the next sections, we briefly introduce the direct and inverse wavelet transforms and some of their properties. Then, we will demonstrate the applications of the CWT in the geophysical time-series analysis.

Continuous wavelet transform

Let us introduce the following notations:

1. $s(t)$ is a square-integrable (finite-energy) real or complex function over time from $L^2(\mathbf{R})$ space: $s(t) \in L^2(\mathbf{R}) \Leftrightarrow \int_{-\infty}^{+\infty} |s(t)|^2 dt < \infty$.
2. $\omega = 2\pi f$ is the angular frequency (in radian/s) and f is the physical frequency (in Hz).
3. $\hat{s}(\omega) = \int_{-\infty}^{+\infty} s(t) e^{-i\omega t} dt, \quad s(t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \hat{s}(\omega) e^{i\omega t} d\omega$ are the direct and inverse Fourier transforms.
4. $g(t) \in L^2(\mathbf{R})$ is a real or complex function called analyzing (mother) wavelet (Grossmann and Morlet, 1984).
5. $T_t : g(\tau) \mapsto g(\tau - t)$ is a shifting operator for the analyzing wavelet.
6. $D_a : g(\tau) \mapsto g(\tau/a)/a$ is a dilation operator for the analyzing wavelet.
7. $W_g s(t, a)$ are the complex wavelet coefficients dependent on the dimensionless scaling factor $a \in \mathbf{R}$ and dimensional time factor $t \in \mathbf{R}$ (in s).
8. The asterisk superscript means the complex conjugate.

The wavelet transform $W_g s(t, a)$ of the signal $s(t)$ with respect to an analyzing wavelet $g(t)$ is the set of L^2-scalar products $\langle T_t D_a g, s \rangle$ of the signal with all dilated and translated wavelets:

$$W_g s(t, a) = \langle T_t D_a g, s \rangle = \int_{-\infty}^{+\infty} \frac{1}{a} g^*\left(\frac{\tau - t}{a}\right) s(\tau) d\tau \,. \tag{1}$$

Note that there are different possibilities to define the dilation operator D_a. We use the factor $1/a$ in this operator. For this factor, the amplitude of the wavelet spectrum is proportional to the amplitude of the signal for pure frequencies. Alternatively, the dilation $D_a : g(\tau) \mapsto g(\tau/a)/\sqrt{a}$ with corresponding adaptation of the transform (1) can be also used (Heil and Walnut, 1989), but the relation between the amplitude of the spectrum and the amplitude of the signal will be in this case frequency (scale) dependent.

Using the properties of the Fourier transform, we can also define the shifting and the dilation operators as $T_t : \hat{g}(\omega) \mapsto e^{-i\omega t} \hat{g}(\omega)$ and $D_a : \hat{g}(\omega) \mapsto \hat{g}(a\omega)$ that allows us to rewrite the transform (1) as being used for Fourier-spectra of the analyzed signal and the analyzing wavelet (Holschneider, 1995):

$$\begin{aligned} W_g s(t, a) &= \frac{1}{2\pi} \langle T_t D_a \hat{g}, \hat{s} \rangle \\ &= \frac{1}{2\pi} \int_{-\infty}^{+\infty} e^{i\omega t} \hat{g}^*(a\omega) \hat{s}(\omega) d\omega. \end{aligned} \tag{2}$$

The last equation can be used for the fast computation methods to calculate the CWT of the discrete signals $s(t_n)$ with the signal length equal to 2^N points. In this way, a fast Fourier transform algorithm can be employed in practice to compute the integral in the Equation 2.

