
Magnetotelluric Interpretation, Figure 4 Apparent resistivities along profiles transecting a vertical contact for two polarizations – TM and TE – of the source field relative to strike.

Computing the corresponding apparent resistivities from the electromagnetic impedances for both cases, we obtain for the *TM* (Transverse Magnetic), or E-perpendicular mode:

$$Z_{xy}^{(\mathrm{surf})} = \frac{E_x}{H_y}, \text{ leading to } \rho_{xy}^{\mathrm{app}} = \frac{1}{\omega\mu}\left|\frac{E_x}{H_y}\right|^2 \tag{4}$$

and for the *TE* (Transverse Electric), or *E*-parallel mode

$$Z_{yx}^{(\mathrm{surf})} = -\frac{E_y}{H_x}, \text{ leading to } \rho_{yx}^{\mathrm{app}} = \frac{1}{\omega\mu}\left|\frac{E_y}{H_x}\right|^2 \tag{5}$$

Impedance matrix. Of course in actual field surveys one usually does not know ahead of time the trend or principal directions of local subsurface geologic features, so the electrode lines and magnetic sensors are usually deployed in standard geographic or geomagnetic coordinates. This leads to a "*mixing*" or "*cross-coupling*" of the field components. With reference to the linear coupling forms in Equation 2, it is convenient to express these relations in the compact matrix form

$$\begin{bmatrix} E_x^{(\mathrm{p})} \\ E_y^{(\mathrm{p})} \end{bmatrix} = \begin{bmatrix} 0 & Z_{xy}^{(\mathrm{p})} \\ Z_{yx}^{(\mathrm{p})} & 0 \end{bmatrix} \begin{bmatrix} H_x^{(\mathrm{p})} \\ H_y^{(\mathrm{p})} \end{bmatrix} \tag{6}$$

where the superscript "p" denotes measurements in the principal coordinates of the feature (such as in the *x*- and the *y*-directions in Figure 4). Rotating relation (6) through an arbitrary angle θ clockwise from the principal coordinates in Figure 4 leads to a relation between the measured electric and magnetic field components of the form

$$\begin{bmatrix} E_x \\ E_y \end{bmatrix} = \begin{bmatrix} Z_{xx} & Z_{xy} \\ Z_{yx} & Z_{yy} \end{bmatrix} \begin{bmatrix} H_x \\ H_y \end{bmatrix} \tag{7}$$

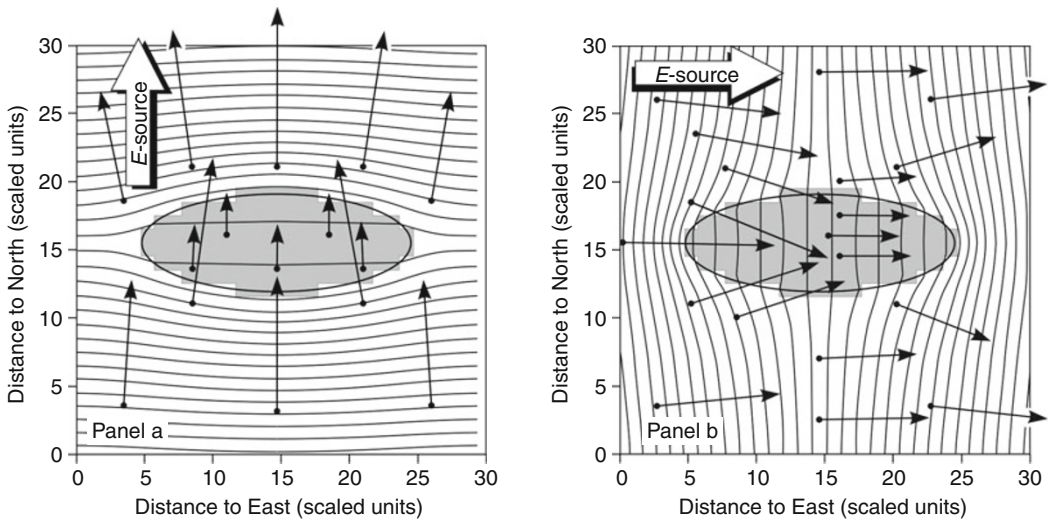
where the *impedance matrix* is often referred to as a *tensor impedance*.

Three-dimensional (3D) heterogeneities. Recognizing that the earth is, in general, 3D, electromagnetic workers have developed various approximate methods to dealing with it since the 1930s (see Keller and Frischknecht, 1966). Moreover, the theory of electromagnetic induction in 3D laterally heterogeneous material has evolved significantly over the decades since 1980, largely through implementing physically representative numerical techniques (see the work cited for Stodt, Wannamaker, Mackie and Madden among others, in Simpson and Bahr, 2005; see also Siripunvaraporn et al., 2005). Several of the principal effects of three dimensionality are illustrated in the example in Figure 5 which is a plan view map of telluric (i.e., electric) field distortions in the vicinity of a small idealized, elliptically shaped conductivity anomaly in the surface layer of an otherwise uniform or plane-layered earth. The embedded "elliptical" feature in the figure is a modest four times more conductive than the host material (although it is not uncommon for lateral contrasts to be an order of magnitude or more). The important point is that the electric field (and the associated magnetic field) can change dramatically in magnitude and direction over very small distances.

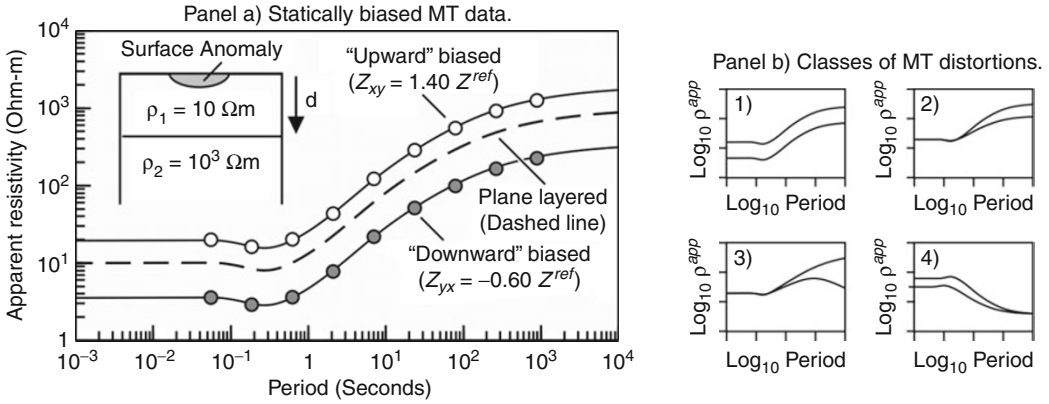
Effects of bias of MT data from lateral heterogeneities. Workers realized early in the development of magnetotellurics that linear coupling relations like Equation 7 are most often the rule in field data (see the collection of reprints assembled by Vozoff, 1985). The first step, therefore, in interpreting MT data often involves decomposing multiple independent sets of observations of both of the electric field components $\left(E_x^{(\mathrm{obs})}, E_y^{(\mathrm{obs})}\right)$ and the associated magnetic field components $\left(H_x^{(\mathrm{obs})}, H_y^{(\mathrm{obs})}\right)$ to extricate estimates of the principal values of apparent resistivity, ρ_{xy}^{app} and ρ_{yx}^{app}, in the principal directions. It is common practice to plot up both resistivity estimates as a function of period, as was done for the plane-layered case in Figure 3. However, the effects of even a small heterogeneity on the MT response of an otherwise plane-layered earth is illustrated in Figure 6, using as the background the plane-layered example in Figure 3 (shown as the dashed line in Figure 6).

The dashed curve in Figure 6a represents the original plane-layered response of Figure 3, along with the hypothetical effects that might be encountered in MT field data acquired at a site within, or in the vicinity of, a small, local embedded surficial anomaly. For one of the principal polarizations, the affected apparent resistivity relative to the original plane-layered curve is "*upward-biased*" by almost a factor of 2, and for the orthogonal polarization the apparent resistivity is "*downward-biased*" to 36% of its undistorted value. (There is no reason, of course, that for some cases *both* $\rho_{xy}^{\mathrm{app}}(T)$ and $\rho_{yx}^{\mathrm{app}}(T)$ might be biased to higher values, or both biased to lower values.)

Such bias effects are endemic to magnetotelluric surveys, and are particularly challenging to those investigations that are intended to be "*deep-sounding*" of the crust and upper mantle (and the mantle transition zones), since it is so easy for an undetected static offset to bias the long period asymptotic values to larger, deeper, and more resistive – or smaller, shallower, and more conductive – values. If, along with the "static" offsets described above, there are 3D induction effects as well, the field data become increasingly more complicated to untangle. Figure 6b shows several selected classes of MT responses often observed in field data due to quasi-static and inductive coupling effects for various combinations of shallow and deep (or distant) lateral heterogeneities. While one must



Magnetotelluric Interpretation, Figure 5 Plan view map of telluric (or electric) field distortions in the vicinity of an idealized embedded conductivity anomaly. (Panel a) Voltage contours and selected electric field directions for a north-directed electric source field. (Panel b) The same parameters as panel a, but for an east-directed source field.



Magnetotelluric Interpretation, Figure 6 Examples of static bias. (Panel a) Example to demonstrate the mechanism of "quasi-static shift" (referred to the dashed plane-layered case). (Panel b) Selected classes of "distortions" of MT data due to various combinations of shallow and deep lateral heterogeneities, with static and inductive coupling effects.

be cautious in drawing too much from a single set of sounding curves, these panels might illustrate the following generic phenomena. Panel b1 illustrates the type of static shift from a shallow surface feature discussed above. Panel b2, on the other hand, suggests a fairly uniform layer at shallow depth, but as the period and depth of penetration increases, the principal resistivities begin to separate indicating a deeper-seated inhomogeneity. One needs to be careful here, as the inhomogeneity may lay off to the side, and be a lateral effect, rather than a simple depth effect. Panel b3 suggests a similar, but more complicated phenomenon in that the two resistivity modes do not simply separate at longer period, but their respective shapes are frequency dependent, indicating that there are significant induction effects as well as static shifts coming into play. Panel b4 is an idealized version of situations commonly encountered in real data that might be theoretically explained by a true anisotropic resistivity layer at the surface, with a more conductive layer at depth. Often, however, for real world data, the merging of the principal resistivity curves with increasing period is simply a precursor to their crossing and then shifting apart again at still longer periods. In all of these cases, drawing 1D inferences from data that are clearly affected by 2D and 3D structure is questionable. For other examples, see Vozoff (1985) and Simpson and Bahr (2005).

Current strategies for MT interpretation

Much of the progress on MT interpretation over the last 3 decades is due to a progressive improvement in data acquisition, robust processing of multi-site data, and careful 2D and 3D numerical modeling. Simultaneously, recording multi-station MT arrays have become the standard practice for industry, academia, and government surveys. Recognizing the importance of high-density coverage using simultaneous observations of MT fields at multiple sites, several national programs are developing multi-station MT arrays. Typical instrumentation for such facilities is described by Smirnov et al. (2008), with some of the preliminary results of the Earthscope MT array in the United States reported by Patro and Egbert (2008) (See also *Instrumentation, EM*).

There is an increasing emphasis, when interpreting MT data, on either explicitly using 3D models, or at least on using 3D models as guides when using the more efficient, less computationally intensive, 2D inverse techniques. The earth, however, *is* three-dimensional, and most workers agree that any attempt to simplify its inherent complexity with 2D or even 1D plane-layered models, needs to be assessed at some level with effective and representative 3D models. Such models have progressively evolved from the initial contributions reported in the reprint collection of Vozoff (1985). A number of notable reports on 3D numerical models – modeling, inversion, and applications – are contained in the compendium of Oristaglio and Spies (1995), with additional developments by Mackie et al. (1993), Siripunvaraporn et al. (2005), and Tong, et al. (2009).

In spite of the promise of full 3D MT interpretations, most recognize that the inversion of data from a large regional array of broadband stations in terms of generalized 3D models tends to be computationally intensive (Newman and Alumbaugh, 2000; Zhdanov and Tolstaya, 2004). Thus, most surveys interpret array data in terms of 2D cross-sections. In many cases, the response of a 3D feature is locally quite 2D in nature. In other cases, it may be possible that the type of localized static shift discussed in an earlier section can be compensated for, and the observed coupling matrix can be decomposed into regionalized principal elements (Groom and Bailey, 1989). Berdichevsky et al. (1998) summarize several of the major concepts that many interpreters employ when analyzing MT data from 2D (and 3D) environments. First, while the *TM* (*E*-perpendicular) mode is often quite sensitive to local near-surface features, the *TE* (*E*-parallel) mode is often more indicative of deeper, more regional features. Second, while the *TM* mode is more susceptible to the effects of static shift, it is not uncommon that the

TE mode may be relatively undistorted. Both modes, however, are essential for a comprehensive interpretation of a study area, but must be used prudently. Ledo et al. (2002) discuss the limitations as well as the computational advantages – when appropriate – of applying 2D model inversions to actual 3D field situations.

For many investigations, the concomitant 2D and 3D effects might be considered unwanted "distortions" of deep-sounding data, and a bane to those studies intended to better understand the deep crust, or to delineate the depth to the lithosphere–asthenosphere boundary, the mantle transition zones, and so forth, on regional or subglobal scales. On the other hand, there is indeed a great deal of information in MT data that could be essential for characterizing the full 3D character of the earth, and the method, when properly executed, is proving to be a powerful means for delineating geologic features having application to a variety of fundamental geophysical and geological problems. However, it should be clear from the example in Figure 5 that in order to identify, characterize, and account for the effects of localized surficial features, one needs to deploy a sufficient density of sites to spatially characterize the surface field patterns. The situation is quite analogous to the "aliasing" problem that governs the strategy for properly sampling a time series; only in MT we are not dealing with simply a 1D sequence, but rather with 2D areal coverage. Berdichevsky (1999) offers a thoughtful critique of several of the underpinning paradigms and procedures of modern magnetotellurics.

Case studies

A number of early applications of the MT method are described in the texts of Patra and Mallick (1980), and Vozoff (1985). More recent case studies are described in the text by Simpson and Bahr (2005). The most exciting of these involve multidisciplinary geophysical field efforts. Particularly, noteworthy is the series of integrated MT, seismic refraction, and gravity investigations initiated by the US Geological Survey in the Pacific Cascades volcanic belt in the Northwest US (see the review by Stanley et al., 1990). Early phases of this work led to the first major international offshore/onshore MT and geomagnetic deep-sounding (GDS) project: the EMSLAB project that extended from the offshore Juan de Fuca Rise to the east side of the Cascades volcanic system (*c.f.*, Wannamaker et al., 1989). Work in this area continues. For example, in a reanalysis of data from the EMSLAB Project, Vanyan et al. (2002) articulate the experience of many that when interpreting a profile of widely spaced, multi-site MT data in such complicated terrains, one needs to be selective in which elements of the MT impedance matrix are most consistent when developing a 2D inversion. They found that under the complex geologic conditions of the region, the strict inversion of both the TE and TM modes simultaneously at each and every site yielded an intricate, but what is likely a geophysically implausible, pattern of conductive and resistive features resulting in a large misfit of the model response to the data. The analysis improved significantly, they felt, when they were more selective in which of the principal impedance components were employed at a site. They also found that using lateral variations of the transient magnetic field, in conjunction with the MT data, significantly complemented their analysis. This point of view probably captures the spirit of most current MT investigations, and certainly underscores the importance of multiple station arrays of closely spaced sites.

In other regions, Sarma et al. (2004) report on a comprehensive MT study of an active seismic zone in western India. Solon et al. (2005) describe a large array MT study of the deep crust beneath the Himalayas in central Tibet. Munoz et al. (2008) investigate mid-crustal conductivity anomalies using 3D models of SW Europe. Wannamaker et al. (2008) describe the application of MT to understanding lithospheric deformation and magmatic processes along the Great Basin-Colorado Plateau transition zone. Continuing the work in the US Pacific Northwest, Patro and Egbert (2008) report on their analysis of data from deployments in 2006 and 2007 of the still-evolving US Earthscope MT Transportable Array. Data were sequentially acquired in the period range from 10 to 10,000 s at 110 sites, covering the region at a nominal station spacing of 75 km. Han et al. (2009), using a 3D model to interpret MT data on the Korean peninsula, emphasize the importance of accounting for the effects of the nearby ocean and coastline. Eaton et al. (2009), in pulling together a variety of geophysical evidence, present a recent update on MT investigations of the lithosphere and asthenosphere beneath cratons, particularly for North America. Similar applications of MT to understanding significant solid earth problems are ongoing in China, Japan, Europe, Great Britain, South America, Antarctica, Africa, New Zealand, and Australia. Clearly, magnetotellurics is becoming an essential tool for a better understanding of earth systems on a variety of scales.

Summary

The magnetotelluric (MT) method is based on the physical theory of electromagnetic wave propagation in electrically heterogeneous materials. Using the "skin-depth" principle that, in a given conductor, long period signals penetrate to greater depth than short period signals, the method typically employs the rich spectrum of natural electromagnetic energy from the ionosphere, magnetosphere, and atmosphere (distant lightning storms) to "probe" the electrical structure of the earth from a few hundred meters depth to tens even hundreds of kilometers. For near-surface applications, active transmitters are used throughout the audio band (100 Hz to 20 kHz) to above a megahertz. The last decades have seen significant developments in the type of low-noise, large dynamic range instrumentation needed for such studies, along with robust real-time data processing, 3D numerical modeling, and geophysical inverse theory. The MT method involves recording and

analyzing the spectral character of the complex amplitudes and phases of the electric and magnetic field components over a wide range of periods from an array of closely spaced sites on the earth's surface. From the spatial and spectral character of such data, one can, in a sense, deconvolve the signatures of lateral and vertical variations in the bulk properties of the subsurface to develop insight on fundamental processes in the earth.

MAGNETOVARIATION STUDIES

Nandini Nagarajan
National Geophysical Research Institute, Hyderabad, India

Definition and introduction

Magnetovariation studies identify the induced component of magnetic variations, from a spatial array of magnetic variation measurements and thereby infer the distribution of subsurface electrical conductivity in the Earth, through a linear transfer function between inducing and induced variations. These induction studies, which investigate the secondary magnetic fields induced in the solid Earth by external current systems, are undertaken to provide constraints on the electrical conductivity of the upper 1,000 km of the finitely conducting earth.

The techniques involved in magnetic variation studies are as follows:

Measurement of magnetic variations over an array of stations

Variations of the earth's magnetic field, caused by processes in the ionosphere and beyond, viz., external variations, and the secondary fields induced by them in the Earth are recorded at observatories or at magnetometer stations explicitly set up for the purpose (see *Geomagnetic Field, Measurement Techniques*). The sampling interval and lengths of data recorded are determined by the depth of investigation desired, limitations of instrumentation, size of the array, etc. Electric currents flow through the Earth's magnetosphere and ionosphere causing a wide spectrum of external magnetic variations ($\sim$ 1 s –1 day), (see *Magnetic Methods, Surface*). These magnetic variations induce secondary electric currents in the conducting layers of the Earth below the source current. The presence of such conducting layers is identified from spatial gradients in magnetic variations measured at that point or nearby stations (Egbert, 2002). The normal field in spectral content is defined as the sum of contributions from the external source field and that part of the internal field that is due to the regional (1D, radial variation) electrical conductivity structure (Parkinson, 1987).

Spectral analysis of magnetic variations to determine sufficiency of signal content based on assumptions regarding uniform inducing fields

Spectral content of magnetic variation is estimated, for desired lengths of time windows, after which, spectra are smoothed, stacked over several time windows, and significant peaks in frequency bands are estimated. To compute these spectra from magnetic variations at a single site, certain assumptions are made about both the external sources and the underlying conductivity distribution (Egbert, 2002). The external variations are generated over large-scale lengths relative to the area of the study and the incident magnetic fields are assumed to be a plane wave. For very large arrays, some modifications to the analysis are required since this assumption may not be valid. Since a large volume of data is collected, where the properties of external variations may be nonstationary, a careful selection of data intervals of suitable characteristics, conforming to the assumptions above, is made. Several techniques to eliminate effects of nonuniform, time-varying characteristics of inducing fields have also been evolved (Egbert, 2002). Further, this spectral analysis provides insights into the character of external variations and their measurement over large spatial extent on Earth. Spectral estimates are also examined to eliminate sources of nonuniformity and man-made noise.

The geometry, intensity, and period of induced anomalous variations depend both on the source and on the distribution of electrically conducting materials within the Earth. Inducing external magnetic variations cover a wide spectrum from minutes to days, thus creating induced responses over a wide spectral range. The longer period responses derive from deeper penetration of induced currents within the crust/mantle. The spectral content of magnetic variations is therefore a useful natural tool to probe the earth's interior.

Computation of transfer functions

For magnetovariation studies, lateral gradients of the magnetic fields are used to obtain estimates of electrical conductivity contrasts in the subsurface. The induced, anomalous field is generated by telluric currents flowing in non-one-dimensional conductivity structures (2D/3D) and, thus, entirely of internal origin. This anomalous field is not uniform and affects both the horizontal and the vertical components – evident as spatial gradients, and may be subjected to noise from man-made sources. Transfer functions, usually estimated by least squares, indicate the relation between inducing and induced variations at a single site, multiple sites, and for signals not recorded simultaneously (hypothetical event analysis). Improved methods of determining transfer functions using robust statistical approaches that incorporate the actual properties of the data, rather than ideal distributions, have refined estimation of transfer functions, improving their reliability. Simultaneous observations also provide information on the spectral space of the data, in each array study, and indicate whether new or modified interpretation parameters are to be evolved for a particular study. Fitting these with a formal inversion procedure, along with more traditional single site parameters such as MT impedances and vertical field TFs, can enhance resolution of some features (Simpson and Bahr, 2005).

Modeling to obtain induced magnetic variations from the conductivity distribution: Interpret in terms of geology and structure

Magnetovariation studies primarily delineate contrasts in electrical conductivity in the subsurface. The depth and

conductivity are poorly resolved. Therefore this method is widely used as preliminary investigation of large- and small-scale anomalies, which may later be intensively investigated using more precise electromagnetic methods (e.g., Magnetotellurics). The conductivity anomalies investigated using magnetovariation often extend over thousands of kilometers across continents, correlate tectonic signatures to deeper crust/mantle properties, and link events of the vast geologic timescale. Many examples of continental-scale structures, as well as sharply defined shallow crustal anomalies that are directly related to tectonic events (faulting, seismicity) are discussed in good reviews (see *Earth's Structure, Continenal Crust*; *Electrical Resistivity Surveys and Data Interpretation*; *Magnetotelluric Data Processing*; *Magnetotelluric Interpretation*; *Electrical Properties of Rocks*) (Gough, 1989). The principles of electromagnetic induction have also been applied to satellite data of denser spatial coverage. Here, the forward response of conductivity distribution is directly modeled and fitted to potential data. In this manner, induced contributions to crustal magnetization of continents and ocean crust have been estimated (Hemant and Maus, 2005).

Interpretation

Magnetometer array studies provide geometry of induced currents, in the Earth's subsurface. The interpretation is not confined to any predetermined shape or single conductive feature, rather delineates broadly any lateral inhomogeneities in the upper 1,000 km of the Earth's crust/mantle. The conductivities are poorly constrained in this method and need to be verified using other methods (e.g., MT).

The significance of these electrical conductivity contrasts are threefold:

1. Indicate change in composition within depth of penetration, more graphite/conducting minerals
2. Changes in temperature, at appropriate depth
3. Indicates accumulation of fluids, interstitial or within the metamorphic mineral structures (Jones, 1992).

The above conditions and geometry of the conductivity anomaly are evaluated or eliminated, for the region under study. The significance of any or either of these conditions can impact the tectonics and evolutionary history of the region. The complementary nature of conductivity anomalies and other geophysical studies were established in the course of several Geotransects over ~1,000 km continental-scale studies. The role of fluids in the crust has been a major contribution of these studies (see *Earth's Structure, Continental Crust*; *Heat Flow, Continental*; *Seismic Velocity-Temperature Relationships*; *Isostasy, Thermal*; *Electrical Properties of Rocks*; *Differential Rotation of the Earth's Inner Core*; *Lithosphere, Continental: Thermal Structure*).

Summary

At the Earth's surface, magnetometers measure the composite of external (from the external source currents) and internal (from the induced currents) field components. The observed magnetic field can be considered as the sum of a normal plus an anomalous induced field. Induced currents in the finitely conducting earth manifest as gradients in magnetic variations over spatial scales of ~10–1,000 km.

The interpretation of electrical conductivity anomalies in the crust, provide additional insights into the nature of the Earth's crust. In the upper crust (<15 km), most conductivity anomalies were correlated with deeper extensions of tectonic elements (faults, sutures) and compositional changes. Simultaneously, the phenomenon of seismic reflectors within the lower crust were found and combined with this, the significant role of fluids in the lower crust/upper mantle came to be recognized. A number of Geotransects across continents were carried out in the 1990s and the complexities of evolutionary history on the lower crust were revealed. The relationship between electrical conductivity, high heat flow, seismic parameters, and tectonic history were formulated (Jones, 1992). Induction studies and later magnetotelluric soundings have contributed to an understanding of processes in the Earth's crust and upper mantle. This was also possible because of the refinements in instrumentation, data processing, and computational approaches in magnetovariation studies.

Definition

Mantle convection. Thermal convection in the terrestrial planetary mantles, the rocky layer between crust and core, in which hot material rises, cold material sinks, and the induced flow governs plate tectonic and volcanic activity, as well as chemical segregation and cooling of the entire planet.

Mantle convection

Introduction and history

All planetary bodies retain some heat from their early formation but are inexorably cooling to space. Planetary surfaces are therefore cold relative to their hotter interiors, and thus undergo thermal convection wherein cold material is dense and sinks while hot material is light and rises (liquid water near freezing being one of the rare exceptions to this process). Planetary atmospheres, oceans, rocky mantles, and metallic liquid cores convect and are subject to unique patterns of circulation in each domain. Silicate mantles however tend to be the most massive and sluggish part of terrestrial planets and therefore govern how planetary interiors evolve and cool to space (See Figure 1).

The theory of mantle convection was originally developed to understand the thermal history of the Earth and to provide a driving mechanism for Alfred Wegener's theory of Continental Drift in the 1930s (see Bercovici, 2007; Schubert et al., 2001). Interest in mantle convection waned for decades as Wegener's theory was criticized and apparently discredited. However, the accumulation of sea-floor sounding data during War World II and refinement of paleomagnetic techniques paved the way for the discovery of sea-floor spreading (Hess, 1962; Vine and Matthews, 1963) and the birth of the grand unifying theory of plate tectonics in the 1960s; this consequently revived interest in mantle convection as the driving mechanism for plate motions (Runcorn, 1962a, b) as well as non-plate-tectonic volcanism such as the possible Hawaiian plume (Morgan, 1971). The success of mantle convection theory in explaining plate velocities, sea-floor subsidence, volcanism, gravity anomalies, etc., led to its further application to other terrestrial planets such as Venus and Mars, which also sustained unique forms of mantle convection, evident from volcanic activity.

Basics of thermal or free convection

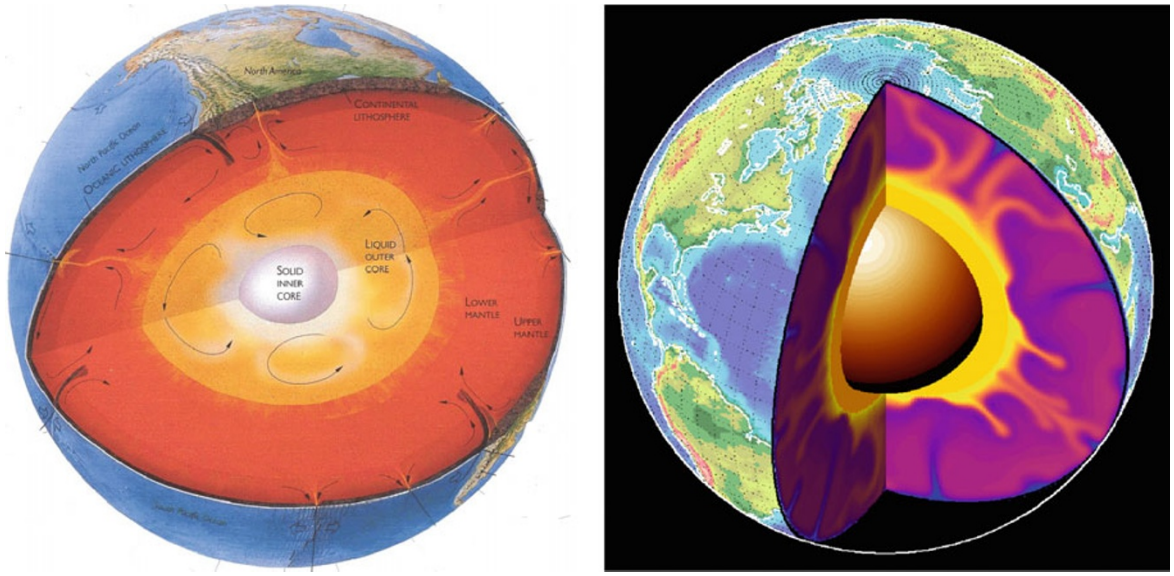
Rayleigh–Bénard convection

The simplest form of thermal convection is referred to as Bénard convection named after the French experimentalist Henri Bénard who in 1900 performed the first systematic experiments on convection in thin layers of oil (spermaceti) and recognized both the onset of convection from a static conductive state and the regular patterns formed in a convecting layer (Bénard, 1900, 1901). Fifteen years later, the British theoretical physicist and mathematician Lord Rayleigh (William John Strutt), attempted to explain Bénard's results for the onset of convection (Strutt, 1916) – the delay in communication between them being caused by World War I. However, the mismatch between theory and experiment was profound, and not resolved until the late 1950s (Pearson, 1958) when it was inferred that Bénard's experiments were strongly influenced by surface tension or Marangoni effects not included in Rayleigh's theory (although Bénard himself was aware of these effects). Because Rayleigh's work provided the framework for nearly all thermal convection theory to follow, the simple Bénard convective system is also referred to as Rayleigh–Bénard convection.

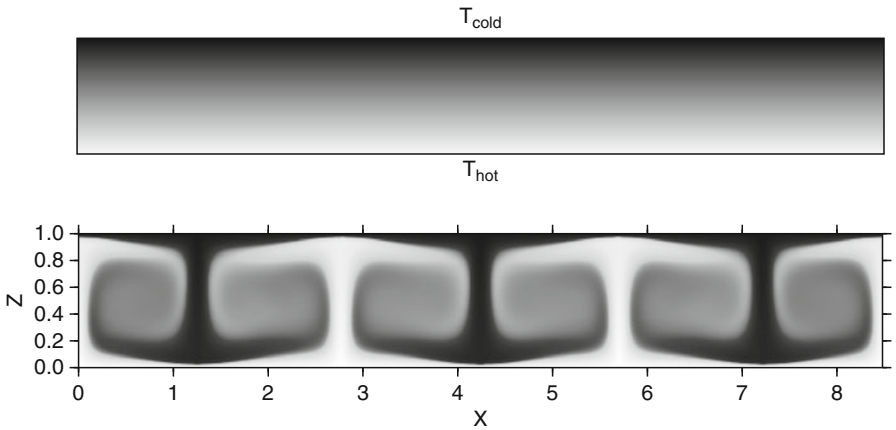
Although Bénard's experiments were in a metal cavity, Rayleigh–Bénard convection actually refers to Rayleigh's idealized model of a thin fluid layer infinite in all horizontal directions such that the only intrinsic length scale in the system is the layer thickness. The Rayleigh–Bénard system is heated uniformly on the bottom by a heat reservoir held at a fixed temperature (i.e., the bottom boundary is everywhere isothermal) and the top is likewise held at a fixed colder temperature by another reservoir (see Figure 2). If the layer were not fluid, heat would flow from the hot boundary to the cold one by thermal conduction. But since the fluid near the hotter base is (typically) less dense than the fluid near the colder surface, the layer is gravitationally unstable, that is, less-dense material underlies more-dense material. To release gravitationally potential energy and go to a minimum energy state, the layer is induced to turn over.

Convective onset and the Rayleigh number

While the fluid in a Rayleigh–Bénard layer might be *gravitationally* unstable, it is not necessarily *convectively* unstable. Convective overturn of the layer is forced by heating but resisted or damped in two unique ways. Clearly, the thermal buoyancy (proportional to density contrast times gravity) of a hot fluid parcel rising from the bottom surface through colder surroundings acts to



Mantle Convection, Figure 1 Graphic renditions of cut aways of Earth's structure showing crust, mantle, and core (*left*), and of the convecting mantle (*right*). The relevant dimensions are that the Earth's average radius is 6,371 km; the depth of the base of the oceanic crust is about 7 km and continental crust about 35 km; the base of the lithosphere varies from 0 km at mid-ocean ridges to about 100 km near subduction zones; the base of the upper mantle is at 410 km depth; the transition zone sits between 410 and 660 km depths; the depth of the base of the mantle (the core–mantle boundary) is 2,890 km; and the inner core–outer core boundary is at a depth of 5,150 km. (*Left frame* adapted from Lamb and Sington (1998). *Right frame*, provenance unknown).



Mantle Convection, Figure 2 Rayleigh–Bénard convection: initially conducting layer (*top*), and numerical simulation of convection (*bottom*).

drive convective overturn. However, viscous drag acts to slow down this parcel, and thermal conduction, or diffusion, acts to erase its hot anomaly (i.e., it loses heat to its colder surroundings). Thus while the fluid layer might be gravitationally unstable, hot parcels rising might move too slowly against viscous drag before being erased by thermal diffusion. Similar arguments can be made for cold material sinking from the top surface through warmer surroundings. The competition between forcing by thermal buoyancy, and damping by viscosity and thermal diffusion, is characterized in dimensionless ratio called the Rayleigh number

$$Ra = \frac{\rho g \alpha \Delta T d^3}{\mu \kappa} \tag{1}$$

where ρ is fluid density, g is gravity, α is thermal expansivity (units of K^{-1}), ΔT is the difference in temperature

between the bottom and top surfaces, d is the layer thickness, μ is fluid viscosity (units of Pa s), and κ is fluid thermal diffusivity (units of m^2/s).

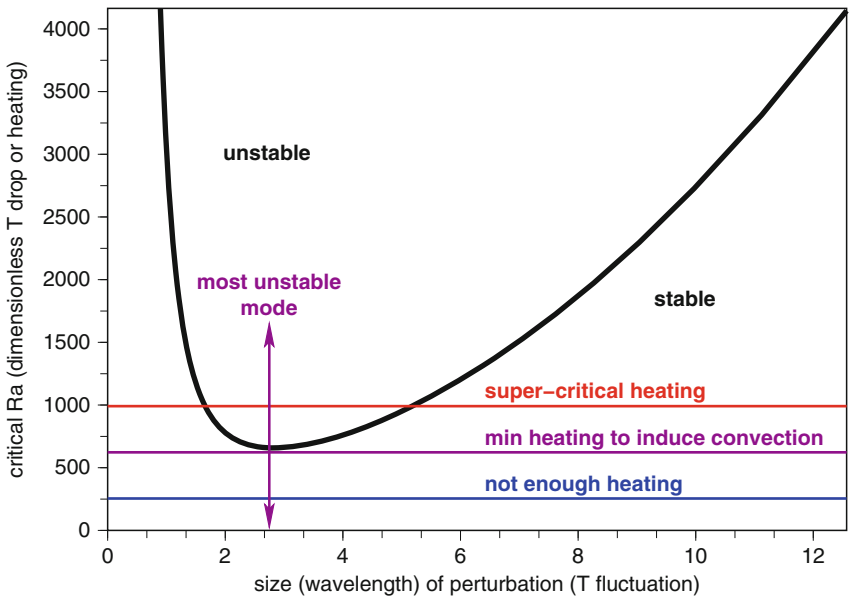
Even though $\Delta T > 0$ (i.e., heating is from below and causes gravitational instability), Ra still must exceed a certain value, called the critical Rayleigh number Ra_c, for convection to occur. For $Ra < Ra_c$ the layer is stable and transports heat by conduction; for $Ra > Ra_c$ the layer will be convectively unstable and transport heat more rapidly via convection. See Figure 3.

Although Ra_c varies depending on the mechanical nature of the horizontal boundaries (whether rigid or a free surface), it is typically of order 1,000. This value is easily understood by considering the fate of a hot (or cold) parcel of size a and temperature anomaly ΔT. Dimensional analysis readily shows that the typical ascent rate of the parcel is $\rho g \alpha \Delta T a^2/\mu$ (with units of m/s). However, the rate that heat diffuses out of the parcel is κ/a (smaller parcels lose heat faster). The critical state occurs when these two rates are equal; that is, if the buoyant ascent rate just exceeds the diffusion rate, the parcel should rise without being erased, but if the ascent rate is less than the diffusion rate it will not rise very far before being lost. Therefore, the critical state occurs if $\rho g \alpha \Delta T a^3/(\mu\kappa) \approx 1$. Scaling purely by orders of magnitude, a small parcel of fluid can be assumed to be of an order ten times smaller than the entire layer; thus assuming $a \approx d/10$ leads to a critical condition for the onset of convection of $\rho g \alpha \Delta T d^3/(\mu\kappa) \approx 1{,}000$.

For the Earth's mantle, the typical average properties from which the Rayleigh number is constructed are $\rho \approx 4{,}000$ kg/m^3, $g = 10$ m/s^2, $\alpha = 3 \times 10^{-5}$ K^{-1}, $\Delta T \approx 3{,}000$ K, $d = 2{,}900$ km, $\mu = 10^{22}$ Pa s (dominated by the lower mantle), and $\kappa = 10^{-6}$ m^2/s (see Schubert et al., 2001). Taken together, these lead to a Rayleigh number of approximately 10^7, which is well beyond super-critical; although the mantle viscosity is extremely high, the mantle is also very hot and very large, and hence convecting vigorously.

Thermal boundary layers and the Nusselt number

For a Rayleigh number Ra above the critical value Ra_c, convective circulation will mix the fluid layer, and the mixing and homogenization of the fluid will become more effective the more vigorous the convection, that is, as Ra is further increased. With very large Ra and vigorous mixing, most of the layer is largely uniform and isothermal. (In fact, if the layer is deep enough such that the pressures are comparable to fluid incompressibility, the fluid layer is not isothermal but adiabatic, wherein even without any heating or cooling, the temperature would drop with fluid expansion on ascent and increase with fluid compression on descent.) Most of the fluid in the Rayleigh–Bénard system is at the mean temperature between the two boundary temperatures. However, the temperature still must drop from the well-mixed warm interior to the cold temperature at the top, and to the hotter temperature at the

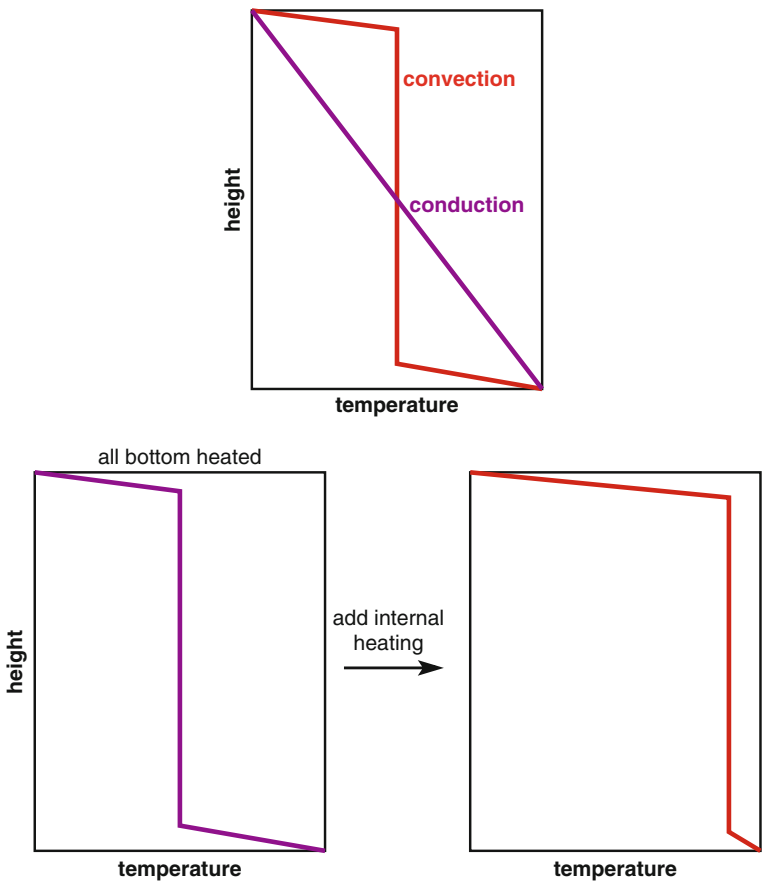


Mantle Convection, Figure 3 The critical Rayleigh number Ra for the onset of convection is a function of wavelength or size of the thermal perturbation to a static conductive state. For a layer with isothermal and free-slip (shear-stress free) top and bottom boundaries, the relationship is $Ra_c = (k^2 + \pi^2)^3/k^2$ where $k = 2\pi/\lambda$ and λ is wavelength (Chandrasekhar, 1961). Values of Ra above the Ra_c curve are associated with the conductive layer being convectively unstable (perturbations grow), while below the curve the layer is stable (perturbations decay). The minimum in the Ra_c curve occurs at the wavelength of the first perturbation to go unstable as heating and Ra is increased, often called the most unstable mode.

bottom. The narrow regions accommodating these jumps in temperature are called thermal boundary layers (Figure 4).

Thermal boundary layers are of great importance in thermal (and mantle) convection for two reasons. First, most of the buoyancy of the system is bound up in thermal boundary layers since these are where most of the cold material at the top and hot material at the bottom reside and from where hot and cold thermals or currents emanate. Moreover, with regard to convection in the mantle itself, the top cold thermal boundary layer is typically associated with the Earth's lithosphere – the 100 km or so thick layer of cold and stiffer mantle rock that is nominally cut up into tectonic plates.

Second, since fluid in these boundary layers is near a horizontal boundary, most of the fluid motion is horizontal and thus heat is only transported vertically across these thin layers by conduction; but since the layers are very thin, such conductive transport is rapid. Indeed, the entire cycle of heat transport occurs by heat conducted in rapidly through the bottom boundary layer, after which hot fluid in this layer will, in various spots, become unstable and rise to form a convective upwelling that carries heat out of the boundary layer rapidly across most of the fluid layer and deposits it at the upper boundary, where the heat is then transported out of the system by conduction across the top boundary layer. The eventual heat flow (power output per unit area) out of the well-mixed layer is essentially $k\Delta T/\delta$ where k is thermal conductivity (units of W K^{-1} m^{-1}), $\Delta T/2$ is the temperature drop from the well-mixed interior to the surface and we define $\delta/2$ is the thickness of the boundary layer. By comparison, the thermal conduction across a static non-convecting layer is $k\Delta T/d$. The ratio of heat flow in the convectively well-mixed layer to the purely conductive layer is thus d/δ, which is called the Nusselt number Nu (named after the German engineer, Wilhelm Nusselt 1882–1957). The relation between Nu and convective vigor parameterized by Ra is important for understanding how convection transports heat and cools off bodies including planets.



Mantle Convection, Figure 4 Sketch of temperature profiles, showing how convective mixing homogenizes the conductive mean temperature into a nearly isothermal state (if the fluid is incompressible) with thermal boundary layers connecting it to the cold surface and hot base (*top frame*). With no internal heating the interior mean temperature is the average of the top and bottom temperatures; the effect of adding internal heating (*bottom frames*) is to increase the interior mean temperature and thus change the relative size and temperature drop across the top and bottom thermal boundary layers.

Convective heat transport is often written as $Nu(k\Delta T/d)$ and in considering this relation Howard (1966) argued that vigorous convective heat transport across the bulk of the well-mixed fluid layer is so fast that it is not the rate limiting factor in releasing heat (only conduction across the thermal boundary layer is), and thus heat flow should be independent of fluid depth d; this implies that since $Ra \sim d^3$, $Nu \sim Ra^{1/3}$, which yields a convective heat flow $Nu(k\Delta T/d)$ that is independent of d. In general, since the fluid is conductive for $Ra \leq Ra_c$, one often writes that $Nu = (Ra/Ra_c)^{1/3}$ (although $Nu = 1$ for $Ra < Ra_c$), which is a reasonably accurate relationship borne out by simple experiments and computer modeling. This relationship also implies that the ratio of thermal boundary width to fluid layer depth is $\delta/d \sim Ra^{-1/3}$, which shows that the boundary layers become increasingly thin as convective mixing of the layer becomes more vigorous.

The relation of $\delta \sim Ra^{-1/3}$ applies to the horizontally averaged boundary layer thickness. However, boundary layers change with time or distance from their first formation, for example, where an upwelling impinges on the top boundary. As the fluid in the boundary layer moves from an upwelling to a downwelling it cools and the boundary layer thickens as more material cools next to the cold surface. The thickening depends on the thermal diffusivity κ (with units of m^2/s) and the residence time or age t near the cold boundary (i.e., time since leaving the upwelling). Simple dimensional considerations show that the boundary layer thickness goes as $\sqrt{\kappa t}$; this corresponds to the well-known $\sqrt{\text{age}}$ law for subsidence of ocean sea floor with age since formation at mid-ocean ridges, implying that sea floor gets deeper because of the cooling and thickening lithosphere.

Patterns of convection, structure of upwellings and downwellings: plumes and slabs

When convection occurs, upwellings and downwellings will be separated horizontally by some optimal distance. If they are too close to each other, they can induce too much viscous drag on each other and/or lose heat rapidly to each other; if they are too far apart, they must roll too much mass between them. The separation distance is also determined by heat transport in the thermal boundary layer between upwellings and downwelling. When hot upwelling fluid reaches the surface, it spreads laterally into the thermal boundary layer. As it travels horizontally, it cools to the surface and eventually gets cold and sinks into the downwelling; thus the upwelling-downwelling separation is also determined by the distance it takes for fluid to cool off and become heavy enough to sink.

The upwelling-downwelling separation distance or convection cell size is predicted by convective stability theory to be approximately equal to the layer depth d (a bit larger at the onset of convection but identically d as Ra becomes very large); that is, the cell that is either least stable and thus most likely to convect – or equivalently the cell that optimizes gravitational potential energy (and thus heat) release – is usually the cell that is as wide as it is deep.

Viewing a convecting layer from above, the upwelling and downwellings may be separated in various patterns, such as 2-D rolls (sheets of upwelling rolling over into sheets of downwelling, and each cell counter-rotating with its neighboring cell). In the Rayleigh–Bénard layer, which is infinite horizontally, no one location of the layer should be different than any other one, and so ideally the pattern should be a regular repeating tile; as there are only so many polygons that can form a repeating tile, the patterns usually involve convection cells in the shapes of rolls (already mentioned), squares, hexagons, and triangles (Figure 5). Of course nonideality and irregularities can occur due to tiny imperfections, for example, in the boundaries, leading to irregular patterns.

In many instances, in the 3-D pattern of convection, especially in fluids where hot fluid is less viscous than cold fluid (as is true in many materials, including the mantle), the upwelling is in the form of a cylindrical plume at the center of a canopy of sheet-like downwellings, much like a fountain.

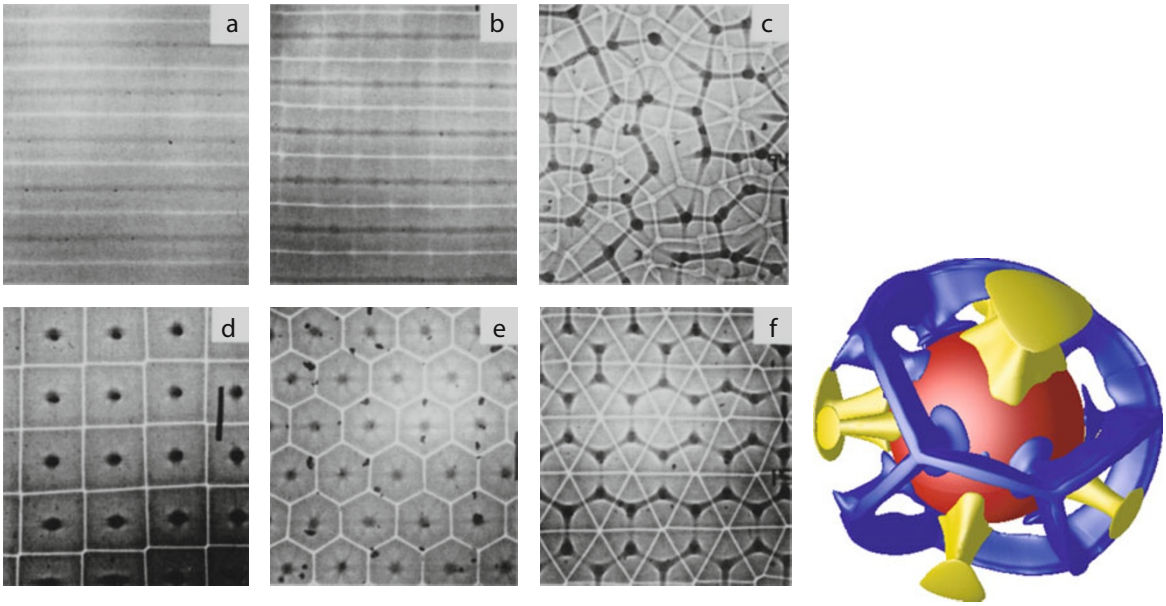
Plumes and slabs in the mantle: simple view

The common occurrence of sheet-like downwellings and columnar upwellings in simple convection is crudely applicable to mantle convection. Subducting slabs are where tectonic plates sink into the mantle; these are analogous to the cold, sheet-like downwellings seen in 3-D convection, although much more complicated by rheology as discussed below. Deep hot narrow upwelling plumes are inferred to explain anomalous intraplate volcanism as in Hawaii, as well as the fixity of these volcanic hotspots relative to each other (which suggests deep anchoring in the mantle). These mantle plumes are ostensibly analogous to the pipe-like upwelling in simple 3-D convection, but again more complicated by unique mantle properties. (See *Mantle Plumes* entry by Farnetani and Hofmann.)

While mid-ocean ridges or spreading centers transport material vertically to surface, they are very narrow features and for the most part involve shallow upwelling (inferred from their weak gravity anomalies that suggest shallow isostatic compensation, that is, they are floating on a shallow buoyant root). Ridges are likely best explained as being pulled and rifted apart passively from a distant force (ostensibly slabs) rather than involving a deep convective upwelling that pries them open.

Energy sources for mantle convection and Earth's thermo-chemical history

Heatflow coming out of the Earth is measured by heatflow gauges (measuring conductivity of rocks first and then thermal gradients in boreholes) both in continents and oceans (see Turcotte and Schubert, 1982). The total heat flowing out from beneath the Earth's surface is approximately 46 TW (46 trillion Watts) (Jaupart et al., 2007), which is in fact not a large number given the surface area of the Earth, and is actually tens of thousands



Mantle Convection, Figure 5 Patterns of convection from laboratory experiments in rectangular tank by White (1988) (*left*), and numerical simulations in a spherical shell by Zhong et al. (2000) (*right*).

of times smaller than the heat absorbed from the Sun. Nevertheless, it represents the source of power driving dynamics inside our planet, including mantle convection (and hence tectonic, volcanological, and other geological activity) as well as core cooling and flow.

The source of the Earth's internal heat is a combination of primordial heat, that is, left over from accretion (gravitational potential energy from formation and collisions), and heat generated by unstable radioactive isotopes, especially the isotopes of uranium (^{238}U), thorium (^{232}Th), and potassium (^{40}K), although the ^{40}K half-life is much shorter than the others and so generated a large heat pulse primarily in the early Earth. Because continental crust is originally formed by partial melting and chemical segregation of early mantle material (indeed the chemical separation allows another energy source in the release of gravitational potential energy, but other than early core formation this is a relatively minor contribution), these radioactive elements tend to be concentrated in crust (i.e., melt more readily dissolves these elements than does solid rock, so they partition toward the melt). Thus the crust itself produces a significant fraction of the net heat output through the surface; removing the crustal component leaves approximately 31 TW emanating from the mantle and core (Jaupart et al., 2007; Schubert et al., 2001).

The relative contributions of primordial cooling and radiogenic heating to the mantle (and core) heat output remains an active area of debate even today and leads to various quandaries. The most direct estimate of the concentration of radiogenic sources (U, Th, K) is by looking at the concentration in chondritic meteorites, which come from the solar systems' main asteroid belt, and because they have been largely unaltered for 4.5 Gyr (i.e., unmelted), they are thought to be the same as the original building blocks of the terrestrial planets. The chondritic concentrations of U, Th, and K would allow for radiogenic heating to contribute 50% or less of the total heat output (Korenaga, 2008); this is often called the Urey ratio, that is, the radiogenic heat output to the total output. With radiogenic heating this small, the only way the mantle could be as hot as it is today – while also transporting heat as it does presently – is if it were very hot and nearly molten in the geologically recent past (a few hundred million years); this is geologically untenable since petrological and geochemical analysis demonstrate the presence of solid rock and even liquid water in the early Earth (see Halliday, 2001), which therefore ceased to be molten not long after its formation 4.5 billion years ago. This paradox has led some researchers to assume that the radiogenic sources are super-chondritic, that is, to allow heat to be produced continuously throughout the past rather than by rapid cooling from a molten state. Alternatively, researchers have sought ways to keep chondritic concentrations of U, Th, and K by arguing that heat transport in the past was different than it is today; for example, higher temperatures in the past might have allowed for more melting and thus more buoyant crust and/or stronger dehydrated lithosphere that kept the top part of the convecting mantle sluggish or immobile, hence bottling up primordial heat for much later release (Korenaga, 2008).

Finally, the release of both radiogenic and primordial heat, again termed collectively "internal heating" (i.e., heat coming from the bulk of the fluid) means that the idealized Rayleigh–Bénard model of convection, where

heating is only along the base, is inaccurate. The effect of internal heating in addition to "basal heating" is relatively straightforward to understand. While in the Rayleigh–Bénard model the temperature of the well-mixed interior is at the average of the two boundary temperatures, the addition of internal heating acts to heat up the well-mixed interior to a higher mean temperature. This puts the interior temperature closer to the hot bottom temperature, but further from the cold top temperature; the effect is to create a larger temperature drop across the top thermal boundary layer than across the bottom one; in essence, the top boundary layer must conduct out heat injected through the bottom plus heat generated or released from the interior (Figure 4). These very different boundary layers tend to cause more negatively buoyant and stronger downwelling currents and smaller and weaker upwelling currents; this effect seems to be borne out in the Earth by the presence of many large cold slabs driving plate tectonic motion with large thermal anomalies (of order 500 K) relative to fewer upwelling plumes with weaker (200 K) thermal anomalies (although this is still somewhat a matter of debate).

Effects of mantle properties

Mantle rheology

The entire mantle of the Earth is potentially a convecting and overturning fluid. However, the mantle is almost entirely solid (with some small portions of melting near the surface delineated by volcanism, and possibly much smaller areas of melting at depth) and thus flows extremely slowly. (Indeed, the term fluid does not suggest a liquid state but refers to how a medium deforms, as opposed to elastic or brittle deformation; these do not necessarily correlate with states of matter, that is, gas, liquid, solid, each of which can display, e.g., either fluid flow or elastic behavior depending on the nature of the deformation; e.g., atmospheric sound waves are elastic behavior in gas.)

The solid-state viscous flow of the mantle is a complex process and there are various mechanisms that permit such "irrecoverable" deformation (one of the definitions of viscous flow). A survey of mantle deformation mechanisms or "rheology" is beyond the scope of this entry (see Karato, 2008; Ranalli, 1995). However, in brief, the two primary deformation mechanisms are called diffusion and dislocation creep. In any solid-state creep mechanism, mobility depends on the statistical-mechanical probability of a molecule in a crystal lattice leaving the potential well of its lattice site; the potential well itself is defined by electrostatic or chemical bonds inhibiting escape, and Pauli-exclusion pressure preventing molecules squeezing too closely to each other. Thus mobility depends on the Boltzmann distribution measuring the probability of having sufficient energy to overcome the lattice potential well barrier, which is often called the activation energy (or allowing instead for pressure variations the activation enthalpy). This probability depends on the (Arrhenius) factor $e^{-E_a/RT}$ where E_a is the activation energy (J/mol), R is the gas constant (J/K/mol) and T is temperature; RT represents the thermal excitation energy of the molecule in the well. As T goes to infinity, the probability of escaping the well goes to 1, while as T goes to 0, the probability of escape goes to 0.

Stress imposed on the medium effectively changes the shape of the potential well, such that compressive stress steepens the walls of the well (squeezing molecules closer makes coulomb attraction in the chemical bonds stronger) while tension lowers the walls (separating molecules weakens the bonds); thus the probability of escape is preferred in the direction of tension and away from compression, thereby allowing the medium to stretch in the tensile direction by solid-state diffusion of molecules.

Simple diffusive creep works much in this way whereby differential stress (i.e., nonuniform stress) causes slow diffusion of molecules to allow the entire substance to deform accordingly. However, such deformation occurs at the grain or mineral level inside a rock, with either diffusion through the grains or along the grain boundaries; thus the response depends significantly on grain size.

Dislocation creep is more complicated. A dislocation can be in the form of a truncated row of molecules in a crystal lattice; shortening of the crystal under compression perpendicular to the row can be accomplished by simply removing that row. Thus differential compressive stress would act to force molecules to diffuse out of that dislocated row into other parts of the lattice. However, stress not only governs the preferential diffusion of molecules (as in diffusion creep) but also the geometry of the dislocations (their spacing and directions), hence the multiple actions of stress are compounded into a nonlinear response.

The viscosities for diffusion and dislocation creep mechanisms can be written as

$$\mu = \begin{cases} Ba^m e^{\frac{E_a}{RT}} & \text{for diffusion creep} \\ A\sigma^{1-n} e^{\frac{E'_a}{RT}} & \text{for dislocation creep} \end{cases} \quad (2)$$

where A and B are proportionality constants, a is grain size, σ is stress (in fact since stress is a tensor σ is the scalar second invariant of the stress tensor), and m and n are exponents, typically both equal to 3 (with variations depending on exact deformation mechanisms; see Karato, 2008). It should be emphasized that diffusion and dislocation creep occur independently of each other depending on stress and grain size: for high stress and large grains dislocation creep dominates; for low stress and small grains diffusion creep dominates.