The inversion formula

The wavelet transform preserves all information of the transformed signal since there is an explicit formula that allows us to recover the signal $s(t)$ from its wavelet spectrum (Holschneider, 1995):

$$\begin{aligned} s(t) &= \mathrm{M}_h W_g s(t, a) \\ &= \frac{1}{C_{g,h}} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \frac{1}{a^2} h\left(\frac{t - \tau}{a}\right) W_g s(\tau, a) d\tau da, \end{aligned} \tag{3}$$

where $h(t) \in L^2(\mathbf{R})$ is a reconstruction wavelet used for the inverse transform; it can differ from the analyzing

wavelet that has been used to calculate $W_g s(t,a)$. The constant $C_{g,h}$ is the normalization coefficient having the same meaning as the coefficient $1/2\pi$ in the inverse Fourier transform. However, this coefficient depends on which pair of wavelets has been taken for direct and inverse transformation:

$$C_{g,h} = \int_0^{+\infty} \frac{1}{\omega}\left(\hat{g}^*(\omega)\hat{h}(\omega) + \hat{g}^*(-\omega)\hat{h}(-\omega)\right)d\omega. \quad (4)$$

Use of the physical frequency

In the practical applications, it is convenient to choose as the scaling parameter the physical frequency f instead of the dimensionless factor a: $f = f_0/a$, where f_0 is the characteristic (central) frequency of the analyzing wavelet. In this case, we can rewrite the direct and inverse transforms (1)–(3) as follows:

$$\begin{aligned} W_g s(t,f) &= \int_{-\infty}^{+\infty} \frac{f}{f_0} g^*\left(\frac{(\tau - t)f}{f_0}\right) s(\tau)d\tau \\ &= \int_{-\infty}^{+\infty} e^{2\pi i t\varphi}\hat{g}^*\left(\frac{f_0\varphi}{f}\right)\hat{s}(\varphi)d\varphi, \\ s(t) &= \mathrm{M}_h W_g s(t,f) \\ &= \frac{1}{C_{g,h}}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \frac{1}{f_0} h\left(\frac{(t-\tau)f}{f_0}\right) W_g s(\tau,f)d\tau df. \end{aligned} \quad (5)$$

Wavelets

The analyzing wavelet, that is, wavelet used for direct wavelet transform, must satisfy the following conditions (Antoine, 2004):

1. The wavelet must be well localized both in the time and in the frequency domain.
2. The wavelet must satisfy the admissibility condition, which guaranties the invertibility of the wavelet transform: $\int_{-\infty}^{+\infty} \frac{|\hat{g}(\omega)|^2}{|\omega|}d\omega < \infty$, see also Equation 4.
3. In the most cases, the previous condition may be reduced to the requirement that the 0-th moment of the wavelet should vanish: $\int_{-\infty}^{+\infty} g(t)dt = 0$.
4. The previous property can be generalized by requiring that some consecutive moments vanish, which improves the efficiency of the wavelet at detecting singularities in the signal: $\int_{-\infty}^{+\infty} t^n g(t)dt = 0$.

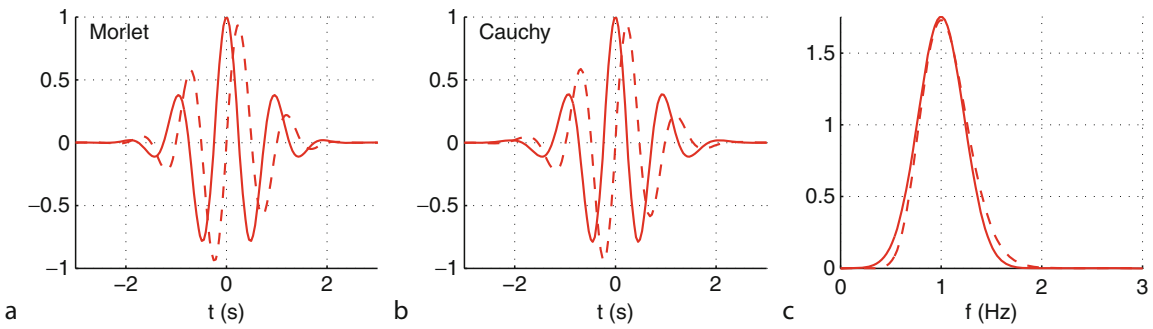
The choice of the analyzing wavelet depends on what typical oscillation modes are present in the signal. For example, to analyze rectangular oscillations, the real Haar wavelet proposed in (Haar, 1910) or a similar but symmetric French hat (FHAT) wavelet is most suitable. The most convenient for the seismic signals are real wavelets based on different-order derivatives of the Gaussian or complex progressive wavelets. If a two-component signal presented in a complex form is analyzed, or the separation into prograde and retrograde wavelet spectrum is needed, the choice of a complex progressive wavelet is preferable.

A special set of progressive wavelets is the set of functions for which the Fourier transform is real valued. Let us consider two such wavelets:

1. The Morlet wavelet is represented in Figure 1a. The solid line corresponds to the real part, and the dashed line to the imaginary part of the wavelet. The Fourier spectrum is plotted in Figure 1c as the solid line. This wavelet can be written with its Fourier transform as:

$$g(t) = e^{i\omega_0 t}e^{-t^2/(2\sigma^2)}, \hat{g}(\omega) = \sigma e^{-(\omega-\omega_0)^2\sigma^2/2}, \quad (6)$$

where the parameter σ describes the variance of the wavelet, and $\omega_0 = 2\pi f_0$ is the central frequency. Strictly speaking, this function is not a wavelet because it is not of zero mean. However, the function values at negative frequencies are small compared to the values at positive frequencies that allow us to use it as



Wavelet Analysis, Figure 1 (**a**) Morlet wavelet in the time domain, (**b**) Cauchy wavelet in the time domain, (**c**) Fourier-spectra of the Morlet wavelet (*solid line*) and Cauchy wavelet (*dashed line*).

a progressive wavelet with necessary precision in almost all practical applications.

2. The Cauchy wavelet is shown in Figure 1b and can be written as:

$$g(t) = \left(1 - \frac{2\pi i t}{p-1}\right)^{-p},$$
$$\hat{g}(\omega) = \frac{(p-1)^p}{(p-1)!}\left(\frac{\omega}{2\pi}\right)^{p-1} e^{-(p-1)\omega/2\pi}. \quad (7)$$

This wavelet has the unit central frequency, the parameter p describes the variance of the wavelet, and the Fourier spectrum is nonsymmetrical (Figure 1c, dashed line). The wavelet transform with respect to this wavelet is closely connected to the analysis of analytical functions over the half plane (Holschneider, 1995).

One can choose the translated δ-function $\delta_t = \delta(\tau - t)$ as the reconstruction wavelet $h(t)$ for the inverse wavelet transform, which gives us a rather simple and fast reconstruction formula (Holschneider, 1995):

$$s(t) = \mathrm{M}_\delta W_g s(t,f) = \frac{1}{C_{g,\delta}} \int_{-\infty}^{+\infty} \frac{1}{f} W_g s(t,f) df. \quad (8)$$

However, the δ-function is not a wavelet and its choice as the analyzing wavelet $g(t)$ for the direct CWT is not possible.

Wavelet spectrum amplitude and phase

Because the wavelet coefficients are complex, when using a complex wavelet, we can write the spectrum $W_g s(t,f)$ as a function of wavelet spectrum modulus $\left|W_g s(t,f)\right|$ and phase $\arg W_g s(t,f)$:

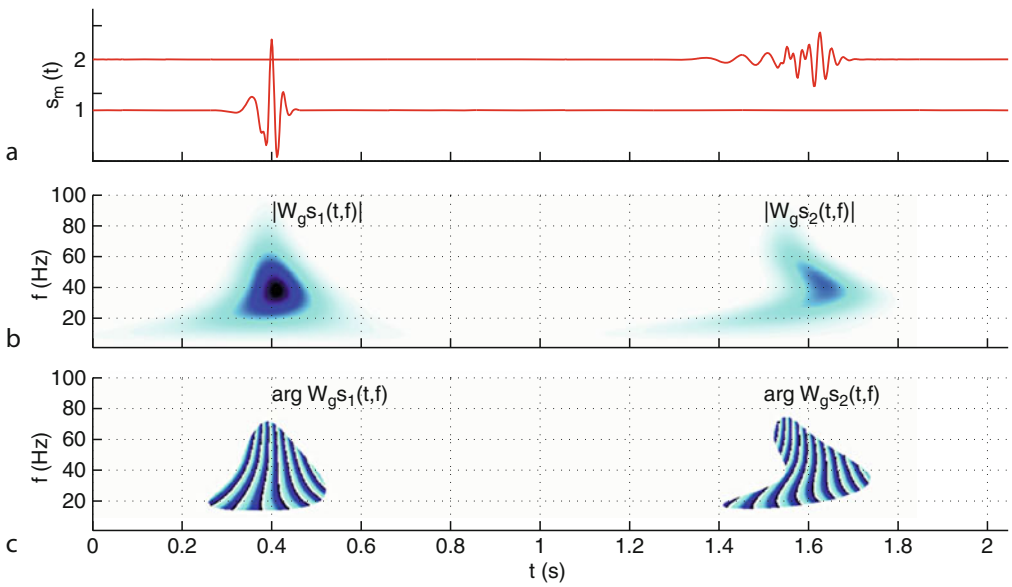
$$W_g s(t,f) = \left|W_g s(t,f)\right| e^{i \arg W_g s(t,f)},$$
$$\arg W_g s(t,f) = arctg\left(\frac{Im W_g s(t,f)}{Re W_g s(t,f)}\right), \quad (9)$$

where $arctg(x) \in [-\pi, \pi]$, which is implemented in most programming languages as atan2().

Thus, the complex wavelet spectrum contains information about the time-frequency distributions of the signal's amplitude and phase, and this amplitude and phase information can be analyzed separately as shown in the Figure 2. In this example, we consider a wave propagating in the medium with dispersion and attenuation (see *Seismic, Viscoelastic Attenuation*). This wave is represented by two signals, $s_1(t)$ and $s_2(t)$, which can be registered from two geophones (see *Seismic Instrumentation*) separated by a distance Δx (Figure 2a).

The wavelet spectrum modulus $\left|W_g s(t,f)\right|$ corresponds to the instantaneous amplitude. We can visualize it, for example, as contour line plot, where the horizontal axis corresponds to the time, and the vertical axis represents the frequency (Figure 2b). The complex wavelets Morlet and Cauchy have a phase shift between the real and imaginary components that prevent here the high-frequency modulus oscillations.

At the same time, a contour line plot of the wavelet spectrum phase $\arg W_g s(t,f)$ represents the instantaneous phase on the different frequencies. Because of practical reasons, the phases must be only plotted for time-frequency areas where the modulus $\left|W_g s(t,f)\right|$ is not infinitesimal (Figure 2c).



Wavelet Analysis, Figure 2 Wavelet spectrum amplitudes and phases for two signals.

To analyze the dynamic behavior of multivariate signals using the CWT, one may be interested in investigating of a diffeomorphic deformation of the wavelet space $W_g s_1(t,f) \mapsto W_g s_2(t,f)$ as shown in Figure 2. Such a deformation corresponds to a pseudodifferential operator acting on signal's wavelet spectrum:

$$D : s(t) \mapsto \mathrm{M}_h D W_g s(t,f). \tag{10}$$

In this context, we will consider in the next sections how the wavelet transforms of the source and the propagated signal are related through a transformation operator that explicitly incorporates the phase and group velocities as well as the attenuation factor of the medium.