Dislocation creep allows for moderate softening as stress increases; diffusion creep potentially allows for significant softening if stress can reduce grain size, although mechanisms to allow this are still controversial (see section below on generating plates), and significant hardening via grain growth by standard coarsening of the material (i.e., what happens to all grained materials under the action of grain-surface energy reduction).

The strongest rheological effect is clearly that of temperature; the temperature dependence of viscosity allows for many orders of magnitude variations in viscosity. For example, while this rheological effect allows subducting slabs to keep their strength and integrity to great depths as they sink, it would make hot upwelling mantle plumes more fluid and, if they have a conduit structure, the plume flow would be relatively rapid, of order 100 cm/year or more. However, this effect is most profound in the cold top thermal boundary layer or lithosphere. If viscosity is strongly temperature dependent, as it is in Earth, the lithosphere can become so stiff that it becomes immobile; in this case, convection in the mantle would proceed beneath the lithosphere, which in turn would act like a rigid lid to the mantle (Solomatov, 1995). If mantle rheology obeyed only diffusion or dislocation creep laws, then the lithosphere should be locked and immobile, and there should be no plate tectonics. While this scenario might be relevant for Venus and Mars (and Moon and Mercury) which have no plate tectonics, obviously it is missing a vital ingredient to allow plate tectonics on Earth. This paradox underlies the fundamental question and mystery about why Earth has plate tectonics at all and how it is generated on our planet but not others in our solar system (Bercovici, 2003).

Compressibility, melting, and solid phase changes

Pressures deep inside the Earth's mantle are so large they are sizable fractions of rock incompressibility or bulk modulus (e.g., mantle pressures reach 140 GPa, or 1.4 million atmospheres, while bulk modulus – which has the same units as pressure – are typically a few to several 100 GPa). As downwelling mantle material travels from near the surface to the base of the mantle its density and temperature increase due to compression, called "adiabatic compression and heating" (and likewise upwelling material undergoes "adiabatic decompression and cooling"), although these increases are not large (of the order of several degree Celsius). The compression and decompression of circulating material establishes a weak adiabatic temperature and density increase with depth, which has a slight stabilizing effect on convection; however, because the mantle is so viscous, the thermal anomalies needed to get it to move – and in particular the temperature variations across the thermal boundary layers – are so large (of order several 100–1,000°C) that the adiabatic variations are small in comparison.

Where compressibility and pressure play a dual important role is in phase changes. First, as hot upwelling mantle material approaches the surface, it actually travels along a gradually cooling adiabatic temperature profile. The upwelling does eventually melt when it gets near the surface but not because it gets hotter. Melting occurs because the melting temperature T_m drops with decreasing pressure faster than the upwelling adiabat (in essence, decreasing confining pressure makes it easier for molecules to mobilize into a melt); thus at a certain (usually shallow depth of a few tens of kilometers to 100 km) the upwelling mantle crosses the melting temperature from solid to liquid phase and undergoes melting; however, the mantle is not a single pure substance so in fact only partially melts. Such "pressure-release" melting is a shallow process but is vital for chemical segregation of the mantle and development of oceanic and continental crust. In particular, melting is sequential in that the most easily melted material (usually more silica-rich material with lower melting temperature) melts first, freezes last, and is typically chemically less dense, and thus comes to the surface as lighter crust eventually gathers, after more weathering and reactions into continental crust. (Continental crustal rocks like sandstone and granite have typical densities of 2,300 and 2,700 kg/m^3, respectively.) The more refractory (harder to melt, silica poor, and heavier) material melts last, freezes first, and either stays in the mantle or lithosphere or sits in the heavy basaltic oceanic crust. (Oceanic crustal rocks like basalt have densities of 3,000 kg/m^3, while mantle peridotites at near-surface pressure have densities of around 3,400 kg/m^3.)

Extreme pressures with depth can also overcome a mineral's elastic resistance to compression and cause solid–solid phase changes where the minerals change their crystallographic structure to a more compact and incompressible state (but of course their chemistry remains the same). Such mineralogical phase changes have been observed in laboratory experiments in olivine, which is the major component mineral of the upper mantle (at about 60% by weight, the remainder being mostly pyroxene at shallow depths, and garnet at slightly greater depth); moreover, the pressures at which they are predicted to occur have been verified seismologically, wherein the seismic wave speeds and density undergo a jump at the predicted pressures. The first major phase change to occur with depth is from olivine to the same material with a wadsleyite structure, at 410 km depth. Wadsleyite changes slightly to a similar ringwoodite structure at 510 km depth. The largest phase change occurs from ringwoodite to perovskite/magnesiowüstite at 660 km depth.

The 410 and 660 km phase changes are the two most remarkable and global phase changes in the mantle, and the region between them is called the transition zone, since it is where most of the mineralogical transitions occur, over a relatively narrow region. The mantle above the transition zone is typically identified as the Upper Mantle, although in some papers and books Upper Mantle includes the transition zone. Below the transition zone is the Lower Mantle and that is universally agreed upon in the literature.

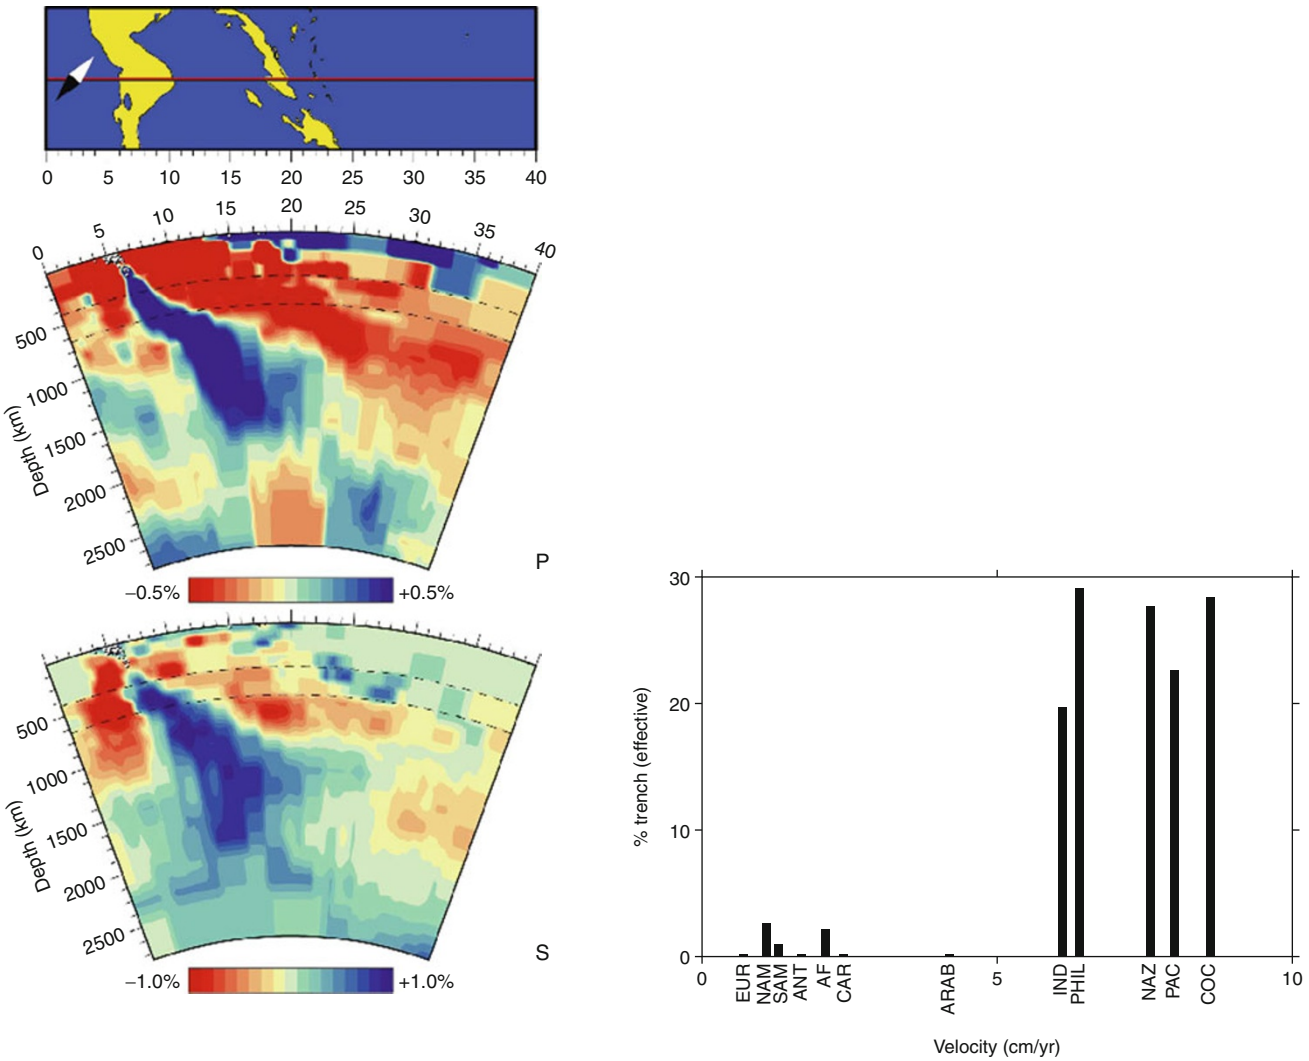
The transition zone has anomalous properties due to mixing and transitions in mineral organization; for example, it is thought to be able to absorb an order of magnitude more water (per kg) than the mantle both above and below it (although this issue is still somewhat controversial).

Other phase changes are thought to occur with depth, although these are less well resolved, and in some instances do not appear to be global. Recently, a new

phase change has been inferred in the lowest part of the mantle (the bottom few hundred kilometers), called the perovskite-post-perovskite (or just the post-perovskite) transition (Murakami et al., 2004). This transition is still an active area of exploration.

The effect of phase transitions on mantle convection has been an active area of research since the 1960s. The discovery of the major phase change at 660 km depth coincided with the fact that deep earthquakes along subducting slabs (the Wadati–Benioff Zone) go no deeper than 700 km. This seemed to imply that subducting slabs, the mantle's equivalent of cold convective downwellings (see below), did not extend into the lower mantle. Recent seismological studies using tomographic techniques to resolve ostensibly "cold" and "hot" areas of the mantle (really seismically fast and slow regions), implied that many slabs might stall or pool temporarily at the 660 km boundary but many penetrate into the lower mantle (Figure 6).

Whether the density jump due to a phase change could impede vertical flow has been a key question in studying the interaction of phase changes and convection. In particular, the 660 km phase change was inferred mineralogically to be "endothermic" whereby the entropy of the deeper heavier phase (below 660 km) increases, or more simply latent heat is absorbed on going down through the boundary into the denser more compact phase (while unusual in most systems, this is also true of the solid–liquid transition in water). This also means that the dependence of the transition temperature on pressure has a negative slope; thus cold material impinging on the phase boundary causes the phase change to deflect in the cold region to greater pressures; this induces



Mantle Convection, Figure 6 Tomographic image of slabs beneath Mexico (W. Spakman via van Keken et al., 2002) extending into the lower mantle (*left*); and plate velocity versus trench length following Forsyth and Uyeda (1975) showing the fastest plates are connected to slabs (*right*). Slabs are not only cold mantle downwellings but effectively drive plate tectonics.

a depression in the boundary that acts to buoyantly rebound upward and oppose the motion of the descending cold material. Thus the endothermic boundary at 660 km depth possibly impedes flow across that boundary. (However, the actual 660 km phase is complex and at higher temperatures might become exothermic; Weidner and Wang (1998).) Computational studies and simulations of mantle flow across this boundary demonstrated that downwellings (i.e., slabs) can indeed be impeded and stalled as they impinge on this boundary, but not permanently or globally; that is, while some are pooling at the boundary others have gathered up enough "weight" to push through the boundary (Christensen, 1995; Tackley et al., 1993). This picture appears to be in keeping with the picture from seismology that while the phase boundary impedes slab and downwelling flow into the mantle, it is not an impermeable boundary and there is in the end significant exchange between the upper and lower mantle and hence whole mantle convection.

However, while the mineralogical, seismological, and geodynamical (fluid mechanical) arguments imply that there is flow between upper and lower mantles, there are numerous data from geochemical analysis of basaltic lavas implying that the mantle is not well stirred on a large scale, that is, it is possibly layered with poor or nonexistent communication between upper and lower mantle.

Structure of mantle convection and mantle mixing

Upwelling mantle reaching the Earth's surface undergoes melting (see above under pressure-release melting) and this melt reaches the surface in two types of volcanic settings: mid-ocean ridges where tectonic plates spread apart and draw mantle up into the opening gap, and ocean-islands or hotspots which are anomalously productive and localized volcanic features not necessarily associated with tectonic activity, Hawaii being the most conspicuous such feature. Melts coming from the mantle in this way are silica poor (relative to more silicic rocks such as granite) and largely basaltic; hence these volcanic regions are said to produce mid-ocean ridge basalts (MORB) and ocean-island basalts (OIB), respectively. These melts are in effect messengers from the mantle, and their petrological composition, bulk chemistry, and trace-element chemistry are extensive areas of research (Hofmann, 1997, 2003; Tackley 2007; van Keken et al., 2002). In the end, while these two basalts nominally come from the same mantle, they have distinct features suggesting they come from parts of the mantle that have been isolated from each other for billions of years. That seismology, mineral physics, and fluid dynamics (geodynamics) argue for a largely well-stirred mantle with whole-layer circulation creates a dichotomy between geophysical and geochemical observations. This paradox has been one of the most fervent areas of debate in mantle dynamics for the last 30–40 years.

Because MORB and OIB are both basalts and thus have similar bulk chemistry, geochemical measurements largely focus on trace elements, in particular incompatible elements, which dissolve more readily in a rock's melt phase than its solid phase; hence during partial melting incompatible elements partition toward the melt. Indeed, the trace-element signature of elements such as uranium, thorium, helium, have demonstrated that MORB and OIB are very distinct. In particular, MORBs appear to be significantly depleted in such trace elements relative to OIB. Since such elements tend to be removed by melting, it implies that MORBs come from a region of the mantle that has already been melted and depleted of trace elements, while OIB come from a region of the mantle that has undergone little previous melting and depletion. This observation implies that MORBs come from an upper mantle that has been cycled repeatedly through the plate tectonic process of mid-ocean ridge melting and separation of crust (and trace elements) from mantle, in essence cleaning the MORB source. In contrast, OIB would appear to come from a part of the mantle that has seen little of this melt processing, and hence would be isolated presumably at depth from the upper mantle and plate-tectonic circulation.

There are other geochemical observations that argue for separated and isolated regions or reservoirs in the mantle. For example the concentration of radioactive daughter isotopes (e.g., ^{206}Pb, which is the final product of the decay of ^{238}U) relative to the abundance of that element's dominant and primordial isotope (e.g., ^{204}Pb) is a metric for reservoir isolation from surface processing. In particular, the relative accumulation of daughter products implies that the rock in which they reside has seen little processing or partial melting that would have cleaned out these elements after they formed. A small relative abundance of daughter isotopes means the sample has been recently processed and cleaned, and thus little time has passed in which to produce new daughter isotopes.

Indeed, many OIBs tend to show distinctly greater relative abundance of daughter products (e.g., the concentration ratio ^{206}Pb/^{204}Pb) than do MORB for many isotopic ratios, implying some isolation of the OIB source. However, OIBs from various islands are also fairly different from each other suggesting that reservoirs isolated from the upper mantle (the presumed MORB source) are possibly also isolated from each other. Moreover, the OIB isotopic ratios have some variation, from low MORB-like values to much higher values, which indicates that there is some mixing of a "young" processed MORB-source-like mantle and a more primitive, isolated one.

These isotopic ratios are also more easily interpreted for refractory daughter products since they do not tend to escape the system (also the reason they are used to radiometrically date rocks). Volatile products, especially isotopes of noble gases such as helium and argon, require different interpretations since they can readily escape the mantle and, for helium, escape the Earth. For example, MORB in fact has a high daughter to primordial isotope ratio, ^{4}He/^{3}He, relative to many OIBs, which is opposite to the refractory ratios involving, for example, lead isotopes. This is often interpreted as resulting from

degassing and loss of primordial helium, ^{3}He, from the upper mantle through plate tectonic and mid-ocean ridge processing, and the subsequent repopulating of helium with its radiogenic isotope ^{4}He (i.e., α-particles from most large element decay sequences); in contrast an isolated lower mantle or OIB source reservoir would have undergone little loss of primordial helium thus maintaining a smaller isotopic ratio ^{4}He/^{3}He.

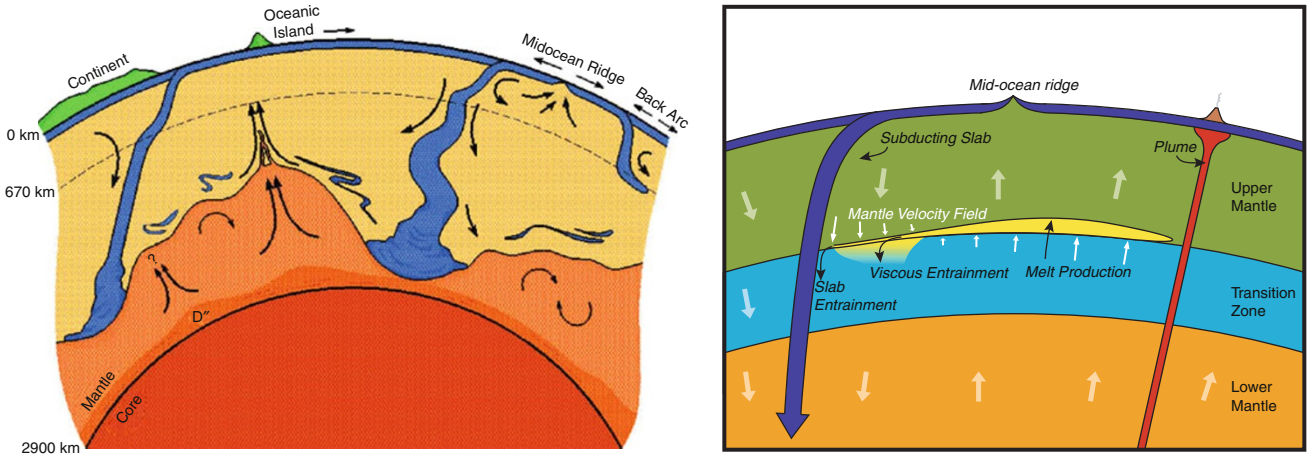
The production of the argon isotope ^{40}Ar from the decay of the potassium isotope ^{40}K has two important arguments relative to mantle layering. First, the total amount of original ^{40}K in the Earth can be roughly estimated from chondritic abundances (and other arguments beyond the scope of this entry). However, the amount of ^{40}Ar it should have produced over the age of the Earth is far in excess (by a factor of 2) of the ^{40}Ar in the atmosphere, implying that much of this argon is still buried and isolated. Moreover, one can also estimate from the trace element composition of MORBs themselves that the MORB source region as it stands now would have been lacking primordial ^{40}K and even if the entire mantle were composed of this MORB source region, it would not have been able to produce even the atmospheric levels of ^{40}Ar; this implies that the bulk of original ^{40}K was buried in a layer different and more enriched than the MORB-source region, which then produced most of the ^{40}Ar, much of which is still buried in this layer.

An often quoted straw-man argument for mantle layering is the heatflow paradox. In this case, it is reasoned that if the entire mantle were composed of MORB source material with its depleted concentration of heat-producing elements (U, Th, K), then it would not be able to produce the total heat output through the top of the mantle (about 30TW). This suggests that the heat-producing elements allowing for the mantle heat output must be buried at depth. However, this makes the assumption that most heat output is from radiogenic heating, whereas possibly less than half of it is; if most heat output is from secular cooling (lost of primordial heat) then the heat-flow paradox argument is questionable. A similar but shakier argument is based on the fact that the volcanic flux of the helium isotope ^{4}He, which is produced from heat producing radioactive decay of U and Th, seems to be very low relative to what would be expected given the heat that is emanating from the mantle, implying that ^{4}He is also buried at depth. Again, if heat output is more than 50% from secular cooling and not all from radiogenic heating, then the low flux of helium is to be expected. Even if that were not the case, mechanisms for the flux of helium are not the same as for flux of heat; that is, heat always escapes to space eventually by convection, conduction even radiation, whereas helium only escapes from the mantle if it passes through narrow melting zones, which is not inevitable, and thus it can be hidden and buried almost anywhere and not only hidden at great depth.

Finally, the production of continental crust also argues for an isolated layer in the mantle. Continental crust represents an accumulated history of mantle melting, segregation of lighter components, and removal of incompatible elements to the surface. If the continental crust were removed uniformly from a whole mantle made of primordial "bulk silicate earth" (i.e., an earth derived from chondritic material and only segregated into mantle and core), then the concentration of incompatible elements would not have been reduced enough to produce a mantle made of MORB source material (i.e., removal of continental crust would not have depleted the whole mantle enough to make MORB source). However, if the crust were removed from 1/3 to 1/2 of the mantle, that resulting depleted portion would very closely match MORB source composition. This argues that the continental crust segregated only from the upper portion of the mantle, not the whole mantle, and thus there remains a deeper unsegregated mantle at depth (see van Keken et al., 2002).

Although there are numerous geochemical arguments for a layered mantle with an isolated and undepleted mantle at depth, they largely conflict with geophysical evidence for whole mantle convection. Mineral physics experiments suggest that the 660 km phase change boundary might provide an impediment to mantle flow but not an impermeable barrier. Seismic tomography consistently shows subducting slabs and apparently cold downwellings extending into the lower mantle (Grand et al., 1997; van der Hilst et al., 1997). Recent high-resolution images of a hot upwelling mantle plume beneath Hawaii (Wolfe et al., 2009) as well as seismic images of other plumes (Montelli et al., 2004) also suggest vertical upward transport across the 660 km boundary. Finally, geodynamical arguments against separated layers suggest that if a lower mantle held most of the mantle's heat-producing elements, it would be implausibly hot, and by heating up the bottom of the upper mantle it would generate much bigger mantle plumes than would be observed (Tackley, 2002).

The contradiction between geochemical and geophysical inference of layered versus whole mantle convection has been and largely remains an unsolved problem. Attempts to reconcile these observations have been numerous. A reasonably popular approach has been to allow that the 660 km boundary is not a barrier to mantle flow, but that the barrier exists at greater depth. There are seismically observable layers at the bottom of the mantle (the D″ layer), which could store enriched material, although these are also so thin they could possibly overheat (depending on the amount of radioactive heat sources stored there). As a compromise, it has been argued that the enriched mantle exists in an approximately 1,000-km-thick layer at the base of the mantle (Kellogg et al., 1999), although this layer has never been seismologically observed (see Figure 7). More recently, chemical heterogeneity gathered into piles on the core–mantle boundary and below upwelling zones (Jellinek and Manga, 2002, 2004) has been suggested by convection models (McNamara and Zhong, 2005) with support from joint seismology-gravity analyses (e.g., Ishii and Tromp, 1999).



Mantle Convection, Figure 7 Two end-member mantle mixing models. In the abyssal layered model (*left*) the source for enriched ocean-island basalt (OIB) is in a deep primordial layer, while the source for depleted mid-ocean ridge basalt (MORB) is in the upper recycled mantle (After Kellogg et al. (1999)). In differential melting models, such as the water-filter model (*right*), the MORB and OIB sources undergo different styles of melting, but the mantle still undergoes whole-mantle circulation; see text for further explanation (After Bercovici and Karato (2003a); Leahy et al. (2007)).

Other mechanisms for reconciling geochemical and geophysical observations, but not invoking layering, have been recently proposed as well, mostly involving differential melting. For example, one model considers the whole mantle as a plum-pudding mix of enriched and volatile (water)-rich plums in a depleted, drier, and harder-to-melt pudding. The pressure-release melting in mantle plumes is stopped at higher pressures at the base of 100 km thick lithosphere, so this could involve mostly melting of easily melted, enriched, and volatile-rich components; melts making it all the way to the surface at ridges would undergo more pressure drop and thus could also melt the depleted mantle component, resulting in MORB that seems depleted relative to OIB (Ito and Mahoney 2005a, b). Another model exploits the fact that transition zone minerals seem to be able to absorb water more readily than material above it (and below it). A transition zone with a little water will be dry relative to its solubility or water storage capacity. However, upwelling material passing through the transition zone would carry this slightly damp material into the upper mantle at the 410 km boundary, and since the upper mantle olivine has poor water solubility, it would be closer to saturation and likely melt. A little melting at 410 km depth of the broad upwelling mantle (forced upward by the downward flux of slabs) passing through and out of the transition zone would cause it to be stripped of incompatible elements as it flows into the upper mantle leaving a depleted MORB source region; because of the high pressures and high compressibility of melt, the partial melt that has cleaned this upwelling mantle would be dense and remain behind, eventually to be entrained by slab-driven downwelling back into the lower mantle. Upwelling mantle plumes on the other hand would go through the transition zone too fast to become hydrated and thus would undergo little melting and filtering at 410 km depths, leaving largely enriched OIB. This model, called the transition zone Water Filter (Bercovici and Karato, 2003a; Karato et al., 2006; Leahy and Bercovici, 2010) (see Figure 7), predicts that the 410 km should be the site of melting, and this has been borne out in various seismological studies (e.g., Revenaugh and Sipkin, 1994; Song et al., 2004; Tauzin et al., 2010); however, the theory is still controversial given poor knowledge of melt properties and their solubilities of incompatible elements at these depths and pressures, so it remains an active subject of investigation.

Mantle convection and the generation of plate tectonics

The oldest problem in mantle convection

The link between plate tectonics and mantle convection is one of the oldest and most challenging problems in the history of geodynamics. The original theories of mantle convection put forward by Holmes (1931) were developed in the context of explaining continental drift as articulated by Wegener (1924). Although the later theory of plate tectonics is considered the grand-unifying principle of geology, it is a kinematic theory in that it describes surface motions but not their cause. Mantle convection is widely accepted to be the engine for plate motions since it is a fundamental mechanism for exploiting the energy sources of the Earth's interior, that is, loss of primordial and radiogenic heat. It is now generally regarded that the plates themselves are a feature of mantle convection in that they are the mobile upper thermal boundary layer of convective cells that thicken as they cool in their migration away from ridges until they are heavy enough to sink along subduction zones.

One of the major accomplishments of mantle dynamics theory is that convective fluid velocities, calculated in any

number of ways, consistently predict the measured scales of plate tectonic velocities, that is, between 1 and 10 cm/year. This was in fact inferred even in the 1930s from both gravity and heat-flow measurements (Hales, 1936; Pekeris, 1935) and is well known by the force balance on sinking slabs (e.g., Davies and Richards, 1992), as well global heat extraction from mid-mantle cooling by slabs (Bercovici, 2003). Moreover, plate motions are well correlated with the presence of slab forcing, in particular that tectonic plates with a significant portion of subduction all have velocities roughly an order of magnitude faster than plates without substantial subduction zone (Forsyth and Uyeda, 1975); see Figure 6. Thus, because cold sinking slabs seem to be the major expression of convection and major drivers of plate motions implies that the plates are convection.

The plate generation problem

While convective and slab-driving forces for plate tectonics are important, understanding how plates self-consistently arise (or why they do or do not arise) from planetary convection has been a major goal in geodynamics. Up until the early 1990s it was believed that since plate-like motion of the lithosphere was essentially discontinuous, it could not be predicted or reproduced by fluid dynamical convection theories. However, in the last 15 years or so there has been major progress with fluid dynamical models yielding very plate-like motion by incorporating more sophisticated rheological weakening mechanisms, such as brittle/plastic yielding or damage mechanics.

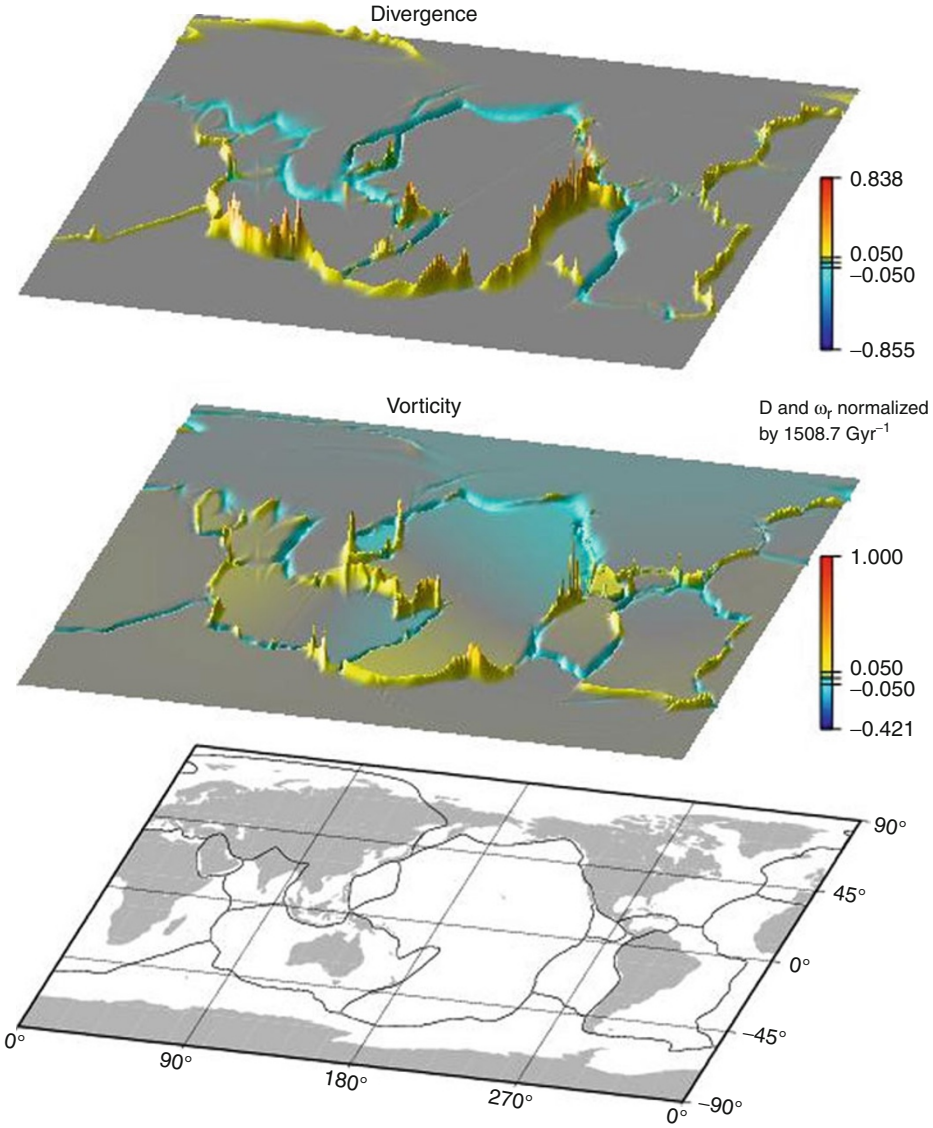
However, even so, there is still no comprehensive theory of how the plates and mantle are related, and in particular how plate tectonics self-consistently arises from a convecting mantle. Both a clue and frustration is that the Earth appears to be the only known terrestrial planet that has plate tectonics in addition to liquid water as well as life, which are all either causative (i.e., necessary conditions for each other) or coincidental. While our planet supports plate tectonics, our ostensible twin, Venus, does not; this remains a leading-order quandary in Earth sciences and to solve it one must understand how and why plate tectonics is generated at all. Of course, geoscience has until recently only sampled the few planets of our own solar system and thus the data is sparse; with the advent of extra-solar planet discovery, this sparseness should be mitigated and perhaps other planets will be discovered with plate-like mantle circulation from which we will learn more about how our own planet works (e.g., Valencia et al., 2007).

There are of course various qualitative and philosophical questions about how and why plate tectonics forms, evolves, and exists, but for these to be predicted or reproduced in a physical theory, one requires quantifiable questions. In short, what are the metrics of plate generation? Two fundamental features of plate-like motion exist for instantaneous motions: *plateness* (Weinstein and Olson, 1992) and toroidal motion (e.g., Bercovici et al., 2000; Hager and O'Connell, 1979; O'Connell et al., 1991). Plateness is essentially the extent to which surface motion and the strength of the lithosphere is like that for nearly rigid blocks separated by narrow weak boundaries. Toroidal flow is characterized by strike-slip motion and plate spin (Figure 8). Toroidal motion has no direct driving force in buoyant convection (which drives only vertical and divergent motion); however, it has as much energy in the present-day plate tectonic velocity field as the buoyantly driven motion (called poloidal motion). The globally-averaged toroidal motion is dependent on the lithosphere's reference frame (e.g., hostpot frame), and the field in general changes through time (Cadek and Ricard, 1992; Lithgow-Bertelloni et al., 1993); however, the toroidal field is a quantifiable and significant feature of global plate motions. Such measurable quantities as plateness and toroidal flow are important for testing the predictions of plate generation theories. Both phenomena rely on reasonably strong nonlinear rheological feedback effects to permit large strength variations for high plateness (i.e., rapidly deforming zones are weak, slowly deforming ones are strong), as well as coupling of buoyantly driven flow to vertical torques that drive toroidal spin and shear (Bercovici, 2003).

Recent progress

In the last decade, plate generation models have become increasingly sophisticated, in concert with further expansion and accessibility of high-performance computing. Instantaneous plate-like behavior has been achieved with convection models employing various forms of plastic yield and self-weakening criteria. Incorporation of these laws has led to the prediction of reasonable toroidal and poloidal flow (Bercovici, 1995) (Figure 9) and by including the rheological effects of melting at ridges have attained localized passive spreading zones (Tackley, 2000) (Figure 10). Most recently, these models have been extended to 3-D spherical models, creating the first global models of plate generation from mantle convection (Foley and Becker, 2009; van Heck and Tackley, 2008) (Figure 11).

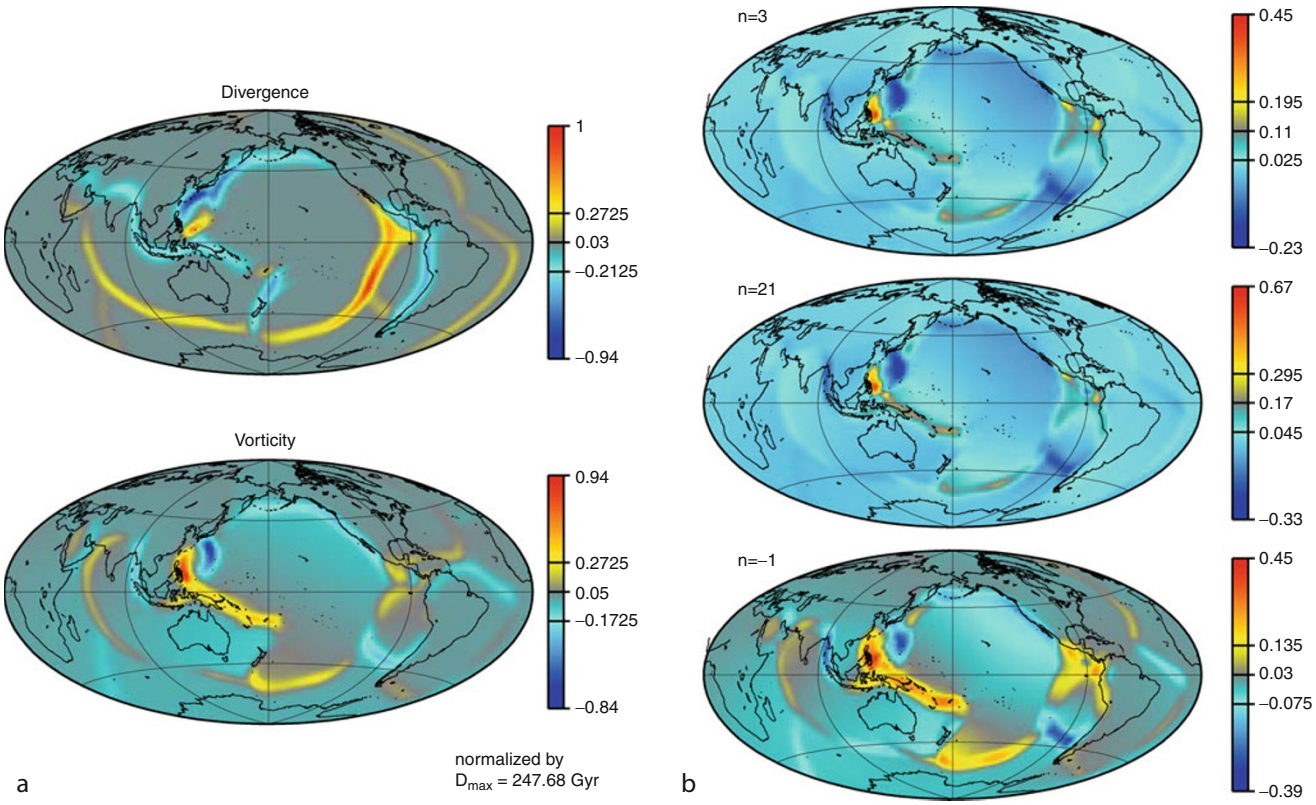
However, models that use plastic or instantaneous self-weakening rheologies only allow weak zones to exist while being deformed, thus cannot correctly model dormant weak zones (e.g., sutures and inactive fracture zones). Rheological mechanisms that allow weakening to persist over time have also been studied. While thermal weakening is a well-understood mechanism, thermal anomalies diffuse too fast, and it is highly unlikely that, for example, sutures are thermal remnants. Weakening by hydration or as a secondary phase (i.e., by providing pore pressure) is a strong candidate as well, although the mechanism for ingesting water to depth is problematic, and requires mechanisms such as cracking enhanced by thermal stresses (Korenaga, 2007). Damage in the form of microcracks (Bercovici, 1998) and grain-size reduction



Mantle Convection, Figure 8 The horizontal divergence (which measures spreading and convergence rates) and vertical vorticity (which measures angular velocity and horizontal shear) of present-day plate motions (from Dumoulin et al. (1998)), which are associated with poloidal and toroidal flow, respectively. Poloidal flow is equivalent to basic convective motion driven directly by thermal buoyancy. Although present in Earth's plate-mantle system, toroidal flow does not arise naturally in basic viscous convection, but requires the coupling of convective motion with nonlinear rheological effects.

(e.g., Braun et al., 1999; Karato et al., 1980; Montési and Hirth, 2003) are also strong candidate-weakening mechanisms because of their longevity and evidence in the form of mylonites (Jin et al., 1998). The need for shear-localization at significant depth makes grain-size weakening particularly appealing and has proven to be successful at creating plate-like mantle flows (Bercovici and Ricard, 2005; Landuyt and Bercovici, 2009b; Landuyt et al., 2008) (Figure 12). However, grain-size reduction and weakening tend to occur in exclusive areas of deformation space (i.e., weakening occurs during diffusion creep while reduction occurs in dislocation creep; see De Bresser et al., 2001) and require mixing of mechanisms in physical or grain-size distribution space (Bercovici and Karato, 2003b; Ricard and Bercovici, 2009).

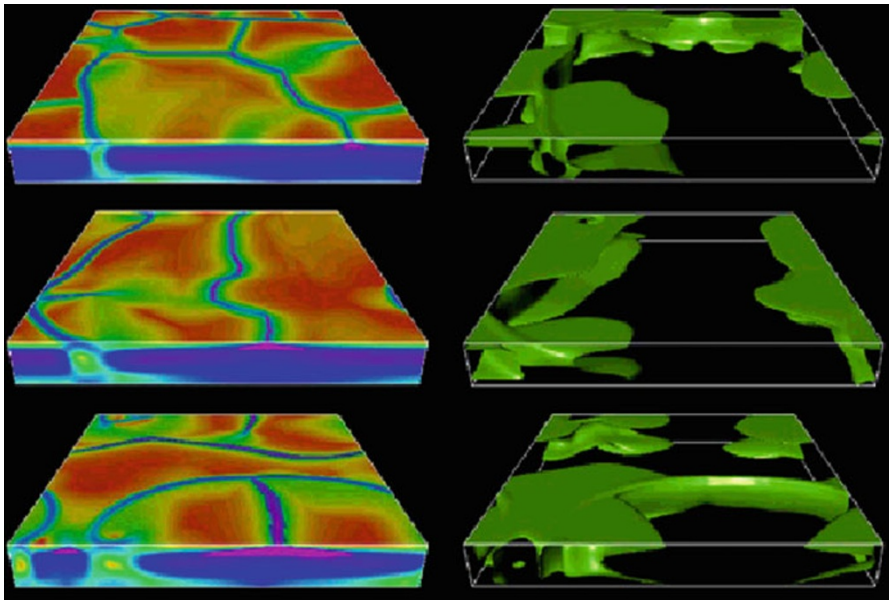
Use of both plastic/brittle yielding and damage theories of plate generation have been used to elucidate the planetary dichotomy between Earth and Venus and the causal link between climate, liquid water, and plate generation. Earth and Venus are ostensible twins but Earth has plate tectonics and Venus does not. This is usually attributed to lack of water on Venus which would otherwise lubricate



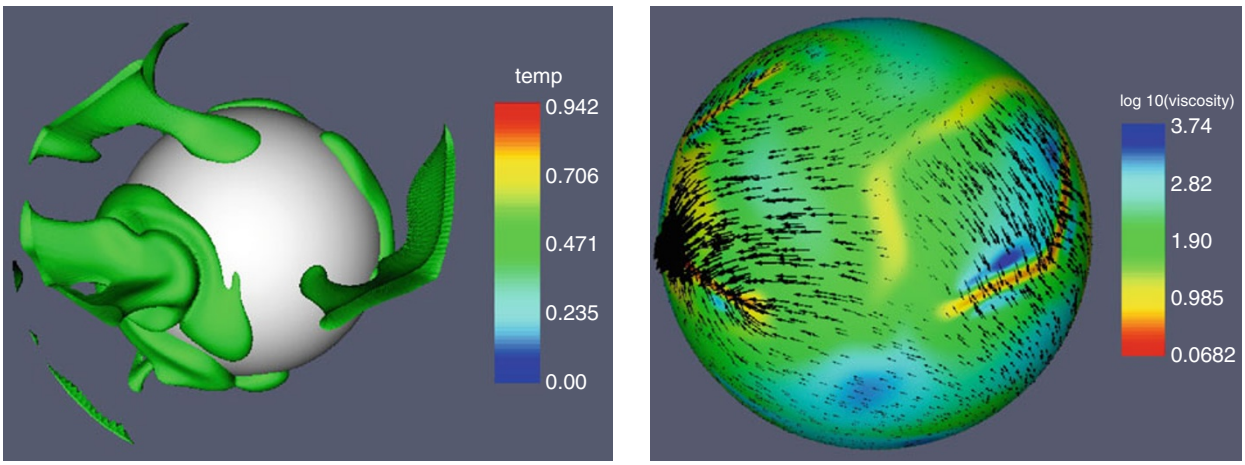
Mantle Convection, Figure 9 The source-sink model of lithospheric motion uses present-day plate motions to drive flow with the divergent field (*upper left*) in order to model and recover the known vorticity field (*lower left*) using non-Newtonian flow calculations (*right column*). Simple power-law or pseudo-plastic rheologies (typical of dislocation creep) do not recover the vorticity field well (*top* two, *upper right*), while velocity-weakening or shear-localizing rheologies (where stress decreases with increased strain rate) recover it very well (*lower right*) (From Bercovici et al. (2000) after Bercovici (1995). American Geophysical Union).

plate motions; however, Earth's lithosphere is likely to be no more hydrated than Venus's because of melting dehydration at ridges (Hirth and Kohlstedt, 1996). Recent studies have hypothesized that the role of water in maintaining plate motion is not to lubricate plates, but to be an agent for the carbon cycle, which thus allows for a temperate climate on Earth. A cool surface on Earth, according to one hypothesis (Lenardic et al., 2008) causes a larger temperature drop across the lithosphere than would occur on Venus (because of temperature-dependent viscosity), and thus lithospheric buoyant stresses are large enough on Earth to induce plastic/brittle failure, but not on Venus. An alternative hypothesis (Landuyt and Bercovici, 2009a) states that plate-like motion depends on the competition between damage and healing (where, e.g., if damage is due to grain-size reduction, healing is due to normal grain growth), where a high damage-to-healing ratio promotes plate-like motion, while a lower ratio yields stagnant-lid behavior. A cooler surface temperature inhibits healing while a hot surface promotes healing, thus leading to plate-like behavior on a planet like Earth with a temperate climate but not on a planet like Venus. Both hypotheses emphasize that water dictates conditions for plate generation by its modulation of climate and not on direct strength reduction.

Finally, subduction initiation continues to be an extremely challenging issue in geodynamics (King, 2007; Stern, 2004). The strength of thick, cold pre-subduction lithosphere is such that it should never go unstable and sink, at least not on geological timescales (or cosmological ones either). Thus, how and why subduction zones form remains enigmatic. Mechanisms range from weakening by rifting (Kemp and Stevenson, 1996; Schubert and Zhang, 1997), sediment loading and water injection (Regenauer-Lieb et al., 2001), and reactivation of preexisting fault-zones (Hall et al., 2003; Toth and Gurnis, 1998), all of which have some observational motivation, although fault reactivation might be the most compelling (e.g., Lebrun et al., 2003). Another unresolved enigma concerns the age of subduction zones. The convective picture of plate motions would have plates subduct when they get old, cold, and heavy. However, the sea-floor age distribution implies that subduction rate is independent of plate age, such that the age of plates at subduction



Mantle Convection, Figure 10 A simulation of plate generation over mantle convection. The plate rheology is visco-plastic and the viscosity reduction associated with melting is parameterized into the model, leading to exceptional plate-like behavior and apparent passive spreading (i.e., narrow spreading centers not associated with any deep upwelling). The *right panels* show surfaces of constant temperature, which here are dominated by cold downwellings; the *left panels* show the viscosity field (red being high viscosity and blue low viscosity). Different rows show different times in the simulation (After Tackley (2000). American Geophysical Union).

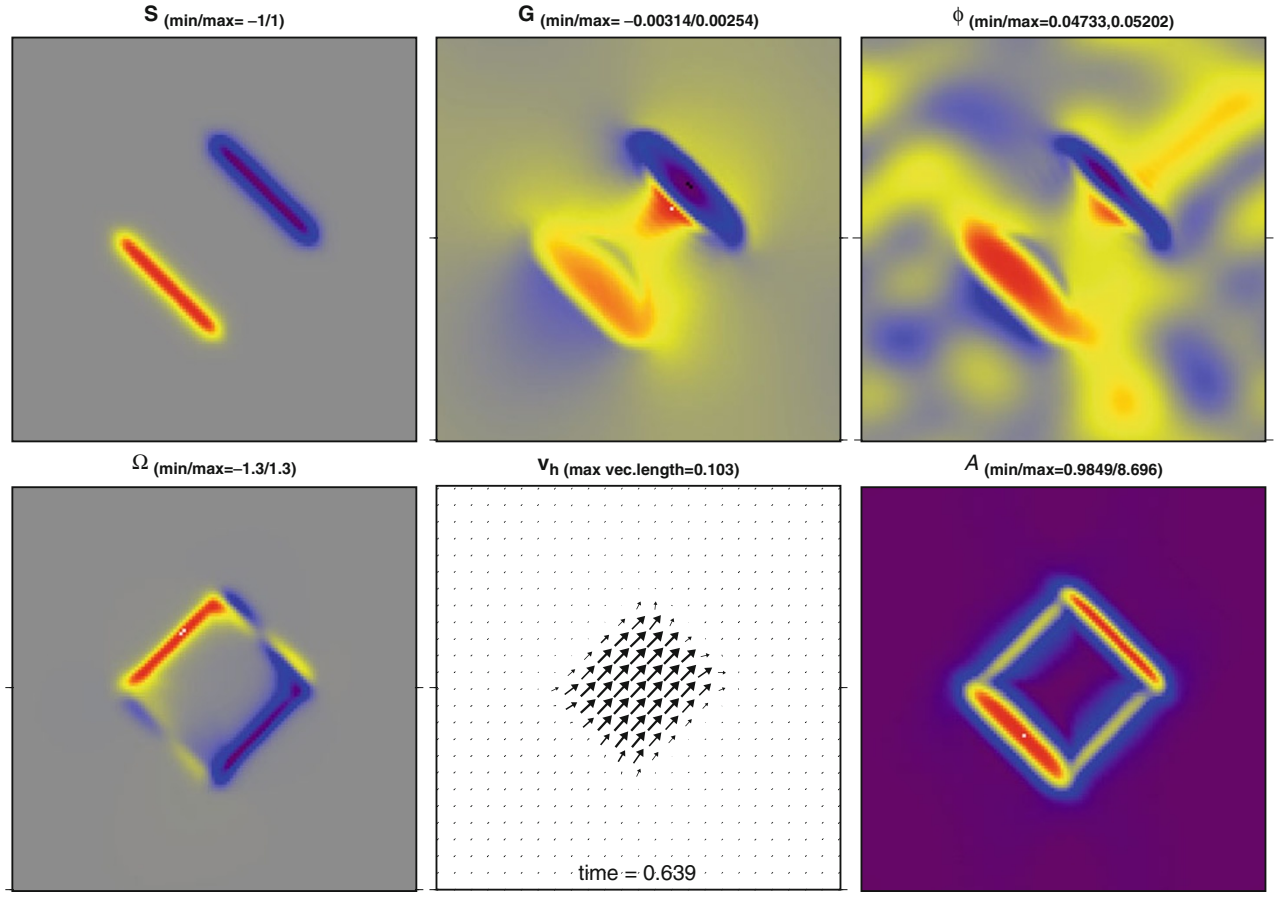


Mantle Convection, Figure 11 Three-dimensional spherical shell convection with a plastic-type lithospheric rheology showing plate-like behavior. *Left panel* shows isothermal surfaces and in particular cold downwellings. The *right panel* shows surface viscosity with velocity vectors superimposed. Note the passive divergent and rheological weak zone forming midway between the two major downwelling regions (Adapted from Foley and Becker (2009). American Geophysical Union).

zones is distributed from age nearly 0 (i.e., subducting ridges), to the oldest ages of roughly 200 Myr (see Becker et al., 2009).

Summary

Mantle convection is the central theory for how the Earth works, that is, what drives geological motions as well as the cooling history and chemical evolution of the planet. The theory is based on the simple notion that the Earth (and other terrestrial planets) must cool to space and in so doing release heat and gravitational potential energy through thermal convection. Thermal convection theory itself is a well-established physical theory rooted in classical mechanics and fluid dynamics. Much of the physics of



Mantle Convection, Figure 12 A simple source-sink model of shallow flow with a two-phase and grain-size-reducing damage mechanism. Damage per se involves transfer of deformational work to the creation of surface energy on interfaces by void and/or grain boundary generation in the continuum. In the case shown, all damage is focused on grainsize reduction. The panel meanings are indicated by symbols where S is the imposed divergence rate (i.e., the source-sink field) that drives flow; G is the dilation rate due to void formation; φ is void volume fraction; Ω is vertical vorticity or rate of strike-slip shear; $\mathbf{v_h}$ is horizontal velocity; and A is the "fineness" or inverse grainsize. This particular calculation shows that fineness-generating, or grain-size-reducing, damage is very effective at creating localized fault-like strike-slip zones in vorticity Ω, and solid-body-like translation in the velocity field $\mathbf{v_h}$ (Adapted from Bercovici et al. (2005). American Geophysical Union).

basic convection goes far in describing circulation and structure in the Earth's mantle, for example, the flow velocities, establishment of thermal boundary layers, and even the prevalence of slab-like downwellings and plume-like upwellings. However, numerous quandaries and paradoxes persist because much remains to be understood regarding the many complexities of the exotic convecting "fluid" in the mantle. How the Earth appears to be stirred by deep subducting slabs, but still appear to be unmixed when it comes up at either mid-ocean ridges or ocean-islands, remains a major mystery, much of which is due to our incomplete understanding of the processes of melting, chemical segregation, and mixing in the mantle. How and why the Earth's mantle convects in the form of plate tectonics at all and unlike other terrestrial planets remains one of the biggest questions in geoscience; this problem is undoubtedly related to the mantle's exotic rheology in which flow depends on multiple properties including temperature, stress, chemistry, and mineral grain size. Even more than 100 years since Kelvin's controversial dating of the Earth's age by cooling, in fact the cooling history of the Earth remains poorly understood because of incomplete knowledge of radiogenic heat sources as well as the complex physics of mantle flow. Thus, while mantle convection remains one of the grand unifying physical theories of how the Earth works, many of the major questions and mysteries about the mantle remain unsolved and are thus ripe for discovery by future generations of Earth scientists.

MANTLE D″ LAYER

Thorne Lay
Earth and Planetary Sciences Department, University of California, Santa Cruz, CA, USA

Definition and introduction

Earth's lower mantle extends from the base of the transition zone (commonly assigned a depth of 660 km, corresponding to the average depth of a global seismic velocity discontinuity) to the core-mantle boundary (CMB) at a depth of ~2,900 km below the surface. This thick layer of rock comprised of silicate and oxide minerals has gradual increases with depth of P- and S-wave seismic velocities and density that are generally consistent with adiabatic self-compression of a uniform composition material over most of the depth range (see *Earth's Structure, Lower Mantle*). Large-scale lateral heterogeneities in the seismic velocities of about ±1% are apparent in the central lower mantle, and these likely involve thermal and chemical signatures of upwellings and downwellings in the slowly convecting deep mantle system (see *Mantle Convection*). The deepest few hundred kilometers of the lower mantle have generally reduced seismic velocity gradients, localized seismic velocity discontinuities, and strong large-scale seismic velocity heterogeneities of ±2–4%. This portion of the lower mantle is called the D″ layer (or, more commonly, the D″ region, because the onset of anomalous properties varies significantly in height above the CMB from place to place) in recognition of its distinctive properties relative to the shallower lower mantle (D′ layer). Localized regions of extreme (10–30%) seismic velocity reductions in thin layers or lumps only tens of kilometers thick are found at the base of D″. The structural heterogeneities in the D″ region are usually interpreted as manifestations of complex thermal and chemical boundary layers at the CMB, to some extent mirroring the structural heterogeneities found in the near-surface lithospheric boundary layers. The structure and dynamics of the D″ region are believed to be of fundamental importance to the mantle and core dynamical systems, prompting many seismological, geodynamical, and mineral physics investigations of D″ properties.

The D″ region may have distinct bulk composition from the rest of the lower mantle, involving residues from deep mantle melting, core formation, chemical reactions between the core and mantle, or dynamical segregation of materials over time, but this possibility has to be assessed in the context of expected behavior of major lower-mantle minerals for the extreme pressure-temperature (P-T) conditions near the CMB. The primary minerals in the lower mantle are thought to be $(Mg_x,Fe_{1-x})SiO_3$ perovskite, $(Mg_x,Fe_{1-x})O$ ferropericlase, and smaller amounts of $CaSiO_3$ perovskite and high-pressure forms of SiO_2 (see *Earth's Structure, Lower Mantle*). The relative amount of Mg versus Fe, given by x, is ~0.9, but the properties of the minor Fe component are being intensely investigated because transitions from high-spin to low-spin in Fe^{3+} and Fe^{2+} are expected in lower mantle perovskite and ferropericlase as pressure increases, with strong effects on chemical and transport properties of the material in the deep mantle. Some Al may substitute in both the Mg and Si sites in the Mg-perovskite. Mg-perovskite comprises as much as 70% of the lower mantle, making it the most abundant mineral in the Earth. A phase change in Mg-perovskite, discovered in 2004, occurs under P-T conditions existing a few hundred kilometers above the CMB, likely giving rise to some of the complexities of the D″ region (Hirose and Lay, 2008). Mineralogical complexity of D″ is expected to be enhanced relative to the bulk of the lower mantle due to proximity to huge contrasts in composition and physical properties across the CMB.

The CMB separates the solid silicate- and oxide-mineral mantle from the molten metallic-alloy outer core. The density increases from about 5,500 kg/m^3 to 9,900 kg/m^3 across the CMB, and the viscosity decreases by many orders of magnitude. These contrasts maintain a very sharp boundary and result in thermal and chemical boundary layers in both D″ and the outermost core, although any core structures may be very thin and hard to detect (see *Earth's Structure, Core*). With any mass flux across the CMB being constrained to involve chemical diffusion, heat transports across the CMB by conduction from the hot core into the lower-temperature

mantle. The temperature drop across the resulting CMB thermal boundary layer is estimated to be in the range 1,000–2,000°C, and there is a heat flow of 5–15 TW across the boundary (the heat flow through Earth's surface is ~46 TW) (Lay et al., 2008). Over time, relatively dense materials in the mantle (for example, any basaltic component in subducted slabs that penetrate into the lower mantle) are likely to have concentrated in D″, while light dross, expelled from the core may have accumulated on the underside of the CMB. Thermo-mechanical and electromagnetic interactions across the CMB couple the mantle and core dynamical systems, and this influences the geodynamo (see *Core-Mantle Coupling*). The D″ region is relatively accessible to seismic imaging, and its inferred structural and dynamical properties are discussed here. Trønnes (2009), Garnero and McNamara (2008), Lay (2007), and many papers in Hirose et al. (2007) provide technical reviews of ongoing research topics and conceptual models for structures and processes occurring in D″.

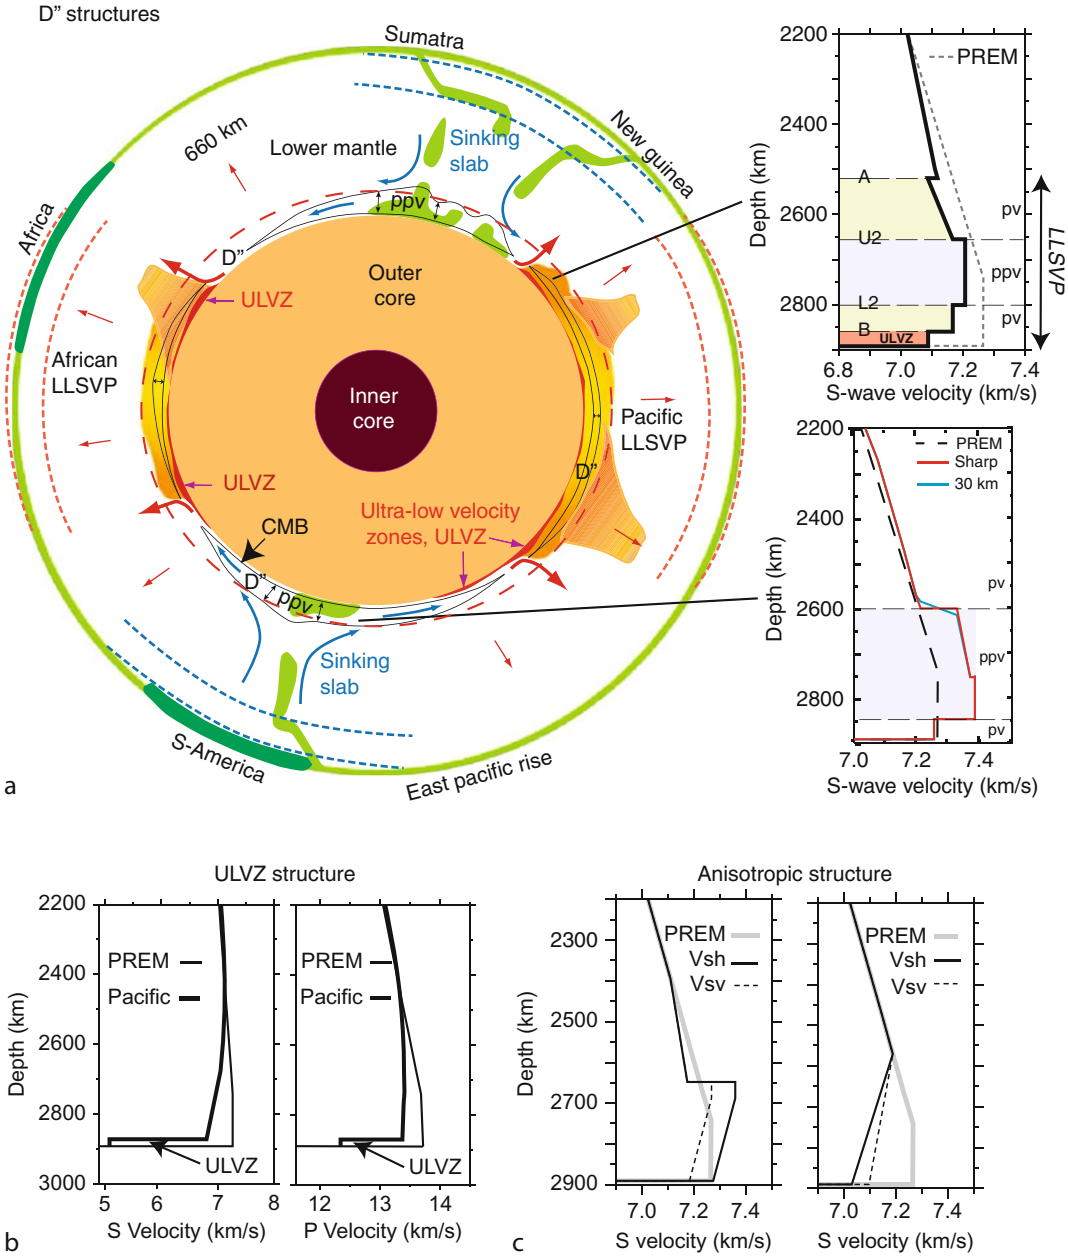
Seismic velocity models for D″

Seismology provides the highest resolution of D″ elastic material properties because it is possible to decipher seismic wave interactions with the lowermost mantle and CMB in recordings of ground shaking at seismic stations around the world. Seismic wave observations can resolve D″ region P- and S-wave velocities, reflections from sharp velocity jumps, shear-wave splitting caused by anisotropy of the elastic structure, and scattering properties. One-dimensional (1D) depth-varying seismic velocity models, such as the Preliminary Reference Earth Model (PREM) of Dziewonski and Anderson (1981), usually have reduced velocity gradients in the deepest ~150 km of the mantle, representing the global departure of D″ velocity structure from that of the overlying lower mantle. Efforts were initially made to interpret the low (or even negative) velocity gradients in such laterally averaged models of D″ structure as the result of a superadiabatic temperature increase across the CMB thermal boundary layer; strong temperature increases are required to account for seismic velocity reductions due to the low thermal expansion coefficient of deep mantle rock under high pressures. However, it is now clear that there is no meaningful "average" 1D structure for the D″ region useful for a robust interpretation of the boundary layer. It is more useful to discuss the seismic properties of D″ by emphasizing the lateral variations in structure, as is also the case for the lithosphere.

Seismic tomography has been applied to develop three-dimensional (3D) seismic velocity models for the entire mantle for over 30 years. This method extracts 3D P-wave and S-wave velocity fluctuations relative to 1D reference models by inversion of massive data sets with crossing ray paths for which seismic wave travel times are measured. 3D velocity inversions indicate that seismic velocity heterogeneity in the mid-lower mantle is relatively weak, but that in the lowermost 300–500 km of the mantle heterogeneity increases with depth, becoming stronger in D″ than anywhere else in the Earth except for the uppermost mantle where major thermal, chemical and partially molten heterogeneities are known to exist.

An unanticipated aspect of the D″ seismic velocity heterogeneity revealed by seismic tomography is that it is dominated by large-scale patterns, with huge continuous volumes of high or low-seismic-velocity material having scale-lengths of hundreds to thousands of kilometers. This predominance of large-scale variations is observed in both P-wave and S-wave velocities, with relatively high-velocity regions of D″ underlying the circum-Pacific margins and two nearly antipodal regions of pronounced low S-wave velocity beneath the southern central Pacific and southern Africa/southern Atlantic/southern Indian Ocean (Figure 1a). High-seismic-velocity regions are likely to have lower temperature than low-seismic-velocity regions, although chemical differences and phase changes may contribute to the variations. Recent global tomographic models have ±4% S-wave velocity variations in D″, two or three times stronger than those found in the mid-lower mantle, and comparable to the ±5–8% variations at depths near 150 km in the upper mantle. While mid-mantle variations tend to have more spatially concentrated heterogeneities, there is a significant degree of radial continuity of high- and low-velocity anomaly patterns throughout the lower mantle, possibly linking subduction zones at the surface to high-velocity regions in D″ and hot-spot locations at the surface to low-velocity regions in D″ (Garnero and McNamara, 2008).

P-wave velocity variations in current tomographic models have ±1.0–1.5% fluctuations, with low-velocity areas beneath the southern Pacific and south Atlantic/Africa and high velocities under eastern Eurasia. There is not as strong of an increase in P-wave velocity heterogeneity in D″ relative to that in the overlying mantle as there is for S-wave velocity, which can be partially attributed to the expected greater sensitivity of S-wave velocity to temperature variations in a thermal boundary layer. There is a large-scale spatial correlation between S- and P-wave velocity patterns, as expected for temperature-induced variations, but in some regions, such as beneath the northern Pacific, this correlation breaks down. In other regions, such as beneath the central Pacific, the S-wave variations are much stronger than the P-wave variations even though both have the same sign. The decorrelation of the seismic velocities and the variation in their relative strengths provide strong evidence that thermal variations alone cannot explain the large-scale patterns of seismic velocity heterogeneity; so there is likely to be chemical heterogeneity present in D″ (Trampert et al., 2004). It is important to recognize that tomography patterns are relative to the global average velocities at D″ depths, and that these averages do not necessarily define "normal" mantle structure. This results in uncertainty in interpretations of the velocity fluctuations (for example, high velocity regions may be anomalously low temperature, perhaps due to cool downwellings that have disrupted an overall hot boundary



Mantle D″ Layer, Figure 1 (**a**) Schematic cross-section through the Earth indicating large structures in the D″ region (below the red dashed line) above the core-mantle boundary (CMB) (adapted from Trønnes, 2009). The two large low shear velocity provinces (LLSVPs) under Africa and the Pacific are indicated, with thin ultra-low velocity zones (ULVZs) at their base and margins. Areas of upwelling warm mantle surround and overlie the LLSVPs. Areas of relatively cool mantle downwellings are underlain by D″ material with post-perovskite (ppv) occurrence. Detailed seismic S-wave velocity models from both an LLSVP margin and a down-welling region are shown on the right, with the D″ velocity discontinuity seen at depths of 2,600–2,650 km. Both regions have a deeper velocity decrease that may represent conversion from post-perovskite back to perovskite (pv) in the steep thermal gradient above the CMB at 2,891 km depth. (**b**) S-wave and P-wave velocity models from areas of intense ULVZ under the central Pacific, showing strong velocity reductions below low velocity (LLSVP) regions. (**c**) Representative anisotropic S-wave velocity models, indicting high Vsh velocities below circum-Pacific regions with strong D″ discontinuities and high Vsv velocities in LLSVP environments.

layer, or low-velocity regions may be anomalously hot regions, perhaps partially melted, within a chemically distinct, high velocity layer). Resolution of finer scale seismic properties in D″ is pursued in order to overcome this ambiguity in interpreting global seismic tomography images.

Seismic velocity discontinuities in D″

Rapid P-wave and S-wave velocity increases and/or decreases are observed several hundred kilometers above the CMB in many regions (Lay and Garnero, 2007), and are sometimes used to define the top of D″. The most prominent structure is a rapid shear velocity increase of 1.5–3% 150–350 km above the CMB found over intermediate-scale (500–1,000 km) regions beneath circum-Pacific margins and some other locations (Figure 1a). The increase in velocity may be distributed over a few tens of kilometers or it may be very abrupt (a "discontinuity") (Lay, 2008), and in some regions it can vary in depth by as much as 100 km over lateral scales of just 200 km. The velocity increase is required to account for observed S-wave reflections that arrive before reflections from the CMB. Similar structures have been found in localized regions for P-waves, usually with a smaller velocity increase of 0.5–1.0%, but in some regions there is a P-wave velocity decrease at the same depth as an S-wave increase (Hutko et al., 2008). Lay and Garnero (2007) review many observations and models for this D″ seismic velocity discontinuity.

The D″ S-wave velocity discontinuity is commonly observed in regions with large volumes of high S-wave velocity material in D″, indicating that it is associated with relatively low temperature environments. An abrupt increase in velocity with depth is not expected for a thermal boundary layer structure, so most interpretations of this correlation invoke the notion of localized ponding of cool subducted lithospheric slabs that have sunk to the lowermost mantle, retaining enough thermal and chemical anomaly to account for the high seismic velocity. However, it is not clear that slab thermal and compositional anomalies can account for a sharp reflecting structure, so additional presence of a phase change may be required. Alternatively, chemically distinct high velocity material may be present in these regions, perhaps involving ancient accumulated material concentrated during core formation or segregated oceanic crustal materials that have accumulated over Earth history. Observations of an S-wave velocity increase beneath the central Pacific, a relatively low velocity region far from any historical subduction zone, complicates any attempt to interpret the velocity discontinuity solely as the result of recent slab thermal anomalies (Lay and Garnero, 2007).

Post-perovskite in D″

The major seismic velocity discontinuities in the transition zone are generally attributed to phase changes in upper mantle minerals that cause abrupt changes in density and elastic wave velocities. The experimental discovery of a phase transition in $MgSiO_3$ perovskite (Murakami et al., 2004) for P-T conditions near the top of D″ may provide a corresponding explanation for the D″ S-wave velocity discontinuity. The high-pressure polymorph is called post-perovskite, and laboratory and theoretical predictions of its properties indicate that it should have 1–2% higher S-wave velocity, little, or no change in P-wave velocity, and 1–1.5% higher density than perovskite, which can account for some of the seismological complexities of D″ (Hirose et al., 2007). Presence of Fe and Al in the perovskite cause the phase transition to occur over a pressure range rather than at a single pressure for a given temperature, and this may be difficult to reconcile with an efficient seismic wave reflector. The perovskite-to-post-perovskite transition occurs at lower pressure for lower temperatures, thus lateral temperature variations in a thermal boundary layer are expected to modulate the depth of the transition. If the phase transition occurs in a relatively cool region of accumulated downwelling slab material, the discontinuity should be higher above the CMB than in warmer areas of D″ with the same composition. Some calculations indicate that the pressure of the transition may decrease if Fe is present in the perovskite, thus chemical heterogeneity could also modulate the depth of the phase transition.

The P-T behavior of the post-perovskite phase change tends to enhance thermal instabilities within the thermal boundary layer, but its thermal transport properties are still uncertain due to the possibility of Fe high-spin to low-spin transition and the lack of constraint on Fe partitioning coefficients between post-perovskite and ferropericlase. One of the most important attributes of the phase transition is that it can provide an absolute temperature tie-point for D″, if an observed S-wave reflector at a specific depth (hence, pressure) is correctly attributed to the phase change and if the P-T-X behavior (where X indicates precise mineralogical composition) of the phase change is experimentally and theoretically constrained. This is important because estimates of temperature structure in the lowermost mantle and outermost core are largely based on extrapolations over tremendous depth ranges of laboratory-estimated-temperature tie-points for the olivine-spinel phase transition near 410-km depth and the iron alloy solidus at the 5,150-km deep inner core-outer core boundary.

Laboratory measurements indicate that the temperature at a depth of about 2,600 km is close to 2,500 K, if the D″ discontinuity is caused by transition to post-perovskite. With an estimated outermost core temperature of 3,500–4,000 K, this favors a 1,000–1,500° increase in temperature across the D″ thermal boundary layer. Such a strong temperature increase could cause a reversion from post-perovskite to perovskite to take place in the hottest region right above the CMB, and some evidence for such a second crossing of the phase boundary has been inferred from seismic observations of a S-wave velocity decrease 50–100 km above the CMB (Figure 1a; Lay et al., 2006; van der Hilst et al., 2007). The effects of the phase

transition on seismic velocities must be considered when inferring lateral temperature structure in D″ from seismic velocity variations, given that the volume of the high S-wave velocity post-perovskite material should vary laterally in either a depth-modulated layer or a "lens," depending on stability of post-perovskite right at the CMB.

Large low shear velocity provinces in D″

The two large antipodal regions with low S-wave velocity appear to be chemically distinct regions of D″ (Figure 1a). The margins of these large low shear velocity provinces (LLSVPs) have abrupt steep-walled lateral gradients, over scales of tens of kilometers, which indicates a chemical change relative to surrounding D″ material rather than just a thermal change. The region beneath the southern Atlantic and Africa has been modeled as having margins with an abrupt −1 to −3% S-wave velocity decrease 250–300 km above the CMB (shallowing to ∼800 km above the CMB under Africa), with average velocities in D″ that are 3–5% lower than for PREM (e.g., Wang and Wen, 2006). The sub-Pacific LLSVP has comparable velocity contrasts and varying vertical extent, and may be two separate mounds of material that extend upward into the central lower mantle. P-wave velocity tends to be slightly low in the LLSVPs, but less than what would be expected if the S-wave velocity reductions were entirely caused by high temperatures. Thus, there is an anomalously high incompressibility in the LLSVPs, which also favors distinct chemistry. While limited in resolution, free oscillation measurements suggest that the LLSVPs are relatively high density, adding to the evidence for chemical inhomogeneity, and suggesting that these are not buoyant 'superplumes' as some researchers have suggested. Internal structure of LLSVPs has been detected in the form of localized velocity discontinuities (Figure 1a) and the presence of underlying ultra-low velocity zones (see below). The velocity discontinuities may represent chemical heterogeneity or possibly post-perovskite phase transition in material with distinct Fe and Al content from surrounding high seismic velocity areas of D″.

The current position of the LLSVPs can be attributed to accumulation of chemically distinct, relatively dense material in D″ that has been displaced away from circum-Pacific areas of downwelling slab materials over the past several hundred million years (Garnero and McNamara, 2008). Thermal calculations indicate that any dense chemical piles in a convecting mantle will be relatively hot as a result of inefficient heat loss, so LLSVPs would likely have combined effects of high incompressibility, high temperature, and high density. This predicts complex dynamical behavior, but the presence of the structures in D″ at this point in Earth's evolution suggests that the features are long-lived and are either remnants of much larger chemical anomalies that have slowly been entrained by mantle flow or they are being regenerated by ongoing chemical differentiation. Aggregation of basaltic (ocean crust) components of subducted slabs is one possible mechanism for accumulation of chemically distinct material that may be sustaining the LLSVPs. The total volume of LLSVP material is several percent of the mantle, so these are significant chemical reservoirs. The possibility that the LLSVPs have been close to their present locations for hundreds of millions of years is supported by the fact that reconstructed emplacement locations of many Large Igneous Provinces (LIPs) overlie margins of the LLSVPs (Torsvik et al., 2006). If plume upwellings rise from the lateral margins of the dense piles, as suggested by numerous dynamical models, this association may be understood as a first order impact of D″ structure on geological processes at Earth's surface.

Ultra-low velocity zones in D″

Thin layers or mounds of material with very strong seismic velocity reductions have been detected in D″ just above the CMB (Figure 1b), and these are called ultra-low velocity zones (ULVZs). P- and S-wave velocity models for ULVZ may have a thin layer or mound of 10–40 km thick and from hundreds to thousands of kilometers across with P-wave velocity reductions of −4 to −10% and S-wave velocity reductions of −8 to −30% (Thorne and Garnero, 2004). These structures are commonly found near the margins of LLSVPs (Figure 1a), but also occur in localized regions elsewhere. They are detected in seismic waves that reflect from or graze along the CMB.

The magnitude of the velocity reductions in the ULVZs and the factor of 2–3 ratio of S-wave velocity/P-wave velocity decrement require either the presence of a melt component or very strong chemical contrast. The temperature in the D″ thermal boundary layer will reach a peak right at the CMB (which is nearly isothermal due to the rapid convective flow occurring in the core); so ULVZs are intrinsically the hottest regions in the mantle. However, they are not globally detectable (a very thin layer $< \sim 1$ km could be present everywhere without being resolved by seismic data); so a combination of partial melting and chemical heterogeneity is implied by the patchy nature of the thicker regions of ULVZ. Seismic data indicate that the ULVZ material may be ∼10% denser than surrounding D″ material, favoring high Fe content, which would contribute to the strong seismic wave velocity reductions. ULVZ affiliation with LLSVP margins may be associated with thermal convection in the LLSVPs, along with interactions with flow in the surrounding mantle (Garnero and McNamara, 2008). It is not yet clear how to account for ULVZ chemical evolution, but one possibility is that they are the residue of a much more extensive lower mantle magma ocean which has largely solidified (Labrosse et al., 2007).

Seismic velocity anisotropy in D″

The seismic velocity structure in D″ is more anisotropic than the shallower lower mantle, with seismic velocities

being dependent on the direction of propagation and the polarization of ground shaking. This results in shear-wave splitting, involving an S-wave separating into two-components with orthogonal polarization, one traveling slightly faster than the other while in the D″ region. By measuring the polarizations and travel time difference between the fast and slow S-waves, it is possible to determine the anisotropic characteristics of the medium. For most S-wave phases with ray paths grazing horizontally through the D″ region, the data can be explained by models in which horizontally polarized (SH) vibrations travel with 1–3% higher velocities (Vsh) than vertically polarized (SV) vibrations (Figure 1c). This behavior is consistent with the medium having vertical transverse isotropy (VTI), which can result from hexagonally symmetric minerals with vertically oriented symmetry axes or from stacks of thin horizontal layers with periodic velocity fluctuations. The regions with the best documented cases for strong VTI in D″ tend to have higher than average S-wave velocities and strong D″ discontinuities (Figure 1c). There are observations favoring slightly tilted (non-vertical) transverse isotropy (Maupin et al., 2005), which results in weak coupling of the SH and SV signals (the fast wave is still close to the SH polarization), as well as limited regions where SV signals are found to propagate with higher velocities (Vsv) than SH signals (such as in the central Pacific LLSVP, Figure 1c).

Anisotropy in D″ is likely to be caused by either lattice-preferred orientation (LPO) or shape-preferred orientation (SPO). LPO can arise when minerals systematically orient within a flowing medium. This may exist in D″ if dislocation creep occurs, which requires relatively high stresses and low temperatures as might be found near slab downwellings. Ferropericlase has been shown to be a viable candidate for development of LPO in horizontal shear flows above the CMB, if suitable temperatures and stresses are present. It is also possible that certain slip systems can be activated such that post-perovskite can account for shear-wave splitting observed in some regions. If a region of D″ is too warm for dislocation creep, deformation will occur by diffusion processes and seismic anisotropy is only viable if heterogeneities (either chemical blobs or pockets of partial melt) are systematically aligned with the flow. Transitions from horizontal to vertical flows may account for SPO transitions from VTI to horizontal transverse isotropy, which can have Vsv higher than Vsh. Efforts continue to improve the characterization of D″ anisotropy because it has the potential to reveal ongoing deformation processes occurring in the boundary layer.

Summary

The diverse seismic properties of the D″ region appear to demonstrate the presence of heterogeneity at the base of the mantle associated with thermal and chemical boundary layers of a complex dynamical system. There is a predominance of large-scale structures in D″, and the strength of heterogeneities at intermediate and large-scales appears to be significantly greater than in the overlying lower mantle. Large low shear velocity provinces (LLSVPs), ultra-low velocity zones (ULVZs), multiple seismic discontinuities, a major phase change, and seismic anisotropy are all fundamental attributes of the D″ region. The present day configuration of D″ structures represents a “snap-shot” of an evolving system, with some aspects reflecting very long time-scale processes (LLSVPs may have been in place for at least hundreds of millions of years; ULVZs may be the last remnant of an extensive magma ocean that dates back to core formation) and much shorter time scales (post-perovskite lenses may be found in recently downwelled slab materials and seismic anisotropy may be sustained by present day dynamic shear flows). Together with the ongoing role of D″ as a thermal boundary layer that regulates cooling of the core and as the site of electromagnetic-mechanical coupling of rotation between the core and mantle, the significance of this region for Earth dynamics appears more evident than ever. While debate continues regarding the extent to which mantle material is fluxing between the shallow and deep mantle, evidence has grown to support a significant feedback/control of D″ structures on geological processes at Earth’s surface.

Definition

Mantle plumes. localized upwelling currents of solid rock that are hotter, thus less dense, than the surrounding mantle.

Hotspots

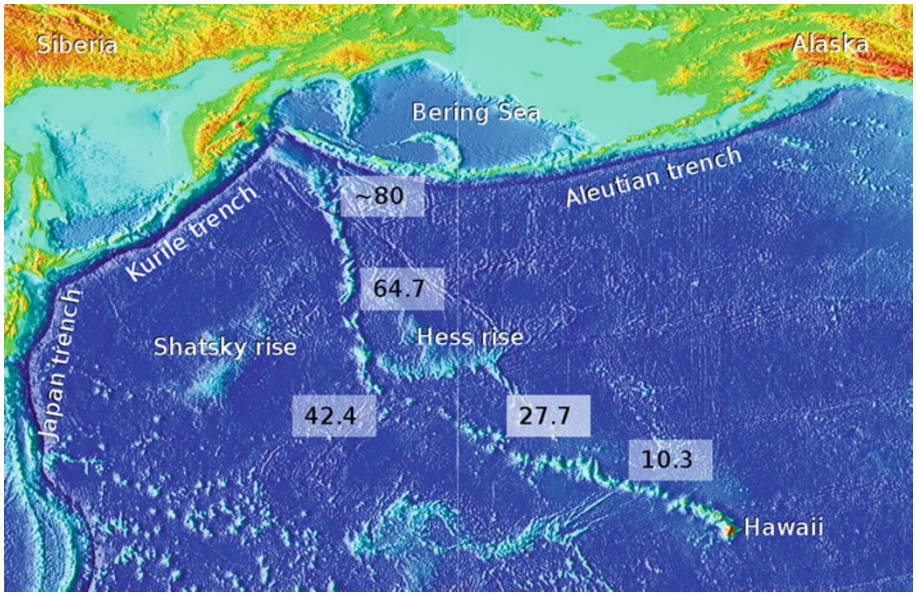
Plate tectonics provides a framework for interpreting volcanism at plate boundaries, namely, along spreading ridges (divergent boundaries) and subduction zones (convergent boundaries). However, it does not explain intraplate volcanism, such as Hawaii, nor the excess volcanism along certain sectors of a spreading ridge, as observed in Iceland. In these regions, called hot spots, the volcanic activity can last more than a hundred million years, as indicated by the resulting age-progressive volcanic chain formed during the hotspot's lifetime. For example, the 6,000 km-long Hawaiian-Emperor volcanic chain (Figure 1) is an alignment of roughly 100 volcanoes of progressively increasing ages. The volcanic chain was created during the last 80 Ma, as the Pacific plate drifted over the Hawaiian hot spot. The vigorous and long-lasting Hawaiian volcanism readily captured the interest of geophysicists: Tuzo Wilson (1963) proposed that the Hawaiian chain was not caused by lithospheric fissures, but by convection currents in the mantle, and Jason Morgan (1971) suggested that hotspots are the surface expression of mantle plumes upwelling from the Earth's lowermost mantle. Mantle plumes can be defined as localized upwelling currents of solid rocks that are hotter, and thus less dense, than the surrounding mantle.

Hotspots are traditionally characterized by some or all of the following features, although exceptions do occur: (1) An age-progressive volcanic chain whose linear trend is consistent with the direction of plate motion. (2) The onset of hotspot magmatism is often marked by a Large Igneous Province (LIP), a term including "continental flood basalts" (CFB) and "oceanic plateaus." Estimated extruded volumes of CFBs are $1–2 \times 10^6$ km^3, with perhaps similar (but unknown) volumes of intrusive magmatism, whereas oceanic plateaus can be one order of magnitude more voluminous (Coffin and Eldholm, 1994). According to the mantle plume initiation model (Richards et al., 1989), the transient and episodic LIP magmatism corresponds to melting of a large plume "head," whereas the subsequent hotspot activity is associated with the long-lasting and narrow plume "tail." (3) The topographic swell is a region of anomalously high topography with a lateral width of ~1,000 km in the direction normal to the volcanic chain (Wessel, 1993) and with an elevation of ~1 km, which decreases along the chain. (4) Hotspot basalts are geochemically distinct and more diverse than mid-ocean ridge basalts.

Some hotspots, however, do not show all of the above features. For example, many volcanic chains lack a clear age progression and, according to Ito and van Keken (2007), there are only 13 long-lived (>50 Ma) and 8 short-lived (<20 Ma) age-progressive volcanic chains. Some hotspots are not associated with a LIP, whereas others such as the Hawaii and Louisville chains terminate in a subduction zone, so that the complete time record of the volcanic activity is lost. A number of LIPs do not have any volcanic track (e.g., the Shatsky rise and the Hess rise in the Pacific Ocean) and their origin is still a matter of debate. In summary, plume magmatism is often, but not always, explained by the classical thermal plume model with a voluminous spherical head followed by a narrow columnar conduit.

Global hotspot distribution and hotspot fixity

Over the years, the estimated number of hotspots has varied from 20 (Morgan, 1971), to a maximum of 117 in the 1980s, whereas in recent compilations (e.g., Ito and van Keken, 2007), the number ranges between 45 and 70



Mantle Plumes, Figure 1 Seafloor topography from Smith and Sandwell (1997). Numbers indicate some ages (in Ma) along the Hawaiian-Emperor volcanic chain.

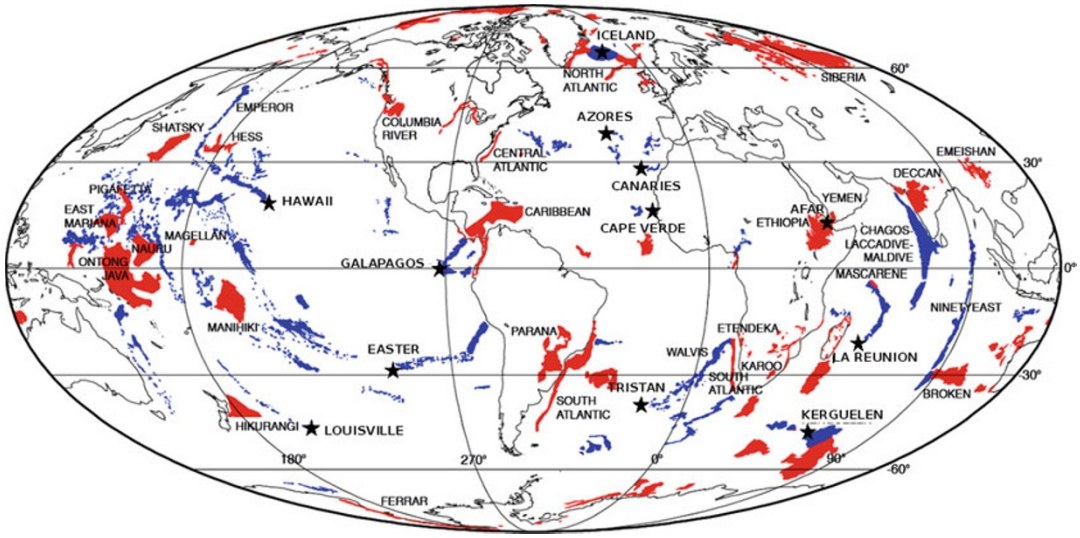
(see Schubert et al., 2001 and references therein). Hotspots younger than 100 Ma are generally active, although their vigor may vary considerably; older hotspots are either waning (100<age<140 Ma) or inactive (age>150 Ma). The best-defined hotspots appear to be relatively stationary over time and are used as a reference frame to determine absolute plate motions. Most hotspots are situated in the oceans, one exception being Yellowstone (USA), whose volcanic activity can be traced back to the 16 Ma-old Columbia River flood basalt. The discrepancy in the number of continental vs. oceanic hotspots has three probable reasons: First, the arrival of a mantle plume can weaken the lithosphere and enhance continental breakup (Courtillot et al., 1999). For example, the magmatic activity of the Iceland plume started with the eruption of the North Atlantic Tertiary Igneous Province (62 Ma ago) and was followed by continental rifting and the appearance of an oceanic spreading ridge after a few million years. In this respect, mantle plumes may have been influential in modifying plate boundaries. The second reason concerns the different thickness (100–150 km) between oceanic and continental lithosphere: weak plumes may not melt beneath a thick continental lithosphere, but are likely do so at lower pressure, beneath a thinner oceanic lithosphere. Third, the lack of hotspots in continents could be due to the continents accumulating over downwellings, precisely where plumes are very unlikely to ascend.

The main oceanic hotspots and their related LIPs (Figure 2) in the Atlantic Ocean are Iceland (0–62 Ma, LIP: the North Atlantic Tertiary Igneous Province) and Tristan da Cunha (0–125 Ma, LIP: the Paraná–Etendeka Province), whereas other hotspots like the Azores (0–20 Ma), Canaries (0–68 Ma), and Cape Verdes (0-Miocene) are not clearly associated with a LIP. In the Indian Ocean, the main hotspots are la Réunion (0–65 Ma, LIP: Deccan Traps), Kerguelen (0.1–120 Ma, LIP: the Kerguelen plateau), and Afar (0–30 Ma. LIP: Ethiopian Traps). In the Pacific Ocean, the main hotspots are Hawaii (0–76 Ma, unknown LIP, since the chain ends in a subduction zone), Louisville (1–77 Ma, possibly 120 Ma if the associated LIP is the Ontong-Java Plateau), and Galapagos (0 to possibly 90 Ma if the associated LIP is the Caribbean Plateau). There are also some hotspots (e.g., in French Polynesia) that may have a plume origin, but with an unclear age progression. Finally, the oceanic floors are "littered" by hundreds of thousands of volcanic seamounts that are certainly not created by plumes (e.g., Hieronymus and Bercovici, 2000; Clouard and Gerbault, 2008).

An interesting aspect of hotspots is that they are relatively stationary with respect to each other. Their respective motions of 1–2 cm/year are much less than the plate velocities, thereby approximating a fixed hotspot frame of reference. However, Tarduno et al. (2009) calculated the age and the paleolatitude of volcanoes belonging to Hawaiian-Emperor chain and concluded that the Hawaiian hotspot moved southward at 4–5 cm/year during the period 80–47 Ma ago, whereas it remained relatively fixed (<2 cm/year) afterward. This complex behavior is probably due to the dynamical interaction between upwelling plumes and the "mantle wind" induced by large-scale mantle convection (Steinberger et al., 2004).

Evidence for mantle plumes

There is now widespread agreement on the existence of mantle plumes, although contrasting views do exist



Mantle Plumes, Figure 2 Distribution of hotspots (*stars*) and Phanerozoic LIPs. In *red*: LIPs (or portions thereof) generated by a transient "plume head." In *blue*: LIPs (or portions thereof) generated by a persistent "plume tail." (Modified from Coffin and Eldholm 1994.)

(see Foulger and Natland, 2003 and the web site www.mantleplumes.org). Several lines of evidence support the existence of mantle plumes:

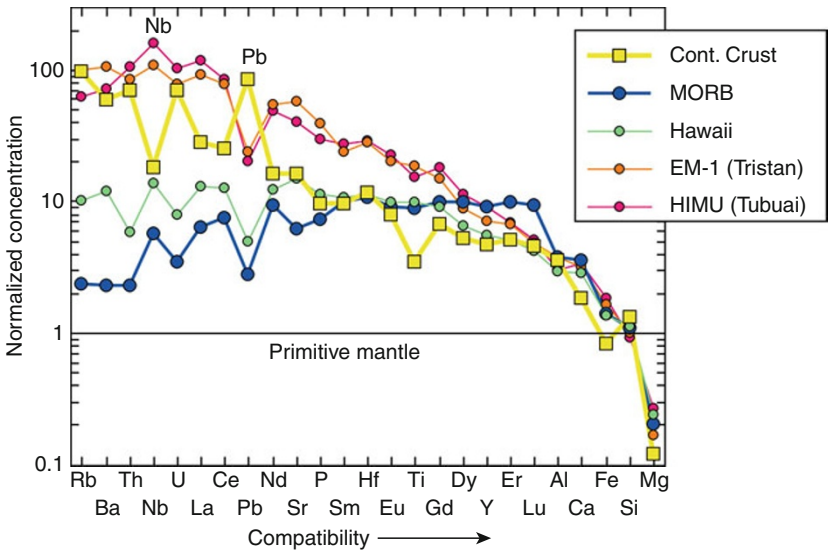
- First, the Earth's Rayleigh number, which governs the vigor of convection, is sufficiently high (10^6–10^8) to insure that mantle convection is time dependent and that its thermal boundary layers (TBLs) become repeatedly unstable. A TBL is a zone characterized by a high-temperature gradient, since heat is transported dominantly by conduction. Fluid dynamical considerations indicate that Rayleigh–Taylor instabilities from a hot TBL generate thermal plumes (Loper and Stacey, 1983). A prominent TBL in the Earth's mantle is possibly the D″ zone, which extends 100–200 km above the core–mantle boundary. The existence of another TBL, for example, at 660 km depth, is still a matter of debate, but it seems unlikely, since the endothermic phase transition does not constitute a complete barrier to mantle convection. Mantle plumes are, therefore, expected to rise from the lowermost mantle, forming cylindrical conduits with a radius of 50–150 km. Such values are based on fluid dynamics, whereas conduit radius estimated by seismology (e.g., Montelli et al., 2004; Wolfe et al., 2009) are much broader.
- Second, seismic detection of narrow plume conduits is challenging, but the first exhaustive study by Montelli et al. (2004) found that at least six plumes (Ascension, Azores, Canary, Easter, Samoa, and Tahiti) extend into the lowermost mantle, whereas others are confined to the upper mantle, and in some cases the model resolution was insufficient. Recently, an extensive ocean-bottom seismological survey of Hawaii (Wolfe et al., 2009) has shown that a low seismic velocity anomaly extends into the lower mantle. Hopefully, future progress in seismic tomography will provide us with further evidence for mantle plumes.
- Third, Oceanic Island Basalts (OIBs) are geochemically distinct and more diverse than Mid-Ocean Ridge Basalts (MORBs), as reviewed by Hofmann (1997). Moreover, isotopic signatures of OIBs indicate an involvement of ancient recycled oceanic crust, as first suggested by Hofmann and White (1982), whereas noble gases indicate that plumes may also carry primordial mantle material, possibly stored in the deep mantle.
- Fourth, Burke and Torsvik (2004) provide another set of evidence supporting the deep origin of mantle plumes. Their plate tectonic reconstruction over the last 200 Ma shows that the paleoposition of 90% of the 25 LIPs considered, were located, at the time of eruption, above lower mantle regions characterized, today, by low S-wave velocities. These broad regions, situated beneath the South-Central Pacific and Africa (see Romanowicz and Gung 2002 and references therein), are likely hotter and possibly compositionally denser than the surrounding mantle and may indeed represent a long-lived source zone of plumes.

Geochemistry of mantle plumes

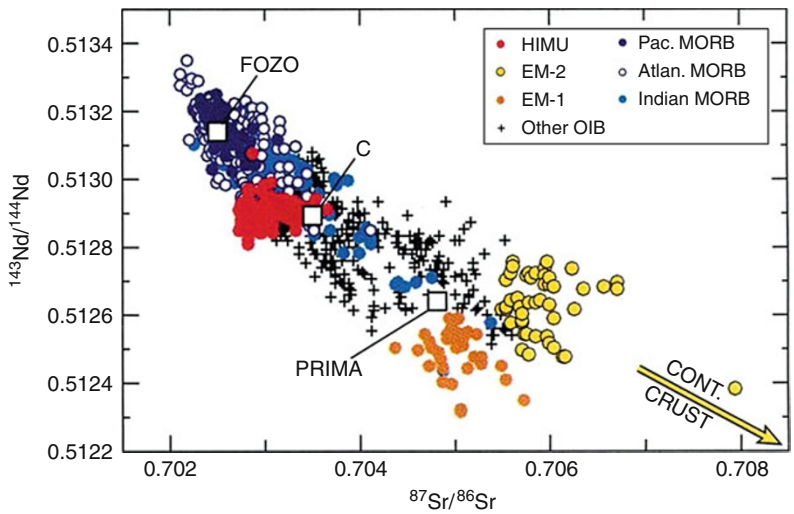
Geochemists became interested in mantle plumes when they discovered that ocean island basalts (OIBs), thought to be derived from plumes, tend to have different chemical (Schilling, 1973) and isotopic (Hart et al., 1973) compositions from mid-ocean-ridge basalts (MORBs). These differences are consistent with the plume model if the deep mantle, the inferred source of plumes, is compositionally different from the upper mantle, source of MORBs. These systematic differences were borne out by many subsequent studies of samples from virtually all available ocean

islands (Hofmann, 2003), as illustrated by Figure 3 for chemical compositions and Figure 4 for isotopic compositions. Both the trace elements and the isotopic compositions indicate that the MORB source has been depleted in "mantle-incompatible" trace elements, that is, those that are scavenged from the mantle by melts that ultimately form the crust, leaving behind a "depleted" mantle. In contrast, plume-type basalts tend to be derived from less depleted mantle sources.

The above observations and conjectures led to the two-layer mantle model, in which "normal" melting producing MORBs and subduction-related magmas have extracted most of the incompatible elements from the upper mantle and sequestered them in the continental crust. By contrast,



Mantle Plumes, Figure 3 Concentrations of selected trace and major elements, arranged in the order of ascending compatibility and normalized to primitive-mantle concentrations, for average continental crust, average MORB, average Mauna Loa, Hawaii, and OIB type representing EM-1 (Enriched mantle 1) and HIMU (high-μ, where $\mu = {}^{238}U/{}^{204}Pb$). The patterns for MORB and OIB differ by their enrichments, but show similar Nb and Pb anomalies, opposite to those of the continental crust. (From Hofmann 1997.)



Mantle Plumes, Figure 4 Nd and Sr isotopic compositions(*) of MORBs and OIBs. EM-1 (Enriched mantle 1), EM-2 (Enriched mantle 2), and HIMU (high μ, where $\mu = {}^{238}U/{}^{204}Pb$). The *squares* indicate compositions of primitive mantle (PRIMA) and of mantle components FOZO and C (see Hofmann, 1997 and references therein). (*)Some basic notions: ^{147}Sm decays to ^{143}Nd. Since Sm is more compatible than Nd, progressive melting enriches the residual rock in Sm, thus MORBs have high $^{143}Nd/^{144}Nd$. ^{87}Rb decays to ^{87}Sr. Since Rb is less compatible than Sr, progressive melting depletes the residual rock in Rb, thus MORBs have low $^{87}Sr/^{86}Sr$.

the lower mantle was thought to be largely undepleted or more "primitive." Thus, plumes, rising from the deep mantle, would sample the lower, relatively primitive reservoir, but they might entrain more depleted mantle rocks on their way up, thus producing a mixing array between primitive and depleted reservoirs (Jacobsen and Wasserburg, 1979). However, mass balance considerations for the incompatible element and isotope budget of the continental crust, the depleted upper mantle, and an undepleted lower mantle, demanded a size of the depleted reservoir of at least 50% of the mantle, which is significantly greater than the roughly 30% mass fraction of the upper mantle. This three-reservoir model (often simply called the "layered mantle" model) was reinforced by the observation that many plume-derived basalts had much higher $^{3}He/^{4}He$ ratios than MORB (Farley and Neroda, 1998), where ^{3}He is a remnant of primordial noble gases from the primitive Earth, whereas ^{4}He is the product of subsequent decay of uranium and thorium.

In spite of its apparent geochemical persuasiveness, the layered mantle model suffered two essentially fatal blows. During the 1980s, evidence began to accumulate that showed isotopically "enriched" (i.e., crustal-like) mantle sources in several ocean islands including Hawaii, Pitcairn, and Tristan da Cunha. This means that the endpoint of the mixing array of the type shown in Figure 4 cannot be an undepleted or "primitive" mantle reservoir but must represent a source component that was crust-like in that it was actually enriched in incompatible elements. And although such a mixing array may pass through the isotopic locus of a primitive mantle reservoir, it clearly does not require the involvement of a primitive reservoir. This is because, when a primitive reservoir is differentiated into enriched and depleted components, any remixing of these differentiated components will produce a compositional array passing approximately through the starting point, the locus of primitive compositions. Therefore, Hofmann and White (1982) proposed that the enriched source components in mantle plumes actually come from subducted oceanic crust rather than a "primitive reservoir."

The second blow to the conventional layered mantle model came from seismic evidence showing tomographic images of high seismic velocities characterizing subduction slabs that penetrate the base of the upper mantle and can be traced into the lowermost mantle (e.g., van der Hilst et al., 1997). If such deep subduction occurred during major portions of Earth's history, convective mixing will have destroyed the chemical separation between upper and lower mantle. The first attempt to integrate numerical convection modeling with chemical differentiation at crustal levels and recycling of ocean crust to generate enriched plume sources at the base of the mantle was made by Christensen and Hofmann (1994), and this has been followed up by more elaborate simulations.

More recently, a variety of new models have sprung up. Some invoke irregularly distributed, relatively primitive plume source regions, which have been protected from convective stirring throughout Earth's history and are thus able to preserve primitive geochemistry. Tolstikhin and Hofmann (2005) and Boyet and Carlson (2005) have proposed a new form of a two-layer mantle, one in which a relatively small, compositionally dense reservoir formed at the base of the mantle, in effect constituting the D″ layer. This irregular layer, on average about 200 km thick, has otherwise been interpreted as a "slab graveyard." The new geochemical model stipulates that these subducted slabs are very ancient, perhaps only a few tens of millions of years younger than the accretion of the Earth. This, in turn, requires stabilization by high intrinsic density, either because they are derived from a primordial iron-rich mafic crust, or because they were generated by downward segregation of dense partial melts in the lowermost mantle (Labrosse et al., 2007) in effect also creating an Fe-rich, dense bulk composition. Such a "new two-layer" mantle model can account for the geochemical differences between plumes and mid-ocean ridge basalts, and it resolves at least two awkward problems with the old model: (1) it does not require that plumes have particularly high helium concentrations, which are never actually observed in plume-derived basalts; (2) it explains trace element characteristics of plume-derived basalts, which are in fact inconsistent with primitive sources. The new two-layer model, by its nature, eliminates the need for any undifferentiated, primitive reservoir, but it creates a repository of primordial noble gases in the permanently sequestered D″-layer at the base of the mantle. From there, these noble gases can easily diffuse into the overlying actual (silicate) source reservoirs of mantle plumes.

It should be emphasized that, by its very nature, geochemical evidence is extremely unlikely to either prove or disprove the existence of mantle plumes or mantle layering, because the mixing and extraction processes that deliver plume-derived or non-plume-derived melts to the surface are not known a priori. Unfortunately, in the past, it has too often been argued that some ocean island must be derived from a deep-mantle plume because it contains high $^{3}He/^{4}He$ ratios, or near-chondritic $^{143}Nd/^{144}Nd$ ratios. Indeed, the inherent weakness of such arguments, which are clearly nonunique, has helped to discredit plume theory in some quarters. On the other hand, the plume model in combination with geochemical evidence can help to elucidate many fundamental aspects of Earth evolution, including the timescale of early Earth evolution and of crustal recycling, as well as the intensity of convective stirring in the mantle.

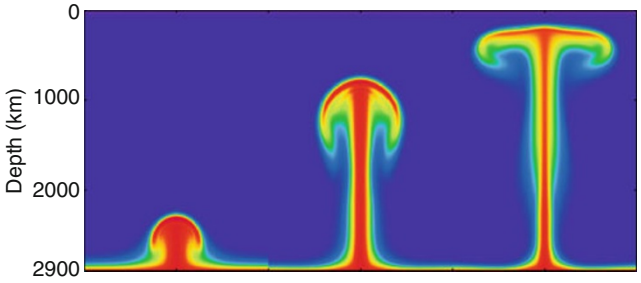
Overall, the "enriched" nature (i.e., enriched in highly incompatible elements relative to more compatible elements), which is evidenced by both the observed trace element and isotope abundances of the decay products of long-lived radioactive decay systems such as ^{87}Rb-^{87}Sr, ^{147}Sm-^{143}Nd, ^{176}Lu-^{176}Hf in plume-derived rocks, is most easily explained by the subduction and recycling of enriched crustal rocks, rather than the involvement of any "primitive" mantle material (Hofmann, 1997). Subduction of crustal materials, including ordinary ocean

crust, enriched ocean crust, ocean islands and seamounts, as well as some sediments and other continental material, is based on geological and geophysical observations. Thus, there is no shortage of suitable source materials in the mantle without the need for alternative enrichment processes, such as "metasomatic" infiltration, which might nevertheless play some role. The recycled enriched materials appear to be more prevalent in mantle plumes than in mid-ocean ridge basalts, because basaltic crust, once subducted, is somewhat denser than ordinary peridotitic mantle. Because of this, it may be segregated and "stored" at the base of the mantle for geologically longer periods of time, and ultimately contribute significant portions of plume source materials (Christensen and Hofmann, 1994).

Genesis and dynamics of plumes and superplumes

On timescales of millions of years, solid mantle rocks behave as highly viscous fluids with a viscosity of $\sim 10^{18}$–10^{22} Pa s (in comparison, the viscosity of a glacier is $\sim 10^{13}$ Pa s, and of a basaltic lava is ~ 10–10^{4} Pa s). Thus, mantle dynamics is governed by a set of equations (conservation of mass, momentum, and energy) for a viscous fluid where inertial effects can be neglected. The growth rate of a Rayleigh–Taylor instability from a thermal boundary layer heated from below is controlled by the Rayleigh number: $Ra = \rho\, \alpha\, \Delta T\, g\, d^3/k\, \eta$ where ΔT is the temperature contrast across a layer of thickness d, density ρ, thermal expansion coefficient α, thermal diffusivity k, and viscosity η. Instabilities are enhanced by the thermal buoyancy and inhibited by viscosity and thermal diffusivity. Using reasonable values for the above physical parameters, growing instabilities of the boundary layer form diapirs. Due to the high mantle viscosity, such a diapir will separate from the TBL only when its volume becomes sufficiently large (e.g., Whitehead and Luther, 1975). The morphology of a thermal plume is controlled by the viscosity contrast between the hot fluid and the mantle above it: If the viscosity contrast is weak, plumes will have a "spout" shape, with little difference between the radius of the leading diapir (the plume head) and the following conduit (the plume tail), whereas increasing viscosity contrast leads to a larger head and a narrower conduit. This "mushroom" shape (Figure 5) is favored, because a hot plume is likely to be 100 times less viscous than the surrounding mantle, owing to the strong temperature dependence of viscosity.

Although fluid dynamics laboratory experiments (e.g., Whitehead and Luther, 1975; Griffiths and Campbell, 1990) and numerical simulations (e.g., Parmenteir et al., 1975; Olson et al., 1993) on purely thermal plumes enabled us to gain a quantitative understanding of plume dynamics, in the 1990s it became progressively clear that the lowermost mantle is compositionally heterogeneous. D″ is a region of preferential segregation and accumulation of denser subducted crust (Christensen and Hofmann, 1994), and larger scale regions of the lower mantle may be chemically



Mantle Plumes, Figure 5 Numerical simulation of a thermal plume.

heterogeneous (Kellogg et al., 1999). This offered new and exciting avenues to explore the complex dynamics of thermochemical plumes, which can be defined as hot (positively buoyant) plumes that carry compositionally denser (negatively buoyant) material. Laboratory experiments by Davaille (1999) investigated a variety of regimes and found that instabilities may form dome-like structures with an oscillatory behavior (i.e., they rise and sink in response to a subtle balance between thermal and chemical buoyancies). Her experiments, together with numerical simulations of thermochemical convection (e.g., Tackley, 1998) provide a fluid dynamically consistent framework to interpret observations that are otherwise unexplained by purely thermal convection. For example, the commonly referred "superplumes," situated beneath the South-Central Pacific and Africa are broad (thousands of kilometers large) lower mantle zones of low seismic velocity most likely associated with active upwelling. Although there is a debate on the thermal and/or compositional origin of "superplumes," several lines of evidence do support their distinct composition (Ishii and Tromp, 1999; Masters et al., 2000). Another issue that can be readily explained by thermochemical plumes is the discrepancy between the petrologically constrained excess temperature of plumes (100–250°C) and the estimated temperature difference across the D″ region (~1,000°C). Numerical simulations (Farnetani, 1997) show that the deepest, hottest part of the thermal boundary layer does not upwell in mantle plumes if the compositional density contrast exceeds 2%. A denser zone in the boundary layer also tends to "anchor" the base of plume conduit, so that the flow pattern remains stable over timescales longer than the plume rise time (Jellinek and Manga, 2002). Finally, thermochemical plumes present a variety of shapes and surface manifestations (Farnetani and Samuel, 2005; Kumagai et al., 2007) that expand the classical plume head-tail model predictions (Figure 6).

Plume melting and plume strength

At spreading ridges, mantle rocks rise to shallow depths in response to plate spreading, and melt by adiabatic decompression (McKenzie and Bickle, 1988). This is not the case for most plumes impinging at the base of a preexisting and unrifted continental or oceanic lithosphere. In order to melt at relatively high pressure

(4–5 GPa), plumes must be either hotter than normal mantle, or compositionally more "fertile" than peridotitic mantle (Condie, 2001, Chap. 4). Plumes are probably both: their excess temperature is estimated between 100 and 250°C (Putirka, 2005), and they can carry 20%, or more, of recycled crust in the form of eclogite (Sobolev et al., 2007). Eclogite is more fertile than peridotite because it has a lower solidus and a greater melt productivity. According to Sobolev et al. (2005), reaction between eclogite-derived liquids and solid peridotite forms a pyroxenite, whose subsequent melting may explain some compositional characteristics of Hawaiian (and many other plume-derived) lavas. Another efficient way of lowering the solidus temperature is to have fluids (H_2O, CO_2) in the upwelling plume rocks; however, the evidence for "fluid-rich" hotspot lavas is scant. Although it is well known that melting is the most efficient way to create chemical differentiation in the mantle and that it is the unavoidable process to generate surface lavas from mantle rocks, many aspects of partial melting remain elusive (e.g., the pressure–temperature conditions during melting; the source heterogeneous composition; the mechanism of melting, of transport and of storage of the magma). This limits our quantitative understanding of the link between petrological and geochemical observations of surface lavas and the underlying mantle plume composition and dynamics.

The strength of a mantle plume can be calculated on the production rate of volcanic rocks. The method utilizes the volcano's volume and growth time, and the estimated melt fraction. For example, Mauna Loa has a volume of ~70,000 km^3 and it grew in ~1 Ma, suggesting that the Hawaiian plume melt production rate M is about 0.1–0.2 km^3/year. Since only a fraction of the upwelling plume melts, the total plume volume flux $Q_v \gg M$. Another method, based on the rate of swell formation (Sleep, 1990), enables one to calculate the plume buoyancy flux $B = Q_v \Delta\rho$ where $\Delta\rho = \rho\,\alpha\,(T_{PLUME} - T_{MANTLE})$. For Hawaii, the most vigorous hotspot, B ~ 8,000 kg/s, for Iceland B ~ 1,400 kg/s, for Galapagos B ~ 1,000 kg/s. Finally, the plume heat flow is $Q_h = \rho_{MANTLE} C_p Q_v (T_{PLUME} - T_{MANTLE})$, where the specific heat at constant pressure is $C_p \sim 1{,}200$ J/kg K. For Hawaii, the heat flow is $Q_h \sim 360 \times 10^9$ W, and it represents ~16% of the global hotspot heat flow of 2.3×10^{12} W, which, in turn is a small fraction of the Earth's total heat flow of 44×10^{12} W (for further reading, see Schubert et al., 2001, Chap. 11).

Continental flood basalts and continental breakup

The eruption of a large igneous province (LIP) represents a major geologic event head. Over the Earth's history, episodic LIP magmatism contributed to continental growth through the emplacement of CFB and through the accretion/obduction of fragments of oceanic plateaus onto continental crust (Ben-Avraham et al., 1981). Accretion may be due to the difficulty of subducting the 20–40 km thick crust of an oceanic plateau. Three notable examples of accreted LIP fragments are found in the Solomon Island arc (from the Ontong-Java plateau), in Central America (from the Caribbean plateau), and the Wrangellia terrane outcropping in British Columbia and in SE Alaska (Figure 7). This allochthonous terrane, locally attaining a thickness of 6 km, is likely to be a fragment of a 230 Ma-old oceanic plateau (Ben-Avraham et al., 1981; Richards et al., 1991; Greene et al., 2008).

Distinctive characteristics of LIP magmatism are the short duration (1–2 Ma) and the huge volumes ($1–10 \times 10^6$ km^3) of eruption. Because of the high eruption rates (>1–2 km^3/year; for comparison Kilauea grows at 0.1 km^3/year) and the enormous surface extent ($1–2 \times 10^6$ km^2; for comparison France's surface is $\sim 0.5 \times 10^6$ km^2), flood basalt eruptions are extraordinary volcanic events. CFBs consist of sub-horizontal flows of mafic (Fe- and Mg-rich) rocks, mainly tholeiitic basalts. Individual flows can extend for hundreds of kilometers, be tens to hundreds of meters thick, and have volumes of more than 10^3 km^3. CFBs are more accessible than submerged oceanic plateaus; however they can be extensively eroded, fragmented, and dispersed on different continents by plate tectonic processes. Clearly, uncertainties regarding the original volume and surface extent increase with their age, for example, for pre-Cambrian CFB only the giant swarm of mafic dikes, feeding surface volcanism, may be left (Ernst and Buchan, 2001).

The Phanerozoic CFBs are, in chronological order: The 258 Ma-old Emeishan Traps (SW China), which

Mantle Plumes, Figure 7 Photograph of 1,000 m of continuous subaerial flood basalt stratigraphy in the Wrangell Mountains, Alaska. The *yellow* line marks the contact between Nikolai basalts and the overlying Chitistone Limestone. (From Greene et al., 2008. With permission.)

presently cover only 0.3×10^6 km^2, probably a tenth of the estimated original surface; the 250 Ma-old Siberian Traps, which might have had a surface extent of $3–4 \times 10^6$ km^2 and extrusive volumes of 10^6 km^3; and the 200 Ma-old lavas and dike swarms of the Central Atlantic Magmatic Province outcrop in once-contiguous parts of North America (e.g., the Palisades sill, NY), West Africa, and Brazil. This flood volcanism, with an estimated total volume of 3×10^6 to 5×10^6 km^3, preceded the opening of the central Atlantic Ocean. The 184–182 Ma-old Karoo (Southern Africa)–Ferrar (Antarctica) traps preceded the breakup of Gondwana by 10–15 Ma. Similarly, the ~135–130 Ma-old magmatism of the Paraná (Brazil)–Etendeka (Namibia) province led to the opening of the South Atlantic Ocean. The Deccan Traps (India) erupted 66–65 Ma ago over an area of $\sim 1.5 \times 10^6$ km^2; the subsequent rifting split apart the Seychelles from India. The North Atlantic Tertiary Igneous Province covers a surface greater than 10^6 km^2 and has an estimated volume of 6×10^6 km^3. The earliest volcanism occurred as flood basalts in Baffin Island, West- and East-Greenland (62 Ma), and later (56–54 Ma) extended to the continental margins of Greenland, the British Isles, and Norway. These rifted edges of continents constitute the so-called volcanic passive margins of up to 8 km-thick seaward dipping basalt layers. The complete opening of the North Atlantic and the appearance of truly oceanic crust occurred about 53 Ma ago. Finally, the Ethiopian–Yemen traps, ~30 Ma old, have been associated with the rifting in the Red Sea and the Gulf of Aden (Courtillot et al., 1999).

Issues concerning the timing of rifting have been hotly debated: One side claims that rifting preceded, and enhanced, flood volcanism (e.g., White and McKenzie, 1989); the other side argues that rifting is not a prerequisite to flood volcanism, since it occurs only during and after volcanism (e.g., Richards et al., 1989). More geological observations are needed, as well as numerical simulations and/or laboratory experiments investigating how anomalously warm mantle can erode the lithosphere and create (or reactivate) weak zones susceptible to rifting.