Prograde and retrograde wavelet spectrum

Both Morlet and Cauchy wavelets are progressive, that is, their Fourier coefficients for negative frequencies are zero. This feature allows us to separate the wavelet spectrum into prograde $W_g^+ s(t,f)$ and retrograde $W_g^- s(t,f)$ components:

$$\begin{aligned} W_g s(t,f) &= W_g^+ s(t,f) + W_g^- s(t,f), \\ W_g^+ s(t,f) &= \begin{cases} W_g s(t,f), f \geq 0 \\ 0, f < 0 \end{cases}, \\ W_g^- s(t,f) &= \begin{cases} 0, f \geq 0 \\ W_g s(t,f), f < 0. \end{cases} \end{aligned} \tag{11}$$

To perform such a separation for nonprogressive (e.g., real) wavelets, one must first calculate the Hilbert transform of the source signal, which makes the numerical procedure more complex.

An example of the prograde and retrograde wavelet spectrum is shown in Figure 3, where we consider a two-component synthetic seismogram related to a Rayleigh wave (see *Surface Waves*). From two signals, $u_x(t)$ and $u_z(t)$ that correspond to the orthogonal components of the record, we construct a complex signal $z(t) = u_x(t) + iu_z(t)$, as shown in Figure 3a, where the solid line corresponds to the real part, and the dashed line to the imaginary part of this complex signal.

For this complex signal, we perform CWT using Equation 5 with respect to Cauchy wavelet (7) and plot only the absolute values of the complex wavelet coefficients as contour line plots for the prograde and the retrograde components (11) separately (Figure 3b). The analysis of the difference between these two spectra is exactly the idea to find out polarization properties of a signal as introduced in the next sections.

Discrete wavelet transform

As the CWT, the discrete transform also has a huge number of applications in science, engineering, mathematics, and computer science. In its basic form, the DWT employs a dyadic grid (integer power of two) in the timescale plane:

$$\begin{aligned} &T_{jk} : g(\tau) \mapsto g\left(\tau - k/2^j\right), \quad D_j : g(\tau) \mapsto 2^{j/2} g\left(2^j \tau\right), \\ &\psi_{jk}(\tau) = T_{jk} D_j g(\tau), j, k \in \mathbf{N}. \end{aligned}$$

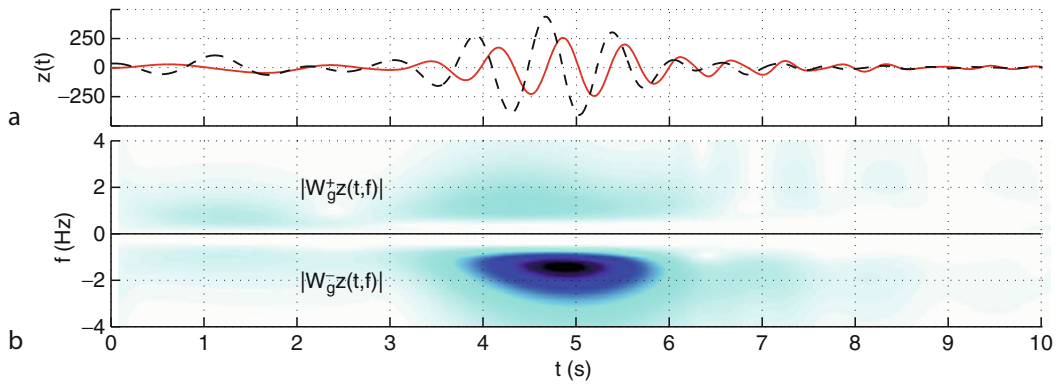
Actually, the transform integral remains continuous for the DWT, but is determined only on a discretised grid of frequencies and time points (Heil and Walnut, 1989):

$$W_g s_{jk} = \left\langle \psi_{jk}, s \right\rangle = \int_{-\infty}^{+\infty} 2^{j/2} g^*\left(2^j \tau - k\right) s(\tau) d\tau. \tag{12}$$