LIP magmatism and environmental effects

The remarkable temporal correlation between LIP magmatism and mass extinctions of terrestrial and marine organisms suggests a cause-and-effect connection (Courtillot and Renne, 2003). The most notable example is the Siberian Traps at the Permian–Triassic boundary (Renne et al., 1995; Svensen et al., 2009). The emplacement of the Deccan Traps, spanning the Cretaceous–Tertiary boundary, certainly had an environmental effect (Self et al., 2006); however, the extinction event coincided with a large asteroid impact at Chicxulub, Mexico (Schulte et al., 2010). The peak of volcanism in the North Atlantic Volcanic Province corresponds to the Paleocene-Eocene Thermal Maximum (PETM) event 55 Ma ago. Svensen et al. (2004) propose that voluminous magmatic intrusions in carbon-rich sediments induced massive release of the methane buried in marine sediments, thus suggesting that volcanic and metamorphic processes associated with the opening of the North Atlantic may explain global climate events. Self et al. (2006), Ganino and Arndt (2009), and Svensen et al. (2009) attempt to quantify the release of volatiles (CO_2, CH_4, SO_2) during flood volcanism and to estimate the consequences on the environment. In particular, the release of volcanic ashes and sulfuric acid aerosols can lead to darkening and cooling, SO_2 and HCl cause acid rains, whereas greenhouse gases like CO_2 and CH_4 cause global warming. Carbon has two origins: magmatic and sediment-derived. Interestingly, Ganino and Arndt (2009) show that the mass of sediment-derived CO_2 can be four to eight times larger than the mass of magmatic CO_2, if contact metamorphism reactions occur in sedimentary rocks such as dolomite, evaporite, coal, or organic-rich shale. In other words, the environmental effect of flood basalt magmatism depends, among other factors, on the rock type in contact with magmatic sills and lava flows (Ganino and Arndt, 2009; Svensen et al., 2009).

Marine eruptions can also have an environmental effect, because they can cause variations in water chemistry and oceanic circulation. The emplacement of the (Alaska-sized) Ontong-Java plateau 120 Ma ago and of the Caribbean plateau correlate temporally with some of the major Oceanic Anoxic Events (OAEs) which occurred ~183, 120, 111, and 93 Ma ago. OAEs are associated with an abrupt rise in temperature, induced by rapid influx of CO_2. The consequent increase of organic productivity causes an increase of oxygen demand in the water column, eventually leading to oxygen depletion in the oceans (for a thorough review see

Jenkyns 2010 and references therein). Furthermore, the formation of black shale (marine carbon-rich sediments) may have been favored by massive hydrothermal release of trace metals, poisonous to marine life.

Plume–lithosphere interaction

A quantitative understanding of plume–lithosphere interaction enables us to relate geophysical observations (e.g., the spatiotemporal evolution of surface topography, variations in lithospheric thickness, etc.) to the physical parameters and dynamics of the plume. Central issues concerning plume–lithosphere interactions include, but are not limited to the following:

- First, estimating the dynamic topography (Definition of dynamic topography, extracted from Lithgow-Bertelloni and Silver, (1998). "Dynamic topography is a deformation of the surface of the Earth, supported by the vertical stresses at the base of the lithosphere, which are generated by flow in the mantle below. This is in contrast to the more familiar mechanism of isostatically supported topography which is in equilibrium at the Earth's surface and would exist even in a static mantle.") induced by the arrival of a mantle plume head. Pioneering laboratory experiments by Olson and Nam (1986) found that a thermal diapir upwelling and spreading beneath the lithosphere induces a rapid surface uplift followed by a slower subsidence. According to Farnetani and Richards (1994), uplift should precede flood volcanism by 1–2 Ma, a prediction that is sometimes validated by geological observations (e.g., for the Emeishan Traps), but not always (e.g., for the Siberian Traps). A present-day example of dynamic topography is provided by Lithgow-Bertelloni and Silver (1998), who suggest that the anomalous elevation (~1 km) of South-Central Africa has a dynamic origin, being induced by mantle upwelling from the African "superplume," a broad lower mantle zone of low seismic velocity anomalies.
- Second, understanding the origin of the topographic hotspot swell and the thermomechanical response of the lithosphere drifting over the plume. Two main mechanisms have been proposed for the Hawaiian swell: "thermal rejuvenation" invokes heating and thinning of the lithosphere above the hotspot, whereas "dynamic support" invokes stresses applied to the base of the lithosphere by the buoyant plume. Seismic studies by Li et al. (2004) around Hawaii found a thinning of the lithosphere from the expected 100 km (beneath the Big Island) to only 50–60 km (beneath Oahu and Kauai, 400 km downstream from the Big Island), thus suggesting a hybrid scenario, whereby "dynamic support" prevails above the plume conduit and "thermal rejuvenation" prevails downstream. Far from the conduit, thermal thinning of the lithosphere may be enhanced by small-scale convective instabilities, which take the form of rolls aligned with the plate motion, as observed in numerical simulations with strongly temperature-dependent viscosity (Moore et al., 1998).
- Third, mechanical and chemical interaction between plume magmas and the lithosphere can explain a number of geophysical and geochemical observations. For example, the occurrence of regularly spaced volcanoes in hotspot chains is probably caused by the interaction of magma transport with lithospheric flexure (Hieronymus and Bercovici, 1999, 2000). Under the load of the volcanoes, the lithosphere deforms and the resulting flexural stresses have a key role in determining the locus where magma preferentially extrudes. There are also clear examples of geochemical interaction between the continental lithosphere and plume magmas "en route" to the surface. In particular, CFB lavas erupted at the onset of flood volcanism often have anomalous compositions, reflecting contamination by the lithosphere and crust. It is thus important to quantify the contribution of the continental lithosphere before inferring the plume's geochemical fingerprint.
- Fourth, plume material may preferentially flow – and partially melt – in preexisting zones of thinned lithosphere (Sleep, 1996). In other words, the thickness of the lithosphere and the slope of its base may control the spatial distribution of plume magmatism. According to Ebinger and Sleep (1998), the Cenozoic magmatism in East Africa (including the Afar, the Cameroon volcanic line to the West, and the Comoros Islands to the South) can be explained by a single plume impinging beneath the Ethiopian plateau and its subsequent lateral flow, "channeled" in preexisting rift zones characterized by a relatively shallow base of the lithosphere.

Plume–ridge interaction

At least 21 hotspots are situated near a spreading ridge, the clearest examples being Iceland, a ridge-centered hotspot, Galapagos, and the Azores. At Iceland, the Mid-Atlantic Ridge rises ~4 km above normal and remains anomalously shallow for ~1,000 km to the North and the South. Below Iceland, the oceanic crust is 40 km thick, whereas more normal crustal thicknesses of 8–10 km are attained only ~500 km far from the hotspot. Furthermore, compositional anomalies in trace elements and isotope ratios observed along the ridge clearly indicate plume–ridge interaction (Schilling et al., 1985). The Galapagos hotspot is situated ~200 km off-axis form the Galapagos Spreading Center, and, also in this case, geophysical and geochemical anomalies along the ridge suggest plume–ridge interaction. These observations raise several questions concerning: (a) how plume material flows toward the ridge, opposite to the plate motion, (b) how plume material, once "trapped" beneath the ridge, flows parallel to the ridge axis, and (c) how the plume–ridge flow is affected by physical parameters such as the plume volume flux, the plume–ridge distance, and plate velocity. As reviewed by Ito et al. (2003), such questions have been

addressed with laboratory experiments (e.g., Kincaid et al., 1995; Feighner and Richards, 1995) and theoretical and numerical models (e.g., Ribe et al., 1995; Ribe, 1996; Ribe and Delattre, 1998) that progressively included more realistic conditions, such as the conductive thickening of the oceanic lithosphere away from the ridge and a migrating spreading ridge. The sloping base of the oceanic lithosphere favors the flow of plume material toward the ridge (Sleep, 1996), and the subsequent channeling of plume flow beneath the ridge has been calculated numerically by Albers and Christensen (2001). Such studies concluded that the width over which plume material flows along the ridge increases with higher plume flux and decreases with higher spreading rate and plume–ridge distance (see Ito et al., 2003; Ito and van Keken, 2007). Another important parameter is plume viscosity, in particular, Ito et al. (2003) find that the plume flow is reduced by the process of dehydration strengthening, which increases the viscosity of the plume residuum. For a fluid dynamical analysis of plume–ridge interaction see the comprehensive paper by Ribe et al. (2007) and the review paper by Ito et al. (2003).

Summary and Conclusion

This chapter on mantle plumes has taken us from the deep Earth's mantle where plumes originate, to sublithospheric depths where partial melting occurs, and up to the surface where LIPs have been emplaced in the geologic past, and hotspot lavas are being erupted today. We also explored the environmental effect of massive LIP volcanism on the oceans and the atmosphere. This range of topics shows that a full understanding of mantle plumes requires a multidisciplinary approach. Important progress will be achieved by linking geophysical, geochemical, and geological observations, to models solving for the fluid dynamics of mantle plumes, melt migration, and physical volcanology, just to mention a few.

Future directions

In our view, fundamental questions for the future include the following:

1. Quantifying the effect of heterogeneities on plume dynamics and fertility. The term heterogeneity is used here in a broad sense, from small-scale (1–10 km) lenses of recycled eclogite to the large-scale (100–1,000 km) denser superplumes that may generate short-lived instabilities rising from their top. Future studies should model heterogeneous plumes in a fully convecting mantle, with physical properties provided by mineral physics experiments at appropriate temperature and pressure conditions. Lithologic variability affects the fertility and the geochemical characteristics of lavas (Sobolev et al., 2005), but, at present, numerical simulations are unable to model the complex petrological and geochemical evolution of the solid matrix and melts.
2. Quantifying the role of the lithosphere is needed to understand how lithospheric stresses and variations in lithospheric thickness and composition may affect partial melting and the ascent of magma. Hieronymus and Bercovici (2000) provide a theory to explain the distribution of non-hotspot island and seamount chains in the South Pacific and conclude that volcanism can be activated by tensile stresses. The hypothesis that thermoelastic cracking of the oceanic lithosphere (Sandwell and Fialko, 2004) can trigger magmatism should be explored quantitatively, to assess the volumes and the composition of such magmas.
3. The cause-and-effect relation between the arrival of a mantle plume and continental breakup is often invoked, but we lack a quantitative understanding of the processes involved. In other words, although there is evidence supporting the role of plumes in the creation and modification of plate boundaries, it is unclear how a large-scale system, with continents and preexisting spreading ridges responds to the arrival of a large mantle plume. Moreover, studies of plume–lithosphere interaction should explore the possibility of dynamic instabilities, such as lithospheric delamination, fingering of low-viscosity fluid, and small-scale convection (see Ito and van Keken, 2007 and references therein), and their ability to generate partial melts.
4. Future studies should address in a constructive and quantitative way the current debate (see www.mantleplumes.org) on the "existence of plumes," or better, on the "coexistence of plumes with other processes" that can produce surface volcanism. Progress will be achieved through improved seismic imaging of plumes and their depth of origin, and through a quantitative understanding of lithospheric processes, as explained above. We also note that much of the ongoing debate questioning the existence of plumes is based on a narrow view of what a plume should look like: the head-tail model is valid in a purely thermal, homogeneous mantle, but a variety of plume shapes are found if the Earth's lower mantle is compositionally heterogeneous (Farnetani and Samuel, 2005; Kumagai et al., 2007). Furthermore, when considering plumes in a convecting mantle, rather than in an unperturbed fluid, it is obvious that conduits cannot be fixed (Steinberger et al., 2004), an observation that does not preclude the existence of deep plumes.
5. Although we have restricted our treatment to Mesozoic-Cenozoic plumes (<250 Ma), it is likely that plumes had an important role also at earlier times, although geological evidence becomes increasingly scant with geological age (Ernst and Buchan, 2001). The early Earth, with its vigorous and highly time-dependent convection, probably had an intense plume magmatism. Hopefully, studies of volcanism on Mars and Venus can complement and improve our knowledge of early terrestrial magmatism (see Condie, 2001, Chap. 3). Both Mars and Venus lack plate tectonics, so that old

geologic features can be better preserved. On Mars, the Olympus Mons is an enormous shield volcano (volume 2×10^6 km^3), and the Tharsis rise, which covers 20% of the Martian surface, has been volcanically active for the last 2 Ga, suggesting the presence of huge and long-lived plumes in the Martian mantle (Harderer and Christensen, 1996).

MANTLE VISCOSITY

W. R. Peltier
Department of Physics, University of Toronto, Toronto, ON, Canada

Definition

By the term "mantle rheology" we mean to imply the nature of the relationship between applied stress and realized strain.

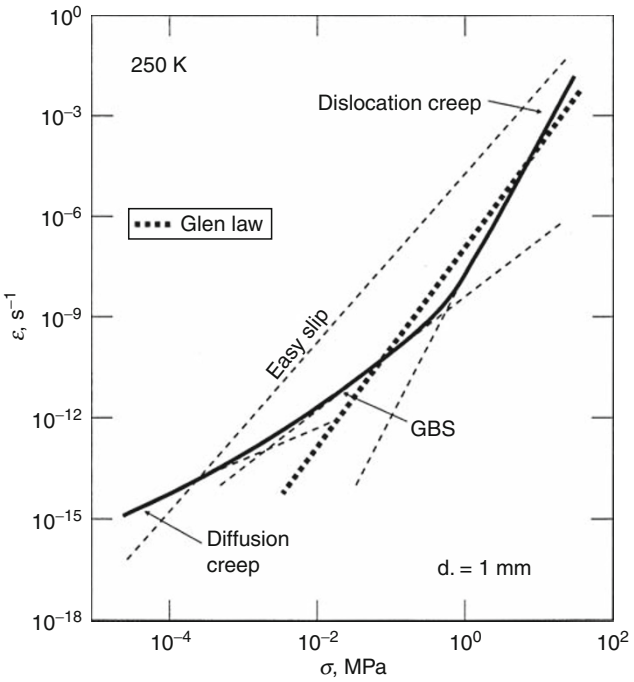
Introduction

The effective viscosity of the Earth's predominantly iron-magnesium silicate mantle is a physical property of fundamental importance. In characterizing this outer shell of the planet by a viscosity at all, one is recognizing that it is capable of flowing as if it were a fluid. This is in spite of the fact that on the timescales characteristic of seismic waves it is known to be accurately describable as a Hookean elastic solid, albeit one which is endowed with a finite quality factor "Q" due to imperfections of elasticity. The idea that viscoelastic materials behave as solids on short timescales but as fluids on sufficiently long timescales is well understood in the material science literature. For Earth sciences, the fact that the mantle behaves viscously on timescales in excess of a few centuries is vital to the understanding of plate tectonics and the origins of continental drift as a consequence of thermal convection in the mantle. This article provides a summary of laboratory and geophysical data that may be brought to bear as a means of measuring mantle viscosity and discusses the compatibility of these measurements with the requirements of the mantle convection process.

Methods of measurement

Laboratory experiments

One might imagine that laboratory measurements of the creep of mantle mineral assemblages at high pressure and temperature would provide all that is required to obtain the data needed to infer effective viscosity. There are several problems with this idea, however, most of which derive from the difficulty of performing the appropriate experiments under the extreme conditions characteristic of the Earth's deep interior. There nevertheless does exist very detailed information on the creep of polycrystalline solids in general which may provide useful insight on the sort of behavior to be expected. Since such polycrystalline aggregates have many characteristics in common insofar as their ability to "flow" is concerned, it is instructive to consider one specific example in order to fix ideas. To this end Figure 1 displays a strain-rate vs. differential stress diagram for fine-grained ice (from Goldsby and Kohlstedt, 1997), an important model system that has been studied in great detail because of its practical importance in glaciology. In this log-log plot, a straight line is indicative of a power law relationship with the slope determining the "stress exponent." Inspection of the figure will show that, as the differential stress is reduced, the flow law undergoes a series of discrete transitions. At the highest values of differential stress, the stress exponent has a value of 4, indicating that the mechanism supporting the "flow" of the polycrystalline aggregate involves the propagation of "dislocations" through the interiors of the individual crystal grains that make up the aggregate. This process is referred to as involving "dislocation climb." As the differential stress diminishes, the stress exponent first drops to a value near 2, indicating that the mechanism supporting flow has come to involve the propagation of dislocations along the boundaries separating individual



Mantle Viscosity, Figure 1 The rheology of fine-grained (d = 1 mm) ice at 250 K temperature, calculated using a particular constitutive equation (Goldsby and Kohlstedt, 1997).

grains. This regime is referred to as involving "grain boundary sliding." With even further reduction of the differential stress, the exponent drops to unity implying that the underlying mechanism involves the diffusion of impurities. In this regime, the stress–strain relation describing the flow of the solid is now equivalent to that which holds for a simple fluid like water which we refer to as being "Newtonian" Investigation of the temperature dependence of the experimentally determined stress-strain relation shows that, as the temperature approaches the melting temperature the strain-rate increases for a fixed value of the differential stress.

Non-Newtonian rheology from seismic anisotropy

It is generally understood that at shallow depths, from the surface through the near-surface "lithosphere" in which the effective viscosity is extremely high, the operative rheology is significantly non-Newtonian. The extent to which this behavior persists to greater depth remains undetermined. That the shallow Earth deforms according to a non-Newtonian stress–strain relation follows from the existence of significant seismic anisotropy. The development of such anisotropy requires nonlinearity of the stress–strain relationship in order that individual crystal grains may be aligned by the ambient shear. Although direct laboratory measurements on the creep of Earth materials at lithospheric depths where the pressures and temperatures are low provide useful confirmation of the seismic observations, they are much less illuminating for the Earth's deep mantle because of the extreme conditions under which measurements must be made.

Natural experiments

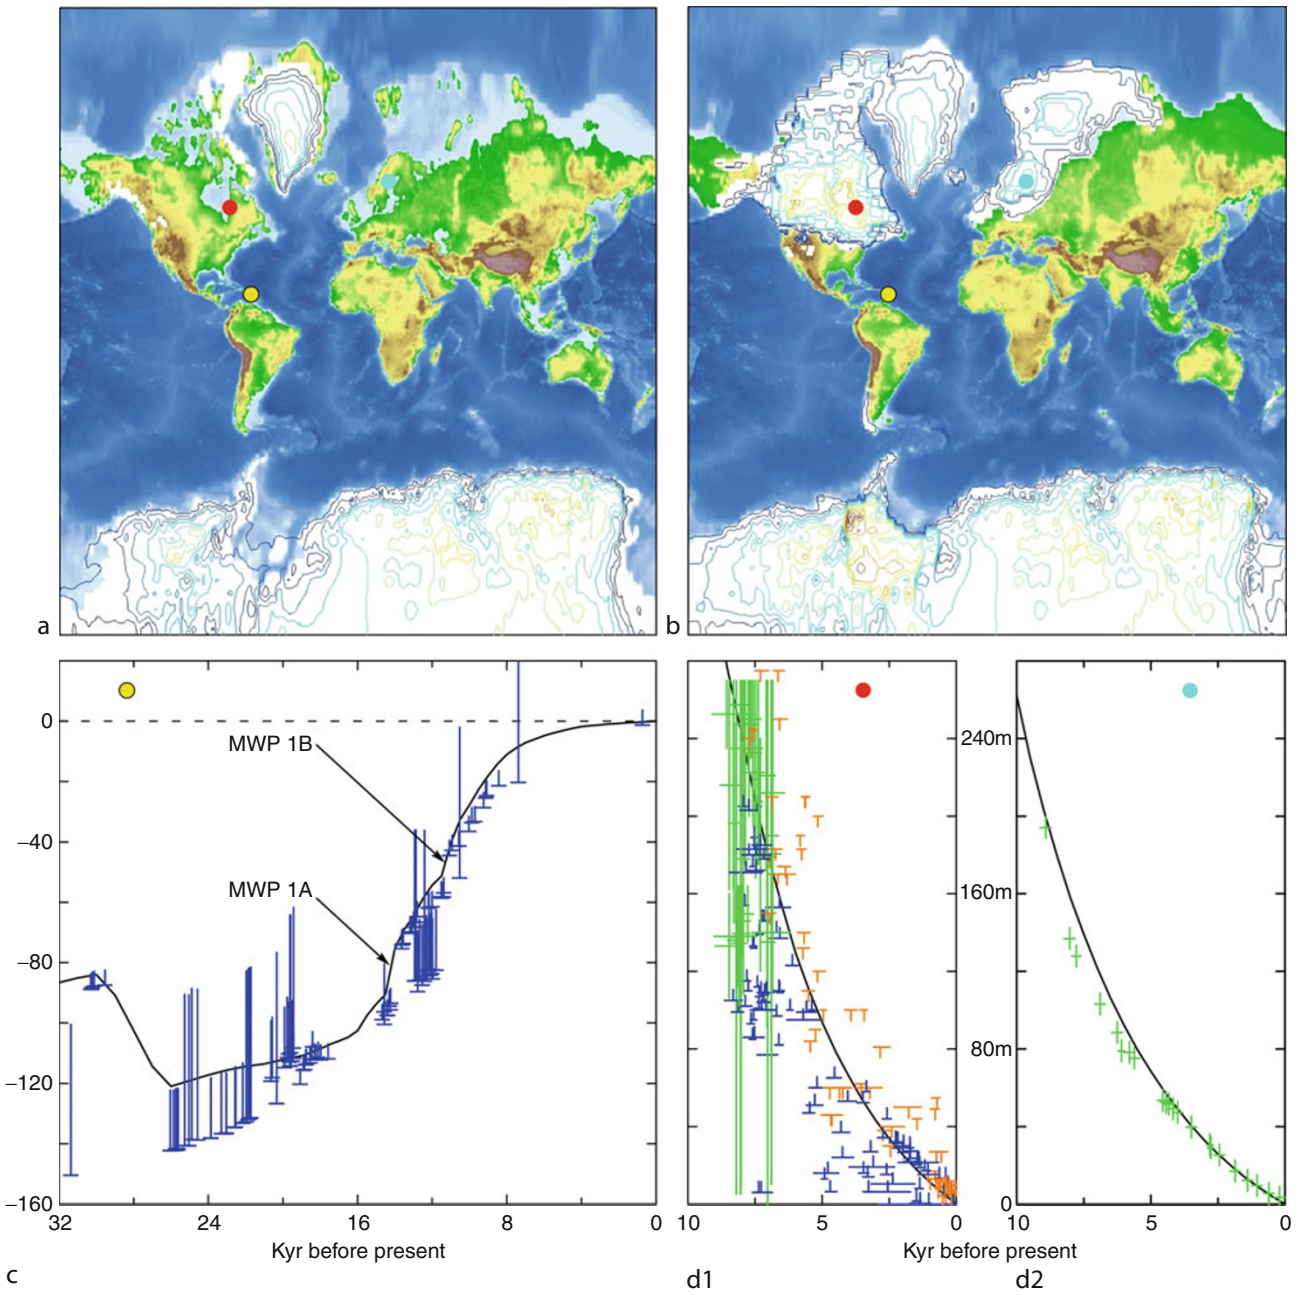
In order to obtain useful estimates of the viscosity at depths below the lithosphere we are obliged to employ the results of "natural experiments" that the Earth itself has performed throughout its history and for which it has also conveniently remembered the results through the fidelity of the geological recording system. The most important such experiment is that associated with the Late Quaternary ice-ages, especially the quasi-periodic sequence of glaciation-deglaciation events that began about 900,000 years before present and during which massive accumulations of land ice began to appear and disappear from the continents, especially at high northern latitudes. Insofar as deep Earth rheology is concerned, these events may be thought of as comprising an experiment during which extreme normal stresses were applied to localized regions of the Earth's surface and thereafter removed. Because the residence time of the land ice on the surface of the continents was sufficiently long, the response to the applied normal stresses was such as to induce a response of the loaded viscoelastic mantle that involved significant viscous flow. This suggests the possibility that the geological data that represent the Earth's record of its response to the time-varying ice load might be interpreted to infer the value of the viscosity that governs the viscous component of the response. Also of interest is the question as to whether the viscosity so inferred is compatible with the requirements of the mantle convection explanation of surface kinematic observations related to the process of plate tectonics.

Mantle viscosity from glacial isostatic adjustment

Observational data sets

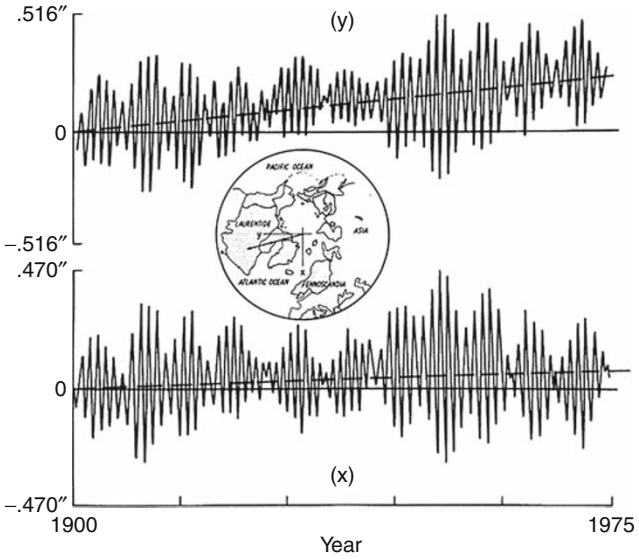
Figure 2 shows examples of critical data related to the Glacial Isostatic Adjustment (GIA) process along with a comparison of maps of the ice-covered regions of the planet under both modern conditions (a), and the conditions that prevailed at the last glacial maximum (LGM) approximately 21,000 years before present (b). Figure 2c shows an extremely important data set for the history of sea level change relative to the surface of the solid Earth at the island of Barbados (Peltier and Fairbanks, 2006). This record covers the interval of time from LGM to the present and has been produced by the uranium/thorium dating of corals, the species Acropora Palmata being the most important as it inevitably dwells within 5 m of the surface of the sea while it remains an open system. These data correlate well with the record of ice-equivalent eustatic sea level history and demonstrate that sea level has risen at Barbados by approximately 120 m since LGM. The Barbados data provide a strong constraint on the total mass of ice that must have been removed from the land in order to cause the rise of sea level observed. In Figure 2 (d1,d2) are shown observations of relative sea level history from sites that were located near the center of the regions in North America and Eurasia respectively that were covered by glacial ice at LGM (Peltier, 1998). Whereas the Barbados data record the extent to which sea level was depressed at LGM, these data from the previously ice-covered regions demonstrate that subsequent to the removal of the ice, the land in these regions has been rising out of the sea. This is the process referred to as postglacial rebound of the crust. The data shown in Figure 2 (d1,d2) may be quantitatively analyzed (Peltier, 1998) to extract information about the amplitude and the relaxation time of the individual sea level cuves and thus the viscosity of the Earth's mantle. The relaxation time data depend almost entirely on the mantle viscosity. Data such as these from hundreds of locations constitute one of the primary data sets that may be invoked to constrain the viscosity model of the Earth's mantle.

The remaining data related to the GIA process that have come to play an increasingly important role in such analyses are those related to the Earth's rotational state. Figure 3 illustrates the first of these additional constraints. It shows the time-dependent position of the Earth's north pole of rotation in a coordinate system with x- and y-axes centered upon the Conventional International Origin (Vincente and Yumi, 1969, 1970). Inspection of the time series in the period between 1900 and 1979, at which time the International Latitude Service, which was responsible for maintaining these measurements, was discontinued,



Mantle Viscosity, Figure 2 (**a**) Global ice cover and surface topography and bathymetry under modern climate conditions, (**b**) same as (**a**) but for Last Glacial Maximum conditions according to the new ICE-6G model. (**c**) A fit of the ICE-6G (VM5a) model to the coral based record of relative sea level history from the island of Barbados. The two major melt water pulses (MWP) are marked. (**d**) VM5a model fit to the records of Holocene relative sea level history at sites near the centers of rebound of the Laurentide (**d1**) and Fennoscandian (**d2**) ice sheets.

shows that the signals are dominated by "beating" at a period very close to 7 years. This is associated with the interference between the 12-month periodic annual wobble of the spin-axis forced by the seasonal variations of the atmosphere and oceans and the 14-month periodic Chandler wobble. The component of these observations that is of interest from the perspective of mantle viscosity measurement, however, consists of the slow secular drift of the pole upon which the oscillatory component is superimposed. These data reveal the secular drift of the pole at a rate near 0.95°/m.y. approximately along the 79°W meridian, i.e., in the direction of present day Hudson Bay. The rate of this "true polar wander" provides a further constraint upon the viscosity of the Earth's mantle.



Mantle Viscosity, Figure 3 Time series for x- and y-components of the location of the north pole of rotation of the planet relative to the coordinate system shown in the inset.

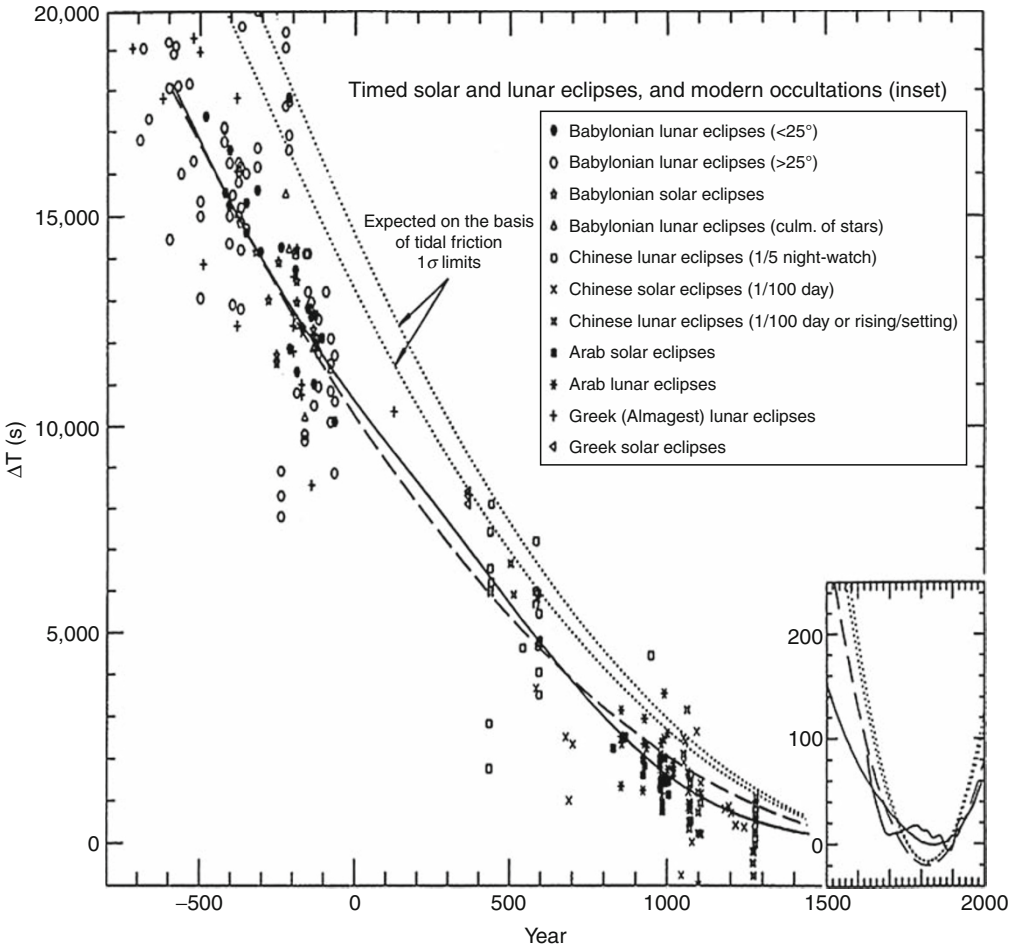
The final observational datum that may contribute to the estimation of mantle viscosity consists of the "nontidal acceleration" of planetary rotation. This datum is illustrated in Figure 4 where specific times of occurrence of total eclipses of the Sun and the Moon are plotted as a function of time spanning the past 2,000 years of the Earth's history covering the periods in both Babylon and China during which naked eye astronomers both recorded, and attempted to make predictions of, the timing of these "epochal" events (from Stephenson and Morrison, 1995). These observations are compared with expectations described by two essentially parabolic curves. The curve that does not go through the data is based on the assumption that only tidal friction has contributed to variations in the Earth's rate of rotation over this period and that this has remained equal to its present day value, a reasonable assumption. Because the predicted times of occurrence of total eclipses of the Sun and the Moon do not agree with expectations based on this assumption, some physical process is missing. The nature of the misfit of this model to the data implies that the action of the missing process is such as to somewhat counteract the influence of tidal friction by decreasing the rate at which angular velocity would otherwise decrease. This is called the nontidal acceleration of rotation and it too is a consequence of ice-age loading and unloading of the continents. The curve in Figure 4 that does go through the data provides a precise measurement of this ice-age influence and this may also be employed to constrain the viscosity of the Earth's mantle.

Results of formal inversion

Models of mantle viscosity may be obtained by formal inversion of the totality of the data related to the Late Quaternary ice-age cycle. It is important to note that each of these data samples the viscosity structure of the deep Earth in a different fashion. The postglacial rebound data from the Fennoscandia region, which was covered at LGM by an ice sheet of moderate horizontal scale, provide information on the viscosity of the upper mantle and transition zone. Data from North America, on the other hand, where the Canadian land mass was entirely covered by the vast Laurentide ice-sheet complex at LGM provide information from depths that extend well into the upper part of the lower mantle. Below a depth of approximately 1,200 km, only Earth rotation data provide any constraint upon the viscosity of this deepest region that extends to the depth of the CMB (Peltier, 1998).

Figure 5 shows a series of the earliest inversion results (Peltier, 1996) based on the application of a formal Bayesian methodology to the simultaneous inversion of all of the data types. For the purpose of these analyses, an initial guess profile (VM1) was assumed and the data were inverted to deduce a best fitting viscosity model. In the model, a 120-km-thick perfectly elastic lithosphere was included on the top of the viscous mantle and so viscosity was inferred as a function of depth only below this level. That such an elastic surface layer should exist is rational on a priori grounds due to the fact that interior temperatures in the near-surface region are so low that viscosity is effectively infinite, thus rendering this layer perfectly elastic. Use of rebound data to provide a direct measurement of lithospheric thickness requires recourse to the incorporation of additional data from the rebound process induced by the removal of ice sheets of sufficiently small lateral extent. Peltier et al. (2002) employed data associated with the rebound of Scotland following removal of the Scottish ice sheet that was in place over this region at LGM for this purpose. Peltier and Drummond (2008) on the other hand employed horizontal motion data from locations outboard of the Laurentide ice sheet for the same purpose. The model labeled VM2 in Figure 5 was obtained from a Bayesian inversion from which the true polar wander data were held back so as to provide the basis for a check on the quality of the results for the deepest mantle that the analysis delivered.

Sensitivity analyses performed by adjusting the magnitude of the observed rate of nontidal acceleration to mimic the influence of a contamination of this observation by the modern melting of land ice from the Polar Regions reveal that the viscosity of the lower mantle is strongly sensitive to this parameter. The model obtained by assuming that polar ice is melting at a rate sufficient to raise global sea level by 1.5 mm/year is the model labeled VM3 in Figure 5. The viscosity in the region shallower than ~1,250 km depth remains "pinned" to the previously determined depth dependence by the relaxation time constraints derived from observations of the rebound of the crust in both North American and Northwestern Eurasia. This clearly implies that below the depth of ~1,250 km, it is only the Earth rotation constraints that deliver information on mantle viscosity.

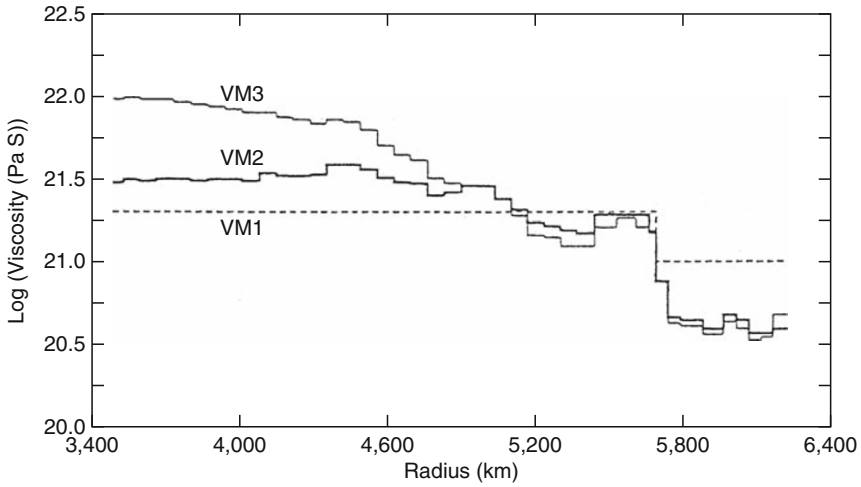


Mantle Viscosity, Figure 4 Plot showing variation of time difference between the observed time of a total eclipse of the Sun or the Moon and the predicted time of the event based on the assumption of constant tidal torque over the past 2,000 years. The inset (on a scale 25 times expanded) includes the continuous curve derived from the lunar occultations in the period 1620–1995.5 AD. The dashed curve is the best fitting parabola and the solid curve is fitted using cubic splines. (From Stephenson and Morrison, 1995.)

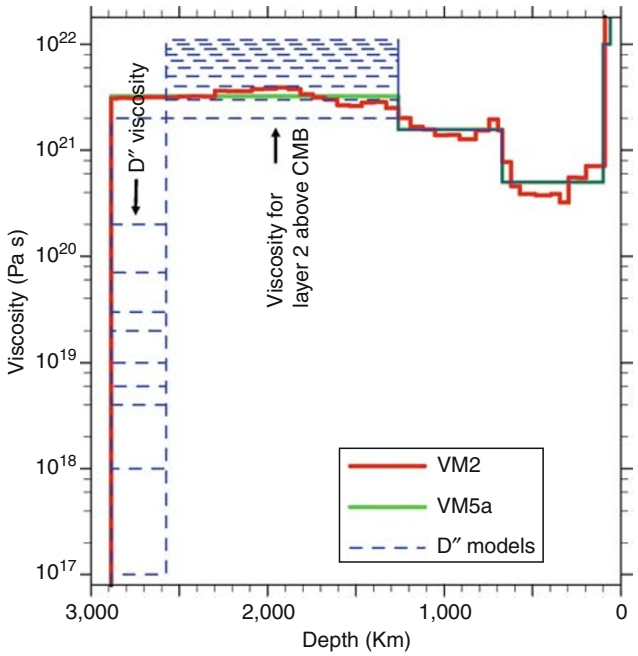
This sets the stage for a focused attempt to measure any variation of viscosity that might exist in the deepest Earth. To this end, Figure 6 illustrates a two-layer parameterization of the mantle below the critical depth of ∼1,250 km in which a multilayer parameterization of VM2, called VM5a, is perturbed by varying the viscosity of the two lowermost layers; the D" layer assumed to be 300-km thick, and the lower mantle layer (layer-2) extending from 1,250 km depth to the top of D". A sequence of such models can be fitted to both the nontidal acceleration and polar wander speed. It is found that for each value assumed for D" viscosity, it is possible to find a corresponding value for the viscosity of layer-2, which enables the model to fit both rotational observables. Figure 7a provides a summary diagram illustrating the manner in which the viscosity of D" trades off against the viscosity of layer-2 (Peltier and Drummond, 2010). As the viscosity of D" decreases, the viscosity of layer-2 first increases as expected in order to recover the fit to the observations. However, once the viscosity of D" is assumed to be sufficiently low, as to be behaving as though it were inviscid, the allowed value of the viscosity of the overlying layer saturates as would be expected on physical grounds. Figure 7b shows the manner in which the prediction of polar wander direction varies for the set of models that provide satisfactory fits to both of the rotational constraints. Since it is the ILS data that correctly capture the direction of true polar wander associated with ancient ice-age influence, it will be clear that the preferred model is one for which the viscosity of D" is only modestly reduced relative to a viscosity of the overlying layer that is itself only modestly enhanced relative to that in the same region of VM5a.

Compatibility of the GIA-based viscosity model with that required by models of the mantle convection process

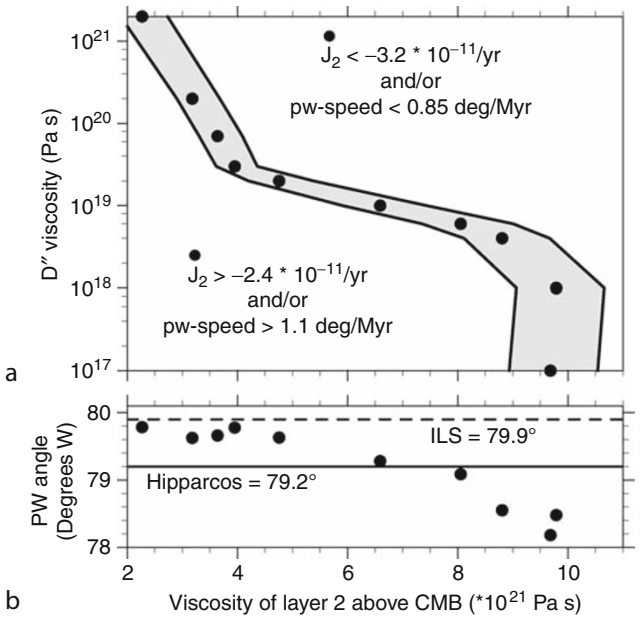
Early efforts to determine the viscosity of the Earth's mantle based on GIA data (e.g., Walcott, 1970) appealed to the



Mantle Viscosity, Figure 5 Models of the mantle viscosity as a function of depth obtained by formal Bayesian inversion of the glacial isostatic adjustment data.

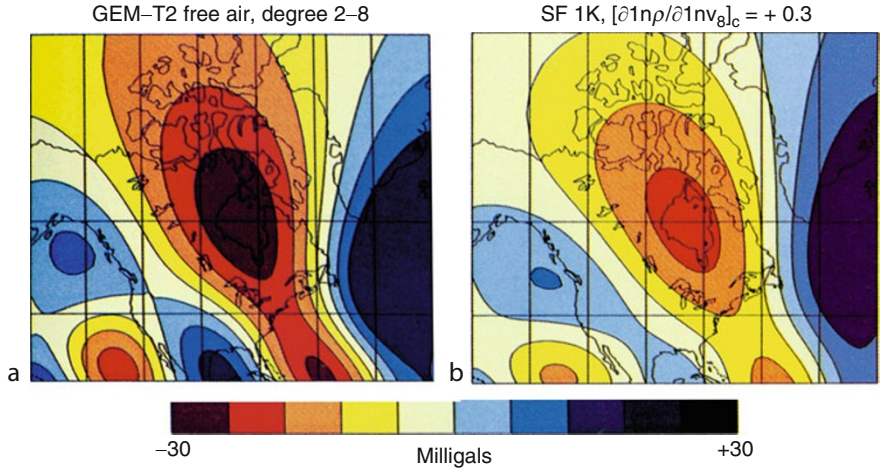


Mantle Viscosity, Figure 6 A family of mantle viscosity models for the D″ layer and the layer-2 above CMB. In these models, the lithosphere consists of two distinct units. The upper 60-km-thick unit is assumed as perfectly elastic whereas the lower 40-km-thick unit has a viscosity of 10^{22} Pa.s.



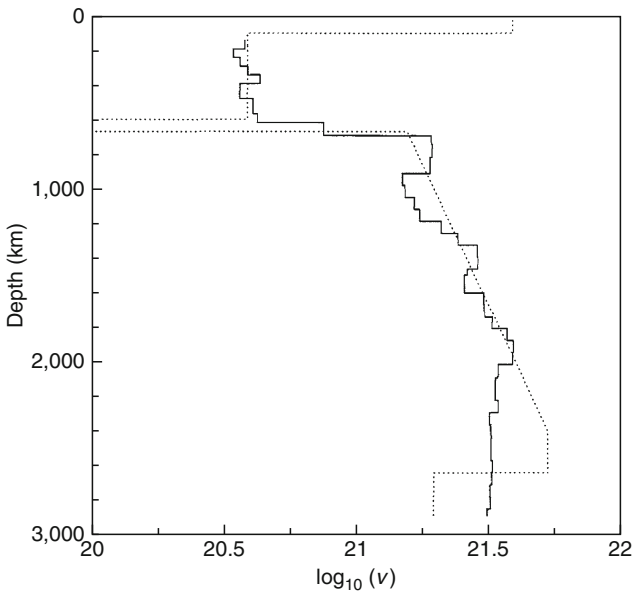
Mantle Viscosity, Figure 7 (**a**) A trade-off diagram describing the relationship between the viscosity assumed for the D″ layer and that of the layer-2 that is required in order that both observables are fit by the same model of the GIA process. (**b**) The predicted direction of polar wander for the above models. Also shown is the observed direction consistent with the International Latitude Service (ILS) data set.

observed magnitude of the free-air gravity anomaly over the Hudson Bay region to argue that the magnitude of this anomaly provided strong evidence that the viscosity of the deep Earth was much higher than implied by the analyses described in the previous section. This anomaly, based on the GEM-T2 model of the Goddard Space Flight Center, is shown in Figure 8a. The anomaly has a magnitude of approximately −30 milligals when the field is restricted to include only spherical harmonic degrees 2 through 8. When the VM2 viscosity model derived by GIA analysis was used in conjunction with an acceptably accurate model of ice thickness history, the predicted free-air



Mantle Viscosity, Figure 8 (**a**) Observed GEM-T2 degree 2–8 non-hydrostatic free-air gravity anomaly over the Hudson Bay region of Canada, and (**b**) the calculated anomaly based on the predictions of the internal loading theory for the density conversion factor for the cratonic root of +0.3.

gravity anomaly had peak amplitude of only −3 milligals. This issue concerning the origin of the free-air gravity anomaly, which is well correlated in its location with that of the LGM Laurentide ice sheet, has been analyzed in detail by Pari and Peltier (1995, 1996, 1998, 2000). Their work focused on the viability of the alternative hypothesis that the anomaly was supported by the mantle convection process. Models of mantle convection incorporating the results of seismic tomography (Forte et al., 1994) and based on internal loading theory were developed and applied in analyses of the non-hydrostatic geoid and free-air gravity anomalies that would be supported by this mantle dynamic process. In the context of internal loading theory for an Earth model with spherically symmetric viscosity distribution, there are only two distinct parameters that need to be specified. The first one is the depth-dependent mapping factor through which the heterogeneity in seismic shear wave velocity is converted into lateral heterogeneity of density and the second is the depth dependence of mantle viscosity. Results were obtained for three different values of the S-wave velocity to density conversion factor in the subcontinental "tectosphere"; −0.3 (positive buoyancy, upwelling flow), 0.0 (neutral buoyancy), and +0.3 (negative buoyancy, downwelling flow). Of the three scenarios, the last model has provided an excellent fit to the free-air gravity anomaly (Figure 8b) and 24 milligals of the 30 milligal free-air anomaly over Hudson Bay could be explained by the mantle convection hypothesis. It needs to be understood that there has been no attempt to tune the model to achieve a best fit locally. Rather the model has been optimized to achieve a best fit to the entire global gravity field. It seems clear on the basis of these results that the free-air gravity anomaly over the Hudson Bay region is essentially entirely due to the mantle convection process. Therefore, the original argument of Walcott (1970) that this anomaly must be due to remaining glacial isostatic disequilibrium and to imply that the viscosity of the mantle of the Earth must be extremely high, is not supported. It seems rather to be explicable as a consequence of thermal convection in a mantle through which the variation of viscosity is rather modest.



Mantle Viscosity, Figure 9 Comparison of the VM2 viscosity profile (*solid line*) to the viscosity profile (*dotted line*) determined on the basis of an optimal fit to the non-hydrostatic free-air gravity anomaly.

The viscosity profile that delivers the high-quality fit to the free-air anomaly of the North American continent is shown in Figure 9 by the dotted line along where it is compared to the GIA-derived model VM2. There are two

primary differences between these profiles which are otherwise extremely close to one another. The first is the structure near the base of the mantle. Evident is the presence of the low viscosity region adjacent to the CMB above which viscosity is enhanced above the level in the VM2 model. The second difference appears in the form of a very soft thin layer coincident with the 660 km discontinuity corresponding to the endothermic phase transformation from Spinel to a mixture of Perovskite and Magnesiowustite. This phase transition acts as a significant, though imperfect, impediment to convective mixing. When mixing does occur across the boundary, however, a significant change in grain size is expected, which leads to the transformational super-plastic softening of the mineral assemblage in the near vicinity of the boundary. An outstanding issue in mantle dynamics concerns the dynamical impact of this feature on the mixing process.

Summary

This article has reviewed the main sources of information on the viscosity of the deep Earth. These sources consist of data pertaining to the phenomena of postglacial rebound and mantle convection. In spite of modest differences between the models of mantle viscosity depth dependence derived in distinct ways, the overwhelming evidence is that the depth dependence of viscosity derived on the basis of GIA observations is in close accord with that required by the mantle convection hypothesis explanation of surface plate tectonics and continental drift.

NUMERICAL METHODS, BOUNDARY ELEMENT

Michele Cooke
Geosciences Department, UMass – Amherst, Amherst, MA, USA

Definition

The boundary element method is a numerical technique for investigating deformation within the Earth. The method is particularly adept at investigations of discontinuities in the crust, such as cracks, faults, and dikes. The numerical method is able to analyze complex problems by discretizing the surfaces of the discontinuities into small elements and solving the problem piecewise.

Introduction

The boundary element method (BEM) is one of several numerical methods used to investigate deformation within the Earth. The principal difference between boundary element method and most other numerical methods of continuum mechanics, such as the finite element method (FEM), is that only the boundaries of the deforming body need to be meshed (Figure 1). While other methods require meshing the entire volume of the deforming body into two-dimensional (2D) or three-dimensional (3D) elements, the BEM only requires discretization of the boundaries (e.g., fractures, bedding planes, or external boundaries) into one-dimensional (1D) or 2D elements. Minimizing discretization decreases model building and run time as well as errors due to discretization (Crouch and Starfield, 1990). The greatest advantages of BEM modeling in geophysics are that (1) very complicated surface geometries, such as undulating fault surfaces, can be incorporated and (2) the method can readily accommodate fracture propagation by addition of new elements (Figure 1). The disadvantages of BEM are (1) that the stiffness matrix relating stresses to strains on the elements is non-sparse so that inverting the matrix to find stresses can be very CPU intensive and (2) heterogeneous material properties are more complex to incorporate in BEM than methods that utilize volume discretization, such as FEM (Becker, 1992).

How does BEM work?

BEM models are based on the solution to Kelvin's problem for the deformation due to a point load within a body. The solution provides the stresses and displacements everywhere due to the point load. We can calculate the effects of distributed loads by integrating the point force. When the loads are applied over discrete elements, the relationships between the displacements at one element due to loads at another are used to build an influence coefficient matrix. When either the displacements or tractions are prescribed to all elements that comprise the BEM model, the method will solve for the unknown element tractions or displacements via the influence coefficient matrix. Once all the displacements and tractions along the boundary elements are known, the stresses and strains at any point within the body can be calculated using the solution of Kelvin's problem. So unlike FEM, where solutions are calculated at each node within the element mesh, within BEM, problems displacements and stresses can be calculated at any point within the body, once all the tractions and displacements along the elements are known.

Two variations of BEMs are commonly used, the *fictitious stress* and *displacement discontinuity* methods. The fictitious stress method is based on Kelvin's problem and applies uniform tractions along each boundary element. In contrast, the displacement discontinuity method applies displacements along each element such that the difference in displacement form one side of the element to the other is constant along the boundary element

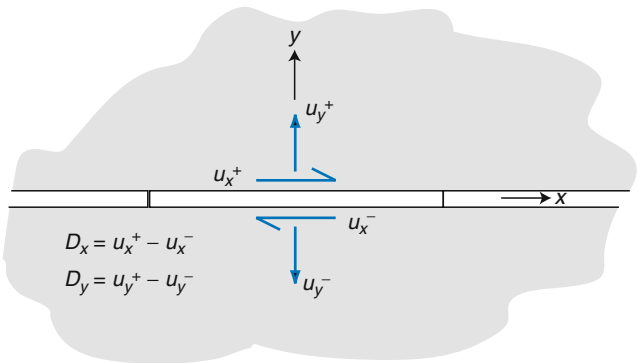
Numerical Methods, Boundary Element, Figure 1 Contrasting discretization approaches of the boundary element method and finite element method. BEM only discretizes the boundaries and/or internal surfaces (*blue line*) rather than the entire volume. Fracture propagation is facilitated by addition of elements (*red line*).



Numerical Methods, Boundary Element, Figure 2 Formulation of the displacement discontinuity along each element within a boundary element method model. The normal and shear displacement discontinuity (D_x and D_y, respectively) are the difference between the displacements along the top and bottom of the element.

(Figure 2). While fictitious stress method works well for homogeneous bodies under external loads, the displacement discontinuity method is better suited for problems of solid bodies containing cracks (Crouch and Starfield, 1990). For this reason, the displacement discontinuity method is more common for geophysical analyses, which investigate deformation associated with dikes, sills, microcracks, joints, and faults within the Earth.

What can BEM do?

Boundary element method codes using the displacement discontinuity formulation have been developed to solve both two-dimensional (e.g., Crouch and Starfield, 1990 and three-dimensional problems (Okada, 1992; Thomas, 1993; Meade, 2007). Two-dimensional formulations use a linear dislocation for each element while three-dimensional formulations utilize either rectangular dislocations (Okada, 1992) or angular dislocations (Cominou and Dundurs, 1975) that can be assembled to form triangular elements of constant displacement discontinuity (Thomas, 1993; Meade, 2007). The advantage of triangular elements over rectangular elements is that complex nonplanar surfaces can be meshed without creating locations of overlaps and gaps.

Important refinements to the basic displacement discontinuity method for investigation of problems in geophysics include incorporation of frictional slip along

crack elements and prevention of interpenetration of crack walls during compressive loading of cracks. These refinements facilitate investigation of deformation associated with subsurface faults and joints. Algorithms for preventing interpenetration include the penalty method (Crouch and Starfield, 1990; Cooke and Pollard, 1997) and the complementarity method (Maerten et al., 2010). The penalty method employs normal and shear stiffness to each element to prevent interpenetration. The complementarity method uses an iterative solver to solve the inequality that opening should be equal to or greater than zero along each element (Maerten et al., 2010).

Heterogeneous properties can be incorporated within BEM formulations by way of a contact boundary. Stresses and displacements are prescribed to be uniform across the boundary between otherwise homogeneous portions of the model. With this constraint along the boundary, the solution for each homogeneous section is found separately. This approach has not been widely applied because it is difficult to implement; finite element methods are generally believed to be better suited for heterogeneous properties.

Applications of the boundary element method

In most BEM implementations, gravitational body forces are superposed onto the solution to the applied loading. This precludes direct investigation of problems related to topographic loading. However, Martel and Muller (2000) developed a formulation for analyzing topographic stresses using a long stress-free crack to simulate the topography.

Investigations of fluid flow through fracture networks has benefited from the surface discretization approach of the boundary element method. Models of subsurface flow through fracture networks utilize a boundary element method model that incorporates fluid flow along each element (e.g., Dershowitz and Fidelibus, 1999). Such approaches can permit the full coupling of mechanical deformation and fluid flow.

The boundary element method has found widespread use in the subfield of structural geology for solving problems of deformation and propagation of opening mode and sliding mode fractures (e.g., joints and faults). Both forward and inverse modeling techniques have utilized the boundary element method. Forward models apply loading to the crack system to determine the resulting deformation of the system. Such investigations may explore the development of secondary cracks around a fault or the aperture of a hydraulic fracture. In contrast, inverse models start with the observed deformation and invert to find the slip on the fault or opening on the crack that must have produced the observations. For example, deformation observed along the surfaces of the earth via GPS stations velocities or InSAR imagery can be inverted to find the slip distribution on the underlying fault (e.g., Maerten et al., 2005).

Definition

Computational domain. A bounded spatial region where a partial differential equation is solved.

Dirichlet boundary condition. A condition imposed directly on the unknown of the differential problem, also called essential boundary condition.

Neumann boundary condition. A condition imposed on the fluxes associated to the differential problem at hand,

that is, stresses, heat flux, etc. Also called natural boundary condition.

Parallel computer. A computer with more than one processing unit capable of computing operations concurrently.

Parallel computation. A numerical procedure executed on a parallel computer.

Preconditioner. In the context of the solution of a linear system by an iterative method, a preconditioner is an easily invertible matrix spectrally similar to the matrix governing the problem.

Introduction

Domain Decomposition (DD) method is a technique for the solution of partial differential equations which can be instrumental to the development of *parallel computations*. It can be used in the framework of discretization methods, for example, finite elements, finite volumes, finite differences, or spectral element methods.

It is based on the reformulation of the given boundary-value problem on a partition of the computational domain Ω into M subdomains Ω_i, with $i = 1, \ldots, M$. Typically M is also the number of processors at disposal, even if it is possible to have more subdomains per processor.

The DD method also provides a convenient framework for the solution of heterogeneous or multi-physics problems, that is, those that are governed by differential equations of different kinds in different subregions of the computational domain. In this case, the subdomains conform with the subregions. In this work, however, we will address only homogeneous DD methods, yet some of the concepts presented here may be readily adapted for the nonhomogeneous case.

We will refer to a partial differential equation of the form

$$-div(\boldsymbol{T}(\boldsymbol{u})) = \boldsymbol{f} \text{ in } \Omega \tag{1}$$

with suitable boundary conditions on $\partial\Omega$.