For the DWT, the orthonormal wavelets are usually used. The wavelet $g(t)$ is called orthonormal, when the functions family $\left\{\psi_{jk}\right\}$ in the Equation 12 corresponds to an orthonormal basis in the $L^2(\mathbf{R})$ space, that is, $\left\langle \psi_{jk}, \psi_{nm} \right\rangle = \delta_{jn}\delta_{km}$,where δ_{jn} is the Kronecker's delta. In this case, each function $s(t) \in L^2(\mathbf{R})$ can be represented as a sum of a convergent series:

$$s(t) = \sum_{j,k} W_g s_{jk} \psi_{jk}(t). \tag{13}$$

The simplest possible orthonormal wavelet is the Haar wavelet:



Wavelet Analysis, Figure 3 Prograde and retrograde wavelet transform of a Rayleigh wave arrival.

$$g(t) = \begin{cases} 1, 0 \le t < 1/2, \\ -1, 1/2 \le t < 1, \\ 0, t < 0, t \ge 1. \end{cases} \quad (14)$$

This function was proposed by Haar (1910) to give an example of a countable orthonormal system for the space of square-integrable functions on the real line. The technical disadvantage of the Haar wavelet is that it is not continuous, and therefore not differentiable.

Use of wavelets in geophysical time-series analysis

Instantaneous parameters

The concept of instantaneous parameters has been widely used in electric engineering and geophysics. Parameters such as instantaneous amplitude $|W_g s(t,f)|$, instantaneous phase $\arg W_g s(t,f)$, and instantaneous frequency $\Omega(t,f)$ are directly related to geometry and physical property variations of the medium through which the radar signal propagates. The instantaneous frequency, for example, responds to both wave propagation effects and depositional characteristics, hence it is a physical attribute and can be used as a hydrocarbon indicator by low frequency anomaly, a fracture zone indicator, or a bed thickness indicator. Using the wavelet spectrum, the instantaneous frequency is defined as follows: $\Omega(t,f) = \frac{\partial}{\partial t} \arg W_g s(t,f)$.

To avoid the numerical derivatives in the above expression, it is possible to derive an exact analytical formula for the computation of $\Omega(t,f)$ that involves the wavelet transforms of the signal with respect to the analyzing wavelet $g(t)$ and its derivative $g'(t)$. This approach is widely used for instantaneous frequency estimate with Gabor transform (Borum and Jensen, 1999) and can be adapted to the case of wavelet transform as follows:

$$\Omega(t,f) = -\mathrm{Im}\left(\frac{W_{g'} s(t,f)}{W_g s(t,f)}\right). \quad (15)$$

Polarization analysis

Perhaps the first successful attempt to combine the time-frequency analysis with the polarization analysis of multicomponent signals was done by (Keilis-Borok et al., 1989). Afterwards, a great number of the different polarization methods working in the time-frequency domain has been proposed. Some of these methods are based on:

1. The DWT with respect to the orthogonal wavelets and the singular value decomposition (Lilly and Park, 1995; Claassen, 2001).
2. The S-transform and elliptical motion approximation (Pinnegar, 2006; Schimmel and Gallart, 2007).
3. The CWT with respect to the orthogonal Mayer's wavelets and the complex covariation method (Soma et al., 2002), the singular value decomposition method (Roueff et al., 2006), the adaptive covariance method (Kulesh et al., 2007), as well as using analytical signals (Burjanek et al., 2009).
4. The wavelet packet decomposition of three-component seismic traces (Lyubushin, 2006).

As an example let us consider a simple polarization method based on the complex trace analysis. This method can be applied for the two-component signals. First, we construct a complex signal $z(t) = u_x(t) + iu_z(t)$ from two orthogonal components $u_x(t)$ and $u_z(t)$ of a record to be analyzed. Next, we perform CWT and split the obtained wavelet spectrum into prograde $W_g^+ z(t,f)$ and retrograde $W_g^- z(t,f)$ components using Equation 11. Then, we can compute the phase difference $\Delta\phi(t,f)$, the major $R(t,f)$ and minor $r(t,f)$ half-axes, and the tilt angle $\theta(t,f)$ of the polarization ellipse in the time-frequency domain as follows