For instance, in a problem of elastostatic, $\boldsymbol{u}$ is the displacement and $\boldsymbol{T}(\boldsymbol{u})$ the stress tensor; in a heat conduction problem $\boldsymbol{u}$ is a scalar variable, the temperature, and $\boldsymbol{T}$ the Laplace operator. With a rather similar formalism we may also account for the Stokes problem. The method is in fact applicable also to time-dependent problems, since in most cases the time advancing scheme required by the numerical simulation leads eventually to a sequence of problems of type (1). For instance, if we consider the evolution equation

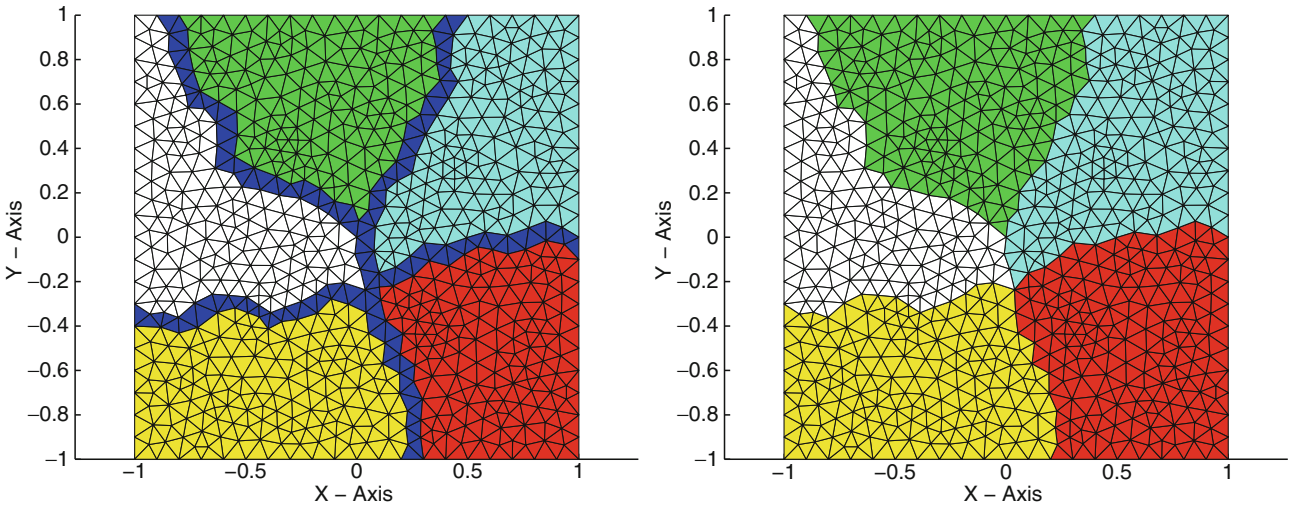
$$\partial_t \boldsymbol{u} - div(\boldsymbol{T}(\boldsymbol{u})) = \boldsymbol{f},$$

a time discretization by the implicit Euler method leads to solve for the unknown $\boldsymbol{u}^n$ at each time step t^n a differential problem of the type

$$\boldsymbol{u}^n - \delta t div(\boldsymbol{T}(\boldsymbol{u}^n)) = \delta t \boldsymbol{f}^n + \boldsymbol{u}^{n-1}.$$

It is still of the form (1) with $div(\boldsymbol{T})$ replaced by $\delta t\ div(\boldsymbol{T}) - \boldsymbol{I}$, δt being the time step and $\boldsymbol{I}$ the identity operator. A similar form is obtained also for the elastodynamic equations, discretized in time, for instance, by a Newmark method (Quarteroni and Valli, 1994).

Typically, and for evident practical reasons, the partition into subdomains is made after having triangulated Ω into a finite element mesh τ_h, each subdomain being in fact formed by a set of elements of the original grid (see Figure 1). The partition is often made automatically, using libraries like METIS (Karypis and Kumar, 1998b) or



Numerical Methods, Domain Decomposition, Figure 1 Partition of a computational domain starting from a given triangulation. *Left*: A partition into subdomains with an overlap equal to one layer of elements. *Right*: Partition of a domain with disjoint subdomains.

PARMETIS (Karypis and Kumar, 1998a), the latter able to exploit a parallel architecture also for this preprocessing stage.

More in particular, there are two ways of subdividing the computational domain into subdomains. The first uses disjoint subdomains, where $\Omega_i \cap \Omega_j = \emptyset$ for $i \neq j$. Here, the interface between subdomains reduces to surfaces (in 3D), and lines (in 2D). The second strategy adopts *overlapping subdomains*, usually built by letting the subdomains of an initial nonoverlapping partition grow of a certain factor δ. In most of the cases δ is dictated by the number of "layers" of grid elements that are added to the original partition. The minimal overlap is of one element, like that shown in Figure 1. For a more complete review of DD methods one may refer to (Smith et al., 1996; Quarteroni and Valli, 1999; Wohlmuth, 2001; Toselli and Widlund, 2005; Mathew, 2008); several examples with emphasis on parallel computations are reported, for instance, in (Bruaset and Tveito, 2006).

Algorithms without overlap

We indicate with Γ_{ij} the interface between subdomains Ω_i and Ω_j and we set $\Gamma = \cup_{ij}\Gamma_{ij}$. We exploit the fact that problem (1) is equivalent to solving the following M coupled problems for $i = 1, \ldots, M$,

$$-div(\boldsymbol{T}(\boldsymbol{u}_i)) = \boldsymbol{f}_i \text{ in } \Omega_i \tag{2}$$

with the same boundary conditions of the original problem applied to $\partial\Omega_i \cap \partial\Omega$, while on each Γ_{ij} we set the continuity of the local solutions $\boldsymbol{u}_i$ and of the fluxes, that is,

$$\boldsymbol{u}_i = \boldsymbol{u}_j, \qquad \boldsymbol{T}(\boldsymbol{u}_i)\cdot\boldsymbol{n}_{ij} + \boldsymbol{T}(\boldsymbol{u}_j)\cdot\boldsymbol{n}_{ji} = 0, \tag{3}$$

where $\boldsymbol{n}_{ij}$ is the normal to Γ_{ij} outward oriented w.r.t. Ω_i. It may be proved that $\boldsymbol{u}_i = \boldsymbol{u}_{|\Omega i}$ (Quarteroni and Valli, 1999).

Problems (2) are coupled because of relations (3). A parallel algorithm may be obtained by an iterative procedure where conditions (3) are enforced in such a way to generate at each iteration decoupled problems that can be run on different processes, with only a small amount of communication needed at the beginning of each iteration. For the sake of space we give an example of just one of these procedures, called *Dirichlet-Neumann* for the case of two subdomains Ω_1 and Ω_2. Starting from a guess for $u_1^{(0)}$ and $u_2^{(0)}$, the algorithm solves for $k = 1, 2, \ldots$ the following sequence of independent problems,

$$\begin{cases} -div(\boldsymbol{T}(\boldsymbol{u}_1^{(k+1)})) = \boldsymbol{f}_1, & \text{in } \Omega_1, \\ \boldsymbol{u}_1^{(k+1)} = \theta u_2^{(k)} + (1-\theta)\boldsymbol{u}_1^{(k)}, & \text{on } \Gamma_{12} \end{cases} \text{ and}$$

$$\begin{cases} -div(\boldsymbol{T}(\boldsymbol{u}_2^{(k+1)})) = \boldsymbol{f}_2, & \text{in } \Omega_2 \\ \boldsymbol{T}(\boldsymbol{u}_2^{(k+1)})\cdot\boldsymbol{n}_{21} = \boldsymbol{T}(\boldsymbol{u}_1^{(k)})\cdot\boldsymbol{n}_{21} & \text{on } \Gamma_{12}. \end{cases}$$

until a measure of the difference $u_1^{(k+1)} - u_2^{(k+1)}$ on Γ_{12} is below a given tolerance; θ here is a convenient relaxation factor. The Dirichlet-Neumann technique is not easily extendable to an arbitrary number of subdomains (unless suitable *coloring techniques* are used) and its convergence characteristics strongly depend on the geometry of the subdomains as well as on the possible jump of characteristic coefficients (for instance, the viscosity of different rocks forming a sedimentary basin). Other more favorable techniques like the Neumann-Neumann, Robin-Robin, and FETI methods are described in (Quarteroni and Valli, 1999; Wohlmuth, 2001; Toselli and Widlund, 2005).

The DD method may be also set from an algebraic viewpoint. Indeed when discretized, for instance, by a finite element method, (2) and (3) reduce to a system of linear equations, which may be written in a block form as

$$\begin{pmatrix} A_{II} & A_{I\Gamma} \\ A_{\Gamma I} & A_{\Gamma\Gamma} \end{pmatrix} \begin{pmatrix} \boldsymbol{u}_I \\ \boldsymbol{u}_\Gamma \end{pmatrix} = \begin{pmatrix} \boldsymbol{f}_I \\ \boldsymbol{f}_\Gamma \end{pmatrix},$$

where A_{II} is a *block diagonal* matrix with M blocks of dimension equal to the number of unknowns internal to each subdomain, the latter being collected in $\boldsymbol{u}_I$, while $\boldsymbol{u}_\Gamma$ is the vector of unknowns on the interface Γ. If A_{II} is invertible (and normally this is the case), we may obtain a problem for the $\boldsymbol{u}_\Gamma$ only (*Schur complement system*), $\Sigma_\Gamma \boldsymbol{u}_\Gamma = \boldsymbol{\chi}_\Gamma$, where $\Sigma_\Gamma = A_{\Gamma\Gamma} - A_{\Gamma I}A_{II}^{-1}A_{I\Gamma}$ is the so-called *Shur complement matrix* w.r.t. $A_{\Gamma\Gamma}$. Having solved for $\boldsymbol{u}_\Gamma$ the computation of $\boldsymbol{u}_I$ can be done in a perfect parallel fashion by solving the block diagonal problem $A_{II}\boldsymbol{u}_I = \boldsymbol{f}_I - A_{I\Gamma}\boldsymbol{u}_\Gamma$.

A DD scheme with no overlap may be interpreted as *preconditioned iterative scheme* (Quarteroni and Valli, 1994; Quarteroni, 2009) for the Schur complement system, where the preconditioner can be efficiently applied in a parallel setting. A crucial issue for parallel computing is that of *scalability*. In the DD setting, an algorithm is said to be scalable if its convergence properties do not depend on the number of subdomains M, and in particular does not degrade if we keep the ratio M/N between number of subdomains and the total number N of unknowns of our problem fixed. Indeed in this case (if we neglect communication overheads), we may solve in the same time a problem twice as large by doubling the number of processors.

A scalable parallel preconditioner cannot be built using only local (i.e., at the subdomain level) approximations of the Schur matrix; we need to add also a *coarse operator* that has the role of transferring information among far away subdomains. The typical form of the preconditioner is (we write directly the inverse operator since it is the one actually required by the iterative procedure (Quarteroni et al., 2007))

$$P_\Sigma^{-1} = \sum_{i=1}^{M} R_i^T \Sigma_i^* R_i + R_0^T \Sigma_0^* R_0, \tag{4}$$

where R_i is a *restriction operator* that selects from all the $\boldsymbol{u}_\Gamma$ those local to the i-th subdomain, and Σ_i^* is a local approximation of the inverse Schur matrix, which

typically can be built using just data related to the i-th subdomain (and thus in parallel). Finally, Σ_0^* is the coarse operator, of small dimension (typically of the order of M), whose role is to guarantee the coupling among all subdomains and it is necessary for scalability. The application of the preconditioner (i.e., the computation of $P_\Sigma^{-1}\boldsymbol{x}$, where $\boldsymbol{x}$ is any vector of the right length), can be done in parallel a part from the coarse operator, which however, being small in size, is irrelevant in the computational cost balance. Several scalable preconditioners are available, see (Toselli and Widlund, 2005) and (Canuto et al., 2007).

Methods with overlap

A typical DD scheme with overlapping subdomains is the Schwarz method. In its basic form, it is an iterative algorithm for the solution of (1) that for $k = 1, 2, \ldots$ solves a series of local problems on each subdomain Ω_i, where on the nonempty interfaces $\Gamma_{ij} = \partial\Omega_i \cap \Omega_j$ we apply Dirichlet boundary conditions using the latest values available from Ω_j, that is,

$$\begin{cases} -div(\boldsymbol{T}(\boldsymbol{u}_i^{(k+1)}) = \boldsymbol{f}_i, & \text{in } \Omega_i, \\ \boldsymbol{u}_i^{(k+1)} = \boldsymbol{u}_j^{(k)}, & \text{on } \Gamma_{ij}. \end{cases}$$

The iteration continues until the difference between two successive iterations is sufficiently small. The convergence analysis of the Schwarz method may be found in (Smith et al., 1996; Quarteroni and Valli, 1999; Toselli and Widlund, 2005), and in (Canuto et al., 2007) in the context of spectral element discretizations.

The method is seldom used in this form, however. Yet, it is probably the most adopted method to build parallel preconditioners for an iterative solver of the global problem, giving rise the so-called *Krylov-Schwarz* (for linear problems) and *Newton-Krylov-Schwarz* methods.

A Schwarz parallel preconditioner P_S may be written similarly to (4), that is,

$$P_S^{-1} = \sum_{i=1}^{M} R_i^T A_i^{-1} R_i + R_0^T A_0^{-1} R_0,$$

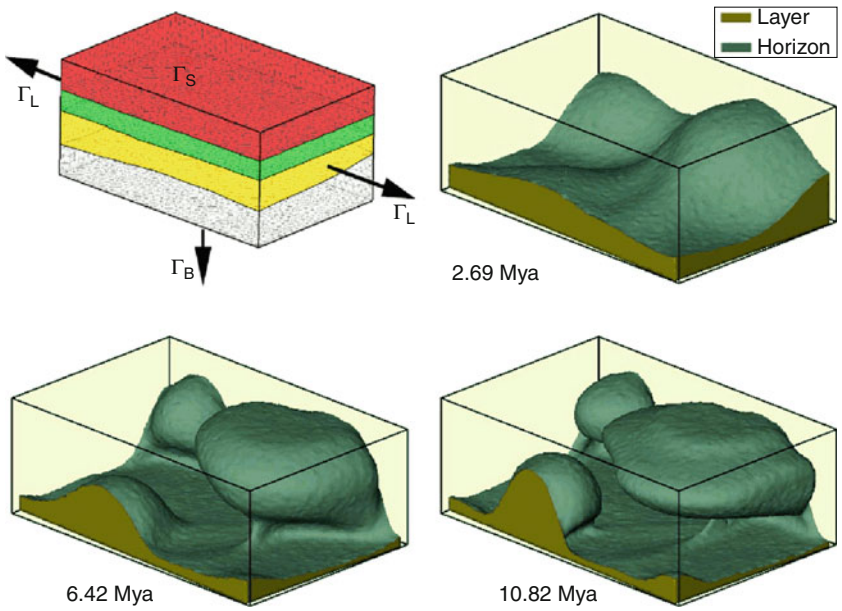
where here the restriction operator R_i extracts from a vector of length N the elements corresponding to the unknowns internal to the extended subdomain Ω_i, $A_i = R_i A R_i^T$ is the local matrix extracted from the matrix A of our problem, and finally A_0 is again a global coarse operator of size of the order M needed for scalability, R_0 being the corresponding restriction matrix.

Again, apart from the coarse operator, the computation of $P_S^{-1}\boldsymbol{x}$ can be done in parallel since the matrices A_i are local, and can be handled by each processor.

Application to geophysical and geological problems

DD methods have been applied successfully in the context of geophysical problems, like acoustic and elastodynamic wave propagation (Faccioli et al., 1997), or full-waveform tomography (Sourbier et al., 2009).

It has been also applied to speed up the simulation of the evolution of sedimentary basins. Here, different types of sediments, such as gravel, sand, rocks, and biological



Numerical Methods, Domain Decomposition, Figure 2 The simulated evolution of a salt diapir. In the first graphic, the computational domain showing the subdivision of the layers. The other pictures show snapshots of the evolution of the salt layer with the formation of a diapir.

remains that have been transported by the wind, the rivers and, sometimes, by the sea, accumulate, are buried deeper and deeper, and are transformed eventually into rocks by a complex process of compaction and diagenesis.

On geological scales, the evolution of a sedimentary basin may be tackled by a fluid approach where each rock layer is modeled as a viscous fluid. This is particularly convenient in the presence of salt tectonics (Massimi et al., 2007).

The computational domain Ω is split in several subdomains Ω_i, which usually correspond to the rock layers, as shown in Figure 2. At each time step, we have to solve in the domain Ω a Stokes problem, possibly with non-Newtonian rheology, to compute the instantaneous velocity field,

$$\begin{cases} -div(\boldsymbol{T}(\boldsymbol{v})) + \nabla p & = \boldsymbol{f}, \\ div(\boldsymbol{v}) & = \phi, \\ \frac{\partial \rho}{\partial t} + (\boldsymbol{v}\nabla)\rho & = 0. \end{cases} \tag{5}$$

Here, $\boldsymbol{v}$ is the velocity, p the pressure, $\boldsymbol{f}$ the external gravitational field, and ρ the density. The stress tensor $\boldsymbol{T}$ depends on characteristics of the rocks, such as viscosity and density, which may be discontinuous across layers. The function ϕ may account for compaction processes, or may be simply set to zero when the hypothesis of isochoric flow is acceptable. The last equation describes the evolution of the density, which is simply advected by the velocity field. The presence of faults is accounted for by appropriately reducing the rock viscosity in the vicinity of the faults.

The movement of the layers has been tracked using a level set technique. A finite element scheme has been adopted for the discretization of the Stokes problem, while a conservative finite volume scheme has been used for the tracking of the layer interfaces. The parallel implementation has been carried out with the help of the TRILINOS library (Heroux et al., 2005), using a Schwarz algorithm with a coarse operator built by aggregation (Sala, 2004).

Figure 2 shows the evolution of a salt dome. Salt is less compressible than the surrounding rock, so during the sedimentation process it ends having a smaller density than the overburden. We are then facing a Rayleigh-Taylor instability and any small perturbation will cause the salt to rise, with large movements that causes the so-called salt diapirism.

Definition

Finite-difference method. A method to approximate derivatives between neighboring points in a grid. The method can be applied to solve partial-differential equations, such as the wave equation.

Introduction

The finite-difference (FD) method is among the most commonly used methods for simulating wave propagation in a heterogeneous Earth. In this article, we describe the FD method for modeling wave propagation on Cartesian grids in acoustic, elastic isotropic, elastic anisotropic, as well as viscoacoustic/elastic media. The basic equations for wave propagation can be formulated in various formally equivalent ways. We will restrict our description to systems of first-order partial-differential equations with pressure/stress and particle velocities as wavefield variables. Due to its versatility, attractive stability, and dispersive properties, particularly for modeling wave propagation in elastic media, this formulation has been by far the most popular formulation over the last several decades. A more extensive review of the FD method is given by Moczo et al. (2007).

We start with a brief review of wave propagation theory and introduce some fundamental concepts including the basic structure (staggering) of the FD grid. In the following two sections, we discuss the choice of FD approximation and introduce two basic numerical properties of the FD method: numerical dispersion and stability. The last two sections are devoted to different boundary conditions and source implementations.

Theory of wave propagation and fundamental concepts

We focus on wave propagation in 3D Cartesian coordinates with coordinate axes (x, y, z). The special cases of 1D or 2D can easily be generalized from the expressions presented here, for example, in 2D, omitting terms or expressions containing components in the y-direction. The particle velocity wavefield is denoted by $\vec{v} = (v_x, v_y, v_z)$. In acoustic media, the second wavefield variable is the scalar quantity pressure, p, whereas in elastic media it is the (symmetric) stress tensor, S. We will often be representing stresses and particle velocities using stress and strain vectors defined as (the so-called Voigt notation):

$$\vec{\sigma} = \begin{pmatrix} \sigma_{xx} & \sigma_{yy} & \sigma_{zz} & \sigma_{yz} & \sigma_{xz} & \sigma_{xy} \end{pmatrix}^T$$

and

$$\vec{\varepsilon} = \begin{pmatrix} \varepsilon_{xx} & \varepsilon_{yy} & \varepsilon_{zz} & 2\varepsilon_{yz} & 2\varepsilon_{xz} & 2\varepsilon_{xy} \end{pmatrix}^T,$$

where the strain vector is related to the particle velocity vector components through:

$$\partial_t \vec{\varepsilon} = \begin{pmatrix} \partial_x v_x & \partial_y v_y & \partial_z v_z & \partial_z v_y + \partial_y v_z & \partial_z v_x + \partial_x v_z \\ \partial_x v_y + \partial_y v_x \end{pmatrix}^T.$$

The system of equations for wave propagation consists of two (dependent) sets of equations. First, the equation of motion (or Newton's second law):

$$\rho \frac{\partial}{\partial t} \vec{v} = \nabla \cdot S + \vec{f}, \tag{1}$$

where ρ is the density of the medium, $\nabla \cdot S$ denotes divergence of the stress tensor and $\vec{f}$ is a point-force source (source formulations driving the FD simulations will be described in detail later). In an acoustic medium, only the diagonal elements of the stress tensor are non-zero and equal to the negative pressure $-p$.

The second set of equations for wave propagation is the constitutive stress–strain relation:

$$\frac{\partial}{\partial t} \vec{\sigma} = C \frac{\partial}{\partial t} \vec{\varepsilon}, \tag{2}$$

where C is the 6-by-6 stiffness matrix. For an elastic isotropic medium, the stiffness matrix takes the form:

$$C = \begin{pmatrix} \lambda + 2\mu & \lambda & \lambda & 0 & 0 & 0 \\ \lambda & \lambda + 2\mu & \lambda & 0 & 0 & 0 \\ \lambda & \lambda & \lambda + 2\mu & 0 & 0 & 0 \\ 0 & 0 & 0 & \mu & 0 & 0 \\ 0 & 0 & 0 & 0 & \mu & 0 \\ 0 & 0 & 0 & 0 & 0 & \mu \end{pmatrix}, \tag{3}$$

whereas in a general anisotropic medium, all components of the stiffness matrix may be non-zero. As we shall see, this has profound implications on the choice of grid geometry to discretize the constitutive relation. Finally, although redundant, the acoustic constitutive relation can also be written using the notation of the stiffness matrix and the stress–strain constitutive relation. As noted above, instead of a stress vector with three independent components, we obtain:

$$\vec{\sigma} = -\begin{pmatrix} p & p & p & 0 & 0 & 0 \end{pmatrix}^T. \tag{4}$$

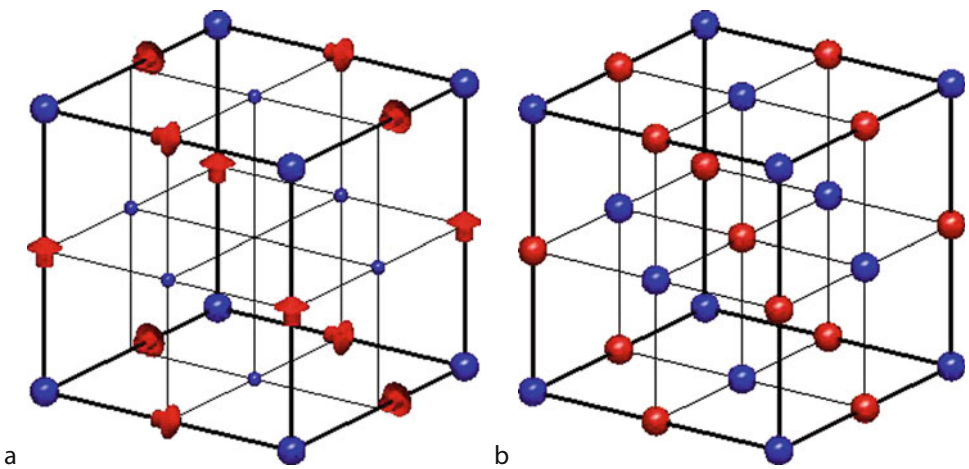
In an acoustic medium, only the (3-by-3) upper left quadrant of the stiffness matrix is non-zero with all elements equal and identical to the bulk modulus of the acoustic medium κ. Clearly this results in three identical equations – the familiar Hooke's law: $\frac{\partial}{\partial t} p = -\kappa \nabla \cdot \vec{v}$.

The FD method comprises solving Equations 1 and 2 by discretizing them in time and space and stepping forward in small incremental time steps. In particular, the exact choice of discretization in space turns out to be of fundamental importance. The so-called staggered grid was introduced for modeling isotropic elastic wave propagation by Virieux (1984, 1986) and Levander (1988, 1989). In the following, we will be referring to this as the Virieux grid. The choice of this grid results in schemes with attractive stability and dispersion properties, which other non-staggered grids do not necessarily possess. FD approximations to first-order derivatives naturally result in outputting the derivative of the wavefield at a location in between the discretized wavefield. By shifting the exact location of individual wavefield components by half a grid step in certain directions within each

grid cell, it is possible to ensure that spatial derivatives can be computed exactly at the locations where they are needed to advance canonical wavefield quantities in time using Equations 1 and 2. The structure of the Virieux staggered grid is illustrated in Figure 1a. The Virieux grid is also a good choice for modeling wave propagation in acoustic media. The resulting sparsely populated staggered-grid cell is equivalent to Figure 1a but without the shear stresses populating the grid cell (small blue balls in Figure 1a). In many situations, it is desirable to have a computational model that may contain both acoustic and elastic regions (e.g., modeling a marine seismic experiment or the seismic response of magma chambers). This is straightforward using a Virieux grid, by simply setting $\lambda = \kappa$ and $\mu = 0$ in Equation 3 in the acoustic regions. Updating the equations will guarantee that the "acoustic stress vector" in Equation 4 is satisfied to within-machine precision.

The Virieux grid is the natural choice for modeling wave propagation in elastic media as long as the stiffness matrix, C, in Equation 2 belongs to a class of anisotropic materials referred to as orthorhombic media and as long as the symmetry axes of the medium are aligned with the Cartesian grid (isotropic media is a special case that belongs in this family of media). For this class of anisotropic materials, all elements that are zero in Equation 3 remain zero. However, as soon as we introduce more complex anisotropic symmetry classes or rotate the symmetry axes with respect to the grid, the elements that are zero in Equation 3 will become non-zero. As a consequence, Igel et al. (1995) noted that spatial derivatives are no longer available at all locations where they are needed. Igel et al. (1995) solved this by interpolating strains between their natural locations. However, the scheme is both expensive and results in fairly complex implementations. Saenger (2000) solved the problem in 2D by observing that a rotation of the staggered grid by 45° results in a natural choice for staggering the wavefield quantities so that no interpolation is necessary. The so-called rotated staggered scheme can also be generalized to 3D, although it can no longer be seen as a simple rotation of the Virieux grid. Another staggered grid that avoids the necessity to interpolate wavefield quantities in anisotropic media is the Lebedev grid (Lebedev, 1964; Lisitsa and Vishnevskiy, 2010), which is illustrated in Figure 1b. Bernth and Chapman (2010) analyzed and compared the different staggered-grid geometries and concluded that whereas the rotated staggered grid and the Lebedev grid are equivalent in 2D, the Lebedev grid is different and a better choice compared to the rotated staggered grid in 3D. The Lebedev grid is both computationally more efficient and also lends itself to a simpler implementation as it can be regarded as a combination of four independent Virieux grids that decouple in isotropic media.

So far, the discussion in this section has concerned lossless media. In order to account for attenuation, a viscoacoustic or viscoelastic model is introduced by using a different constitutive stress–strain relation compared to Equation 2. Equation 2 can be thought of as a model of springs connecting particles in a lattice. When compressing the springs, energy is stored for an infinite time or until the compressed springs are released after which the particles return to their original positions. In a viscoelastic medium, dashpots are introduced in parallel or in series with the springs causing energy to dissipate after compression. The stiffness matrix becomes time-



Numerical Methods, Finite Difference, Figure 1 Staggered-grid geometries. (**a**) (*left*): Virieux staggered grid (Virieux, 1986). Large blue ball: normal stress components; *small blue ball*: shear stress components; red arrows: particle velocity components in the directions indicated. (**b**) (*Right*): Lebedev staggered grid (Lebedev, 1964; Lisitsa and Vishnevskiy, 2010; Bernth and Chapman, 2010). *Large blue ball*: all stress components; large red ball: all particle velocity components. The authors acknowledge Chris Chapman and Henrik Bernth (Schlumberger Cambridge Research) for providing the figure.

dependent and the multiplication with the time derivative of the strains is replaced by a convolution in time. The new viscoelastic constitutive relation becomes:

$$\frac{\partial}{\partial t}\vec{\sigma} = G(t) * \frac{\partial}{\partial t}\vec{\varepsilon}, \tag{5}$$

where *G(t)* is the new relaxation stiffness matrix, which contains elements that are functions of time. Such a particularly useful function corresponds to a spring/dashpot configuration called a standard linear solid (Robertsson et al., 1994a). First, due to the exponential kernel (in time) in the relaxation function of a standard linear solid, the convolution in Equation 5 can be eliminated at the expense of introducing a new set of differential equations to be solved at each time step and spatial location. No additional complications due to various grid geometries arise after introducing the new differential equations solving for the so-called viscoelastic memory variables as these equations are fairly simple ordinary differential equations in time (as opposed to partial-differential equations with additional spatial derivatives). Second, Robertsson et al. (1994a) and Blanch et al. (1995) showed how arrays of standard linear solid elements can advantageously be used to model constant quality factor Q versus frequency and also how to model attenuation of P and S waves in elastic isotropic media separately. However, exactly what attenuation to model for different wave types in an anisotropic medium is unclear and remains a topic for research (there are no pure P and S waves in an anisotropic medium).

Finite-difference approximations

The FD method approximates derivatives by combining neighboring function values on a grid, where the particular combination is commonly derived using the Taylor expansion of the function at the different sample points. The simplest example of a FD approximation is the first derivative of a function p at x_0 using only two samples:

$$\frac{\partial p(x_0)}{\partial x} = \frac{1}{\Delta x}\left(p\left(x_0 + \frac{\Delta x}{2}\right) - p\left(x_0 - \frac{\Delta x}{2}\right)\right) + C_1 \frac{\partial^3 p(x_0)}{\partial x^3}(\Delta x)^2 + O\left((\Delta x)^4\right), \tag{6}$$

where Δx is the sampling interval and C_1 is a constant. The lowest-order error term in this expansion is proportional to the square of the sampling interval. Hence, as we decrease Δx, the FD approximation will become increasingly accurate (the increase in accuracy proportional to the square of Δx) and in the limit be equivalent to the first derivative of p. The approximation is therefore considered second-order accurate since the lowest-order error term depends on the square of the sampling interval. Higher-order approximations of the first derivative can be expressed as a weighted sum of additional adjacent sample points:

$$\frac{\partial p(x_0)}{\partial x} = \frac{1}{\Delta x}\sum_{i=1}^{M}\alpha_i\left(p\left(x_0 + \frac{(2i-1)\Delta x}{2}\right) - p\left(x_0 - \frac{(2i-1)\Delta x}{2}\right)\right) + O\left((\Delta x)^{2M}\right). \tag{7}$$

The coefficients α_i describe what is often called the FD stencil and are chosen such that terms containing lower-order error factors are canceled (Table 1).

The accuracy of the FD approximations for the temporal derivatives and the spatial derivatives are often different and schemes are accordingly named with two accuracy orders. An O(2,8) accurate scheme would be second-order accurate in time and eighth-order accurate in space.

From Equation 6, we note that the derivative estimate of a spatial derivative is computed in between sample points of the wavefield quantity in question. As described in the previous section, this is the reason why the staggered-grid formulation is particularly well suited for FD modeling of the system of first-order differential equations describing wave propagation. The grid staggering is also applied in time, typically utilizing the simple second-order accurate approximation in Equation 6, resulting in a time-stepping method referred to as a "leap-frog" scheme. The leap-frog scheme is in turn referred to as an explicit FD scheme since the differential equations only contain one unknown after discretization in space and time, and which, therefore, can be computed directly without solving further systems of equations. For example, if we are in the process of updating particle velocities at a new time step $t_0 + \Delta t$ using Equation 1, we can compute the particle velocities directly from the known particle velocities at time t_0 and through spatial FD approximations of the known stresses at time $t_0 + \Delta t/2$. We then proceed to update stresses at time $t_0 + 3\Delta t/2$ using Equation 2 explicitly from the stresses at $t_0 + \Delta t/2$ and particle velocities at $t_0 + \Delta t$. In this fashion, we march through the FD simulation until we reach the desired maximum time of the simulation. Clearly, we need to initiate the simulation with a so-called initial conditions for particle velocities at time 0 and stresses at time $\Delta t/2$.

Accuracy and numerical dispersion

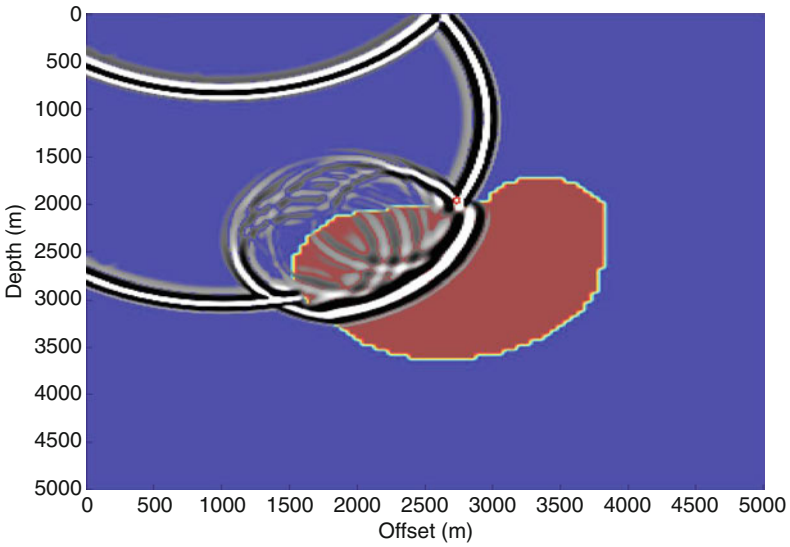
The most visible error introduced through the FD approximation is called numerical dispersion and appears when

Numerical Methods, Finite Difference, Table 1 Examples of α_i for different accuracies

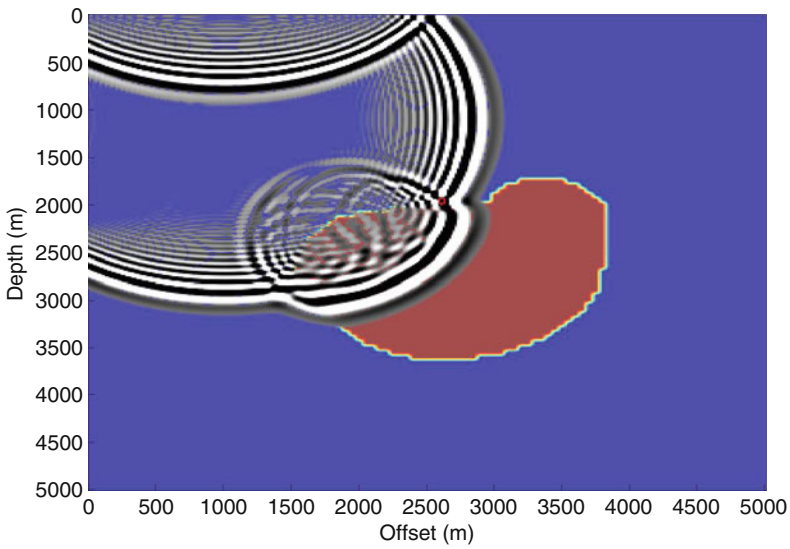
	α_i		
Order	$i=1$	$i=2$	$i=3$
2	1	N/A	N/A
4	9/8	−1/24	N/A
6	75/64	−25/384	3/640

either the sampling interval is too large or the approximation is not of sufficiently high order. Numerical dispersion is defined as the effect when different frequencies of the wavefields propagate slower or faster compared to the correct speed of wave propagation in the medium. Figures 2 and 3 show wave propagation simulations with two different order schemes using the same spatial sampling and clearly demonstrate severe effects of numerical dispersion of the lower-order scheme.

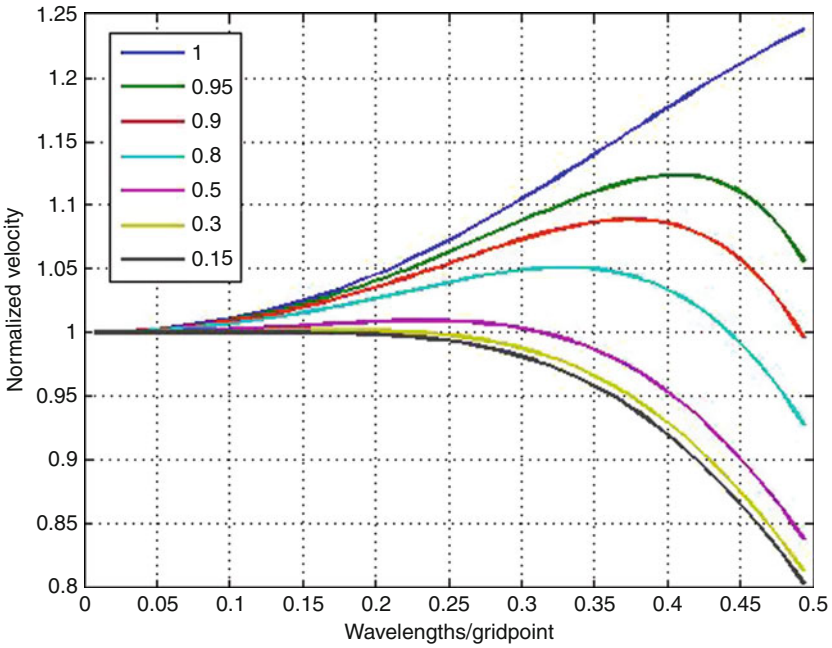
The numerical dispersion can be predicted by Fourier transforming the FD expressions in time and space. Using the Fourier-transformed expressions, we obtain a relationship that shows how the propagation velocity in the medium is affected by numerical dispersion. It is a function of several parameters including the spatial grid step and the so-called Courant number (see stability section below). Figure 4 shows several such dispersion curves (phase velocity error as a function of the number of



Numerical Methods, Finite Difference, Figure 2 Snapshot in time of a simulation using the acoustic wave equation. The black-and-white wave front indicates the location of a travelling wave. The wave has been reflected in the upper free surface and changed polarity. The left side shows the radiating boundary condition, which in this case is a PML. The blue area has slower propagation velocity than the red area. The solution has been computed using an O(2,16) scheme.



Numerical Methods, Finite Difference, Figure 3 Similar snapshot in time to that shown in Figure 2. The spatial sampling and medium is the same as in Figure 2, but in this case the simulation has been performed with an O(2,2) scheme. The trailing ripples of the wave front are typical for numerical dispersion.



Numerical Methods, Finite Difference, Figure 4 Dispersion curves for a O(2,6) FD Scheme. A perfect solution should be equal to one. The dispersion curves vary depending on the ratio of the velocity of the medium and the maximum velocity used to determine the time step, that is, the (normalized) Courant number displayed in the legend. To yield a sufficiently accurate solution, this scheme should probably not be run with less than five to seven gridpoints per minimum wavelength (0.14–0.2 wavelengths/gridpoint).

wavelengths per gridpoint) for different choices of time steps (resulting in different Courant numbers, see below). The numerical dispersion is dominated by the slowest wave speed in the medium, where the wavelength is the shortest. The number of sampling/gridpoints per wavelength necessary for a certain level of accuracy is thus determined by the dispersion curve and the slowest wave speed in a medium.

In practice, it is still difficult to define exactly how fine the wavefields must be sampled to avoid numerical dispersion as the severity of the numerical dispersion depends on the accuracy of the approximation and how far the wave has to propagate. However, as general rules of thumb, in order to roughly limit effects of numerical dispersion within a 2.5% error in propagation velocity, an O(2,4) scheme requires at least eight grid points per minimum wavelength, whereas an O(2,6) scheme requires six grid points per minimum wavelength.

It is obvious from Equation 8 that a higher-order derivative approximation requires more computations than a lower-order approximation. However, in general higher-order approximations (up to some limit) are preferred as the computational requirements increase linearly with accuracy order, whereas a finer grid increases the computational requirement to the fourth power of the refinement in 3D. The fourth power dependence originates from the fact that the temporal step must be proportional to the spatial step (see stability below). Thus, if the spatial step is reduced by a factor n, then a factor n^3 more gridpoints are required in 3D in addition to another factor n more time steps, therefore resulting in an increase of a factor n^4 in the number of computations required.

Lax–Wendroff corrections and optimally accurate FD schemes

The higher-order FD approximations are usually applied to spatial derivatives. To construct a functional scheme that has a higher order of accuracy in time, it is often necessary to use implicit time stepping, which results in a substantial increase in computational requirements. A solution to increase the formal order of accuracy (in a Taylor sense) without resorting to implicit schemes or saving several time levels is to apply a so-called Lax–Wendroff correction (Lax and Wendroff, 1964; Dablain, 1986). The Lax–Wendroff correction works by using the system of equations to express higher-order derivatives in time as spatial derivatives. The approximations of the higher-order time derivatives can be used to construct correction terms to cancel errors of successively higher order. Using the system

$$\begin{cases} \dfrac{\partial p}{\partial t} = \kappa \dfrac{\partial v}{\partial x} \\ \dfrac{\partial v}{\partial t} = \dfrac{1}{\rho} \dfrac{\partial p}{\partial x} \end{cases}, \tag{8}$$

the corresponding Lax–Wendroff correction for a third-order time derivative is:

$$\frac{\partial^3 p}{\partial t^3} = \kappa \frac{\partial^3 v}{\partial x \partial t^2} = \kappa \frac{\partial}{\partial x} \frac{1}{\rho} \frac{\partial^2 p}{\partial x \partial t} = \kappa \frac{\partial}{\partial x} \frac{1}{\rho} \frac{\partial}{\partial x} \kappa \frac{\partial v}{\partial x}. \quad (9)$$

However, the method is somewhat cumbersome in multi-dimensions as it requires mixed derivatives and also derivatives of the material parameters, that is, ρ and κ in Equations 8 and 9 (see for instance Blanch and Robertsson (1997) or Bergmann et al. (1999) for applications of the Lax–Wendroff correction).

The FD stencil can also be adjusted such that it is optimal for a certain frequency/wavelength range and thus achieves a higher accuracy than a standard scheme (Holberg, 1987; Robertsson et al., 1994b; Geller and Takeuchi, 1995; Zingg, 2000). Note that in a strict (and in this case misleading) Taylor sense, these schemes do not necessarily appear to be high-order schemes.

Time stepping and stability

As discussed above, the time stepping is most commonly explicit using a second-order approximation resulting in a leap-frog scheme. The explicit time stepping introduces a so-called CFL (Courant–Friedrich–Levy) stability condition prescribing the maximum size of the time step Δt. The CFL condition can be derived from the same Fourier transformation as described above (in the context of numerical dispersion) and requiring the resulting difference equation to have roots of absolute value less than or equal to one. As a result, the maximum time step is determined by the fastest wave speed in a medium, the spatial step, and a constant depending on the particular FD approximations used:

$$\Delta t \leq \frac{K}{\sqrt{D}} \frac{\Delta x}{c_{\max}}, \quad (10)$$

where the constant K depends on the spatial accuracy and is slowly decreasing with increasing accuracy of the scheme from a value of 1 for an O(2,2) scheme, D is the dimension of the simulation (e.g., D = 2 for 2D) and $c_{\max}$ is the maximum wave propagation speed in the medium. Rapid changes in material parameters may require an even smaller time step, but do not, in general, cause problems (Haney, 2007). Using a temporal step larger than determined by the CFL condition yields an unstable simulation, that is, parasitic solutions will grow at an exponential rate and swamp the physical solution.

The Courant number is often used in the context of discussing stability and numerical dispersion. It is defined as

$$\gamma = c_0 \frac{\Delta t}{\Delta x}, \quad (11)$$

where c_0 is the local velocity of the medium. The Courant number can be interpreted physically as the fraction of the spatial increment that a wave can advance in a time step. From Equation 11, we see that the Courant number controls the stability of the numerical scheme. In a heterogeneous medium, there exists a large range of velocities and it is thus important to study a FD scheme's behavior (i.e., numerical dispersion) for a range of Courant numbers (e.g., see Figure 4). In the literature, the normalized Courant number is often used:

$$\gamma_{norm} = c_0 \frac{\Delta t}{\Delta x} \frac{\sqrt{D}}{K}, \quad (12)$$

which needs to be less than or equal to 1 for a stable simulation.

Boundary conditions

The most important boundary conditions for wave simulations are radiating and free-surface boundary conditions. Radiating boundary conditions are applied at the edge of the finite computational domain to annihilate undesired reflections from the edge of the domain. In this fashion, we are able to emulate an infinite grid without reverberations appearing to occur at or beyond the physical boundary. The radiating boundary conditions can be implemented as "one-way" wave equation propagators using special operators at the boundaries. A first-order simple version is to implement the following equation at the boundary:

$$\frac{\partial p}{\partial t} = \pm c_0 \frac{\partial p}{\partial x}, \quad (13)$$

where the sign depends on which boundary (maximum or minimum x coordinate) and c_0 is the (local) propagation velocity. For a single propagation velocity, Equation 13 is fairly straightforward to implement. However, significant complications arise for elastic or anisotropic media and for higher dimensions than 1D where it is the apparent velocity perpendicular to the boundary that is the relevant parameter (Clayton and Engquist, 1977; Higdon, 1986, 1990).

The radiating boundary conditions are more commonly implemented as absorbing (or attenuating) boundary conditions applied in a finite region just inside the computational domain (Cerjan et al., 1985). The absorbing boundary conditions rapidly attenuate the wavefields such that any reflections from the numerical boundary are so small that they do not affect the result of the simulations. Absorbing boundaries do, however, need to have a transition zone, where the attenuation of the wavefield is gradually increased, since a rapid change in attenuation will cause reflections as well. These gradually increasingly attenuating boundaries are often referred to as sponge layers. The most efficient absorbing boundary condition is called a "Perfectly Matched Layer" (PML) (Bérenger, 1994; Gedney, 1996; Collino and Tsogka, 2001). The PML allows the attenuation to be increased extremely rapidly without causing reflections. The PML boundary conditions are implemented by introducing artificial anisotropy to the boundary and matching the reflection

coefficient in different propagation directions. The most straightforward realization of a PML boundary is through the split-field technique, where the wavefield is split depending on which spatial derivatives are used to update it. For the system in Equation 8 in two dimensions, an implementation for the p variable would be

$$\begin{cases} \dfrac{\partial p_x}{\partial t} + \beta_x p = K \dfrac{\partial v}{\partial x} \\ \dfrac{\partial p_z}{\partial t} + \beta_z p = K \dfrac{\partial v}{\partial z} \\ p = p_x + p_z \end{cases}. \tag{14}$$

The coefficients β_i control the attenuation in either the x or z directions independently.

The straightforward split-field implementation is equivalent to a fully anisotropic implementation (Teixeira et al., 2002) but suffers from a mild instability for waves impinging on the boundary at an incidence angle higher than 45°. A slightly more complex implementation avoids this instability (Bécache et al., 2002).

The free-surface boundary condition is used to approximate the interface between a water/solid material and air. Since the acoustic impedance of air is significantly different from that of water or the Earth, explicit modeling results in a computationally much more expensive simulation. In fact, it is possible to use a (pressure release) free-surface condition instead (water or Earth in contact with vacuum). For a water/air contact it is simply implemented through mirroring,

$$\begin{cases} p(-z) = -p(z) \\ v_z(-z) = v_z(z) \end{cases}, \tag{15}$$

assuming the boundary is located at $z = 0$. The upper boundary in Figure 2 is implemented using a free-surface condition. The free-surface condition for a solid elastic material is more complicated and cannot be achieved solely through mirroring. Care must be taken to ensure that all wavefield components satisfy the wave equation and the free-surface condition in order to accurately model wave phenomena such as Rayleigh waves at the free surface (see Robertsson, 1996, for details). In an anisotropic material the constitutive relationship is more complex and leads to an equation involving a larger amount of elastic constants and components of the strain tensor.

Topography and conformal mapping of grids

Topography can either be implemented explicitly into a FD scheme (Robertsson, 1996) or by stretching the grid through conformal mapping of the regular computational grid onto a grid with continuously varying grid spacings where the top of the grid follows the topography (Fornberg, 1988; Hestholm and Ruud, 1994). The explicit method will lose some of its flexibility to implement rapidly varying topography if a higher-order scheme is used for the solution. If a conformal mapping is used, all derivatives will depend on the mapping function through the chain-rule. For instance,

$$\frac{\partial v_z(f(z))}{\partial z} = \frac{\partial v_z}{\partial f}\frac{\partial f}{\partial z}. \tag{16}$$

This may lead to stricter stability conditions and stricter requirements on spatial sampling.

Source implementations

Seismic sources can be introduced in terms of body forces as indicated in Equation 1 or as moment-tensor sources using an equivalent source term in the constitutive equation (e.g., Equation 2 or 5). A straightforward approach is to simply drive a body force at one point by feeding Equation 1 with the value of a desired source wavelet in a single spatial grid point at each time step. Although this approach tends to work fairly well, researchers have sometimes reported on high-frequency noise being introduced. The origin of this noise has been attributed to the intrinsic difficulty in representing delta functions on a discretely sampled model with continuous wavefields. As a consequence, researchers have attempted to smooth the (delta-like function) source excitation in space by introducing source terms in a vicinity of grid points and scale the grid points accordingly with, for example, a Gaussian taper.

Practitioners in exploration seismology often mimic explosive sources by equal excitation of the diagonal elements of the stress tensor at the source location or alternatively model compressional or shear vibroseis source by either exciting vertical or horizontal body forces. By implication from the body-force equivalence theorem, earthquake seismologists who wish to model a moment-tensor source can do this either through a stress or body-force representation as described by Moczo et al. (2007).

An alternative way to introduce a source wavefield on a FD grid is by means of a boundary condition on an artificial surface interior to the grid. The method was first described by Alterman and Karal (1968) and followed by many authors clarifying the concept (Kelly et al., 1976; Levander, 1989; Robertsson and Chapman, 2000; Moczo et al., 2007). The technique relies on two prerequisites. First, that the spatial FD operators have a limited extent in space and second, that the (isolated) source wavefield can be computed in a region around the source location without reverberations from the rest of the model at the (simulated) time of source insertion. The artificial surface is defined enclosing a volume around the desired source location. Since the source wavefield often is computed in the vicinity of the artificial surface by some different means (e.g., an analytical solution), it is often practical to ensure that the artificial surface encloses a homogeneous medium.

The method of introducing a source wavefield as a boundary condition along an internal surface can also be used in so-called hybrid methods where two different numerical solutions are coupled together (e.g., Robertsson et al., 1996; Zahradník and Moczo, 1996; Robertsson and Chapman, 2000; van Manen et al., 2007). However, the

wavefield on opposite sides of the artificial surface in the technique above is reversed so that the source wavefield is present inside the artificial surface only. Typically, the artificial surface will be designed to be as large as possible just inside the absorbing boundary or free surface of the FD model. If the source wavefield is computed using a different numerical method such as Gaussian beams (Robertsson et al., 1996), some (limited) numerical artifacts will be introduced as the artificial surface crosses sharp discontinuities in medium properties.

Conclusions

We have outlined the basic principles of FD approximations to the systems of first-order partial-differential equations describing acoustic, isotropic elastic, anisotropic elastic, or viscoacoustic/elastic wave propagation. The method is based on explicit leap-frog time-stepping and staggered-grid representations. Most commonly Taylor-series-derived stencils are used to approximate the spatial derivatives, although other means to optimize FD stencils have also been described.

Two types of boundary conditions exist. First, radiating or absorbing boundary conditions (e.g., PML) are used to truncate the model while avoiding boundary reflections. Second, a free-surface boundary condition can be used to simulate the surface of the Earth with or without topography.

Sources are introduced either as point-force or stress sources, or along closed (artificial) surfaces inside the FD grid.

The maximum possible spatial grid size in order to limit numerical error is computed from the slowest propagation velocity in the model (e.g., a shear-wave velocity in the near-surface) using the so-called numerical dispersion relation for the FD scheme. Once the grid spacing has been chosen, the maximum possible time step is computed from the CFL-stability condition. The maximum possible time step is proportional to the spatial grid size and inversely proportional to the maximum propagation velocity in the grid. Since the computational cost of a 3D FD simulation increases to the power of four with a linear reduction of grid size, high-order accurate FD stencils are usually preferred.

NUMERICAL METHODS, FINITE ELEMENT

J. N. Reddy
Department of Mechanical Engineering, Texas A&M University, College Station, TX, USA

Definition

The finite element method is a numerical method, like the finite difference method, for solving differential equations arising in the study of physical phenomena. In the finite element method, a given domain is viewed as a set of nonintersecting subdomains, called *finite elements*, and over each element the governing equation is approximated by any of the traditional variational methods (e.g., Ritz, Galerkin, and least-squares methods). The main reason behind seeking approximate solution on a set of elements is the fact that it is easier to represent a complicated function as a sum of simple polynomials. Of course, each individual segment of the solution should fit with its neighbors in the sense that the function and possibly its derivatives up to a chosen order are continuous along the interface between elements. This entry is a brief introduction to the finite element modeling of diffusion processes and the Navier–Stokes equations governing viscous incompressible fluids. Both phenomena play crucial role in modeling a variety of geological or geomechanics processes.

General introduction

Scientists and engineers model (i.e., develop mathematical models and numerically simulate) natural phenomena with the objective of understanding it. Virtually every phenomenon in nature, whether aerospace, biological, chemical, geological, or mechanical, can be described in terms of algebraic, differential, and/or integral equations relating various quantities of interest. Determining the stress distribution in a mechanical structure with oddly shaped members and numerous stiffeners and subjected to mechanical, thermal, and/or aerodynamic loads, finding the concentration of pollutants in lakes and estuaries or in the atmosphere, predicting geophysical and geological events, and simulating weather in an attempt to predict the formation of tornadoes and thunderstorms are a few examples of many important practical problems that scientists and engineers are occupied with.

In the last four decades, the finite element method has emerged as a powerful computational tool for solving nonlinear partial differential equations over irregular domains with complex domain properties (Reddy, 2003, 2006; Reddy and Gartling, 2010; Bathe, 1996; Belytschko et al., 2000). Applications of the method to geology, geophysics, and geomechanics problems are numerous (see, e.g., Reddy et al., 1982; Wickham et al., 1982; Bird, 1989; Parsons, 2002; Dyksterhuis et al., 2005 and references therein). This brief introduction is meant to provide some insight into the workings of the finite element method as applied to the Poisson equation as well as the Navier–Stokes equations that are used to model certain geomechanics processes in two dimensions.

Finite element model of 2-D Poisson equation

Consider the problem of finding $u(x, y)$ such that the following partial differential equation (a generalized Poisson's equation) is satisfied

$$-\left[\frac{\partial}{\partial x}\left(a_{xx}\frac{\partial u}{\partial x}\right)+\frac{\partial}{\partial y}\left(a_{yy}\frac{\partial u}{\partial y}\right)\right]=f(x,y)\text{ in }\Omega \tag{1}$$

where Ω is a two-dimensional domain with boundary Γ. Here a_{xx} and a_{yy} are material coefficients in the x and y directions, respectively, and $f(x,y)$ is the known source. For example, in a ground water flow problem u denotes the water head (i.e., velocity potential), a_{xx} and a_{yy} are the permeabilities in the x and y directions, respectively, and $f(x,y)$ is distributed water source. Equation 1 also arises in many areas of science and engineering.

In the finite element method, the domain $\bar{\Omega}=\Omega\cup\Gamma$ is divided into a set of subdomains $\bar{\Omega}^e=\Omega^e\cup\Gamma^e$, called finite elements. Any geometric shape qualifies as an element, provided that the approximation functions ψ_i^e can be derived uniquely for the shape.

Suppose that the dependent unknown u is approximated over a typical finite element $\bar{\Omega}^e$ by the expression

$$u(\mathbf{x})\approx u_h^e(\mathbf{x})=\sum_{j=1}^{n}u_j^e\psi_j^e(\mathbf{x}),\ \mathbf{x}=(x,y)\in\bar{\Omega}^e \tag{2}$$

where $u_h^e(\mathbf{x})$ represents an approximation of $u(\mathbf{x})$ over the element $\bar{\Omega}^e$, parameters u_j^e denote the values of the function $u_h^e(\mathbf{x})$ at a selected number of points (i.e., element nodes) in the element $\bar{\Omega}^e$, and ψ_j^e are the Lagrange interpolation functions associated with the element.

We seek to satisfy the governing differential equation in a weak-form sense, with the weight functions being the same as the approximation functions. The resulting finite element model, i.e., set of algebraic equations) is called the *weak-form Galerkin finite element model* (Reddy, 2006). The weak form is

$$\begin{aligned}0=&\int_{\Omega^e}\left(a_{xx}\frac{\partial w_i^e}{\partial x}\frac{\partial u_h^e}{\partial x}+a_{yy}\frac{\partial w_i^e}{\partial y}\frac{\partial u_h^e}{\partial y}-w_i^e f\right)\mathrm{d}x\mathrm{d}y\\&-\oint_{\Gamma^e}w_i^e q_n\mathrm{d}s\end{aligned} \tag{3}$$

Suppose that u_h^e is represented over a typical finite element Ω^e by expression of the form 2. Substituting the finite element approximation 2 into the weak form 3, we obtain

$$\mathbf{K}^e\mathbf{u}^e=\mathbf{f}^e+\mathbf{q}^e\equiv\mathbf{F}^e \tag{4}$$

where the coefficients K_{ij}^e, f_i^e, and q_i^e are defined by

$$\begin{aligned}K_{ij}^e=&\int_{\Omega^e}\left(a_{xx}\frac{\partial\psi_i^e}{\partial x}\frac{\partial\psi_j^e}{\partial x}+a_{yy}\frac{\partial\psi_i^e}{\partial y}\frac{\partial\psi_j^e}{\partial y}\right)\mathrm{d}A\\&+\oint_{\Gamma^e}h_c\psi_i^e\psi_j^e\mathrm{d}s\\f_i^e=&\int_{\Omega^e}f\psi_i^e\,dA,\ q_i^e=\oint_{\Gamma^e}(\hat{q}_n+h_c u_c)\psi_i^e\mathrm{d}s\end{aligned} \tag{5}$$

We note that $K_{ij}^e=K_{ji}^e$ (i.e., $\mathbf{K}^e$ is symmetric).

Finite element models of the 2-D Navier–Stokes equations

In this section, we develop the finite element models of steady flows of viscous, incompressible fluids in two-dimensional domains. The governing equations are the conservation of linear momentum and conservation of mass, expressed in terms of the Cartesian components

$$\rho\left(u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}\right)-\frac{\partial\sigma_{xx}}{\partial x}-\frac{\partial\sigma_{xy}}{\partial y}-f_x=0 \tag{6}$$

$$\rho\left(u\frac{\partial v}{\partial x}+v\frac{\partial v}{\partial y}\right)-\frac{\partial\sigma_{xy}}{\partial x}-\frac{\partial\sigma_{yy}}{\partial y}-f_y=0 \tag{7}$$

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0 \tag{8}$$

$$\begin{aligned}&\sigma_{xx}=2\mu\frac{\partial u}{\partial x}-P,\ \ \sigma_{yy}=2\mu\frac{\partial v}{\partial y}-P,\\&\sigma_{xy}=\mu\left(\frac{\partial u}{\partial y}+\frac{\partial v}{\partial x}\right)\end{aligned} \tag{9}$$

Here we present two different finite element models associated with Equations 6–9. The first one is a direct formulation in which the three equations in (u,v,P) are used in their original form. This formulation is known as the *velocity–pressure formulation*. The other formulation is based on the interpretation that the continuity equation (Equation 8) is a constraint on u and v, and the constraint is satisfied in a least-squares (i.e., approximate) sense. This particular method of including the constraint in the formulation is known as the penalty function method, and the model is termed as the *penalty-finite element model*. It is informative to note that the velocity–pressure formulation is the same as the Lagrange multiplier formulation, wherein the constraint is included by means of the Lagrange multiplier. The Lagrange multiplier turns out to be the negative of the pressure.

Velocity–pressure (mixed) model

The weak forms of Equations 6–8 over an element Ω^e can be constructed following the standard procedure (Reddy, 2003). The weight functions have the following physical interpretation:

$$w_1\sim u\ ,\ w_2\sim v\quad\text{and}\quad w_3\sim -P \tag{10}$$

Assuming approximations of the form

$$u=\sum_{j=1}^{m}v_j\psi_j^e,\quad v=\sum_{j=1}^{m}v_j\psi_j^e,\quad P=\sum_{j=1}^{n}P_j\phi_j^e \tag{11}$$

where ψ_j^e and ϕ_j^e denote the Lagrange type interpolation functions $(n<m;\quad n+1=m)$ and substituting into the weak forms of Equations 6–8, we obtain the following finite element model:

$$\begin{bmatrix} \mathbf{K}^{11} & \mathbf{K}^{12} & \mathbf{K}^{13} \\ \mathbf{K}^{21} & \mathbf{K}^{22} & \mathbf{K}^{23} \\ \mathbf{K}^{31} & \mathbf{K}^{32} & \mathbf{K}^{33} \end{bmatrix} \begin{Bmatrix} \mathbf{u} \\ \mathbf{v} \\ \mathbf{P} \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}^1 \\ \mathbf{F}^2 \\ \mathbf{F}^3 \end{Bmatrix} \tag{12}$$

where $F_i^3 = 0$

$$\begin{aligned}
K_{ij}^{11} &= \int_{\Omega^e} \left[\mu \left(2 \frac{\partial \psi_i}{\partial x} \frac{\partial \psi_j}{\partial x} + \frac{\partial \psi_i}{\partial y} \frac{\partial \psi_j}{\partial y} \right) \right. \\
&\quad \left. + \rho \psi_i \left(u \frac{\partial \psi_j}{\partial x} + v \frac{\partial \psi_j}{\partial y} \right) \right] \mathrm{d}x\mathrm{d}y \\
K_{ij}^{12} &= \int_{\Omega^e} \mu \frac{\partial \psi_i}{\partial y} \frac{\partial \psi_j}{\partial x} \mathrm{d}x\mathrm{d}y, \\
K_{ij}^{13} &= -\int_{\Omega^e} \frac{\partial \psi_i}{\partial x} \psi_j \, \mathrm{d}x\mathrm{d}y, \quad K_{ij}^{33} = 0 \\
K_{ij}^{22} &= \int_{\Omega^e} \left[\mu \left(\frac{\partial \psi_i}{\partial x} \frac{\partial \psi_j}{\partial x} + 2 \frac{\partial \psi_i}{\partial y} \frac{\partial \psi_j}{\partial y} \right) \right. \\
&\quad \left. + \rho \psi_i \left(u \frac{\partial \psi_j}{\partial x} + v \frac{\partial \psi_j}{\partial y} \right) \right] \mathrm{d}x\mathrm{d}y \\
K_{ij}^{23} &= -\int_{\Omega^e} \frac{\partial \psi_i}{\partial y} \psi_j \mathrm{d}x\mathrm{d}y, \quad K_{ij}^{21} = K_{ji}^{21}, \\
K_{ij}^{31} &= K_{ji}^{13}, \quad K_{ij}^{32} = K_{ji}^{23} \\
F_i^1 &= \int_{\Omega^e} f_x \psi_i \mathrm{d}x\mathrm{d}y + \oint_{\Gamma^e} t_x \psi_i \mathrm{d}s, \\
F_i^2 &= \int_{\Omega^e} f_y \psi_i \mathrm{d}x\mathrm{d}y + \oint_{\Gamma^e} t_y \psi_i \mathrm{d}s
\end{aligned} \tag{13}$$

Here (t_x, t_y) denote the components of the stress vector $\mathbf{t}$ on the boundary

$$t_x = \sigma_{xx} n_x + \sigma_{xy} n_y, \quad t_y = \sigma_{xy} n_x + \sigma_{yy} n_y \tag{14}$$

and (n_x, n_y) are the components of the unit normal vector $\hat{\mathbf{n}}$.

Penalty-finite element model

Use of the penalty function method amounts to replacing the pressure with

$$P = -\gamma \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \right) \tag{15}$$

where γ is known as the penalty parameter. For complete details, the reader may consult (Reddy, 2003, 2006; Reddy and Gartling, 2010). Note that Equation 15 is used to post-compute P once the velocity field is available.

Assuming interpolation of the form

$$u = \sum_{j=1}^{n} u_j^e \psi_j^e, \quad v = \sum_{j=1}^{n} v_j^e \psi_j^e \tag{16}$$

where ψ_i^e are Lagrange interpolation functions. Substituting Equation 16 into the weak forms of Equations 6 and 7, we obtain the finite element model

$$\begin{bmatrix} \mathbf{K}^{11} & \mathbf{K}^{12} \\ \mathbf{K}^{21} & \mathbf{K}^{22} \end{bmatrix} \begin{Bmatrix} \mathbf{u} \\ \mathbf{v} \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}^1 \\ \mathbf{F}^2 \end{Bmatrix} \tag{17}$$

where

$$\begin{aligned}
K_{ij}^{11} &= \int_{\Omega^e} \left[\mu \left(2 \frac{\partial \psi_i^e}{\partial x} \frac{\partial \psi_j^e}{\partial x} + \frac{\partial \psi_i^e}{\partial y} \frac{\partial \psi_j^e}{\partial y} \right) \right. \\
&\quad \left. + \rho \psi_i^e \left(u \frac{\partial \psi_j^e}{\partial x} + v \frac{\partial \psi_j^e}{\partial y} \right) \right] \mathrm{d}x\mathrm{d}y + \int_{\Omega^e} \gamma \frac{\partial \psi_i^e}{\partial x} \frac{\partial \psi_j^e}{\partial x} \, \mathrm{d}x\mathrm{d}y \\
K_{ij}^{12} &= \int_{\Omega^e} \mu \frac{\partial \psi_i}{\partial y} \frac{\partial \psi_j}{\partial x} \mathrm{d}x\mathrm{d}y + \int_{\Omega^e} \gamma \frac{\partial \psi_i^e}{\partial x} \frac{\partial \psi_j^e}{\partial y} \, \mathrm{d}x\mathrm{d}y \\
K_{ij}^{22} &= \int_{\Omega^e} \left[\mu \left(\frac{\partial \psi_i}{\partial x} \frac{\partial \psi_j}{\partial x} + 2 \frac{\partial \psi_i}{\partial y} \frac{\partial \psi_j}{\partial y} \right) \right. \\
&\quad \left. + \rho \psi_i \left(u \frac{\partial \psi_j}{\partial x} + v \frac{\partial \psi_j}{\partial y} \right) \right] \mathrm{d}x\mathrm{d}y + \int_{\Omega^e} \gamma \frac{\partial \psi_i^e}{\partial y} \frac{\partial \psi_j^e}{\partial y} \, \mathrm{d}x\mathrm{d}y \\
F_i^1 &= \int_{\Omega^e} f_x \psi_i^e \mathrm{d}x\mathrm{d}y + \oint_{\Gamma^e} t_x \psi_i^e \mathrm{d}s, \\
F_i^2 &= \int_{\Omega^e} f_y \psi_i^e \mathrm{d}x\mathrm{d}y + \oint_{\Gamma^e} t_y \psi_i^e \mathrm{d}s
\end{aligned} \tag{18}$$

The numerical evaluation of the coefficient matrices appearing in Equation 17 requires special consideration. Equation 17 is of the general form

$$(\mathbf{K}^{\mu} + \mathbf{K}^{\rho} + \mathbf{K}^{\gamma}) \Delta = \mathbf{F} \tag{19}$$

where $\mathbf{K}^{\mu}$, $\mathbf{K}^{\rho}$, and $\mathbf{K}^{\gamma}$ denote the contributions from the viscous, inertia, and penalty terms, respectively. In theory, as we increase the value of the penalty parameter γ, the conservation of mass is satisfied more exactly. However, in practice, for some large value of γ, the contribution from the viscous and inertia terms would be negligibly small compared to the penalty terms in the computer. Thus, if $\mathbf{K}^3$ is a nonsingular (i.e., invertible) matrix, the solution of the final equations associated with Equation 19 for a large value of γ is trivial

$$\lim \gamma \to 0 (\mathbf{K}^{\mu} + \mathbf{K}^{\rho} + \mathbf{K}^{\gamma}) \Delta = \mathbf{F} \to \mathbf{K}^{\gamma} \Delta = \frac{1}{\gamma} \mathbf{F} \tag{20}$$

which will yield $\Delta = 0$. While the trivial solution satisfies the continuity equation, it does not satisfy the momentum equations for nontrivial boundary data or body forces. In this case, the discrete problem (Equation 17) is said to be over-constrained or "locked." If $\mathbf{K}^{\gamma}$ is singular, then the sum $\mathbf{K}^{\mu} + \mathbf{K}^{\rho} + \mathbf{K}^{\gamma}$ is nonsingular (because $\mathbf{K}^{\mu}$ is nonsingular after the imposition of proper boundary conditions), and a nontrivial solution to the problem may be obtained.

The numerical problem described above is eliminated by proper evaluation of the integrals in $\mathbf{K}^{\gamma}$. It is found that if the coefficients of $\mathbf{K}^{\gamma}$ (i.e., penalty terms) are evaluated using a numerical integration rule of one order less than

that required to integrate them exactly, the finite element equations (Equation 17) will give acceptable solutions for the velocity field. This technique of under-integrating the penalty terms is known in the literature as *reduced (order) integration*. For example, if a linear rectangular element is used to approximate the velocity field in a two-dimensional problem, the matrix coefficients $\mathbf{K}^{\mu}$ as well as $\mathbf{K}^{\rho}$ are evaluated using the 2×2 Gauss quadrature, and $\mathbf{K}^{\gamma}$ are evaluated using the one-point 1×1) Gauss quadrature. The one-point quadrature yields a singular $\mathbf{K}^{\gamma}$. Therefore, Equation 17 cannot be inverted, whereas $\mathbf{K}^{\mu} + \mathbf{K}^{\rho} + \mathbf{K}^{\gamma}$ is nonsingular and can be inverted (after assembly and imposition of boundary conditions) to obtain a good finite element solution of the original problem. When a quadratic rectangular element is used, the 3×3 Gauss quadrature is used to evaluate $\mathbf{K}^{\mu}$ and $\mathbf{K}^{\rho}$, and the 2×2 Gauss quadrature is used to evaluate $\mathbf{K}^{\gamma}$.

The choice of the penalty parameter is largely dictated by the ratio of the magnitude of penalty terms to the viscous and convective terms (or compared to the Reynolds number, *Re*), the mesh, and the word length in the computer. The following range of γ is suggested in computations

$$\gamma = 10^4 R_e \text{ to } \gamma = 10^{12} R_e.$$

Summary

Numerical simulation of geomechanical processes requires a good understanding of computational fluid mechanics, heat transfer, and solid mechanics and their couplings. The increase in computing power in both single processor and parallel environments has allowed realistic geomechanics problems of significant complexity and fidelity to be routinely solved and utilized in technological advances. Commercial software has made rapid progress in providing a broad spectrum of analysis capabilities to a variety of industries. Though software is increasingly robust, accurate simulations still require a knowledgeable user, with a background in both mechanics and numerical methods. This entry only provides an introduction to an individual who is interested in the use of the finite element method as a numerical simulation tool for the study and understanding of geomechanical phenomena. The Poisson equation and the Navier–Stokes equations visited here provide the necessary background for the study of diffusion processes and viscous flow problems. Interested readers may consult the references listed.

Definition

A multigrid method is an algorithm for the iterative solution of partial differential equations using a sequence of discretizations on multiple scales.

Introduction

The numerical solution of a partial differential equation (PDE) requires its discretization and a method to solve the resulting large system of algebraic equations. For linear equations, the resulting system is often a sparse matrix and a direct solution method suffices if the size of the problem is modest. For problems in three space dimensions, the computational cost of a direct solver may be too large. An iterative method that improves the accuracy of an approximate solution step by step can be a good alternative.

The multigrid method has optimal complexity: the amount of work required to solve a problem with N unknowns is $O(N)$, meaning that it scales with N. It achieves its efficiency by employing several discretization grids for the same problem.

History

Fedorenko (1964) introduced the multigrid method as an iterative scheme for solving Poisson's equation on a square and showed that the number of computations required to determine a solution with a prescribed accuracy is proportional to the number of unknowns, N. Therefore, the method has an optimal computational complexity. Brandt (1973) found that the actual computational cost for a sufficiently accurate result was about 10 work units, where a work unit is the cost of evaluating the discretized equations. He connected the method to local adaptive grid refinement and introduced nonlinear multigrid. Hackbush (1976, 1985) discovered the method independently and provided a mathematical foundation. Since then, the method was developed further to handle PDEs other than Poisson's, which is elliptic, and to go beyond PDEs.

Textbooks include those by Hackbush (1985), who includes convergence proofs; by Wesseling (1991), with chapters on computational fluid dynamics; by Briggs et al. (2000), an easy to read introduction; and by Trottenberg et al. (2001), among others.

Two-grid scheme

A discrete representation of a PDE provides an algebraic system of equations with relations between solution values at neighboring grid points. It is fairly easy to make local corrections that reduce the solution error on a short range, but much harder to correct the long-range or long-wavelength components of the solution that have a more global character. By projecting the solution onto a coarser grid, the long wavelengths become shorter and can effectively be solved for. Combining the corrections to the solution from coarser and finer grids yields an efficient solver.

A simple 1D example can help to understand the fundamentals of the multigrid method. The PDE is $Lu = f$, with $u(x)$ the unknown solution as a function of position x on a finite interval $[x_{min}, x_{max}]$ on the real axis, $f(x)$ a source term or forcing function, and L a linear differential operator, for instance, minus the laplacian, which in 1D is $-\frac{d^2}{dx^2}$. Dirichlet boundary conditions let the solution be zero at the endpoints of the interval. To obtain a discrete representation of the problem, an equidistant 1D grid is defined with grid points $x_k = x_{min} + kh$, index $k = 0, \ldots, N+1$, where $N+1 = 2^M$ and M is a positive integer. The grid spacing is $h = (x_{max} - x_{min})/(N+1)$. A standard second-order finite-difference scheme leads to

$$\frac{-u_{k-1} + 2u_k - u_{k+1}}{h^2} = f_k, \quad k = 1, \ldots, N,$$

where u_k approximates $u(x_k)$ and $f_k = f(x_k)$. At the boundaries, $u_0 = u_{N+1} = 0$. The discrete equations represent the problem $L^h u^h = f^h$, where L^h is a $N \times N$ sparse matrix and u^h and f^h are vectors of length N. The residual is defined as $r^h = f^h - L^h u^h$ and should vanish once the numerical solution has been found.

A simple iterative method is Jacobi relaxation, in which the matrix L^h is replaced by its diagonal $D^h = 2/h^2$. One step of Jacobi relaxation amounts to

$$u^h := u^h + \omega (D^h)^{-1} r^h.$$

The symbol " := " indicates that the solution values are replaced by the expression on the right-hand side. The factor ω controls the amount of damping. Convergence requires $0 < \omega \leq 1$. Fourier analysis (Hackbush, 1985) shows that the convergence rate, the factor by which the norm of the difference between the current and the exact numerical solution is reduced per iteration, is $1 - O(h^2)$ for Jacobi relaxation. Convergence slows down for increasingly finer grids.

The Fourier analysis reveals that the slow convergence is caused by the long-wave components of the solution. Because long waves can be represented on coarser grids, it makes sense to have a look at a two-grid scheme, outlined in Figure 1 and its caption. The coarse grid consists of every other grid point of the fine grid: $x_K = x_0 + KH$, with $H = 2h$ and $K = 0, \ldots, \frac{1}{2}(N+1)$. A restriction operator $\tilde{I}_h^H$ maps the current fine-grid residual r^h to the coarser grid: $r^H = \tilde{I}_h^H r^h$. The simplest restriction operator is injection: $r_K^H = r_{2K}^h$, $K = 1, \ldots, \frac{1}{2}(N-1)$. Full weighting, which lets $r_K^H = \frac{1}{4} r_{2K-1}^h + \frac{1}{2} r_{2K}^h + \frac{1}{4} r_{2K+1}^h$, applies some smoothing to the residual and is more common. The exact solution of the coarse-grid problem yields the coarse-grid correction $v^H = (L^H)^{-1} r^H$, which should be interpolated back to the fine grid and added as a correction to the latest fine-grid solution. The interpolation or prolongation operator is denoted by I_H^h and lets $u^h := u^h + I_H^h v^H$.

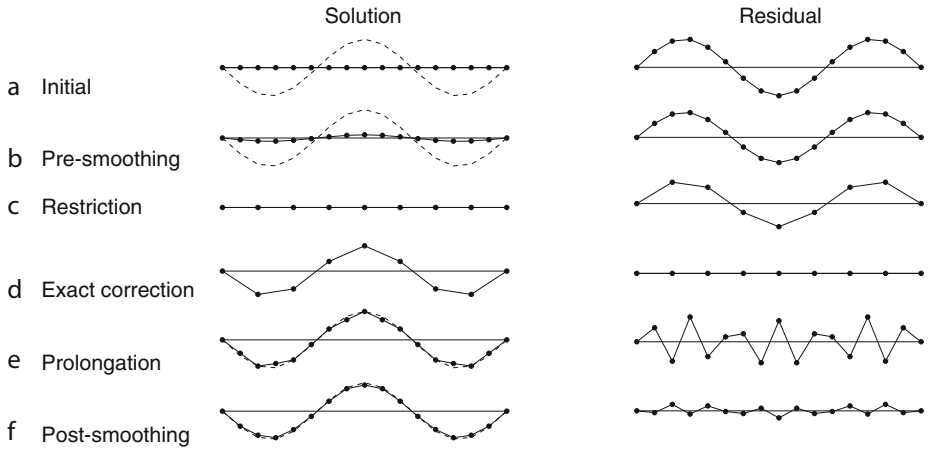
If linear interpolation is used for prolongation, this becomes

$$u_{2K}^h := u_{2K}^h + v_K^H, \quad K = 1, \ldots, \frac{1}{2}(N-1),$$

$$u_{2K-1}^h := u_{2K-1}^h + \frac{1}{2}(v_{K-1}^H + v_K^H),$$

$$K = 1, \ldots, \frac{1}{2}(N+1).$$

Here, it is assumed that $v_0^H = v_{(N+1)/2}^H = 0$. After prolongation, an additional relaxation step with damped Jacobi further removes oscillatory error components of the solution. Jacobi relaxation inside this two-grid scheme has a different purpose than when used as an iterative solver by itself. Instead of removing both the short- and long-wave components of the numerical solution error, it only has to deal with those components that cannot be represented on the coarser grid without aliasing. Therefore, a damped version with $\omega < 1$ can be more effective as it can be optimized to remove the short-wave or



Numerical Methods, Multigrid, Figure 1 Steps in a two-grid cycle. (**a**) The initial solution on the fine grid is set to zero and the residual equals the forcing function. The dashed line represents the exact numerical solution. (**b**) After one step of pre-smoothing with damped Jacobi relaxation, the solution error is still large and the residual has hardly changed in this example. Its restriction to the coarser grid (**c**) is solved exactly, using a coarse-grid version of the discrete differential operator. The resulting correction to the fine-grid solution (**d**) is interpolated or prolongated back to the fine grid and added to the fine-grid solution (**e**). The error in the solution is now dominated by the short wavelengths and appears as an oscillatory function, which is reflected in the corresponding residual. A post-smoothing step (**f**) removes most of the solution error. Repeating the whole cycle will further reduce the error.

oscillatory components. For Figure 1, $\omega = 2/3$ was used. The optimal choice requires a more detailed analysis (Hackbush, 1985).

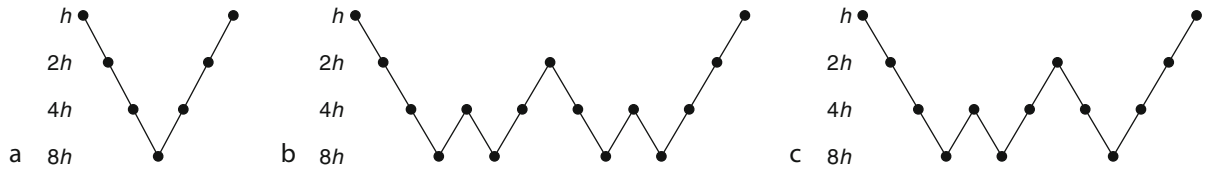
A relaxation scheme geared toward removing oscillatory components is called a smoother. Another popular choice is Gauss–Seidel relaxation. The operator is then approximation by a lower or upper triangular matrix, which is easy to invert. The implementation of the scheme is similar to Jacobi, but the residual is evaluated with the most recent solution available. The result will depend on the order in which the grid is traversed. With lexicographic Gauss–Seidel, one follows the natural index k in increasing order, or in the opposite direction. Symmetric Gauss–Seidel performs both these smoothing steps in sequence. An alternative is red-black Gauss–Seidel, where first the points with an odd and then those with an even index are updated, always using the latest solution values for the residual. In 2D, this would follow a checkerboard pattern.

The grid transfer operator, restriction and prolongation, should obey $m_p + m_r > 2m$ (Hackbush, 1985), where $2m$ is the order of the differential equation and $m_p - 1$ is the highest degree of the polynomial that is interpolated exactly. The scaled adjoint of the restriction operator is an interpolation operator for which m_r can be defined in the same way as m_p. In the example above, $2m = 2$, full weighting has $m_r = 2$, and prolongation based on linear interpolation has $m_p = 2$. More advanced grid transfer operators are based on the differential operator L^h, leading to operator-weighted restriction and prolongation.

The coarse-grid operator L^H can be based on the same discretization as the fine-grid operator L^h. An alternative is the Galerkin coarse-grid approximation $\tilde{I}_h^H L^h I_H^h$. In the current example with full weighting, these happen to be the same. Operator-weighted grid transfer operators can accelerate the convergence by using the coefficients of the differential operator in the construction of restriction and prolongation operators, which in turn will affect the Galerkin coarse-grid approximation of the differential operator.

Multigrid

Instead of using the exact numerical solution on the coarser of the two grids, a two-grid scheme can be applied to the coarse-grid problem. Extending this recursively to a coarsest grid with three points and one unknown, a multigrid solver is obtained. All these grids can be visited in different orders. The standard approach is to start on the finest grid, perform a number of pre-smoothing steps, then move to the coarser grid, again perform pre-smoothing, and continue this until the coarsest grid is reached. There, the exact numerical solution is computed and the resulting coarse-grid correction is prolongated back to the finer level, followed by a number of post-smoothing steps. This is repeated up to the finest grid. Such a sequence is called a V-cycle. A single V-cycle may be insufficient to obtain a convergence rate on the coarser grid that is similar to the smoothing rate on the finer grid. Convergence on coarser grids can be improved by performing more than one cycle. In the W-cycle, the number of cycles doubles on each coarser grid. Figure 2 illustrates the order in which grids are visited for a V-, W-, and F-cycle. The last one is less expensive than a W-cycle, as the number of cycles increases by only one for increasingly coarser grids. Another option, adaptive



Numerical Methods, Multigrid, Figure 2 (**a**) V-cycle, (**b**) W-cycle, and (**c**) F-cycle.

cycling, decides on the sequence of grids by monitoring the decrease of the residuals.

With a proper choice of relaxation scheme or smoother and grid transfer operators, the multigrid method can reach a grid-independent or h-independent convergence rate. This does not, however, mean that the amount of work required to reach a sufficiently accurate solution is proportional to the number of grid points N. The exact numerical solution differs from the true solution of the PDE because of the numerical error due to the discretization, typically with some power p of h. In the earlier example, the discretization is second-order accurate, so $p = 2$. Given this numerical error, convergence to machine precision is more than needed. An iteration error somewhat smaller than the discretization error should suffice. Therefore, more iterations should be carried out if a more accurate solution on a finer grid has to be computed. This leads to an overall complexity of $O(N\log N)$ rather than $O(N)$. Successive grid refinement, in which one first computes a solution on a coarse grid and uses that as an initial guess for the next finer grid and so on, enables removal of the factor $\log N$, assuming that a fixed number of multigrid cycles are used at each level. The combination of successive grid refinement with a multigrid solver is called Full Multigrid (FMG).

Nonlinear multigrid

One way to apply the multigrid method to nonlinear PDEs is the use of Newton's method. A multigrid solver is then applied to a linearization of the discretized nonlinear problem. An example is the computation of galactic gas flow (Mulder, 1986). Another approach is the use of the discretized nonlinear PDE inside the multigrid algorithm. This requires the full solution to be available on the coarser grids. In the example above, only corrections to the solution were represented on coarser grids. The Full Approximation Scheme (FAS) is a reformulation of the multigrid method that includes the full solution (Brandt, 1982). It requires a restriction of the full solution, $u^H = I_h^H u^h$, and of the coarse-grid forcing function, $f^H = L^H(I_h^H u^h) + \tilde{I}_h^H r^h$. The prolongation needs to be changed to $u^h := u^h + I_H^h(u^H - I_h^H u^h)$, where u^H is the sufficiently converged solution on the coarser grid and $I_h^H u^h$ the restriction of the latest fine-grid solution. The restriction operators for the residuals, $\tilde{I}_h^H$, and for the solution, I_h^H, do not have to be the same. Note that the coarse-grid problem, $L^H u^H = f^H$, can be interpreted in a different way: $L^H u^H = f^H = \tilde{I}_h^H f^h + \tau_h^H$. The fine-to-coarse defect correction, $\tau_h^H = L^H(I_h^H u^h) - \tilde{I}_h^H (L^h u^h)$, ensures that the coarse-grid equations maintain the accuracy of the fine-grid equations.

Nonlinear equations of the form $L^h(u^h) = f^h$ fit into this scheme. For $L^H(u^H)$, the same discretization scheme as on the fine grid can be adopted. Smoothing operators can be based on a local linearization of the residuals.

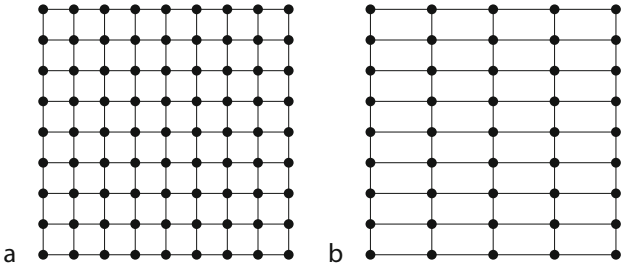
Generalizations

Multigrid is highly efficient for the solution of Poisson's equation on the square, discretized by the finite-difference method on a cartesian grid. For other PDEs, describing convection, diffusion, waves, flow, the method may be less easy to apply. The same is true for unstructured grids, for instance based on triangles or tetrahedra. With suitable modifications and at the expense of additional code complexity, the multigrid method can still be the optimal approach. With unstructured grids, the coarser and finer grid are generally not nested, leading to grid transfer operations that are less easy to code than on a cartesian grid.

Anisotropy in the PDE can degrade performance. Consider the equation

$$-\frac{\partial^2 u}{\partial x^2} - a\frac{\partial^2 u}{\partial y^2} = f(x,y).$$

For $0 < a \ll 1$, smoothing operators may have difficulty with the y-direction where there is only weak coupling between neighboring unknowns. Effective anisotropy in the discretized equation can also happen with grids that have widely different spacings in the various coordinate directions. A more powerful relaxation scheme may repair the poor performance of a simple smoother. For 2D problems, line relaxation will smooth in one direction and solve in the other. An example is line Jacobi relaxation, which approximates the matrix L^h by dropping the off-diagonals in one coordinate direction, while keeping them in the other. The dropped off-diagonals can be subtracted from the main diagonal with a suitable weight factor to obtain better smoothing properties. For 3D problems, plane relaxation is required, which may be too expensive. An alternative is semi-coarsening, where the coarse grid has the same number of points in the direction of weak coupling and is coarsened only in the direction in which the smoothing effectively removes the shorter wavelengths. Figure 3 shows



Numerical Methods, Multigrid, Figure 3 Semi-coarsening of grid (**a**) in the horizontal direction provides grid (**b**).

an example of a grid before and after semi-coarsening in the horizontal direction. In the more general case where semi-coarsening is required in all coordinates, it can be applied in alternating directions. A more costly but powerful approach is simultaneous semi-coarsening in all coordinates (Mulder, 1989), which still retains optimal complexity.

Beyond partial differential equations

The application of the multigrid method is not restricted to the solution of PDEs. There are generalizations to eigenvalue problems (Brandt et al., 1983), integral equations, optimization and optimal control (Borzì and Schulz, 2009), statistical physics (Kandel et al., 1988), image processing (Terzopoulos, 1986), image segmentation, and edge detection. In all cases, the simultaneous use of different scales overcomes the problem of slowly converging solution components.

Algebraic multigrid (AMG), or, better, algebraic multilevel method, refers to a class of solvers that construct sets of coarse-level equations without referring to grids or geometrical properties (Trottenberg et al., 2001; Shapira, 2008). Coarsening is applied to subsets of unknowns for which smoothing is effective. If the problem is specified by a large matrix, these subsets can be determined by examining the coefficients of the matrix. Strongly coupled unknowns, say u_i and u_j, are related by a matrix coefficient a_{ij} that is relatively large. In that case, smoothing is effective and one of the unknowns can be removed from the equations on the coarser level. The coarser level will then be mainly populated by weakly coupled variables. Operator-weighted grid transfer operators are natural in this context, as well as the Galerkin approach for the construction of the coarse-level operator. Algebraic multilevel methods are a popular choice for finite-element discretizations on unstructured grids, as they can be used as a black-box solver and do not require the tedious coding of grid transfer operations between non-nested elements.

Deflation (Vuik et al., 1999) is a technique that accelerates convergence of an iterative procedure if that is slowed down by only a few solution components. Their projection to a subspace that singles them out can be readily solved if the subspace is small.

The multigrid method bears some resemblance to other techniques such as wavelets, hierarchical-basis finite elements, multi-scale techniques, cyclic reduction, fast multipole methods, and other divide-and-conquer methods.

Geophysical applications

Multigrid has been applied successfully to a wide range of partial differential equations, describing static and dynamics problems, diffusion, convection, and flow problems. Examples in geophysics include elliptic problems in potential theory, such as gravity (Boulanger and Chouteau, 2001; Kusche, 2002), magnetostatics (De Gersem and Hameyer, 2001), electrostatics (Bailey and Cheesman, 1996), and Darcy's law in porous media flow (Schmidt, 1995). Controlled-source electromagnetics (Aruliah and Ascher, 2002; Mulder, 2006) and mantle convection (Trompert and Hansen, 1996) are examples of parabolic problems. The wave equation for seismic applications is a hyperbolic problem. Iterative solution of its frequency-domain formulation, the Helmholtz equation, was a notoriously difficult numerical problem but can nowadays be accomplished by using a damped version as preconditioner in a conjugate-gradient-type iterative scheme. Multigrid efficiently deals with the approximate inversion of the preconditioner (Erlangga et al., 2006; Riyanti et al., 2006).

Summary

The multigrid method provides an optimal iterative solution method for a wide class of problems governed by partial differential equations. Its application to a finite-difference discretization of Poisson's equation on a square is the easiest. For other problems, a bit more effort may be required.

Ocean bottom seismology

Introduction

Ocean bottom seismics, recording of seismic waves on the ocean floor by seismometers placed on the ocean floor, is becoming increasingly common both in academic research surveys and for hydrocarbon exploration. The main advantages of ocean bottom seismics over reflection seismics with hydrophone streamers (see *Seismic Data Acquisition and Processing*) are that the use of receivers on the seafloor yields sufficient source-receiver offsets to analyze the deeper crustal velocity structure, deploying multicomponent receivers allows recording of shear waves, and that instruments can be deployed for an extended time to record natural seismicity. In most cases, the seismic sources are either airguns towed on the sea surface or natural seismicity. Seafloor sources are rare.

Instrumentation

Seismic seafloor receivers fall broadly into three categories, (1) ocean bottom seismometers (OBSs), individual receivers that can be deployed and recovered without the need of any specialized vessels, (2) ocean bottom cables (OBCs), streamer-like arrays of receivers that are deployed from a specialized vessel, and (3) ocean bottom seismic nodes, individual receivers that require underwater vehicles for deployment and retrieval.

Ocean bottom seismometers

OBSs are individual stations that contain sensors and electronics for data storage (Figure 1). These instruments are deployed from a vessel, and descend to the seafloor weighted by an anchor. A release mechanism is activated toward the end of the survey, detaching the instrument from the anchor. The instrument then rises to the surface buoyed by flotation devices. The instrument is recovered onto the vessel where the recorded data are downloaded. The term ocean bottom seismometer is sometimes used for any instrument that records seismic waves at the seafloor, including OBCs and ocean bottom seismic nodes.

Communication with OBSs while on the seafloor is usually performed with acoustic transmission. This includes releasing the instrument from the anchor; although sometimes, a time-based release is used as backup in case communication fails. Acoustic communication is also used for determining the position of the instrument at the seafloor by triangulation and for checking the status of the instrument.

OBSs that contain only a hydrophone as receiver are often called ocean bottom hydrophones. Hydrophones record pressure waves in the water. Some instruments contain vertically oriented geophones, mostly in combination with hydrophones. But, more commonly used OBSs have 3-component geophones (one vertical, two horizontal components) or 4-component (4-C) OBSs that contain 3-component geophones and a hydrophone. The type of geophone varies, depending on application – usually 4.5 Hz geophones (geophones with a resonance frequency at 4.5 Hz) for active-source experiments. Broadband seismometers with varying frequency bands (with periods as low as several tens of seconds) are used for recording of natural seismicity. In a few cases, accelerometers

Ocean Bottom Seismics, Figure 1 Ocean bottom seismometer (instruments used by IfM-Geomar, Kiel, Germany).

(measuring particle acceleration rather than velocity as in geophones) are used to record seismic waves.

Seismic data are recorded continuously. Storage media have evolved from analogue tapes to hard drives and flash drives. Exact time stamps from an internal clock are critical for OBS records. GPS time synchronization is completed before and after deployment. Modern high precision clocks keep the deviation as low as 0.05 ppm (4.3 ms/day). For active-source experiments, the records are split into receiver gathers using shot times, usually in SEG-Y format. Data processing varies widely depending on the application and resembles that of land data. Some peculiarities of OBS records include unknown receiver locations, unknown orientations of the horizontal components, and a lack of continuous GPS time stamps. Typical specifications of a modern OBS are listed in Table 1.

Until the 1990s active-source OBS surveys typically involved 10–50 OBSs deployed along a seismic transect. Spacing between instruments for a survey targeting the deeper crustal structure typically was between 5 and 20 km, allowing traveltime analysis of wide-angle reflected and refracted arrivals. In the past decade, significant improvements in hardware and electronics have made instruments less expensive and shortened turnaround times. This has led to a number of experiments with considerably more OBSs allowing imaging of deep crustal structures and 3D traveltime analysis (e.g., Kodaira et al., 2000; Morgan et al., 2002).

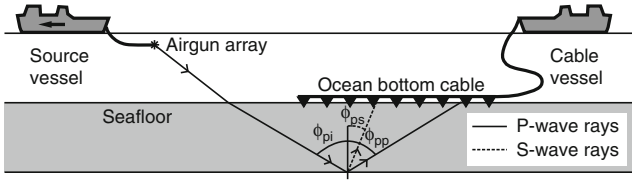
Advances in batteries and storage devices also make it possible to continuously record seismicity with OBSs for up to ~1 year. The use of additional batteries may extend this time window but even for frames and housing made of titanium, corrosion is a problem. Therefore a service recovery after ~1 year is good practice. Such passive-source experiments are becoming more common to study the earth's deep structure, subduction zones on regional scales, as well as seismically active local features such as mud volcanoes (Brueckmann et al., 2009). A combination of onshore and offshore seismological networks has shown to significantly improve the determination of near-shore hypocenters (Husen et al., 1999; Arroyo et al., 2009).

Ocean Bottom Seismics, Table 1 Specification of modern OBS

Recording channels	Min. 4 (hydrophone, 3-component seismometer) Optional additional channels for supplementary sensors (e.g., pressure, CH_4, temperature)
Sampling rate	20 Hz to 1 kHz (passive or active seismology)
Data capacity	Tens of GB with flash memory (lowest power) >50 GB with low power disk drives
Time stability	GPS synchronized prior and after mission Timing accuracy 0.05 ppm/0.03 ppm (2.6/4.3 ms/day; depending on power consumption)
Resolution	20 + bit, 32 bit ideally wanted (not yet available)
Power consumption	<250 mW when active (depending on sensors)
Time of operation	Depending on battery supply up to 1 year
Release system	Acoustic release (optional with additional time release); burn wires, gradually replaced by motor-driven hooks
Recovery aids	Radio beacon, flash light Optional: flag, shroud line

Ocean bottom cables

OBCs are densely spaced receivers attached to a cable. The cable is deployed from a vessel, usually a specialized ship (Figure 2). Seismic data are transmitted along the cable to be recorded on the vessel. Typical receiver spacing is 25 m. Most modern cables are equipped with 4-C receivers. Cables are often dragged



Ocean Bottom Seismics, Figure 2 OBC acquisition. Part of the downgoing P-wave energy is converted upon reflection to upgoing S-wave energy. ϕ_{pi}: angle of incidence, downgoing P-wave. ϕ_{pp}: exit angle, reflected P-wave. ϕ_{ps}: exit angle, P-to-S converted wave. Ray angles according to Snell's Law, that is, $\phi_{pi} = \phi_{pp}$ and $\sin(\phi_{ps})/V_s = \sin(\phi_{pi})/V_p$.

along the seafloor to achieve deployment in a straight line. Some OBCs use geophones that are being pushed into the seafloor by remotely operated vehicles (ROVs) to improve coupling to the seafloor. OBCs may also be deployed in trenches to improve coupling and reduce noise, such as for the Life of Field experiment for long-term monitoring of the Valhall oil field, North Sea (Barkved and Kristiansen, 2005).

OBCs allow imaging of the subsurface with similar coverage as surface-towed streamers. Furthermore, coupling between receivers and seafloor is generally far better than for OBSs partly because the mass of the recording equipment is much smaller, and partly because the deployment techniques for OBCs facilitate slight "burrowing" of cables into the seafloor. OBCs are widely used in the oil and gas exploration industry. The need for a specialized cable deployment vessel, however, normally makes OBCs prohibitively expensive for academic research to date.

Ocean bottom seismic nodes

Ocean bottom seismic nodes are individual receivers with independent recording units – essentially, OBSs without anchors and flotation devices. They are typically deployed with ROVs making their deployment relatively expensive compared to OBSs. Nodes are often deployed to fill coverage gaps in OBC surveys, for example, in the immediate vicinity of platforms where it is unsafe to deploy OBCs (or OBSs). Nodes are often pushed into the seafloor, which potentially leads to improved receiver coupling (Caldwell, 1999).

Ocean bottom seismic sources

By far the majority of active-source OBS surveys use pressure waves generated by airguns towed behind a vessel, although some ocean bottom sources have been pioneered, mainly to generate shear waves.

Explosives have been used as sources at the seafloor for an experiment to record shear waves in boreholes during Ocean Drilling Program Leg 156 but because of the strong increase of shear (S-) wave velocity with depth beneath the seafloor, rays were bent away from the borehole and did not reach borehole receivers (Peacock et al., 1997). Furthermore, environmental and health and safety concerns preclude large-scale use of seafloor explosives.

Imploding glass spheres are the source of the SEEBOSEIS system, for which glass spheres containing air at atmospheric pressure are punctured on the seafloor (Nguyen et al., 2009).

Shear-wave "sleds" are occasionally used to study the high-resolution shear-wave structure of the first few meters beneath the seafloor. One such system uses an electromagnetic coil to generate seismic shear energy at the seafloor. Receivers are dragged along the seafloor behind the source. This system has been used successfully, for example, to measure near-seafloor S-wave velocity offshore California (Huws et al., 2000).

Applications

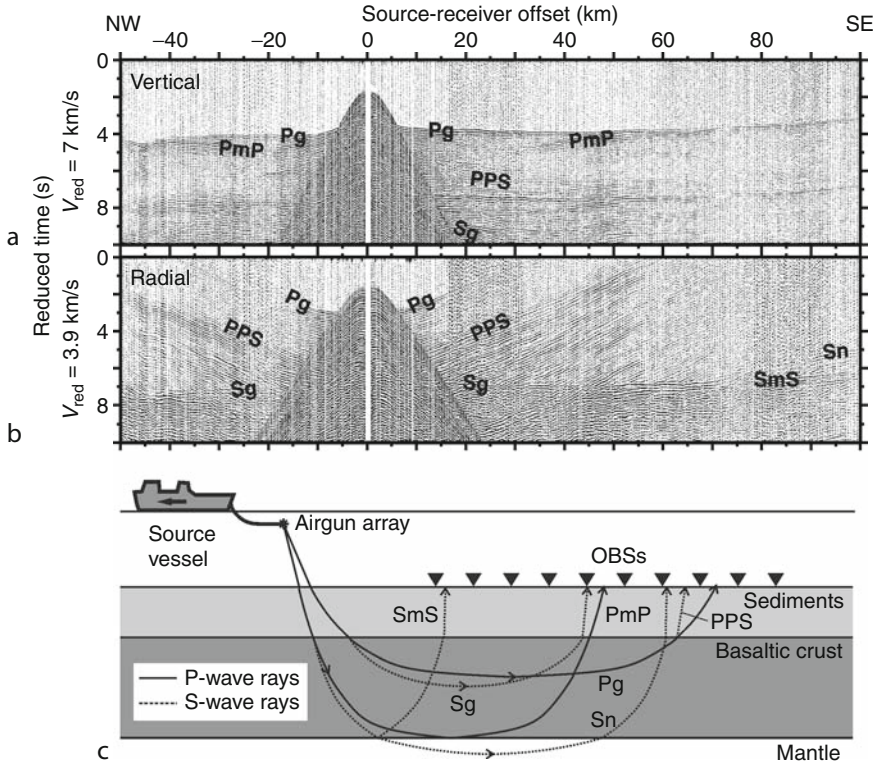
P-waves

OBSs have been used extensively in the last 4 decades to study the crustal structure beneath the seafour (see *Deep Seismic Reflection and Refraction Profiling*) from P-wave traveltime analysis. A typical survey, for example, for a transect across a subduction zone consists of 20+ instruments spaced between 5 and 20 km. Seismic shot lines with maximum offsets of often >100 km are acquired with a large (~4,000–8,000 cu-in = 65–130 l) airgun array. Often, a coincident seismic reflection profile is acquired with the shot vessel although, in order to avoid noise from previous shots to interfere with arrivals from deep targets, shot intervals for crustal OBS surveys should be much larger (~60 s, equivalent to 100–150 m shot spacing) than would be desired for reflection surveying (~15 s) (Christeson et al., 1996) (see *Single and Multichannel Seismics*).

Such a configuration typically allows recording of reflected and refracted arrivals down to the base of the crust as well as refracted waves through the upper mantle (Figure 3). Records are similar to those from land surveys, albeit often at considerably higher signal-to-noise ratio, and receivers and shots are reversed; land crustal wide-angle surveys typically have sparse shot and dense receiver spacing, whereas marine OBS surveys have dense shot but sparse receiver spacing.

Data processing often only involves bandpass filtering and amplitude scaling. Typical sources of noise or data contamination include reverberations particularly on horizontal components, previous-shot noise, water-column multiples, and noise from underwater currents that may shake the instruments.

As for land surveys, data are often displayed using a reduced traveltime ($t_{red} = t - x/v_{red}$, where t_{red}: reduced time, x: source-receiver offset, v_{red}: reduction velocity). The origin of arrivals is identified and their traveltimes are picked, followed by traveltime analysis to determine seismic velocities (see *Traveltime Tomography Using Controlled-Source Seismic Data*). The latter is performed based on ray-trace modeling (e.g., Zelt and Smith, 1992). In the past decade, traveltime inversion has become



Ocean Bottom Seismics, Figure 3 Example of an OBS record from offshore the Faeroe Islands with interpreted arrivals (after Eccles et al., 2009). (**a**) vertical component, (**b**) rotated radial component, (**c**) schematic ray paths. See text in chapter on converted waves for details on radial component. Reduction velocities 7 km/s for vertical component, 3.9 km/s for radial component. Arrivals P-waves: Pg: diving wave in the crust, PmP: reflection from the top of the mantle (Mohorovičić discontinuity). Converted S-waves: PPS: S-wave, converted upon transmission from upgoing P-wave at basalt-sediment interface. Sg: S-wave, converted upon transmission from downgoing P-wave at basalt-sediment interface and diving as S-wave in the basaltic crust. SmS: S-wave, converted upon transmission from downgoing P-wave at basalt-sediment interface and reflected as S-wave at the top of the mantle. Sn: S-wave, converted upon transmission from downgoing P-wave at basalt-sediment interface and diving as S-wave in the mantle. Courtesy Jennifer Eccles (University of Auckland, New Zealand).

common allowing better determination of the uncertainties and uniqueness of resulting velocity models (e.g., Korenaga et al., 2000). However, the uncertainty from potentially misinterpreting the origin of arrivals is difficult to quantify.

Coincident OBS and seismic reflection surveys are being used for high-resolution studies of the first few hundreds of meters beneath the seafloor, in particular to obtain velocity information in the gas-hydrate zone. Data analysis usually comprises joint analysis of reflected and refracted P-waves often with additional structural information from seismic reflection data (Hobro et al., 1998). Many of these experiments are designed to achieve 3D ray coverage, sometimes coincident with 3D seismic reflection data (Plaza-Faverola et al., 2010). OBS experiments designed for 3D traveltime analysis have also become more common for surveys targeting the deeper crust (e.g., Morgan, et al., 2002).

The increased availability of OBSs has also led to a number of surveys using OBSs with sufficiently dense spacing to allow imaging of deep crustal structures similar to seismic reflection data (e.g., Kodaira, et al., 2000). Advancements in wide-angle migration techniques are key toward successful imaging with OBSs (e.g., Talwani and Zelt, 1998). Imaging using OBSs is also improved by increased reflection coverage by utilizing rays from seafloor multiples, that is, rays that are reflected at the seafloor and sea surface, often referred to as mirror imaging (e.g., Grion et al., 2007).

High-resolution (sub-seismic-wavelength) P-wave velocities have been extracted from OBS data using 1D full-waveform inversion techniques similar to those applied to multichannel reflection data (Korenaga et al., 1997). Increases in computing power now also allow 2D visco-acoustic full-waveform tomography (Sourbier et al., 2009a, b) (see *Seismic, Waveform Modeling and Tomography*).

P-to-S converted waves

Identification of P-to-S converted (PS-) waves in horizontal-component records has led to a paradigm shift in ocean bottom seismics in the late 1990s and early 2000s by the

use of OBCs for multicomponent seismic exploration (Figure 2) (see *Energy Partitioning of Seismic Waves*; *Seismic Data Acquisition and Processing*). P-waves are generated on a shooting vessel. They are partly converted at layer interfaces to S-waves. Upgoing S-waves are then recorded with OBCs or sometimes, densely spaced OBSs. The most prominent PS-arrivals are usually arrivals that are converted from downgoing P-waves upon reflection to upgoing S-waves.

Processing sequences for PS-waves require additional steps compared to conventional P-wave seismic reflection data acquired with surface-towed streamers (Stewart et al., 2002). In particular, processing of PS-waves requires separation of P- and S-waves, a rotation of the horizontal components such that a maximum amount of energy is projected into a single component, the radial component, and various modifications to adjust for the asymmetry of the PS-raypaths. A key step of data analysis is the correlation of P- and PS-events. Once P- and PS-events from the same horizons have been identified, determination of the ratio of P-wave velocity (*Vp*) over S-wave velocity (*Vs*) is straight-forward (e.g., Granli et al., 1999).

Multicomponent PS-wave surveys are being conducted routinely by the exploration industry, chiefly with the following objectives:

Imaging through gas clouds. P-waves are attenuated significantly in gas-bearing layers, whereas S-waves are almost unaffected by gas. Converted-wave surveys often yield superior images of structures in and beneath gas-bearing sediments even though in many cases the downgoing P-wave still has to penetrate gas (Granli et al., 1999).

Fluid discrimination. Reflection strength of PS-waves is only marginally affected by the pore fill (through its effect on density). Therefore, flat spots, oil-water or gas-water contacts at the base of hydrocarbon reservoirs, which generate P-wave reflections, usually do not cause any noticeable PS-reflections (e.g., MacLeod et al., 1999). For the same reason, PS-waves may help establish whether high negative-polarity P-wave reflections (bright spots) are likely to be caused by gas in sediment pores.

Mapping of sand–shale interfaces. Sand and shale layers often have similar *Vp* and density, which leads to low P-wave reflectivity. However, because *Vs* in sands is usually considerably higher than in shales, sand–shale interfaces often cause strong P-to-S conversion and have been imaged successfully with PS-waves (e.g., MacLeod et al., 1999).

Lithology from Vp/Vs. *Vp* – *Vp*/*Vs* crossplots may be employed to delineate between sands and shales and to constrain the shale content of reservoir sands (Margrave et al., 1998). *Vp*/*Vs* may also allow to distinguish between different types of carbonates (Rafavich et al., 1984).

Fracture detection from shear-wave splitting. Near-vertical fractures common, for example, in carbonate reservoirs, causes an azimuthal dependence of velocities, azimuthal anisotropy (see *Seismic Anisotropy*). The propagation of S-waves that are polarized perpendicularly to fractures is slower than that of S-waves polarized parallelly to fractures. This leads to PS-waves being split into fast and slow waves, depending on the azimuth of the incoming P-wave, and allows determination of azimuth and magnitude of anisotropy, from which fracture orientation can be inferred (Gaiser et al., 2002).

In recent years, P-to-S converted waves have been utilized increasingly to study *Vs* in the Earth's crust (e.g., Eccles et al., 2009). Unlike for hydrocarbon exploration, with the aim of imaging the sedimentary section with S-waves converted from P-waves upon reflection, studies of the deeper crust often analyze traveltimes of S-waves converted from downgoing P-waves upon transmission. The sediment-basalt interface on the North Atlantic margin between the UK and Iceland, for example, provided a conversion horizon to allow determination of *Vs* in the deeper crust (Figure 3). *Vp* – *Vp*/*Vs* crossplots allowed lithological conclusions indicating mixing between continental crust and mafic intrusions across the ocean-continent transition and the presence of sub-basalt sediments on the Faeroe Margin (Eccles et al., 2009).

Wide-aperture (wide-azimuth) studies

Wide-aperture studies are increasingly conducted in the hydrocarbon exploration for "undershooting" in order to illuminate the subsurface beneath features that are difficult to penetrate with seismic energy and/or exhibit prominent localized velocity anomalies, such as gas clouds or salt domes: Rays in wide-aperture surveys may bypass these features and reach deeper targets of interest. The length of seismic streamers towed behind the same vessel that tows the airgun sources may not be sufficient for wide-aperture studies. Seismic arrivals at wide apertures may be recorded with surface-towed streamers by using separate vessels for sources and receivers. Alternatively, receivers deployed at the seafloor may be used. An acquisition campaign partly aimed at obtaining wide-aperture data across the Atlantis Field in the deep-water Gulf of Mexico involved 900 ocean bottom seismic nodes (Barley and Summers, 2007). 3D surveys with ocean bottom receivers also provide illumination of seismic targets from different azimuths (multi-azimuth surveys), which allows analysis for azimuthal anisotropy and may improve image quality. Wide-aperture seismic in the hydrocarbon exploration industry is often acquired as part of "seismic-on-demand" 4D surveys over permanently installed seismic surveillance systems such as at the Valhall Field (Barley and Summers, 2007 and references therein).

Passive-source seismology

The use of modern storage media has led to a decrease in power consumption and an increase of storage capacity allowing deployments of OBSs for several months to over

a year to record natural seismicity (Figure 4). Because of the lower frequencies of natural seismic sources usually, broadband geophones are used with a lower resonance frequency than the 4.5 Hz geophones typically used for active-source surveys. Both local seismicity and teleseismic events are being evaluated similarly to data from land-seismic records. Unlike for land data, however, receiver location and geophone orientation need to be established. Local noise conditions in the deep oceans vary significantly throughout the seasons, but in general, noise is higher than on well-placed land stations. In addition, the seismic waveforms are contaminated by water-column multiples.

A very different application of passive-source ocean bottom seismology is to measure seafloor compliance. Pressure variations from ocean waves (gravity or infragravity waves) are being transmitted into the seafloor. Seafloor compliance is the transfer function between pressure loading and seafloor deformation. This transfer function is determined as a function of frequency and depends largely on the subsurface shear modulus (Crawford et al., 1991). Pressure variations are typically recorded with differential pressure gauges, seafloor deformation derived from acceleration measured with self-leveling gravimeters. The frequency range of the analyzed pressure variations depends largely on water depth – because of the dispersion of ocean-surface waves, short-period waves are not transmitted into deeper waters. The resolution of subsurface shear-modulus analyses from compliance measurements decreases with decreasing frequencies. As an example, the frequency range for studying gas-hydrate-bearing sediments at 1.3 km water depth and 2 km beneath the seafloor was 0.003–0.049 Hz (Willoughby et al., 2008).

Future developments

One of the most significant challenges for autonomous OBSs is still the power supply. Both data loggers and storage media are becoming increasingly energy efficient. Together with new battery technology and further improvement of fuel cells, this is leading to reduction of weight and size of instrumentation. Some study areas may provide additional power sources, such as thermal energy. Weight and size reduction in modern instruments is achieved in most cases by installing all the components in a single glass sphere. On the other hand, glass spheres require increased service efforts and precautions compared to more robust, but larger and heavier titanium pressure casing.

The use of ocean bottom sensors in permanent ocean-floor observatories is likely to become more common. OBSs have already been installed for long-term monitoring at seafloor observatories (e.g., GEOSTAR, Beranzoli et al., 2003) and have been integrated in deployments for tsunami warning systems. These observatories generally have the capability of data transmission to shore. Regional studies usually require a deployment of an array of sensors distributed over an area of several square kilometers. Several seismic seafloor observatories have been established to study the seismogenic zone offshore of Japan and a network of 20 instruments is being developed as part of the Japanese Dense Oceanfloor Network System for Earthquakes and Tsunamis (Kaneda et al., 2009).

Combined seismic and electromagnetic field experiments are becoming more common as the combination of both methods is proving powerful for studying subsurface lithology (Constable and Srnka, 2007 and references therein). Despite significant technical challenges, especially with contamination of electromagnetic signals from the seismic instrumentation, it is conceivable that future ocean bottom instruments will include sensors for both seismic and electromagnetic waves.

The use of OBCs and nodes for hydrocarbon exploration and field appraisal appears to have become a “mainstream” technique. While costs for deployments of either type of instruments are still high compared to conventional 3D streamer seismic, they need to be weighed against the risk of mispositioning considerably more expensive appraisal wells (Barley and Summers, 2007). Furthermore, several hydrocarbon fields are now being monitored with permanent installation of ocean bottom sensors for repeat-seismic surveys in order to guide field development (Barley and Summers, 2007 and references therein).

Conclusions

The last decade has seen a substantial increase of ocean bottom seismic studies. While seafloor seismic sources are rarely deployed, the use of seafloor seismic sensors has established itself primarily for recording offshore wide-angle data, P-to-S converted waves, and natural seismicity. Academic research surveys, for studying the

deeper crustal structure, are usually conducted with autonomous OBSs, which are relatively inexpensive and versatile. Surveys by the exploration industry for evaluating and developing hydrocarbon reservoirs mostly involve deployment of ocean bottom cables or ocean bottom seismic nodes, which give superior data quality compared to OBSs but at much higher cost. In recent years, permanent deployment of instruments has become more common in ocean bottom observatories and for monitoring the development of hydrocarbon fields. The rapid development of ocean bottom seismic instruments is leading to improvements in reliability, data quality, and efficiency, which makes it likely that ocean bottom seismics will continue to expand significantly in the future.

Definition

The *oceanic spreading center*, also known as the midocean ridge, is an underwater mountainous feature lying between the two lithospheric plates, through which new magma material being continuously spread out and lead to growth of the lithospheric plates.

Ridge structure, partial melted mantle upwelled through the midocean ridge, forms a 3–6 km thick basaltic crust, but at a later stage the same crust moves away from the ridge crest and allows growth of mantle component.