$$\begin{aligned} \Delta\phi(t,f) &= \arg\left(\frac{W_g^+ z(t,f) + W_g^- z(t,f)^*}{W_g^+ z(t,f) - W_g^- z(t,f)^*}\right) + \pi/2, \\ R(t,f) &= |W_g^+ z(t,f)| + |W_g^- z(t,f)|, \\ r(t,f) &= |W_g^+ z(t,f)| - |W_g^- z(t,f)|, \\ \theta(t,f) &= \arg(W_g^+ z(t,f)\, W_g^- z(t,f))/2. \end{aligned} \quad (16)$$

Thus, the particle motions can be represented by instantaneous attributes that show distinct features for waves of different polarization characteristics. These attributes are explicitly related to the wavelet transform coefficients of the analyzed signal that can be used to perform the complete wave mode analysis (Pacor et al., 2007) and separation/filtering (Diallo et al., 2006) of two-component seismograms in the wavelet domain.

Dispersion analysis

Surface wave propagation in heterogeneous media can provide a valuable source of information about the subsurface structure and its elastic properties. For example, surface waves can be used to obtain subsurface rigidity through inversion of the shear wave velocity. The processing of experimental seismic data sets related to the surface waves is computationally expensive and requires sophisticated techniques in order to infer the physical properties and structure of the subsurface from the bulk of available information.

One of these techniques is the calculation and interpretation of the phase and group velocities from the experimental seismograms. The time-frequency representation is today commonly used for the phase and group velocities computation (Levshin et al., 1972; Abbate et al., 1995; Prosser et al., 1999; Niethammer et al., 2001; Pedersen et al., 2003). Most of the methods are essentially based on the study of the square modulus of the representation, which can be interpreted as the energy density in the time-frequency plane. These methods provide only partial information that cannot be directly used to characterize the phase velocities and the different propagation modes.

In order to analyze the dynamical behavior of multi-arrived signals using the model (10), it is also possible to develop a wavelet transformation operator that approximates the wave propagation in the dispersive medium and explicitly incorporates the phase and group velocities as well as the attenuation function (Kulesh et al., 2005):

$$W_g s_m(t,f) = e^{-\alpha(f)D_{mj}} \left| W_g s_j\left(t - \frac{D_{mj}}{C_g(f)}, f\right)\right| \times e^{i\cdot \arg W_g s_j\left(t - D_{mj}/C_p(f), f\right)}. \quad (17)$$

In this operator, $C_p(f) = f/k(f)$ is the phase velocity, $C_g(f) = 1/k'(f)$ is the group velocity, and $\alpha(f)$ is the attenuation function. The signals $s_m(t)$ and $s_j(t)$ correspond to records obtained from two geophones placed with distance $D_{mj} = D_m - D_j$ apart, and $k(f)$ is the frequency-dependent wave-number function.

The relationship (17) has the following interpretation. The group velocity is a function that "deforms" the image of the absolute value of the source signal's wavelet spectrum, the phase velocity "deforms" the image of the wavelet spectrum phase, and the attenuation function determines the frequency-dependent real coefficient by which the spectrum is multiplied (see also Figure 2b and c). Based on this property, one can construct the optimization (Holschneider et al., 2005) and correlation (Kulesh et al., 2008; Waltisberg and Raišutis, 2008) methods that allow us to extract both phase and group velocities from the wavelet spectra of multi-arrived signals containing waves with several wave modes.

Summary

In contrast to the Fourier transform, the CWT provides a two-dimensional spectrum of the analyzed signal, where the frequency and the time are treated as independent variables. As a result, we can investigate the signal in the time domain and in the frequency domain at the same time. The fact that the time-frequency-dependent polarization attributes are explicitly related to the wavelet transform of the signals enables us to perform the wave mode separation in the wavelet domain. It is also possible to construct the wavelet-based dispersion operators that can be used to model wave propagation in a dispersive and attenuating medium.