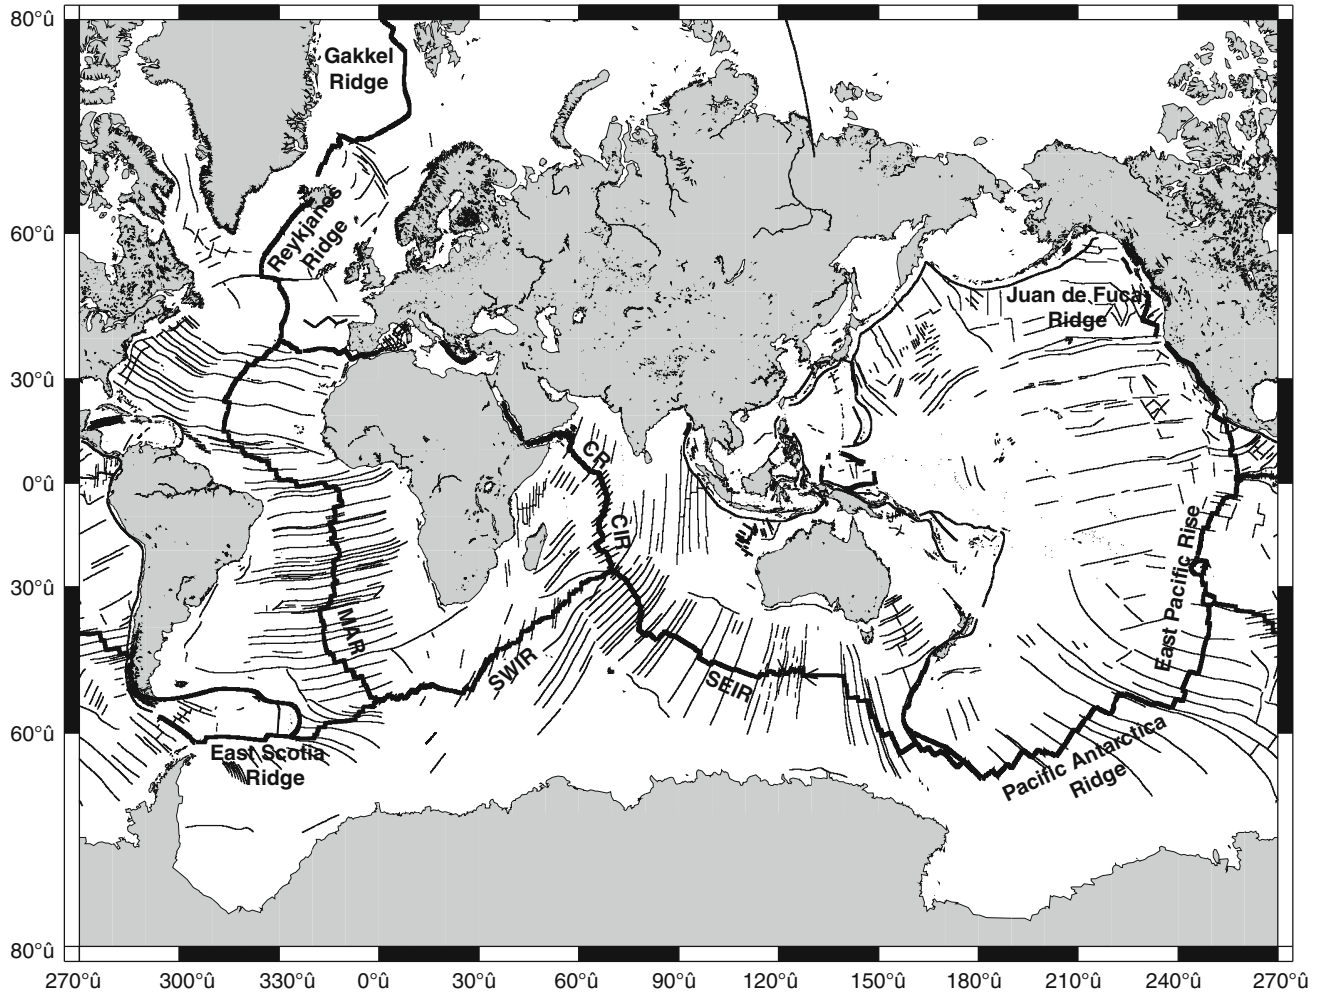
Introduction

The rigid surface layer (generally about 70–100 km thick) of the Earth comprising the crust and uppermost mantle, *termed as lithosphere*, is divided into a number of tectonic plates. Presently, there are about eight primary plates, namely, North American, South American, African, Indian, Australian, Antarctica, Eurasian, and Pacific; seven secondary plates; and several more tertiary plates covering the Earth's surface (for details, see wikipedia web site: http://en.wikipedia.org/wiki/List_of_tectonic_plates). The lithospheric plates are bounded by one of the three main types of geological features: (1) midoceanic ridges, (2) subduction zones, and (3) transform faults. The boundaries are narrow deforming zones and are associated with intense seismicity, whereas the plate's interiors are relatively stable. The plates upon which continents and ocean floor lie are in continuous motion at a speed of few centimeters per year. Each plate is in relative motion with respect to the other on the surface of the Earth. The relative motion produces new crust at midoceanic ridges and consumes old lithosphere at subduction zones. Apart from these tectonic processes, plates do undergo breakups and unifications through geologic time.

Morphology and spreading rates of midoceanic ridge

A midocean ridge is an underwater linear physiographic feature and serves as a divergent tectonic boundary between two lithospheric plates. The midocean ridges, those encircle the entire globe, are physically connected and extend for a total length of about 65,000 km as a single global entity in the world oceans (Figure 1). Many of the major oceanic ridges in the world oceans have been reconfigured in the geological past that led to unification and split of the lithospheric plates. One of the well-mapped ancient oceanic ridges in the Indian Ocean is the Wharton Ridge, once separated the Indian and Australian plates, and the ridge cessation at about 42 million years ago led to unification of both the aforesaid plates into a single Indo-Australian plate (Liu et al., 1983; Krishna et al., 1995).

On the ocean floor, long, linear, and elevated features are observed with variable seafloor undulations (Figure 2). They are the places where magma is continuously upwelling and being added to the previously formed oceanic crust on either side. The upwelling magma rates along the global midoceanic ridges are not fixed; they greatly vary with a range from 6 to 200 mm/year. Following the seafloor expansion rates, the midoceanic ridges are classified into categories of slow, intermediate, and fast spreading ridges. The Gakkel midoceanic ridge located in the Arctic Ocean between Greenland and Siberia (Figure 1) is the slowest spreading ridge with an upwelling magma rate of about 6 mm/year. On the other hand, the East Pacific Rise particularly in equatorial zone generates magma at the fastest rates up to 200 mm/year. The seafloor morphology on the flanks of the midoceanic ridge is largely controlled by the rate of seafloor expansions. Fast expansion spreading rates contribute to generally smooth and flat seafloor surfaces in the vicinity of the ridge, while the slow expansion spreading rates add exceptionally



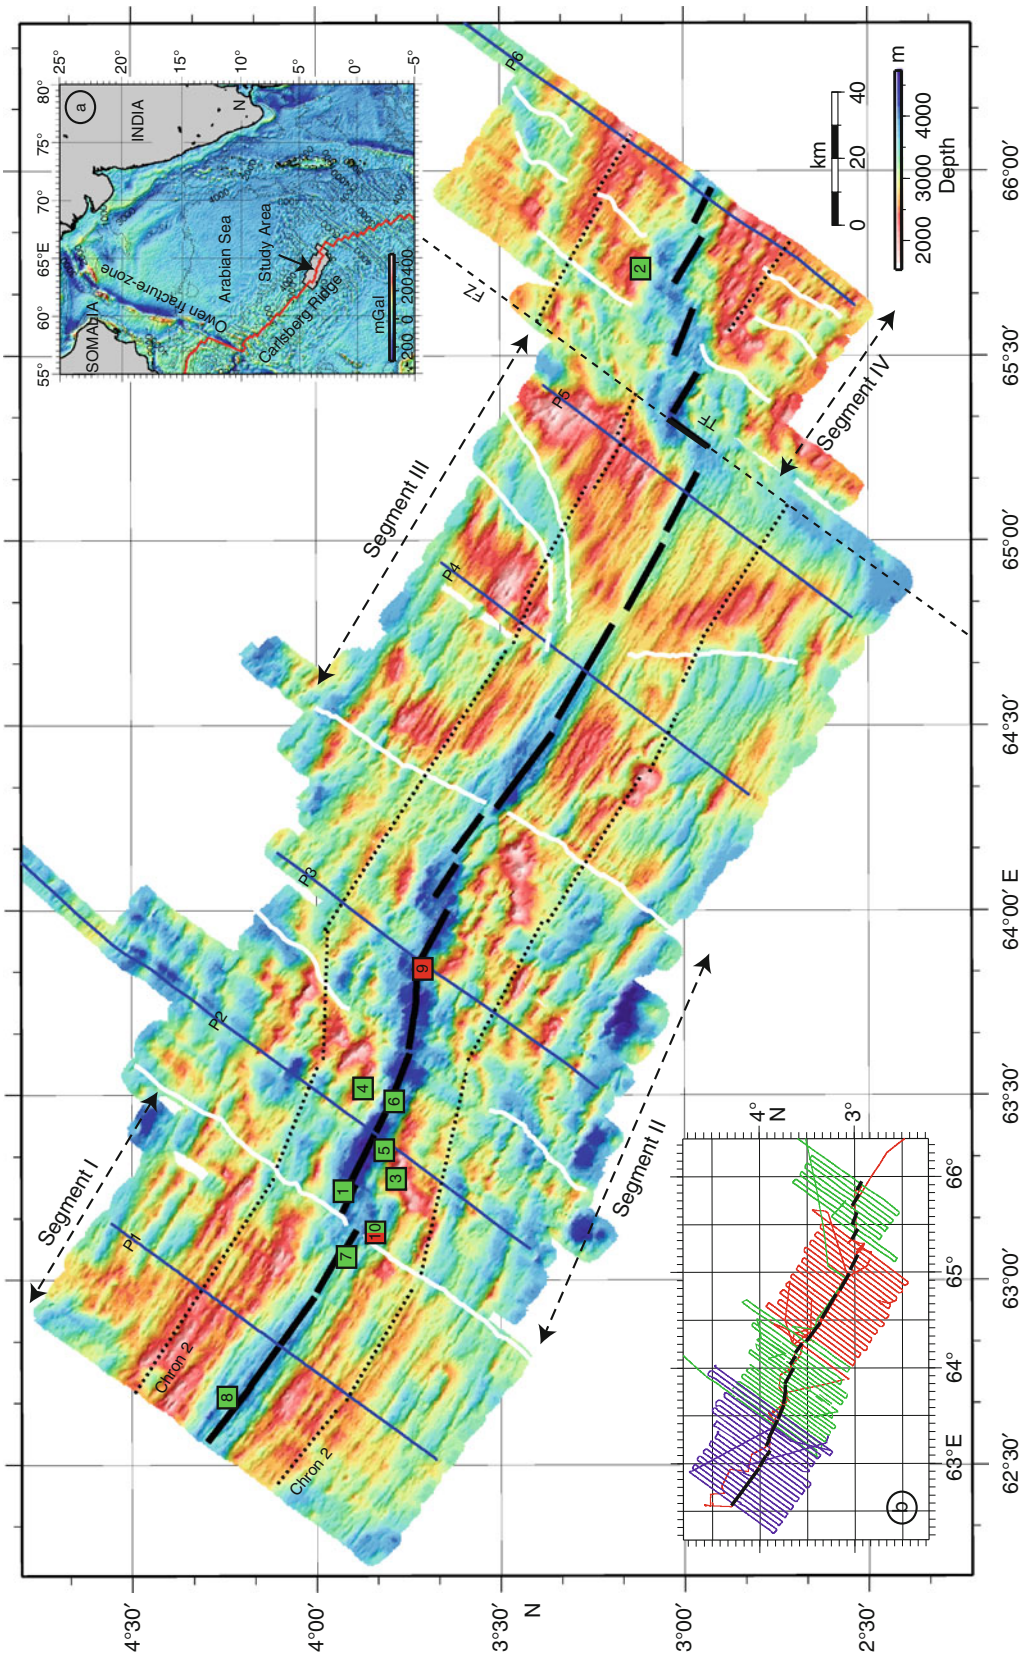
Ocean, Spreading Centre, Figure 1 General map of the global oceans showing midoceanic ridge system, subduction zones, and major fracture zones (after Royer et al., 1989; Müller et al., 1997). MAR indicates Mid-Atlantic Ridge in the Atlantic Ocean. CR, CIR, SWIR, and SEIR represent Carlsberg Ridge, Central Indian Ridge, Southwest Indian Ridge, and Southeast Indian Ridge, respectively, in the Indian Ocean.

rough surfaces. The slow spreading ridges are generally marked in their crest parts by an axial valley, called rift, which is clearly distinguishable along the Carlsberg Ridge in northern Indian Ocean (Figure 2). The ridge crest is strongly characterized by rugged topography, steep valley walls, and wide rift valley floor (Kamesh Raju et al., 2008). Further, the long ridge segment is bisected by less-known non-transform discontinuities.

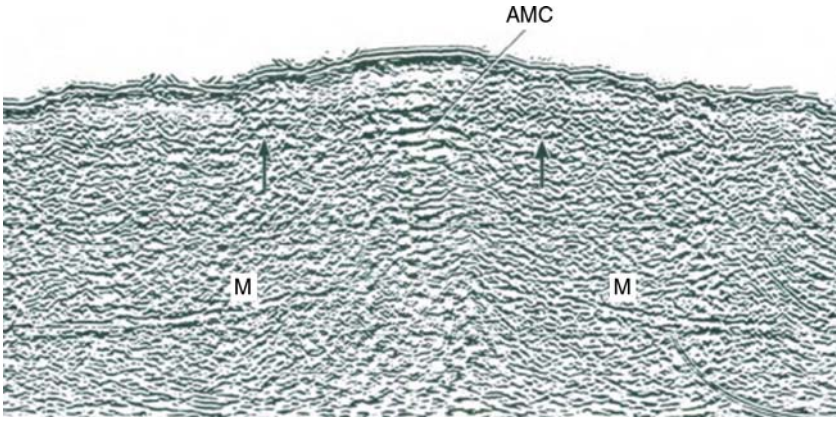
Internal structure of the midoceanic ridge

Along the midocean ridge, the lithospheric plates grow, which eventually lead to partial melting of the upwelling mantle and to form a layer of basaltic crust 3–6 km thick. Close to the ridge crest, the lithosphere may consist of oceanic crust only, but at a later stage the same crust moves away from the ridge crest and allows growth of mantle component due to thermal cooling. Both lithosphere and elastic plate thicken continuously with the age of the ocean floor until about 60 Ma and stabilize thereafter.

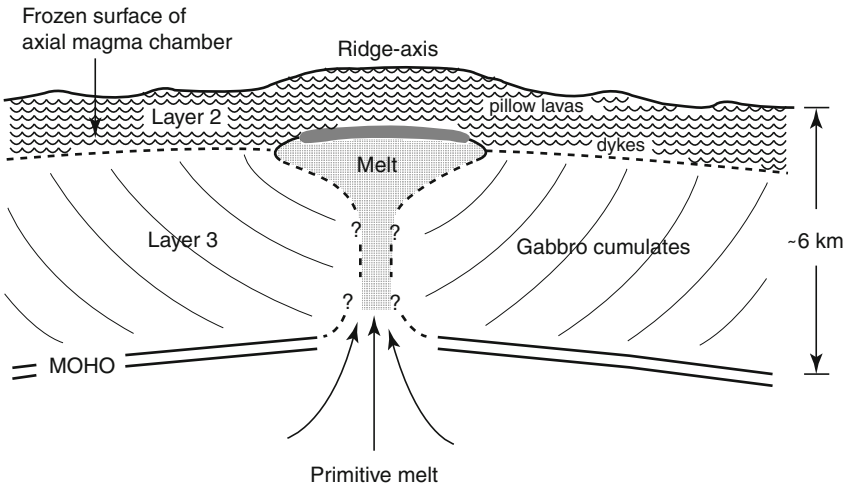
A seismic image across the East Pacific Rise is shown in Figure 3 (Detrick et al., 1987). It shows the reflections received from an interface present at about 6 s two-way travel time possibly marking a Moho boundary and reflections from a shallow event indicating the top of a crustal low-seismic-velocity zone (LVZ). Detrick et al. (1987) interpreted the top of the LVZ as the roof of an axial magma chamber (AMC) within the crust beneath the ridge axis. On either side of the chamber, the reflections are weaker and perhaps represent the frozen top of the magma chamber body (shown with arrows in Figure 3). Also, the reflections from Moho boundary are absent below the magma chamber. A sketch of the interpreted seismic structure of the East Pacific Rise is presented in Figure 4.



Ocean, Spreading Centre, Figure 2 Seafloor image of the Carlsberg Ridge segments, northern Indian Ocean. Inset maps a and b show the study area (*shaded box*) and cruise tracks over the segment of the Carlsberg Ridge. The image is reproduced from Kamesh Raju et al. (2008).



Ocean, Spreading Centre, Figure 3 Seismic reflection cross section across the East Pacific rise shows the internal structure of the oceanic crust beneath the ridge axis. AMC represents significant seismic signals reflected from the roof of an axial magma chamber. Solid arrows on either side mark relatively weaker reflections, perhaps representing frozen top of magma chamber, away from the ridge axis. M indicates the Moho boundary. The image is reproduced from Detrick et al. (1987).



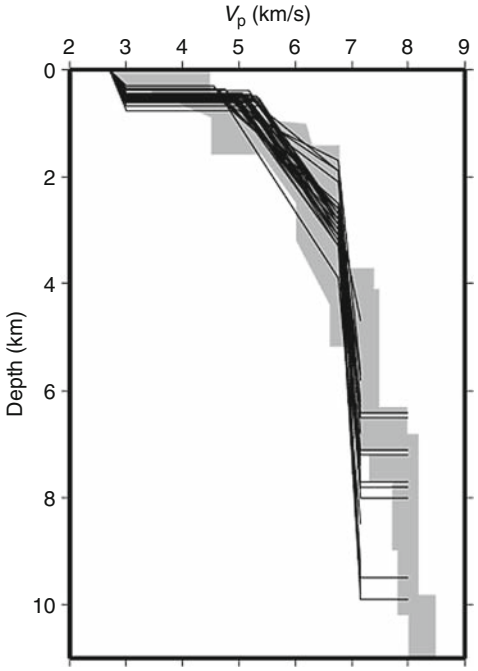
Ocean, Spreading Centre, Figure 4 A sketch showing the crustal structure beneath the East Pacific rise (Reproduced from Detrick et al., 1987).

Under some midoceanic ridge segments, it is found that the axial magma chamber is either small or absent altogether. For example, multichannel reflection experiment carried out on the Mid-Atlantic Ridge (Detrick et al., 1990) did not find evidences for the presence of intracrustal reflections associated with an axial magma chamber. Seismic experiments, in general, demonstrated that along slow-spreading ridges, magma chambers are either absent or extremely short-lived, if at all they exist.

Seismic experiment carried out on a ridge segment between 8° and 9°S of the Mid-Atlantic Ridge revealed largely a different seismic structure from that of the East Pacific Rise. In general, an axial magma chamber is not traceable within the Mid-Atlantic Ridge crust. Velocity models of the Mid-Atlantic Ridge segment (Minshull et al., 2003) suggest a total thickness of crust ranging from 6.5 to 10 km with individual layers 2 and 3 having thickness of approximately 3 and 5 km, respectively (Figure 5). The velocity heterogeneities are much greater in layers 2A and 2B, ranging from 2.65 to 3.0 km/s and 4.6–6.8 km/s, respectively, while the velocities in layer 3 are remarkably uniform.

Relationships between spreading rate, seismic structure, and ridge-axis morphology

Geophysical experiments over the global midoceanic ridges have led to the discovery of some explicit relationships between spreading rate, seismic structure, and ridge-axis morphology. Purdy et al. (1992) found that as full spreading rate decreases from 150 to 20 mm/year, the depth to the top of the axial low-seismic-velocity zone



Ocean, Spreading Centre, Figure 5 Velocity-depth profiles (*solid lines*) beneath the Mid-Atlantic Ridge segment between 8° and 9°S. Shaded region marks the range of velocities for 0–7 Ma Atlantic oceanic crust (White et al., 1992). The figure is reproduced from Minshull et al. (2003).

(LVZ) increases from ~1 to ~4 km. In another study, Minshull et al. (2003) established a relationship between crustal thickness and ridge-axis morphology at constant spreading rate. The ridge segments having large crustal thicknesses are associated with rifted axial highs, whereas the segments with reduced crustal thickness have deep axial valleys. Investigations over the midoceanic ridges have also proven that they are important locations for metallic mineral deposition (Rona, 1980).

Summary

A midocean ridge, an underwater mountainous feature, extends for a length of about 65,000 km as a single continuous body in the global oceans. It is a window to the Earth's interior, through which magma is continuously upwelling and drives the lithospheric plates on either side in order to accommodate newly accreted crust. Many of the oceanic ridges in the world oceans have been abandoned in the geologic past and led to resume the activity elsewhere either in the intra-oceanic or intracontinental plate regions. Partial melted mantle upwelled through the midocean ridge forms a layer of basaltic crust 3–6 km thick, but at a later stage the same crust moves away from the ridge crest and allows growth of mantle component. The upwelling magma rates along the mid-oceanic ridges, in general, control the internal structure. Fast spreading ridge such as East Pacific Rise has an axial magma chamber (AMC) at a shallow depth within the crust, whereas beneath an intermediate spreading ridge, the Mid-Atlantic Ridge, an axial magma chamber, is not traceable. Geophysical experiments over the global midoceanic ridges have found some explicit relationships between spreading rate, seismic structure, and ridge-axis morphology.

Definition

Intense deformation of the oceanic crust in the middle of the Indo-Australian plate is not anticipated as per the theory of plate tectonics, because the plate's interiors are considered rigid, and deformation area is limited to narrow zones occurring at the plate boundaries only. Compression is an accepted mechanism for the deformation and related to plate end dynamics, spreading ridge push and slab drag at trench, its temporal and spatial evolution is still being debated. The recent scientific studies results should provide more evidences in support of early Neogene origin of the Himalaya and its backward push resisting northward motion of the Indian Plate resulting in compression and the deformation of large areal extant in the Indian Ocean.

Introduction

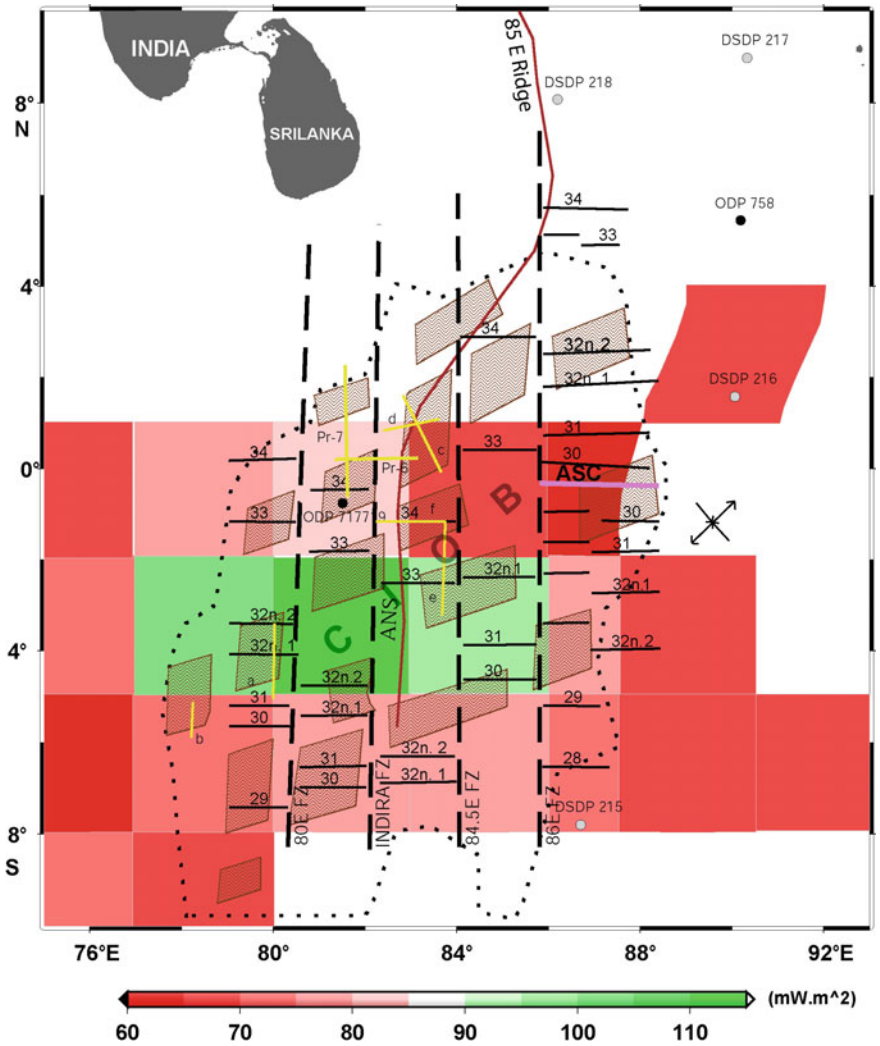
Deformation of the late Cretaceous crust of the Central Indian Ocean Basin (CIOB) in the middle of the Indo-Australian plate between 5° N and 10° S (Figure 1) is puzzling and is contrary to the paradigm that plate's interiors are rigid and deformation occurs at plate ends only. Seismic imaging of the upper crust and overlying sediments of the CIOB area have revealed intensely deformed crust consisting of anticline structures. Satellite Free-air gravity anomalies show E-W structural trends. The mid-plate deformation area is ~1,600 km wide and ~3,300 km long between the Central Indian Ridge in the west (CIR) and Sunda Trench (ST) in the east. Gordon et al. (1998) named it as "Diffuse Plate Boundary" between India and Australia. The putative boundary has deformed along its entire length as the plates jostle against each other (Kerr, 1988). But earthquake focal mechanism studies suggest north-south crustal deformation due to compression in CIOB and right-lateral strike-slip faults along the Ninetyeast Ridge (NyR), bounding the deformation area in the east (Stein and Okla, 1978). Microseismicity studies indicated episodic tectonic activity in the deformation zone (Neprochnov et al., 1988). Recent seismic reflection investigations have noted periodic deformation of Miocene (7.5–8.0 Ma), Pliocene (5.0– 4.0 Ma), and Pleistocene (0.8 Ma) ages due to in-plane (spreading ridge push from south) compressive forces (Krishna et al., 2001b). Closely spaced high-angle faults (Figures 2b and c) and tight folds are the characteristic features marking intense deformation. Subsidence of the crest of anticline structures against vertical faults (Figure 2d) indicates extension in compressional regime. Strike-slip faults with some dip-slip component near the CIR, right-lateral strike-slip faults and north-south compression of the CIOB, and left-lateral strike-slip faults and north-south compression of the Wharton Basin (WB) adjoining CIOB in the east are the striking dissimilarities in strain pattern noted from earthquake focal mechanism solutions (Delescluse and Chamot-Rooke, 2007). But the time of initiation of deformation in this region is not known for certain.

The characteristic anticline structures, 100–300 km long, 1–3 km high, and sediment-filled troughs, are bounded by longitudinal fractures zones (Fzs.) and east-west faults extending to basement (Figure 1). They are superposed by short wavelength E-W folds within the sediments at the crest (Figures 2a, c, and d) and high-angle reverse faults (Figure 2b). These are explicit expressions of ongoing tectonics of the deformed crust and overlying sediments. The style of deformation and strain pattern in the CIOB and at the three plate (India, Australia, and Capricorn) boundaries are site-specific and mark varied mechanisms of deformation and localized tectonics of the present and past times as well.

Several geophysical investigations including Deep Sea Drilling studies have been carried out in the area to understand physical processes and onset time of deformation. According to these studies, the deformation occurred by one of the following processes: (1) in-plane compression created by the plate end geodynamics and resistive forces, (2) thermo-mechanical subsidence under excess loading of igneous material initiating lithosphere flexure and eventually leading to crustal deformation under compression, or (3) periodic deformation due to resistive forces (backward push) due to the stationary Himalayas and plate end geodynamics – ridge push from the south and slab drag at the trench in the north. Even though, it is generally accepted that the mountain-building activity at the plate end in north and deformation of the CIOB are tectonically related, the Himalaya's temporal and spatial evolution has always been debated and it still remains a big scientific question. Furthermore, it is not clear whether the lower crust and entire lithosphere are involved in the deformation. The lower crustal (oceanic crust 3A) P-wave velocity (7.9 km/s) beneath the anticlines was found to be anomalously low (Louden, 1995; Neprochnov et al., 1998) and could not be unambiguously explained by any single physical process in the absence of further evidences. An overview of recent investigations on temporal evolution of the Himalayas and Tibet plateaus, structure of the northern Indian Ocean crust and sediments and sedimentary basins tectonics of the northwest continental margin of India (WCMI) is presented in the following, which shall provide some crucial evidences to address some of these points raised above.

Temporal evolution of the Himalaya and Tibetan Plateau

Geologic structure and tectonics of the Tibetan Plateau have been investigated extensively to constrain temporal



Oceanic Intraplate Deformation: The Central Indian Ocean Basin, Figure 1 Mosaic of deformed crustal blocks. Heat flow budget shown in color coded rectangular grid. Black dotted (closed line) is the limit of the deformed blocks imaged. *FZ* fracture zone, *ASC* Abandoned Spreading Center, *ANS* Afanasy Nikitin Seamount. Arrows are compression/extension directions. (Modified after Gopala Rao et al. (2004), heat flow budget from Delescluse and Chamot-Rooke (2007)).

evolution of the Himalayas. The most significant observations are: (1) fossil leaf assemblages (Spicer et al., 2003) and stable isotope Paleo-altimetry studies (Rowley and Currie, 2006) of the southern and central Tibetan plateaus, respectively, which indicate that the plateau attained its present elevations, (~5,000 m) long before 8 Ma and sometimes between 15 and 35 Ma ago instead of rapid increase in height. (2) Rapid denudation of the Tibetan Plateau occurred during 21 to 15 Ma ago (Harrison et al., 1992), leading to flat surfaces of the plateau of the western Himalayas and the southwest Tibetan Plateau areas requiring the same geological processes and the time of formation (Unsworth et al., 2005), (3) the existence of high Himalayas prior to 15 Ma leading to push southwards causing the crust deformation in CIOB (Gordon, 2009). Paleogene granetoids, relicts of the intra-oceanic island-arc assemblages are observed beneath the Himalayas and Tibetan Plateau. Aitchison et al. (2007) have proposed the existence of Cretaceous back-arc basin island-arc and its closure ~20–25 Ma after the initial collision 50–55 Ma (Muller, 2010), (4) diachronous uplift of the Tibet Plateau (Chung et al., 1998) and trench migration (Capitanio et al., 2010) immediately after initial collision of the Indian Plate with Eurasian Plate infer the early mountain ranges building. The contemporaneous tectonics and geologic processes can be considered to support the early temporal evolution of the Himalayas and its impact on the deformation of the CIOB crust.

(**c**) Long wavelength fold superposed by closely spaced folds bounded by vertical faults extending to basement. (**d**) Long wavelength fold with subsided crest part against normal faults. (Modified after Neprochnov et al. (1998)).

Crustal processes in the northern Indian Ocean and CIOB

Recent geophysical investigations have brought to light several anomalous crustal processes that could be explained by plate end geodynamics, and are discussed in the following sections.

The northern Indian Ocean

Pause in the seafloor spreading during Oligocene, 42 to 24 Ma, in the East Arabian Sea (EAS) (Chaubey et al., 1998), late Oligocene-mid Miocene turbidite sediments in the EAS (Clift et al., 2002; Gopala Rao, 2008) and in the Bay of Bengal (Gopala Rao et al., 1997; Gopala Rao, 2008), rapid subsidence of sedimentary basins of WCMI during late Oligocene and Miocene (Whiting et al., 1994), and the deformation of the CIOB crust/lithosphere prior to 20 Ma are contemporaneous and unique imprints noting active geological processes of the northern Indian Ocean. Lower Miocene age turbidites are possibly eroded from the high Himalayas and Tibetan Plateau and some of them reaching beyond equatorial region. Therefore, the anomalous crustal features shall mark the period of active tectonics in the northern Indian Ocean crustal processes.

The central Indian Ocean Basin (CIOB)

The CIOB crust in Figure 1 is late Cretaceous according to seafloor spreading magnetic isochrons 34 to 28 (Norton and Sclater, 1979). It is diachronous in age in the east as an extra oceanic crust was transferred between 86° E Fz (Fracture Zone) and NyR (parallel to 90° E) from Antarctic plate to Indian Plate during 60 and 42 Ma (Krishna et al., 1998). Furthermore, Abandoned Spreading Centers (ASCs) are also observed in the CIOB (Figure 1) and its adjoining regions. A 1.5-km high and 10-km wide structure associated with 8 mGal gravity high is present in center of a trough between anticlines associated with long wavelength gravity low of 20 mGal. It has been identified as serpentinite diapires structures of Paleogene age (Krishna et al., 2002). The low P-wave velocities of the oceanic layer 3A of the anticline structures infer serpentinites at subcrustal level.

Presence of serpentinites rocks along flanks of the volcanic Afanasy Nikitin Seamount (ANS), an edifice (~3.5 km in length, ~1.6 km wide and ~3.5 km high) of subaerial origin of the late Cretaceous in the middle of the deformation area, has been reported by Murdmaa et al. (1998). The tectono-magmatism, spreading ridge migration onto earlier evolved oceanic crust and presence of heterogeneous

(semi-ductile-serpentinites) crustal rocks point to reheating of the diachronous age crustal rocks in the CIOB area during the geological past (Figure 1). Due to the ongoing tectonism the crustal layers response might vary resulting varied physical properties of the lower crust rocks and contributing to selective deformation in the anomalous area. Kasintsev and Sborshchikov (1998) from analyses of the magmatic rocks collected along flanks of the ANS during MIR submersible cruise have noted evidences for continued tectono-magmatism since Paleocene. The tectonism might have as well prevailed in the CIOB as the ANS is placed in the middle of the deformed zone under compression. The diapires are characteristic features of the deformed crust blocks that evidently confirm compression tectonics as major component (Figures 2a and b) and early tectonics. A mosaic of the deformed crustal blocks/anticlines imaged in the CIOB (Neprochnov et al., 1998) and superposed gridded heat flow (Delescluse and Chamot-Rooke, 2007) (Figure 1) show wide deformation around the chain of the ANS of large dimension and excess heat flow around the emplaced igneous rocks.

Pelagic (pre-fan sediments) and pre-deformation sediments above the basement are ~1.6 s and 1.2–1.4 s thick, respectively. They are 1.5–2.2 s (TWT) thick in the south and 2.3–2.6 s in the north of the deformation area (Levchenko and Milanovsky, 1998) (Figures 2a–d). Numerous elongated seafloor rises of 15–20 m highs and about 45 km wide features are superposed along crests and flanks of the deformed blocks (Figure 2a).

The NE to ENE – SW to WSW trends of the free-air satellite gravity anomalies of the Wharton Basin (WB) to the east of the CIOB (Louden, 1995) differ from E-W trends of the CIOB. Furthermore, the anticline structures consist of low velocity (~7.9 km/s) oceanic crust, layer 3b (Figure 3a) (Neprochnov et al., 1998). High average heat flow of 65 mW/m², which is 12 mW/m² higher than average of 54 mW/m² for the 70 Ma age crust of the CIOB (vary from 44 to 161 mW/m²), was observed by Verzhbitsky and Lobkovsky (1998). Each deformed blocks heat flow and the high anomalous heat flow associated with the ANS reflect excess heating of rocks of the CIOB area.

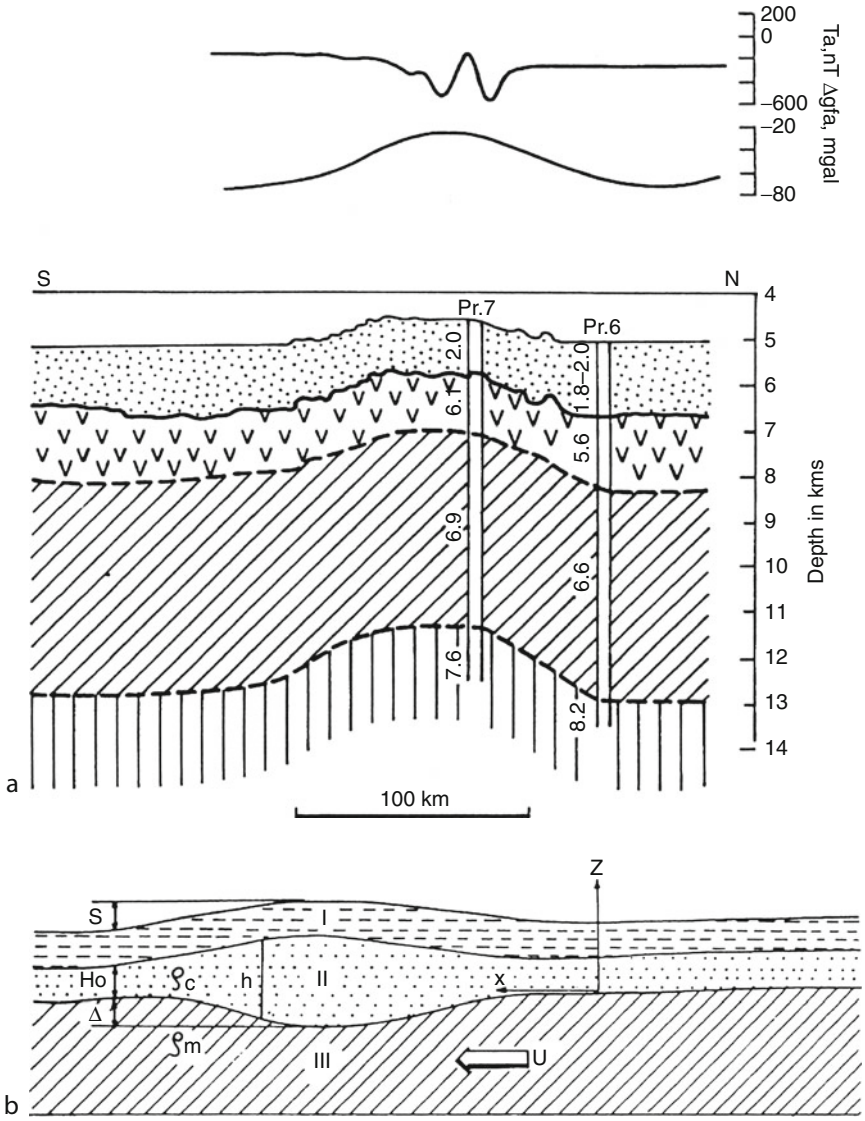
The mass sediment fluid flows, turbidites of the northern Indian Ocean, seafloor spreading processes in the EAS, and rapid subsidence of the WCMI sedimentary basins mark intraplate kinematics. The high mountain ranges' eroded sediments have reached the ocean basins since beginning of Neogene. The Cretaceous Paleo-Tethys Ocean (comprises of continental margin, mid-plate volcanic island-arc and back-arc basin) volcanic island-arc subduction was suggested 20–25 Ma later to initial plate's collision (Muller, 2010). So, it is possible that there was pause in plate motions due to the subduction of island-arc during the initial stage (locking) as it is likely to diminish northward slab pull decelerating India's northward motion and seafloor spreading in the EAS. On completion of subduction of the arc and closure of Cretaceous back-arc basin (unlocking) the subduction slab pull force had resumed at plate boundary in the north, which might have allowed resumption in seafloor spreading in EAS. Therefore, the high raised Himalaya's erosion has contributed to the turbidite sediments that are traced up to 8° S in the northeast Indian Ocean. Periodic crustal deformation was observed in CIOB and was attributed to the Himalaya's Tectonics (Krishna et al., 2009b). Paleogene granetoids of island-arc beneath the Himalayas/Tibetan Plateau mark suturing process at plate end in the north prior to the subduction. The turbidites, seafloor spreading, and the basin's tectonics are result of plate end geodynamics at least since ~30 Ma. The onshore and offshore geologic records can be considered to mark tectonics of the Himalayas; especially the outward push shall indicate crustal deformation (extension and compression) of the CIOB crust in a wide area. It implies that the selective deformation in CIOB is due to anisotropic geologic structure, which favored the deformation besides plate end geodynamics.

The observed intense intraplate oceanic crust deformation and the associated geophysical signatures can be explained assuming three-layer oceanic crust consisting of oceanic layers 2, 3A, 3B (Figure 3a), and two-level plate tectonic model (Figure 3b) similar to the one suggested earlier by Lobkovisky (1998). The low velocity viscoelastic serpentinites creep reported in the lower crust might have evolved either in situ due to dewatering during the deformation process or was part of crust/lithosphere during the seafloor spreading process and moved northward as a part of oceanic plate. The changes in rheology and the presence of the viscoelastic creep in the form of serpentinites possibly favored the selective deformation in the middle of the large Indo-Australian plate, culminating in the spatial and temporal variation of deformation and their geophysical signatures. Beneath the Tibetan plateau also mid-crustal fluid flows are inferred from resistivity and seismic reflection images and was inferred for the tectonics and uprise of the Himalayas/Tibet (Unsworth et al., 2005). The records of folded sediments along flanks and subsidence at the crest of the deformed blocks indicate later stage tectonics, reactivation, and deformation. During the ongoing tectonic process, the penetration of faults to subcrustal lithosphere, thrust faults reactivation, and development of series of syn-genetic faults at upper brittle crustal levels might have occurred.

The fault and structural style, temporal and spatial variations in compression and stress/strain distribution, and the long and short wavelength deformations of the crustal blocks are explicit expressions of the regional and localized tectonic processes. Despite the best effort to unravel the temporal and spatial evolution of deformation, it is not yet possible to explain whether the deformation is confined to crustal (upper?) level only or the entire lithosphere is involved.

Summary

Intense deformation of the late Cretaceous oceanic crust of the Central Indian Ocean Basin (CIOB) in the Indian Ocean equatorial region, between the Central Indian Ridge



Oceanic Intraplate Deformation: The Central Indian Ocean Basin, Figure 3 (**a**–**b**): (**a**) Illustrates modeled three layered crustal structure associated gravity and magnetic anomalies and refraction velocities across deformed crustal block. Dotted-sediments, v-oceanic layer 2, oblique lines-oceanic layer 3 and vertical lines-mantle. Numbers-refraction velocities in km/s obtained along profiles across deformed block. (**b**) Crustal model of two-level plate tectonics. ρ_m and ρ_c are the densities of the mantle and crust, respectively. I, II, and III are upper crust, lower crust, and mantle, respectively. *Open arrow* shows direction of the compressional stress. S-amount of deformation at the top of the upper crustal level. Δ-amount of deformation at mantle. *h* and H_0 are thickness of viscoelastic layer beneath the deformed block and in case of normal crust, respectively. (Modified after Lobkovisky (1998) and Neprochnov et al. (1998)).

(CIR) in the west and the Sunda Trench (ST) in the east, is noted for ongoing, periodic, and plate end geodynamics especially resistive forces of the high Himalayas against the northward moving Indian plate oceanic crust.

The tectono-magmatism, spreading ridge southward migration onto the already evolved late Cretaceous oceanic crust and large extrusion of volcanics in the form of voluminous seamounts of the area during early Tertiary and Eocene are unique geodynamic crustal processes that might as well contribute to altered thermal regime of the past and changes in crustal rocks properties responding differently to external forces.

The numerous onshore and offshore proxy evidences shall support the early Neogene origin of the Himalayas, which contributed to the southward push onto northward moving oceanic crust since their formation.

The question unanswered is whether deformation is limited to crust only or entire lithosphere, which needs to be understood by probing deeper parts of the lithosphere as it is classical example of crustal deformation.

P

PALEOMAGNETIC FIELD INTENSITY

Andrew Biggin, Neil Suttie, John Shaw
Geomagnetism Laboratory, University of Liverpool, Liverpool, UK

Synonyms

Archeointensity; Paleointensity

Definition

Absolute paleointensity: a paleomagnetic measurement of geomagnetic field intensity recorded at the time and place that a measured material acquired a thermoremanent magnetization.

Archeointensity: an absolute paleointensity estimate produced from a material (frequently, a heated archeological artifact) which acquired its thermoremanent magnetization in archeological times.

Relative paleointensity: the record of relative geomagnetic intensity variations measured from the natural remanent magnetization of sedimentary rock samples.

Cosmogenic isotope paleointensity: the record of relative geomagnetic intensity variations measured using the concentration of cosmogenic isotopes as a proxy.

Introduction

Direct measurements of the intensity of the geomagnetic field only became possible in 1832 when a method of obtaining them was developed by Carl Frederich Gauss (Stern, 2002). If we wish to know how the field intensity has varied before this time, then we are required to use the geological and archeological records to make indirect measurements. Paleomagnetic approaches are based on the principle that, for weak fields such as the Earth's, the intensity (M_{anc}) of the natural remanent magnetization (NRM) recorded by a material is linearly proportional to the strength (H_{anc}) of the paleofield. For absolute paleointensity measurements, the material in question must have acquired a thermoremanent magnetization (TRM) whereas, for relative paleointensity, it is required to be a depositional (DRM) or postdepositional (pDRM) remanent magnetization. Unfortunately, for all types of remanence, the constant of proportionality linking the magnitude of the NRM to the paleofield intensity is a sensitive and complicated function of the magnetic properties of the recording material and extremely difficult to measure directly. Absolute paleointensity experiments obviate this difficulty by imparting the sample with a new TRM (M_{lab}) in the laboratory by heating the sample up and cooling it in a controlled field of known intensity (H_{lab}). The linear relationships between M and H can then be combined to eliminate the constant and solve for the ancient field intensity:

$$H_{anc} = \frac{M_{anc}}{M_{lab}} H_{lab} \quad (1)$$

Depositional-type remanences cannot be reliably reproduced in the laboratory and therefore paleointensity experiments performed on sediments produce records only of relative *variations* in H_{anc}.

In order for any type of paleointensity measurement to be useful, an independent estimate for the age of the magnetization (often assumed or demonstrated to be the same age as the material) is usually required.

Absolute paleointensity measurements

Absolute paleointensity experiments may only be performed using materials which have cooled from elevated temperatures in nature and which therefore possess a TRM imparted by the ambient (geomagnetic) field. Materials that may be used include any fired archeological materials (ceramics, kiln lining, hearths, burnt bricks,

Harsh K. Gupta (ed.), *Encyclopedia of Solid Earth Geophysics*, DOI 10.1007/978-90-481-8702-7,

etc.), most types of igneous rocks, and metamorphic rocks (e.g., baked sediments), which have been extensively reheated.

Producing unequivocally accurate measurements of the absolute paleointensity is extremely demanding since there are a large number of factors which can potentially bias the estimate. The list below describes the criteria that a hypothetically ideal absolute paleointensity estimate would meet.

1. The remanence carriers must retain a pure TRM and have undergone no chemical or physical changes since cooling beneath their Curie temperature (see e.g., Fabian, 2009).
2. Any secondary components of magnetization (e.g., viscous or isothermal overprints, see *Remanent Magnetism*) must be removed so that the primary TRM is isolated.
3. The remanence carriers must undergo no chemical or physical alteration as a consequence of the laboratory heating that is required to obtain the paleointensity (or this must be corrected for; see, e.g., Valet et al., 1996).
4. The remanence carriers should be noninteracting single domain grains or at the least, it must be shown that multidomain, vortex state, or magnetically interacting grains are not biasing the measurement by violation of Thellier's laws of thermoremanence.
5. Any anisotropy of TRM must be avoided or corrected for (see e.g., Selkin et al., 2000).
6. Any effect that the difference in the cooling rate between the natural and laboratory cooling cycles has on the calculated paleointensity must be corrected for (see e.g., Perrin, 1998).
7. Any deviation from Thellier's law of linearity must be detected and corrected for (Selkin et al., 2007).
8. The number of individual sample estimates from a single rock unit or archeological horizon must be sufficient to obtain a reasonable mean and to demonstrate internal consistency (see e.g., Biggin et al., 2003).

The high failure rates and time-consuming nature of many absolute paleointensity studies has stimulated a wealth of innovation in terms of both the types of materials which are used and the manner in which the experiments are performed. In the former respect, two noteworthy materials are submarine basaltic glass (SBG) generally taken from ocean drilling cores and ophiolites (Tauxe, 2006), and single silicate crystals isolated from both extrusive and intrusive igneous rocks (Tarduno et al., 2006). Both of these have been argued to be higher fidelity recorders (less prone to problems numbered 1, 3, 4, and/or 6 in the list above) than more conventional paleointensity recorders (e.g., whole-rock subaerial lava samples).

In addition to providing an estimate, the choice of absolute paleointensity methodology is also made to enable verification of some or all of the criteria that are listed above. To some extent, this may be achieved directly through the paleointensity experiment itself, but it is also very common for supporting rock magnetic, microscopic, and/or paleodirectional experiments to be undertaken for this purpose. Table 1 summarizes some of the more commonly used absolute paleointensity techniques and provides the relevant references. The Thellier method (Thellier and Thellier, 1959) and its derivatives remains the most widely used and trusted technique. These are based on stepwise removal of the NRM alongside simultaneous stepwise replacement with a laboratory TRM. For a general introduction to this method and some of the other techniques listed in Table 1, the reader is directed to comprehensive reviews by Tauxe and Yamazaki (2007) and Valet (2003).

Relative paleointensity measurements

Paleomagnetic analyses of sedimentary rock and soft sediment samples can produce continuous time series of geomagnetic intensity variations, which may be calibrated using absolute paleointensity estimates or used alone as records of relative geomagnetic behavior. Relative paleointensity studies are generally undertaken on the assumption that the samples retain a depositional remanent magnetization (DRM) acquired as the magnetic grains in the sediment physically align themselves during or shortly after deposition from the water column. The DRM acquisition process is sensitively related to the size, shape, and composition of the remanence carriers and is further complicated by flocculation effects in saline environments. Much later, the intensity of the magnetization can be significantly affected by consolidation and compaction processes (see review by Tauxe and Yamazaki, 2007).

Some normalization of the measured magnetization intensity is required to account for changes (which should ideally be small) in the concentration and nature of the magnetic recorders and produce a record of geomagnetic intensity variations. Candidates for normalization include anhysteretic remanent magnetization (ARM), isothermal remanent magnetization (IRM), and low-field susceptibility. These should ideally display a strong coherence with the NRM signal (after removal of any secondary components of magnetization) but no coherence with the normalized record (Valet, 2003). The reliability of a relative paleointensity record can be further supported by the presence of antipodal directions (suggesting that secondary components of magnetization have been removed) and by the coherence of multiple curves from the same region covering the same time interval (as calibrated using independently obtained timescales).

The sedimentation rate and the interval over which the magnetization is "locked in" sets a limit on the time resolution of any relative paleointensity record. In deep-marine sediments, a standard 2.5 cm paleomagnetic sample can represent a time period of 10 kyr or more,

Paleomagnetic Field Intensity, Table 1 Selection of absolute paleointensity methods currently in use

Family	Variants	Benefits	Criticisms
Thellier (Thellier and Thellier, 1959)	Coe (1967), Aitken et al. (1988), Perpendicular (Kono and Ueno, 1977), IZZI (Tauxe and Staudigel, 2004), QP (Biggin et al. 2007)	Sound theoretical basis for single-domain grains (Néel, 1955); potential to recover estimate from a sample which both contains secondary magnetizations at low temperatures and which alters at high temperatures; additional checks for alteration (Prévot et al., 1981) and multidomain behavior (Riisager et al., 2001; Krasa et al., 2003) can easily be added	Multiple heatings are time consuming and increase likelihood of sample alteration; bias due to multidomain effects may be prevalent in lava samples (Biggin, 2010)
Microwave (Shaw et al., 1996; Hill and Shaw, 2000)	All Thellier-type variants may be used	In principle, all benefits of Thellier but with reduced sample heating in terms of both temperature and time; faster experiments which can be individually tailored to samples	Requires highly specialist equipment (microwave paleointensity system); theoretical basis not yet firmly established; samples may not unblock as cleanly as in thermal experiments
Shaw (1974)	ARM-alteration corrections (Kono, 1978; Rolph and Shaw, 1985); Double heating (Tsunakawa and Shaw, 1994); low-temperature demagnetization (Yamamoto et al., 2003); Microwave (Yamamoto and Shaw, 2008)	Original method is fast; arguably domain-state independent as uses full TRMs	The use of ARMs to check and correct for alteration in terms of the TRM properties is not always valid (Tanaka and Komuro, 2009)
High-temperature measurement	Wilson (1961) Le Goff and Gallet (2004)	Very fast methods; Wilson method is arguably domain-state independent as it uses full TRMs (Muxworthy, 2010); Le Goff–Gallet method designed to incorporate cooling rate and anisotropy corrections	Requires specialist equipment (high-temperature magnetometer); samples must survive heating to Curie temperature without altering in Wilson method; unknown effect of multidomain grains in Le Goff–Gallet method
Multispecimen (Hoffman et al., 1989)	Hoffman and Biggin (2005), Dekkers and Böhnel (2006)	Fast; *inter*-specimen consistency is implicitly considered; domain state effects can be minimized in Dekkers–Böhnel experiments; fewer heating steps implies less alteration	Fewer checks for *intra*-specimen consistency; no internal checks for alteration; domain-state benefits of Dekkers–Böhnel method may be lost if secondary magnetizations require removing (Michalk et al., 2010)
IRM Normalization (Cisowski and Fuller, 1986)		No heating required	Precision limited to orders of magnitude

which will produce significant smoothing of secular variation (see *Geomagnetic Field, Secular Variation*).

Cosmogenic isotope paleointensity measurements

This method of paleointensity measurement, applicable to the last few hundreds of kyr, is based on the fact that production rate of certain radioisotopes (^{14}C, ^{36}Cl, and ^{10}Be) is strongly influenced by the degree of shielding the geomagnetic field provides the Earth from incoming cosmic rays. Records of the concentration of these isotopes in sediment and ice cores (and tree rings and corals in the case of ^{14}C) can therefore provide a proxy for geomagnetic dipole moment once the necessary corrections for latitude and relevant physical, chemical, and biological processes have been made. See review by Valet (2003) for more information.

Geophysical implications

Paleointensity measurements provide information about the geodynamo across a variety of timescales. Direct observations indicate that the strength of the main field has fallen by around 10% since the first measurements were made in the 1830s. A key aim of archeointensity studies has been to establish the longevity of this recent trend. A recent analysis of the global dataset of archeointensity data from 1600 onward showed little evidence of a rapidly decaying field prior to 1840 (Gubbins et al., 2006). Longer time series

have been constructed for specific regions and Genevey et al. (2009) show periods of rapidly changing strength in France over the past 800 years. Archeointensity and paleointensity data are particularly important for constructing global models of field behavior on millennial timescales (e.g., CALS7K.2; Korte and Constable, 2005). Each of the observable paleomagnetic field components (declination, inclination, and intensity) can be mapped, via their respective Green's functions, to the radial field at the core–mantle boundary (Johnson and Constable, 1997). Intensity measurements sample the field at the core–mantle boundary at different locations (tending to higher latitudes) than directional data from the same site (Johnson and Mcfadden, 2007). Recently, updated databases of paleointensity estimates include measurements from the last 10 kyr (Genevey et al., 2008), 50 kyr (Korhonen et al., 2008), and the period spanning 50 kyr to 3.5 Gyr (Biggin et al., 2010).

Relative paleointensity records from varved sediments are capable of providing good temporal resolution over the Holocene and agree well with absolute intensity records as well as records of cosmogenic nuclide production (Snowball and Sandgren, 2002). Correspondingly, absolute archeointensities have been combined with the ^{14}C record from tree rings and the ^{10}Be record from ice cores to infer variation in solar activity, with implications for understanding solar forcing of climate (Solanki et al., 2004). Marine sediments have provided relative paleointensity records over longer timescales. Here, it is usually assumed that a typical sample will represent a sufficiently long period for nondipole features to be averaged out (Valet, 2003) allowing composite stacks of relative paleointensity from different areas of the world to be constructed. A global stack for the past 2 Myr, Sint 2000 (Valet et al., 2005), agrees well with absolute paleointensity from lava flows and confirms a low field strength during excursions. Importantly, this record is long enough to include reversals and finds a correlation between polarity interval length and field strength., This same correlation is seen, albeit weakly, in the 11 Myr Oligocene record from site Deep Sea Drilling Project, site 522 (Constable et al., 1998).

It becomes increasingly difficult to obtain relative paleointensities from sediments more than a few million years old. Consequently, longer term variations in field strength are studied using absolute paleointensity data derived from igneous rocks. By studying paleointensity throughout the Phanerozoic, it may be possible to understand the relationship between reversal frequency and intensity. Theoretical models have been proposed that link a stable nonreversing field with a high dipole moment (Glatzmaier et al., 1999; Driscoll and Olson, 2009). On the other hand, by considering properties of self-exiting dynamos, Hide (2000) finds a high field strength is likely to promote reversal. The study of paleointensity during superchrons is a natural approach to testing these models (Fuller and Weeks, 1992). A fertile field of study has been the Cretaceous normal superchron (CNS) but the suite of results obtained so far has as yet been unable to settle the issue. Pick and Tauxe (1993) found samples of submarine basaltic glass (SBG) from the CNS gave paleointensities less than half the present day value today (although later SBG data gave higher values; Tauxe and Staudigel, 2004). Prévot et al. (1990) found evidence of a longer period of low field intensity which they called the *Mesozoic dipole low*, but only one result in their analysis came from the CNS. Subsequent analyses have argued both for (Perrin and Shcherbakov, 1997; Biggin and Thomas, 2003) and against (Selkin and Tauxe, 2000; Goguitchaichvili et al., 2002) the existence of the Mesozoic Dipole Low. Studies based on the measurement of single silicate crystals have found evidence of high fields during the CNS (Tarduno et al., 2001; Tarduno and Cottrell, 2005) and a clear inverse relationship between reversal frequency and dipole moment. Other more recent studies based on whole rock samples have not confirmed this (Granot et al., 2007; Hill et al., 2008) although it has been claimed that these data are biased (Tarduno and Cottrell, 2005). There remains no consensus regarding the magnitude of the field during a superchron. However, the hypothesis of a positive relationship between reversal frequency and dipole moment (i.e., weaker field strength in superchrons) has now arguably been rejected (Biggin and Thomas, 2003). Tauxe (2006) argued that the average paleointensity is proportional to the length of the *specific* chron from which it is derived as opposed to the *average* length of chron during the time period in question. This is a subtle but important difference from the case generally presented.

The dynamo process producing the geomagnetic field is powered, in large part, by the growth of the inner core. The nucleation and subsequent growth of the inner core may then have had a profound effect on the geomagnetic field strength (Stevenson et al., 1983). Estimates for the age of the inner core range from 3.5 billion years (Gubbins et al., 2004) to 1 billion years (Labrosse et al., 2001) or younger, so paleointensities from Archean to Proterozoic rocks may carry a signal emanating from the onset of its crystallization. Studies on rocks of this age have been hampered by the alteration of the remanence carriers and once again no clear picture has yet emerged. Studies based on single silicate crystals from Paleoarchean (3.2–3.5 Ga) intrusive rocks suggest a dipole moment in the range of 50–70% of today's value (Tarduno et al., 2007, 2010). This could be taken as indicating either an early age for the onset of inner core nucleation or that thermal convection alone was capable of producing a field with intensity comparable to today's. In contrast, the paleointensity record has been interpreted as indicating a significant increase in field strength sometime between 1000 and 300Myr, suggesting a later formation of the inner core (Macouin et al., 2004). Biggin et al. (2009) raised the possibility that both observations were true and that a *Proterozoic dipole low* separates periods of dominantly high field strength in the Archean and Phanerozoic.

Paleointensity experiments have not been confined to terrestrial rocks. Lunar rocks from the Apollo missions

showed what appeared to be a thermoremanence and a variety of paleointensity techniques seemed to hint at a lunar dynamo operating between 3.9 and 3.6 Gyr (Cisowski, 1982). However, recently the reliability of the lunar paleointensity record has been questioned and the evidence for a lunar dynamo reconsidered (Lawrence et al., 2008). Paleointensities from meteorites have been used to estimate the ancient Martian field (Shaw et al., 2001; Weiss et al., 2008b) and may even be evidence of dynamos operating within the metallic cores of planetisimals in the early solar system (Weiss et al., 2008a).

Definition

Magnetic stratigraphy. Application of magnetic methods to obtain the magnetic polarity pattern in stratified rocks, allowing them to be correlated to the global magnetic timescale.
Remanent magnetism. Permanent magnetism in rocks, caused by the orientation of the Earth's magnetic field at the time the rock was formed.

Magnetic stratigraphy

Introduction

Since the 1960s, one of the most important tools for dating and correlating fossiliferous sedimentary rocks has been magnetic stratigraphy. First developed to aid in the correlation of deep-sea sediment cores from the Deep Sea Drilling Project, by the 1970s it had also been applied to dating terrestrial sedimentary rocks as well. The early efforts were hampered by the slowness and insensitivity of old spinner magnetometers, but with the widespread availability and the increased reliability, sensitivity, speed, and precision of cryogenic magnetometers in the 1970s, the field has grown tremendously. It has now been applied to many of the important marine and terrestrial sequences that were the type sections for biostratigraphic zones and timescales, and is routinely used whenever there are suitable outcrops and age control to allow global correlation.

Magnetic stratigraphy works by obtaining a dense sampling of oriented samples from stratigraphic sections of layered sedimentary rocks or volcanic rocks. These samples record the direction of the magnetic field (*normal*, as in today's field, or *reversed*, about 180° from today's field) in a random pattern of polarity zones. If there is a sufficiently long pattern of polarity zones, it can be matched up to the global magnetic polarity timescale by calibrating it with radiometric ages, or by means of biostratigraphy, or both. Once sections have been correlated, the magnetic polarity reversals represent time planes, and their ages can be resolved to less than 10,000 years, much better dating and resolution than obtainable by any other means.

Detrital remanent magnetization

Although it is possible to correlate lava flows by magnetic methods, by far the most common application of magnetic stratigraphy is to layered sedimentary rocks. These rocks become magnetized by *detrital remanent magnetization* (DRM). When the sediment is loose and fluid, it will contain a small number of tiny (less than 60 μm in diameter) grains of magnetic minerals, such as magnetite or hematite. While these sediments settle out and become liquefied, the magnetic mineral grains are influenced by the ambient magnetic field at the time the sediment was deposited, and thus line up to be parallel to it. Thus, the magnetic grains act like tiny bar magnets, or like iron filings near a bar magnet. As the sediment becomes compacted or cemented and turned into sedimentary rock, the orientation of these magnetic grains is preserved. Although there are instances of sediment compaction causing the grains to rotate and thus flattening the inclination angle, most sedimentary rocks seem to record field directions that closely match those produced from the cooling of igneous rocks, which are not subject to compaction (Butler, 1992, pp. 183–187).

Field and laboratory techniques

In order to undertake a magnetostratigraphic study, a large number of oriented samples densely spanning the total stratigraphic interval of exposed rock are required. The density of sampling is dictated by how many exposures are suitable, and the logistics of how many people and man-hours of field work are available to conduct the sampling, since it is a tedious and exhausting task. Typically, each stratigraphic level or

"site" is sampled at least in three places, and more if possible, so that Fisher statistics can be calculated. In deep-sea cores, sampling is conducted on the split core, with small subsamples taken from the core so that an excessive amount of material is not removed.

The lithology of rock is also critical. Most remanence is held in tiny (less than a few tens of microns) *single-domain grains* of magnetic mineral, or in slightly larger *pseudo-single domain* grains. Above a certain size, it is possible to have two or more magnetic domains in a grain, and then they will tend to form antipodally oriented domains within a single grain and cancel each other out, giving no net remanence. Thus, a fine-grained component is essential for a sedimentary rock to retain useful remanence. For this reason, sampling usually concentrates on shales, mudstones, and fine-grained sandstones. Coarser sandstones may work if they have a fine-grained matrix. A well-sorted, very clean coarse sandstone with no matrix should be avoided for this reason.

If the rocks are very hard and well cemented, it is possible to sample using a coring drill, as is commonly practiced in igneous and metamorphic rocks. Most sedimentary rocks, however, are too friable and crumbly to stand up to the stress of drilling and the flow of water through the drill bit (required to cool the bit and flush out the drilled rock chips). In this case, samples of terrestrial rocks are taken by scraping oriented surfaces on hand samples, and then subsampling them into cubes or cores in the laboratory using a coring drill or band saw, or hammer and sandpaper for very soft rocks. If the samples are very friable (such as loose soils or unconsolidated sediments), it is still possible to obtain oriented samples. Typically, this is done by pressing open tubes of a high-temperature glass (such as quartz glass or sometimes Pyrex) into the exposure, measuring the orientation, then removing it and pouring a high-temperature-tolerant hardener (such as sodium silicate) into the sediment. The tube is then taped shut, and in the lab it can be sealed at the open end by a high-temperature ceramic, such as Zircar aluminum cement. The sealed glass tube is then measured as if it were a normal drill core. In addition, samples may crumble during preparation until they are too small for a core or cube. They can be salvaged by placing them oriented face down on a piece of wax paper, surrounding them with a plastic ring the diameter of a core (such as a cut piece of plastic test tube), and pouring in Zircar aluminum ceramic to make them into a molded ring that will survive the high temperatures of the thermal demagnetization.

Once samples are fully prepared, they can be measured in a magnetometer to determine the direction and intensity of their magnetic remanence. Before the late 1970s, all the studies were done with older-generation *spinner magnetometers*, which required over 30 min to measure a single sample, and were not sensitive enough to measure most sedimentary rocks. For this reason, only a few measurements could be made on each sample, and only a limited number of samples could be taken if the project were to remain reasonable in size.

In the 1970s, the invention and widespread adoption of *cryogenic magnetometers* revolutionized the study of paleomagnetism. These devices have a sealed jacket of liquid helium at 4 K surrounding a superconducting region in the bottom of the magnetometer. The electronics in the cryogenic chamber are thus sensitive to extremely small magnetic moments, and can make measurements in a few seconds. They are four to five orders of magnitude more sensitive than spinner magnetometers, so samples can be measured that are extremely weakly magnetized. These include not only every kind of rock but even organic tissues like the magnetite in bacteria or birds or bees or butterflies. Early cryogenic magnetometers were very temperamental and prone to problems. They bled off the evaporating helium at such a fast rate that a single shipment costing hundreds of dollars would only last a few weeks. Only a few measurements could be taken on each sample, and the lab had to work 24/7 to use every precious second of magnetometer time. Now most cryogenic magnetometers have a cryocooler pump that circulates liquid helium or nitrogen around the cryogenic container, and keeps it cold for many months at a time, greatly reducing the cost of operation, wear and tear on the magnetometer, and improving reliability. In many labs (especially those equipped with a Caltech-style automatic sample changer), it is possible to make dozens of measurements in an hour, allowing paleomagnetists to make dozens of different measurements on each sample.

Each sample contains a mixture of remanences acquired during the long history of the rock unit. There will be a primary, or characteristic, component from when the rock originally formed, which may be overprinted by one or more magnetizations that were acquired at later times. For a reliable paleomagnetic study, the researcher must attempt to remove these overprinted components by gradually demagnetizing the sample, and gradually stripping off the younger, less stable magnetizations until only the characteristic remanence is left. Consequently, it is typical for a modern paleomagnetic study to measure the samples first at NRM (*natural remanent magnetization*, or the magnetization of the sample before treatment). The samples can then be demagnetized using *alternating fields* (AF), which helps remove remanence due to low-coercivity minerals such as magnetite, and eliminates magnetization from transient fields (such as lightning strikes) or from VRM (*viscous remanent magnetization*). Examination of the magnetic behavior and the drop in intensity at each AF step allows the paleomagnetist to determine how much of the remanence is held in a low-coercivity mineral, or whether significant high-coercivity minerals (which do not respond to AF demagnetization) are present. AF treatment is usually sufficient for samples from deep-sea cores, which have not undergone any significant diagenesis or alteration. Another method, known as *thermal demagnetization*, heats the samples in field-free space to a preset temperature, then cools them down to room temperature without acquiring any new magnetization from the earth's field. In some cases, the

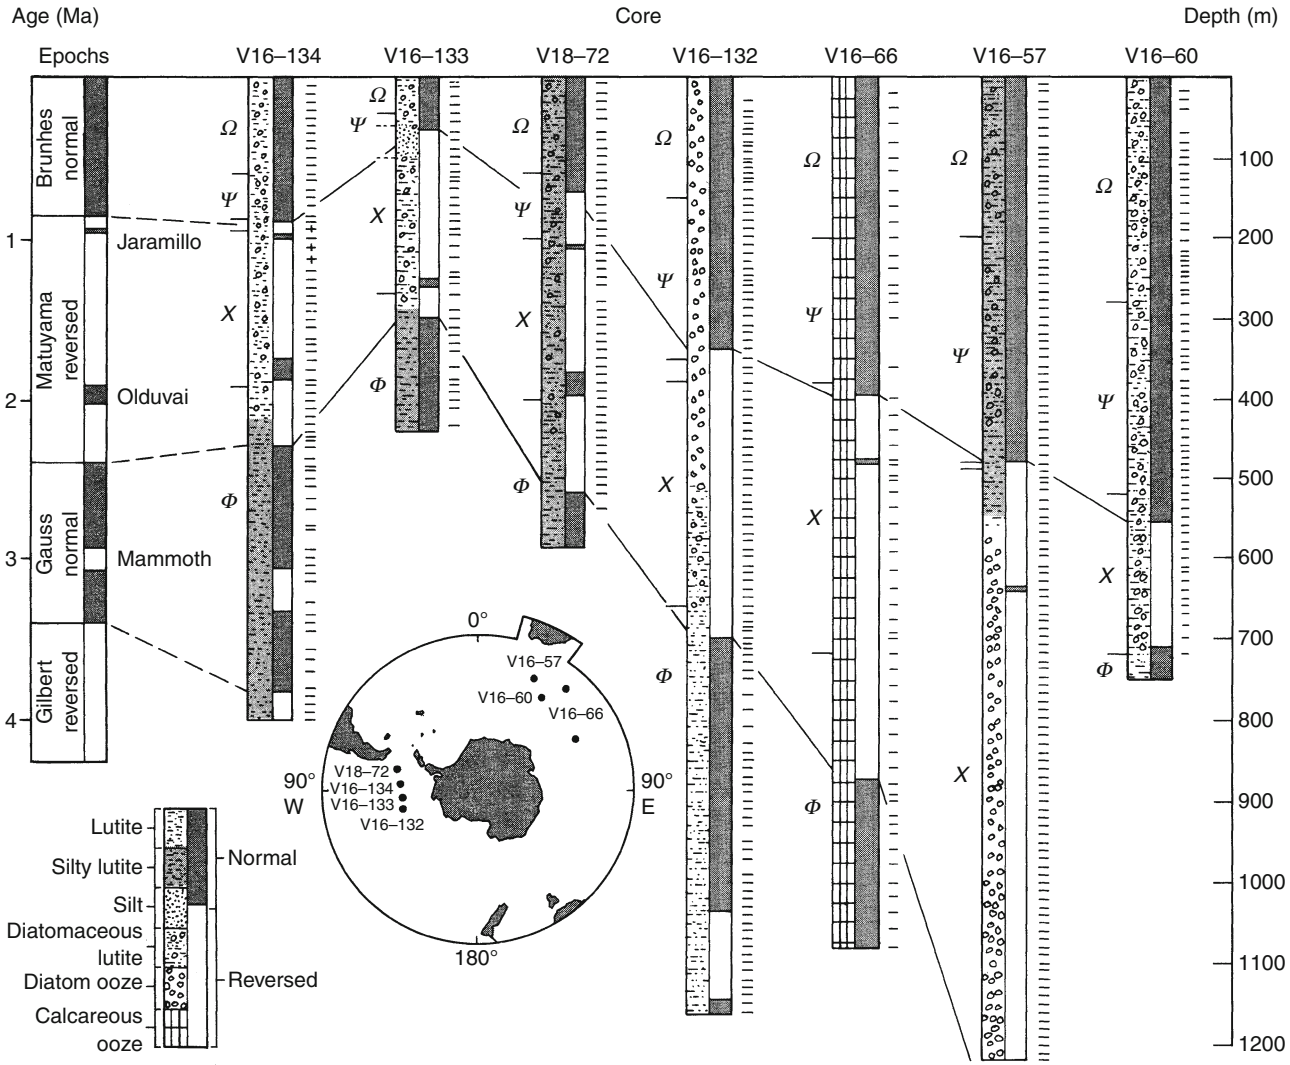
oven is saturated by a jet of nitrogen gas to reduce the possibility of minerals oxidizing as they cool down. Thermal demagnetization in many steps of increasing temperature allows the paleomagnetist to see how the remanence changes as higher and higher temperatures are reached and the *blocking temperature* of the magnetic minerals (578°C for pure magnetite; 630° for hematite) is approached. At high temperatures, the behavior of the sample above the blocking temperature of magnetite tells the researcher about the intensity and direction of the magnetic components that are held in hematite. Thermal demagnetization has an additional advantage. Above 200°C, iron oxides and hydroxides such as goethite are converted to hematite, and their remanence is removed. These "rusty" minerals are often formed by weathering of sedimentary rocks at the surface, and usual form as a *chemical remanence* deposited in the rock long after the primary or characteristic remanence was formed. Thus, they are a form of overprinting that must be removed, but cannot be affected by AF demagnetization. For this reason, nearly all terrestrial sedimentary rocks (even if they are not visibly reddish) should be thermally demagnetized to insure that there are no false overprinted magnetic components. Many studies use both AF and thermal demagnetization on every sample to strip off overprints due to iron oxides, to determine the relative contribution of high-coercivity and low-coercivity minerals, and to obtain a clear sense of the dominant magnetic mineralogy of each sample. The samples can also be studied in polished thin sections, where the light reflects differently off magnetite, goethite, and hematite, and the depositional fabric of the magnetic mineral and size of the grains can be determined.

These magnetic directions can be plotted and analyzed in a number of different ways. For simple visual plotting of the three-dimensional changes in directions, a conventional *stereonet* can be used. But a stereonet only shows direction, where as an *orthogonal demagnetization plot* ("Zijderveld plot") shows both the direction and intensity of each demagnetization step (Zijderveld, 1967). Most paleomagnetics labs have software that rapidly creates these plots, so the behavior of the sample can be studied as the demagnetization proceeds. Once a stable remanence has been obtained and overprints isolated and removed, the inferred characteristic remanence components are usually summarized by the *least squares method* of Kirschvink (1980). These directions for each sample can then be averaged using Fisher (1953) statistics, which give the mean and ellipse of 95% confidence for each sample. Using Watson's (1956) criteria, the statistical significance of each site can be assessed. Frequently they are ranked using the criteria of Opdyke et al. (1977), where Class I sites are statistically significant at the 95% confidence level, that is, there is a 95% chance that the sample distribution differs from a random distribution. These sites were labeled "Class A" by Johnson et al. (1985). Class II sites have fewer than three samples (so statistics cannot be calculated), and Class III sites ("Class B" sites of Johnson et al., 1985) have at least two sample directions that are in agreement, but one which is divergent due to incomplete removal of overprints. These directions can then be plotted against a stratigraphic column to show the overall polarity pattern for the section, and also indicate the degree of reliability of individual samples at each site.

As in any other paleomagnetic study, there are a number of techniques for assessing the stability and reliability of the sample directions (see Butler, 1992, pp. 123–128). The most commonly used in magnetostratigraphy is the *reversal test*, which compares the statistical mean of all normal directions and reversed directions to see if they are antipodal (as they should be if they represent the original magnetic field of the earth). Most long stratigraphic sections yield both normal and reversed polarity samples, providing the data for a stability test like this. In some cases, there are conglomerates in the section, so a *conglomerate test* can be performed. In this test, samples are taken from a large sample of clasts in a conglomerate. If their directions are randomly scattered, then they have not been remagnetized since the conglomerate formed. If, on the other hand, they yield directions that are clustered, then there has been overprinting not only of that conglomerate, but also of the rocks in the rest of the section. Another common test in rocks that have been deformed is the *fold test*. The researcher can compare the directions of the samples with and without dip correction. If these directions are clustered with dip correction, and more scattered without dip correction, then the directions were acquired before folding. If the directions are more clustered in their uncorrected, folded orientation, then the directions were acquired after folding (and thus are not primary or characteristic directions). Not all these stability tests are available in every study, but at least one (usually the reversal test) should be attempted to obtain credible results. If other tests are also available, they should also be analyzed to increase the rigor of the study.

Calibration and correlation

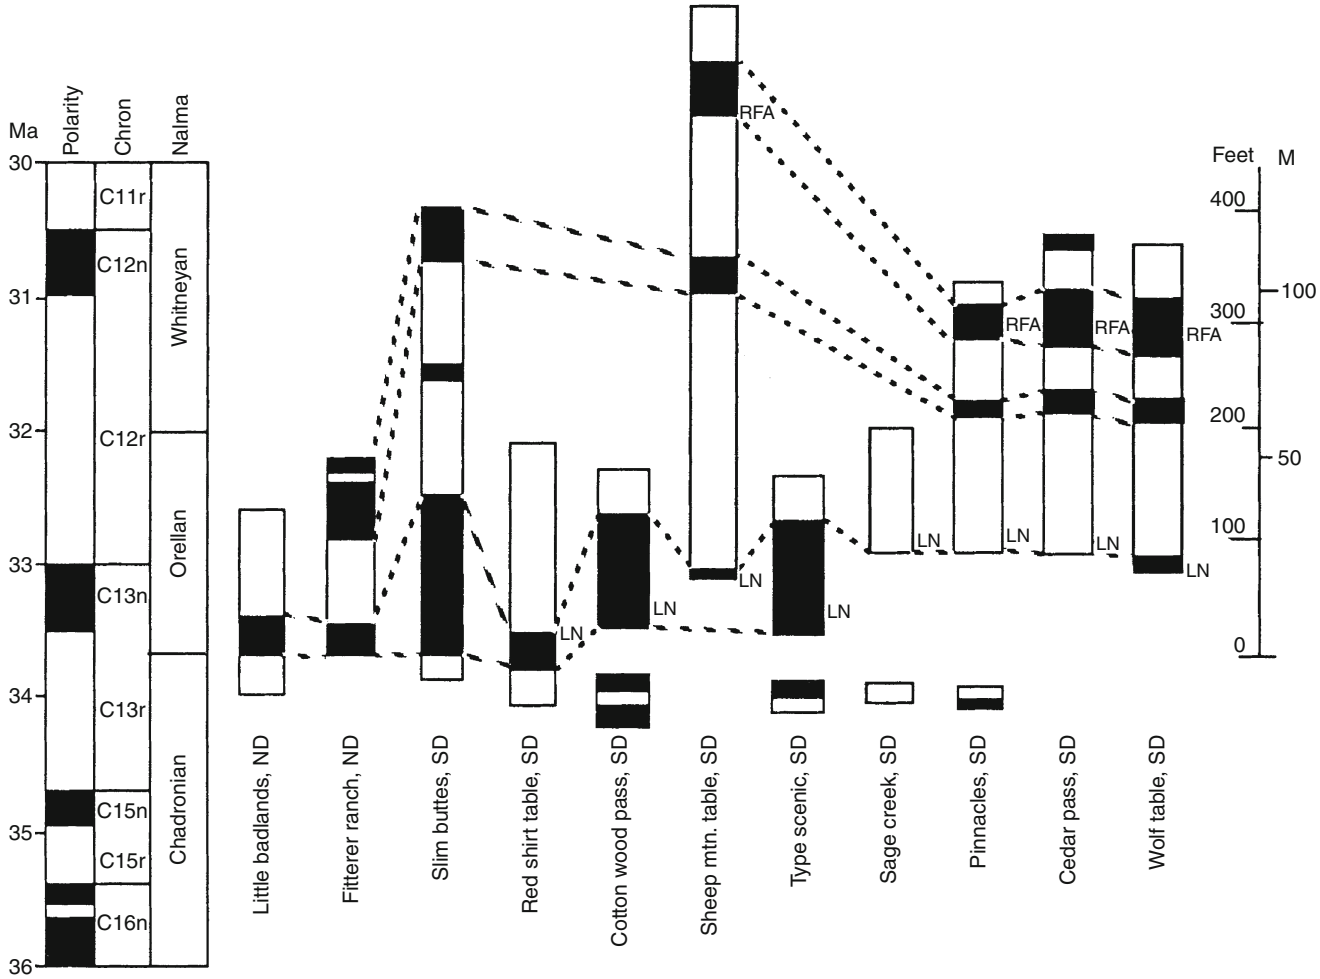
Once characteristic directions that have passed stability tests have been obtained from each site and they are plotted, then the overall polarity pattern for each individual section can be assessed. Polarity zones are not diagnostic or unambiguous by themselves, but must be correlated based on other criteria, such as lithostratigraphy or biostratigraphy. In the early days of magnetic stratigraphy, deep-sea cores (Figure 1) could be sampled down from the modern sediments at the top of the core, and each polarity zone could be calibrated by the Brunhes normal polarity magnetozone at the top. Most deep-sea cores, however, do not have a continuous sedimentary record from the present backward, but represent an older geologic span of time separated by unconformities. In such cases, the biostratigraphy of the planktonic microfossils enables the scientist to calibrate a core directly against the magnetic polarity timescale.



Paleomagnetism, Magnetostratigraphy, Figure 1 Magnetostratigraphic correlation of Antarctic cores, based on the modern Brunhes normal polarity sediments at the top of each section, and the biostratigraphic zones of radiolaria (*shown by the capital Greek letters*) in each core. To the right of each column, minus signs indicate normally magnetized specimens, while plus signs are reversed specimens (After Opdyke et al., 1966, Figure 1; by permission of the American Association of the Advancement of Science).

In another example, Figure 2 shows the correlation of magnetozones of many different stratigraphic sections across the Eocene-Oligocene White River Group from northeastern Colorado to Nebraska and Wyoming to the Big Badlands of South Dakota to North Dakota. The correlations are based on the lithostratigraphic units and the biostratigraphic zonation, with the common datum based on a widespread ash horizon found throughout most of the sections. Note that the polarity magnetozones are roughly consistent in thickness from one section to another, although each of the magnetozones is proportionally thicker where the total sediment accumulation rate is higher (e.g., Slim Buttes, South Dakota).

But these polarity matches do not establish correlation with the global magnetic polarity timescale. Magnetic polarity can only be "normal" or "reversed," and that pattern has occurred thousands of times in the geologic past, so it is not sufficient just to get a raw polarity pattern and attempt to correlate it to the global timescale (unless you are working down from modern sediments at the top of a section, in which case the uppermost normal magnetozone is the Brunhes Chron, or Chron 1n). For reliable correlation, the section needs to be calibrated by some sort of independent means of time control. Ideally, this is provided by at least one and preferably more radiometric dates, which will place the local section on the global



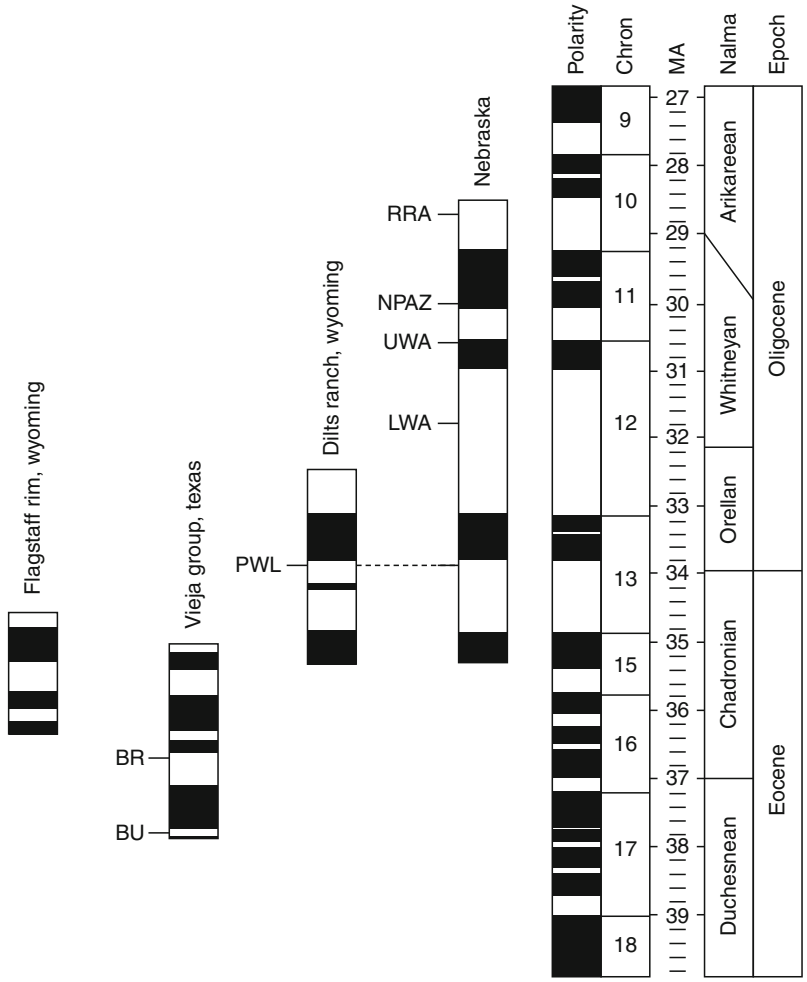
Paleomagnetism, Magnetostratigraphy, Figure 2 Correlation of magnetostratigraphic sections in the White River Group from North and South Dakota. All of the sections are correlated based on the datum of the base of the Orellan. Abbreviations as follows: NALMA = North American land mammal ages; LN = Lower Nodular Zone of the Big Badlands; RFA = Rockyford Ash. From Prothero (1996, Figure 9).

magnetic polarity timescale (Figure 3). Where radiometric dates are not available, it is often possible to use a finely resolved well-calibrated biostratigraphy (whose precise correlation to the global timescale is already known) to correlate another section containing those key fossils.

Strengths and weaknesses of magnetic stratigraphy

Like any other stratigraphic technique (see Prothero and Schwab, 2003), magnetic stratigraphy has great strengths – and also some weaknesses. The strengths include:

1. *Worldwide*: magnetic polarity events happen around the globe simultaneously. By contrast, most other stratigraphic markers (volcanic ashes, biostratigraphic events, lithologic boundaries, even isotopic events) occur only locally.
2. *Independent of facies or lithology*: any fine-grained sedimentary rock or volcanic rock will work, allowing us to correlate between deep-sea muds to shallow-marine silts to terrestrial floodplain mudstones. By contrast, rock units are typically time-transgressive as facies migrate, and are not found on both land and sea. Stable isotope curves are usually restricted to marine rocks.
3. *Geological instantaneous*: polarity reversals take place over 4,000–5,000 years, which is a geological instant for most studies of the deep past. By contrast, most lithostratigraphic units are time-transgressive over millions of years.
4. *Constant resolution regardless of age*: the duration of magnetic polarity transitions is constant whether the rocks are Pleistocene or Permian, so the resolution is always in the order of a few thousand years.



Paleomagnetism, Magnetostratigraphy, Figure 3 Calibration of the White River-Arikaree Group magnetic stratigraphy of Figure 2, based on $^{40}Ar/^{39}Ar$ dating of key volcanic ashes. Abbreviations: BR = Bracks Rhyolite; BU = Buckshot Ignimbrite; LWA = Lower Whitney Ash; NPAZ = Nonpareil ash zone; RRA = Roundhouse Rock Ash; UWA = Upper Whitney Ash (Modified from Prothero and Swisher, 1992, Figure 2.3).

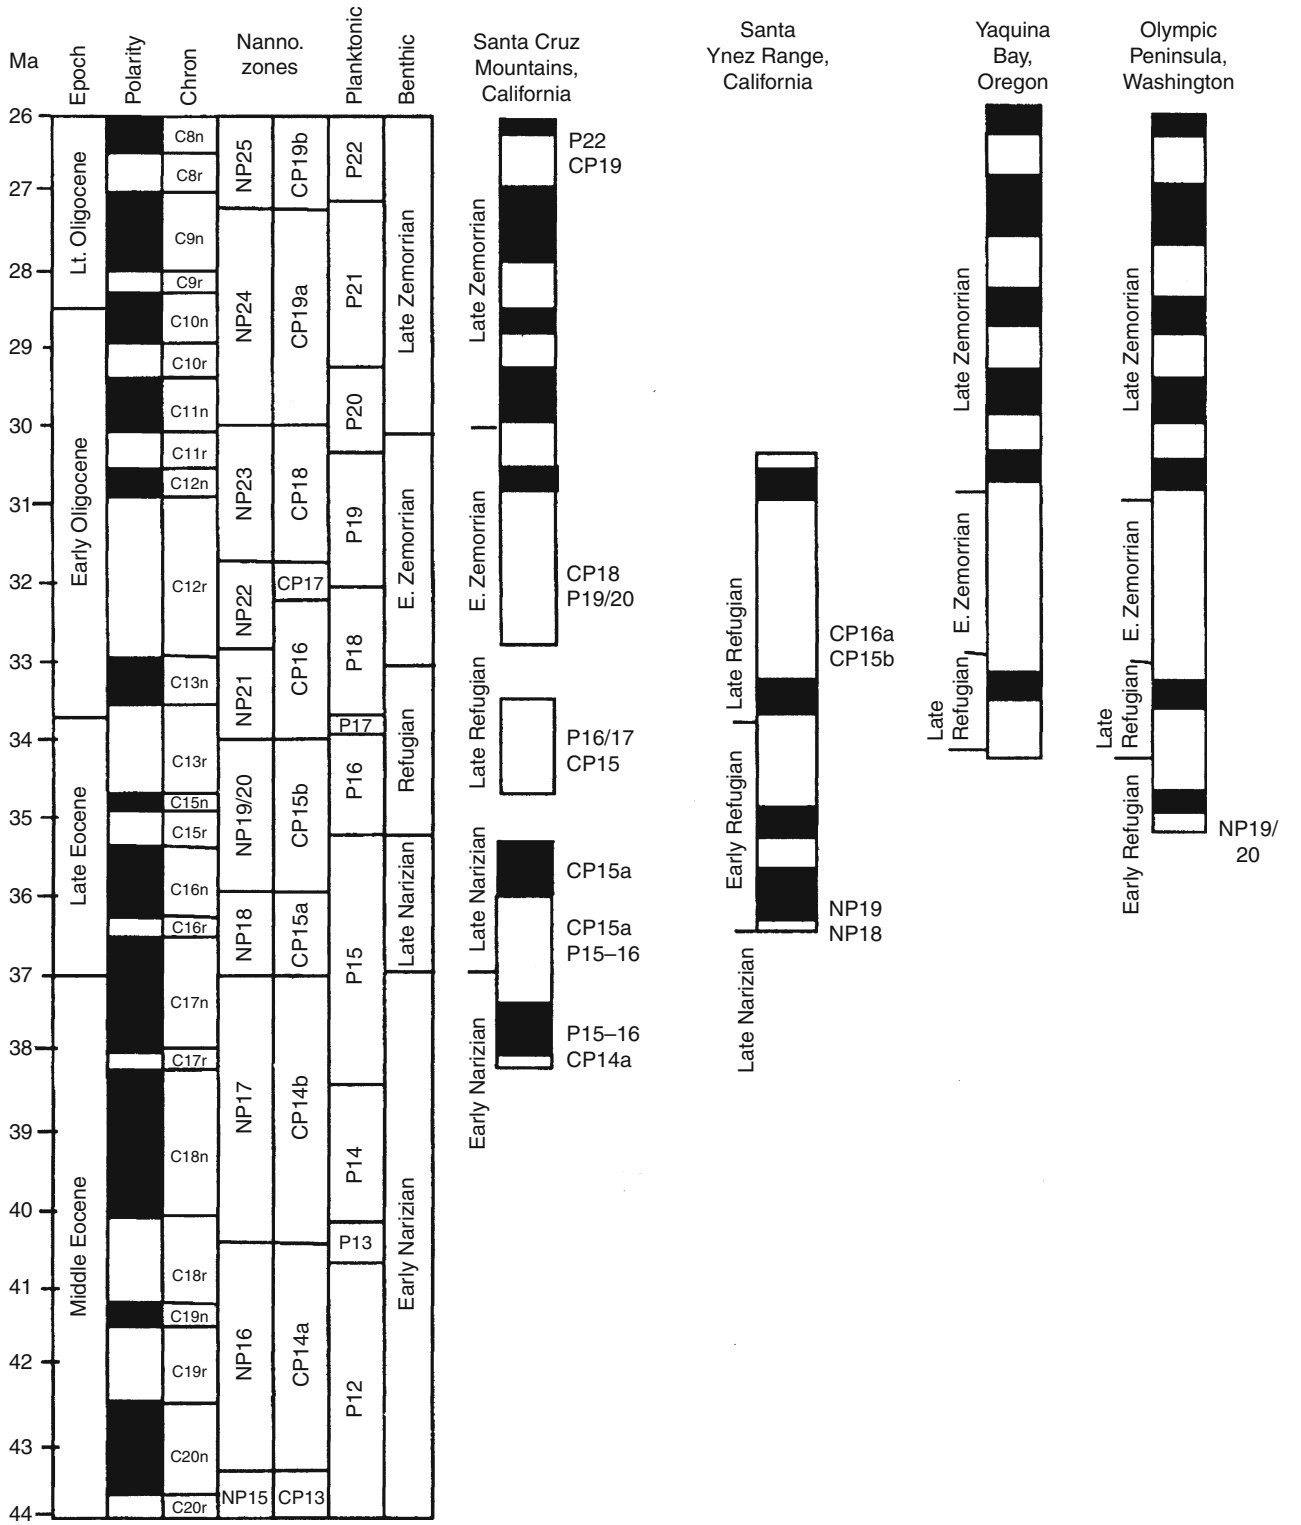
By contrast, radiometric dates have an error bar that is a proportion of the mean age and therefore gets larger as the rock gets older. For example, if the error estimates are ±5% for a rock of 1 Ma, then the true age is 1 million ± 50,000 years. If the age is 100 Ma, however, then the true age is 100 million ± 5 million years. In other words, there is a 95% probability that the true age lies between 95 and105 Ma. These error bars get larger with older and older rocks.

There are some limitations to magnetic stratigraphy as well:

1. Only *finer-grained lithologies*, or sandstones with clay matrix, are suitable (as discussed above).
2. If there are *unconformities* in the section, then magnetozones can be shortened or deleted altogether. This problem can best be addressed by biostratigraphic methods, the usual way in which we test for evidence of slow or no deposition.
3. *Demagnetization problems* can hamper the quality of the data, particularly in yielding spurious normal overprinted zones that have not yet been removed by thermal demagnetization of iron oxides and hydroxides (e.g., Butler and Lindsay, 1985).
4. *Independent form of age control* is required to calibrate the section.

Some applications and implications

Since the late 1960s, magnetic stratigraphy has become one of the most powerful tools available for precise dating of sedimentary sequences and geologic events, and for correlation of events between the terrestrial, shallow-marine, and deep-sea records. In most detailed



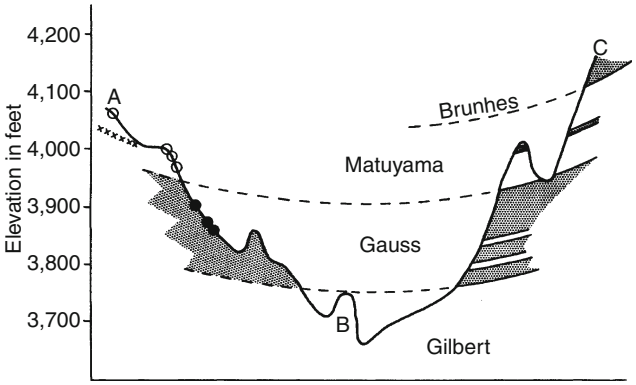
Paleomagnetism, Magnetostratigraphy, Figure 4 Magnetostratigraphic correlation of marine sections from the Pacific Coast, based on the magnetic polarity pattern and the biostratigraphy of microplankton. On the left is the standard geological time scale and polarity chrons with the planktonic zones of nannofossils and foraminifera (after Prothero, 2001).

stratigraphic studies, it is routine to do magnetostratigraphic analysis along with biostratigraphy to form a network of correlation now called *magnetobiostratigraphy* (Figure 4). Combined with stable isotope stratigraphy (especially in deep marine cores), it is possible to obtain very high-resolution, high-precision dating of many stratigraphic sections and correlate their events with high precision on a global basis. This, in turn, has allowed reliable and detailed comparison between climatic and biotic events on the land and the sea, and has revolutionized our understanding of climatic change and global correlations of climate and evolution.

The application of magnetic stratigraphy has also changed our conceptions of many geologic problems. For example, the dating of strata before the advent of magnetic stratigraphy has been radically rethought as these correlations improve. In North America, for example, the Uintan and Duchesnean land mammal ages of Wood et al. (1941) were once thought to be late Eocene, the Chadronian land mammal age early Oligocene, and the Orellan and Whitneyan land mammal ages middle and late Oligocene, respectively. However, with the advent of magnetobiostratigraphy and high-resolution argon/argon dating, all these correlations have changed radically (Prothero and Swisher, 1992). The Uintan and Duchesnean are now middle Eocene, the Chadronian late Eocene, and the Orellan and Whitneyan early Oligocene. The Arikareean, once thought to be early Miocene, is now largely late Oligocene. Every one of the original mid-Cenozoic stratigraphic interpretations of the Wood Committee (1941) was miscorrelated to the standard European timescale by at least one stage of the Eocene or Oligocene (and the same was true of their North American Miocene-Pliocene stages). Prior to magnetic stratigraphy and radiometric dating, the Deseadan land mammal age of South America was thought to be early Oligocene (27–37 Ma). Today it is considered late Oligocene to early Miocene (22–27 Ma) in age (MacFadden et al., 1985), or about 10 million years younger than originally thought.

Magnetic stratigraphy has also been used as a device for testing other geologic ideas. Because it produces geologically instantaneous time planes, it is valuable in testing whether biostratigraphic datums are synchronous or not. By and large, this has proven true, confirming the importance of biostratigraphy as a time indicator. Prothero (1982) showed this in the Eocene-Oligocene strata and fossils of the White River Group of the American High Plains. Lindsay et al. (1984) did the same for the biostratigraphy of the late Cenozoic of southwestern North America and Europe, as did Flynn et al. (1984) for the Eocene of the Rocky Mountains. A few biostratigraphic events, like *Lepus* event in North America (Lindsay et al., 1990), or the *Hipparion* horse datum in Europe, are demonstrably time-transgressive (Woodburne et al., 1981; Woodburne, 1989), but these are the exceptions to the rule.

In some cases, magnetic stratigraphy produces powerful inferences about the rock record. For example,



Paleomagnetism, Magnetostratigraphy,
Figure 5 Topographic profile across the San Pedro Valley of Arizona, showing the interpretation of "invisible magnetic zones" lying within the outcrops based on the sampling of Johnson et al. (1975). (Modified from Johnson et al., 1975, Figure 8).

Johnson et al. (1975) showed that magnetozones could be mapped along the Miocene-Pliocene exposures in the San Pedro Valley of Arizona. These "invisible magnetic time planes" (Figure 5) exist in the outcrops and can be mapped and interpreted using standard magnetostratigraphic methods. Magnetic stratigraphy allows precise determination of sedimentation rates in marine and terrestrial sections, and relative completeness of sections, which are important to many different kinds of stratigraphic studies (Sadler, 1981; May et al., 1985; Johnson et al., 1988).

Summary

Magnetic stratigraphy is now one of the principal tools that allow the precise, high-resolution correlation of geologic events in the stratigraphic record, especially climatic events. It is unique among stratigraphic methods in that global high-resolution correlations are possible between terrestrial and marine records, and does not suffer from issues of local facies changes or limited lateral extent of most other stratigraphic markers. Of course, the researcher must be aware of the limitations: relatively complete well-exposed sections of fine-grained rocks are required, as is an independent form of time control to allow calibration. Every sample must be carefully analyzed by multiple techniques to insure that the primary or characteristic remanence has been recovered and overprinting removed. Nonetheless, magnetic stratigraphy has improved our correlations of global events by several orders of magnitude, and corrected many erroneous correlations that were once widely accepted. It has allowed for many other interesting studies, such as analysis of rates of sedimentation, and tests of the isochroneity of biostratigraphic events. In short, the horizon is limitless for the application of paleomagnetism to stratified rocks.

Definition

Paleomagnetism is the study of the Earth's magnetic field in past times. A permanent record of the ancient magnetic field is recorded by certain ferromagnetic minerals formed in rocks either as they form, and/or when they are

subjected to later geological events. The past direction, and sometimes the intensity, of the geomagnetic field can be determined from this fossil magnetism. This information is essential for quantifying the motions of the tectonic plates that comprise the outer shell of the Earth (Plate Tectonics) and for evaluating the history of the geodynamo seated within the Earth's core. Although this contribution is concerned primarily with the record of fossil magnetism in the rock, the acquisition of magnetism is an ongoing process within materials forming during the present day; thus it is found, for example, in soft sediment, soils, and in organic material such as magnetotactic bacteria.

Introduction

The permanent magnetism residing in a natural material, lodestone, has been known for many centuries for its ability to align, and it has long been used for this purpose by navigators. It was generally believed that the pole star (Polaris) or a large magnetic island at the North Pole attracted lodestone compasses. However, William Gilbert (1544–1603) in his book *De Magnete, Magneticisque Corporibus, et de Magno Magnete Tellure* published in 1600, concluded that the Earth was a giant magnet. He argued that the centre of the Earth was iron. He documented an important and related property of magnets by showing that they could be cut so that each new magnet possessed north and south poles. In the nineteenth century, it was found that rocks were capable of becoming permanently magnetized in the direction of the ambient geomagnetic field, and Bernard Brunhes (1867–1910) found that young volcanic lavas in central France were magnetized in a direction opposite to the prevailing field. This is the phenomenon of geomagnetic reversal and in 1929 the Japanese scientist Motonori Matuyama (1884–1958) was the first person to show that reversals of the field had occurred at specific times during the geological past.

The geometry of the magnetic field direction at the surface of the Earth is described in terms of declination and inclination. Declination refers to the angle in the horizontal plane between true north and the geomagnetic direction along which the lines of magnetic field are directed. Since the magnetic field is also directed toward, or away from, the center of the earth it is usually inclined to the horizontal. The angle above or below the horizontal is termed the inclination; it is latitude-dependant and varies from vertically up or down at the magnetic poles to zero at the equator. For paleomagnetic study to yield a useful geometrical parameter for resolving ancient continental movements, it is important to demonstrate that the magnetic poles are constrained to the geographic poles of rotation. Records kept in London show that the declination of the magnetic field direction changed from 11°E in 1580 to 24°W in 1820, while the calculated position of the magnetic pole executed a path around, and close to, the pole of rotation. This is secular variation. When averaged over intervals of 1,000 years or more, the mean magnetic pole has been found to lie very close to the pole of rotation and this led P.-L. Mercanton (1876–1963) to suggest that fossil magnetism could be used to monitor the movements of the continents. An outcome of research conducted during World War II was the development by Patrick Blackett (1897–1974) of a sensitive magnetometer able to accurately measure the direction of magnetism in rock samples. It was first employed in the mid-1950s by Blackett and Keith Runcorn (1922–1995) to show that continents had moved over the surface of the Earth. This evidence placed the theory of continental drift, which had languished since being proposed by Alfred Wegener (1880–1930) in 1915, on a firm observational basis. When it was realized that the ocean crust could also preserve paleomagnetism, continental drift was rapidly integrated in the 1960s with the hypothesis of sea floor spreading to develop the theory of Plate Tectonics, a paradigm that has prevailed, with much refinement, to the present day. During this time, paleomagnetism has proved to be one of the most important techniques in the Earth Sciences with applications to many other fields including environmental sciences and archeology.

In addition to its long-term value for tracing the movements of continents and evaluating paleogeography, paleomagnetism has been used to unravel the history of reversals of the geomagnetic field polarity and derive the geomagnetic polarity time scale (GPTS), the chronology of periods of normal and reversed polarity. This in turn is the basis of magnetostratigraphy, the use of magnetic reversals to date rocks and correlate them from place to place. The evaluation of the intensity and the direction of the geomagnetic field from rocks such as lava flows that are rapidly formed and magnetized can be used to resolve secular variation. This latter phenomenon embraces the continuous and ongoing changes in the strength and direction of the geomagnetic field and is thus a signature of behavior of the geodynamo. In addition the direction and the fabric of fossil magnetism in rocks have applications to sedimentology, resolution of paleostress, fluid-migration through rocks, and to mineral exploration.

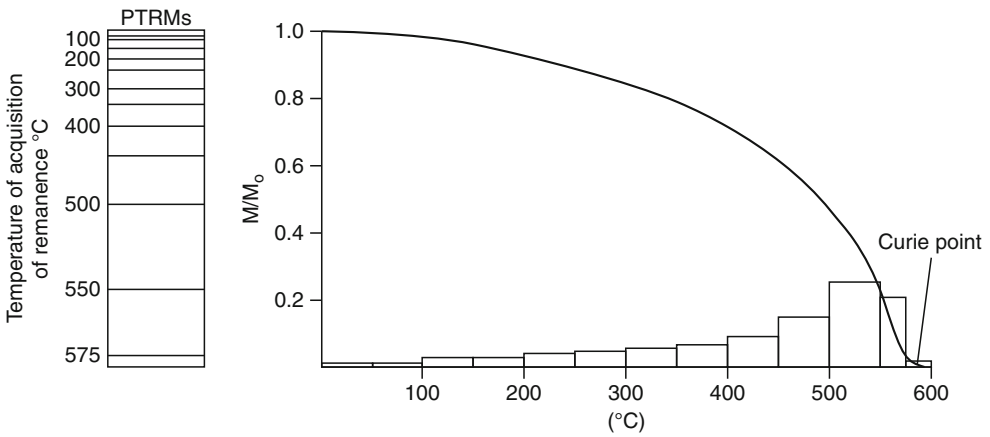
Rocks, like all natural materials, possess a weak *diamagnetism* in applied magnetic fields as the electron spins align with, and oppose, the field. Minerals containing transition elements such as iron and manganese also possess a stronger *paramagnetism* as unbalanced electron orbits align with and reinforce the field. However, these effects are transient and only survive as long as the applied field is present. Although important to the interpretation of the magnetic field over the ground, they are not relevant to paleomagnetism. Instead this relies on a memory of the magnetic field aligned with the ambient magnetic field lines at the time of rock formation, or at some later time period that can be determined from the geological history of the rock. In igneous and metamorphic rocks this magnetic memory resides in grains with ferromagnetic properties, which are usually iron-titanium oxides

(titanomagnetites) comprising a few percent of the total rock volume. Although the intensity of the Earth's magnetic field is quite weak (~0.5 T), as these rocks cool through the Curie point they are capable of acquiring a strong and stable magnetism from this field. The ferromagnetic minerals only have a transient weak diamagnetism and paramagnetism in the ambient field at high temperatures, but they acquire a permanent magnetization (ferromagnetism) as they cool through a critical temperature called the Curie point (generally <680°C). This is much lower than the temperatures at which many igneous rocks start to crystallize (~1,200°C) and is lower than the higher grades of metamorphism. If an igneous rock such as a dyke or lava flow cools rapidly at, or near to, the surface it will cool rapidly to this temperature over period of only days or weeks. It will then record a field direction that is instantaneous in geological terms and part of the secular variation rather than a long-term average of the field representative of the Earth's rotation axis. In contrast igneous rocks that cool slowly deep within the Earth's crust will integrate a record of the magnetic field over long periods of time; they may even record reversals of the geomagnetic field.

Since rocks contain magnetic grains with a wide diversity of size and magnetic domain properties, their magnetizations are acquired over a broad range of temperature below the Curie point. This trapping of remanence over a range from the Curie point down to ambient temperatures defines a blocking temperature spectrum (Figure 1). In igneous rocks the total spectrum is a Thermal Remanent Magnetization (TRM). This can be considered to be the sum of Partial Thermal Remanences (PTRMs), which obey the Law of Additivity: the remanence fraction acquired over any particular interval is discrete and independent of the fraction acquired over any other interval (Figure 1).

Many sedimentary rocks include grains of ferromagnetic minerals derived from the erosion of older rocks. When these grains are deposited they can be geomagnetically aligned if the influence of the Earth's magnetic field is stronger than gravitational and hydraulic forces. This is a Depositional Remanent Magnetism (DRM). Usually sediments undergo a protracted history of compaction and cementing (lithification) and sometimes chemical alteration (diagenesis), and may well also be disturbed by the burrowing of organisms (bioturbation). As these processes operate, the ferromagnetic grains usually have the opportunity to become more precisely aligned along the ambient geomagnetic field to give the rock a Post-Depositional Remanent Magnetism (PDRM). Chemical changes resulting in the precipitation of new ferromagnetic minerals produce a Chemical Remanent Magnetism (CRM). In sedimentary rocks such as limestone ferromagnetic grains may be formed directly by diagenetic processes or may incorporate magnetite grains precipitated by magnetotactic bacteria. Although these secondary processes are often still poorly understood, they operate over long time periods and therefore always tend to integrate the geomagnetic field to provide information that is of paleomagnetic rather than of short-term geomagnetic significance.

Paleomagnetism is a time relaxation phenomenon since all natural magnetizations decay with time and relax into the field prevailing at the present day. Nevertheless this relaxation time is very long, and longer than the age of the Earth for many small ferromagnetic grains. It is the very great length of time required for some natural magnetizations to decay, which means that a record of permanent magnetism is still preserved, even from the oldest rocks on Earth. Nevertheless, it also means that if a rock is metamorphosed at an elevated temperature below the Curie



Paleomagnetism, Measurement Techniques and Instrumentation, Figure 1 A blocking temperature spectrum of Thermal Remanent Magnetization (TRM) showing the progressive fraction reduction of an initial magnetization M_o. Each segment of the TRM is referred to as a Partial Thermal Remanence (PTRM) and these segments obey a Law of Additivity: TRM = PTRM (550–500°) + PTRM (500–450°) + PTRM (450–400°) +.

point and this temperature is sustained for many millions of years, it is capable of being totally demagnetized. It will then acquire a new magnetism recording the time of metamorphism.

In the late 1950s it was also recognized that the rocks commonly acquire secondary magnetizations by a range of processes that include not only later temperature elevation, but also chemical change. The total magnetism in a rock, referred to as the Natural Remanent Magnetization (NRM), is then the vector resultant of the primary magnetization acquired when the rock was formed and the secondary magnetization (which may include several components) acquired during subsequent geological times, or even during coring and sampling. The chief goal of paleomagnetic investigations is to isolate the various components of remanence, and ascribe an origin, age, and reliability to them. The resolved directions from each component may then be used to compute geomagnetic (short-term) or paleomagnetic (long-term) pole positions. This calculation usually assumes that the source of the field can be approximated by an axial geocentric dipole (GAD) constrained to the Earth's rotation axis. The following sections describe the laboratory procedures and techniques of analysis employed in paleomagnetism to achieve these goals.

Techniques of sampling, measurement, and analysis

Field sampling

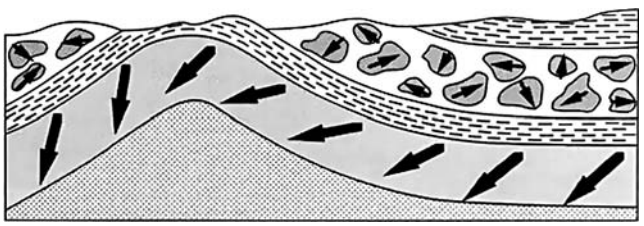
Paleomagnetic sampling procedures follow a hierarchical approach to average out the secular variation and compensate for other inaccuracies. The sampling strategy will be adapted to the time scale of the scientific objective. Typically oriented samples are collected from a number of different localities termed *sites*, each of which can be considered to represent a single time-instant record of the geomagnetic field. A number of such sites will be sampled within a single rock formation. The rock formation may comprise, for example, a suite of lava flows recording a volcanic episode, an igneous intrusion, or a succession of sedimentary beds. The sites clearly need to be in situ, cover a significant regional area, and comprise a representative distribution through the time interval represented by the rock formation. This will ensure that although units such as lavas may record an instantaneous record of the field, the time interval covered by the collective survey is adequate ($\sim 10^5$–10^6 years) to average the effects of secular variation and any longer term excursions of the geomagnetic field. It can then derive a long time-average assessment of the paleomagnetic field direction. Each site will constitute a number of separately oriented samples (N) to compensate for orientation and instrumental errors, and for possible failures to completely separate magnetic components during laboratory treatment. Sample orientation procedures typically have an uncertainty of $\sim 3^\circ$ and precision is gained in proportion to $N^{1/2}$ where N is the number of samples; hence to improve the precision from 3° to 1°, nine or ten individually oriented samples are required. In the case of magnetostratigraphy, where determination of the polarity of a rock level is the major objective, three samples are usually regarded as sufficient to determine the polarity unambiguously.

The samples are taken as oriented cores drilled in situ using portable drilling equipment (Figure 2), or are extracted in the laboratory from oriented block samples; the former method is preferred both because initial accuracy is higher, and because accuracy is lost when block samples are reoriented for laboratory drilling. There are several orientation schemes currently in use but each one employs an orientation device designed to provide an in situ geographic orientation using magnetic and Sun compasses (Figure 2). Since the magnetism of the rock outcrop can influence the reading of a magnetic compass, Sun-compass observations are preferred and use the direction of the shadow, together with a record of the time and sampling location; the azimuth is determined with the aid of the Astronomical Almanac or a simple algorithm. A new orientation device developed by C. Constable and F. Vernon at the Scripps Institution of Oceanography (Lawrence et al., 2009) uses the Global Positioning System (GPS) and laser technology to produce similar accuracies to the Sun compass, although its application requires at least an additional half hour. Nonetheless, achieving sun-compass accuracy is a major breakthrough for paleomagnetic field procedures in regions where siting of the Sun may not be possible. The paleomagnetic specimens recovered for laboratory analysis are typically cylinders $\sim$1 in. long and 1 in. in diameter (Figure 2).

A paleomagnetic field sample should be integrated with geological evidence so that it incorporates widely separated localities linked to defined rock formations for which the tectonic setting is properly understood; this will enable any effects of tectonic deformation on the recovered directions of magnetization to be accounted for. The survey will also need to accommodate any effects of regional or local heating by metamorphism or igneous activity, and also the possible influence of any chemical alteration, for example, by hydrothermal activity. It is also best to avoid elevated exposed locations because these are liable to have been struck by lightning. Lightning is a line current and the associated magnetic fields can induce a strong Isothermal Remanent Magnetization (IRM), which is capable of largely or completely replacing an ancient remanent magnetism in the rock.

A number of paleomagnetic field tests exist, which can be applied to help constrain the age of the magnetization in a rock formation. The fold test compares the directions of magnetization derived from two limbs of a fold before and after adjusting for the tilting of the beds (Figure 3); an improved grouping after adjustment indicates that the magnetization was acquired before the folding episode occurred. Sometimes the optimum grouping of directions from the limbs is attained at an intermediate stage of untilting, which would indicate that the magnetization was acquired during the tectonic event responsible for

Paleomagnetism, Measurement Techniques and Instrumentation, Figure 2 Collecting and orienting rock samples for paleomagnetic study. The cores are drilled (**a**) with a portable motorized coring machine. (**b**) An orienting tool is inserted around the core to determine the inclination and the azimuth by Sun and magnetic compasses. (**c**) The core is extracted and coded. (**d**) A line on the core is used to fix the extracted core with respect to the orientation readings using a directed line on the top or the bottom.



Paleomagnetism, Measurement Techniques and Instrumentation, Figure 3 Schematic cross section of ground showing a fold and conglomerate layer with magnetic components (*black arrows*) illustrating the concepts behind the fold and conglomerate tests used in paleomagnetism.

the folding. The conglomerate test compares the directions of magnetization in a number of pebbles in a boulder bed, preferably when these pebbles can be linked to a source in an underlying bed (Figure 3). If the directions are random it demonstrates that pebble bed has not been remagnetized since formation and that the magnetization in the bed that they were derived from is likely to be primary. If the directions of magnetization in the pebbles are uniformly directed, it is apparent that a later remagnetization event has influenced the formations including the pebble bed. The reversal test compares directions of opposite polarity to evaluate whether they are statistically antiparallel and therefore likely to be the record of a reversing dipolar field. Each of these tests can be placed on a sound statistical basis using methods described in textbooks on paleomagnetism (e.g., Tauxe, 1998).

Measurement and treatment

The Natural Remanent Magnetization (NRM) of a rock sample is the vector sum of the remanent magnetic moments of all the magnetized particles contained within it. These particles are likely to have a wide range of sizes and magnetic domain structures, so the record of primary to secondary magnetization (or even no preserved remanent magnetism at all) will vary greatly. Magnetometers measure the magnetization of rock samples in three mutually perpendicular directions (X, Y, and Z) and the values are compounded to yield the magnitude and direction of the resultant vector. Using the field orientation parameters for the sample (usually as noted above, in the form of a short cylindrical core) the data from the specimen coordinate system can be transformed into geographic coordinates and displayed graphically on a stereonet. The geographic vector can be considered in terms of declination (D), inclination (I), and magnitude (M); M does not change during the transformation of coordinate systems.

The observed NRM of rocks may consist of any combination of primary and secondary components and it is essential to separate these to unravel the magnetic history of the rock. This separation is achieved by partial demagnetization procedures referred to as "cleaning," which rely

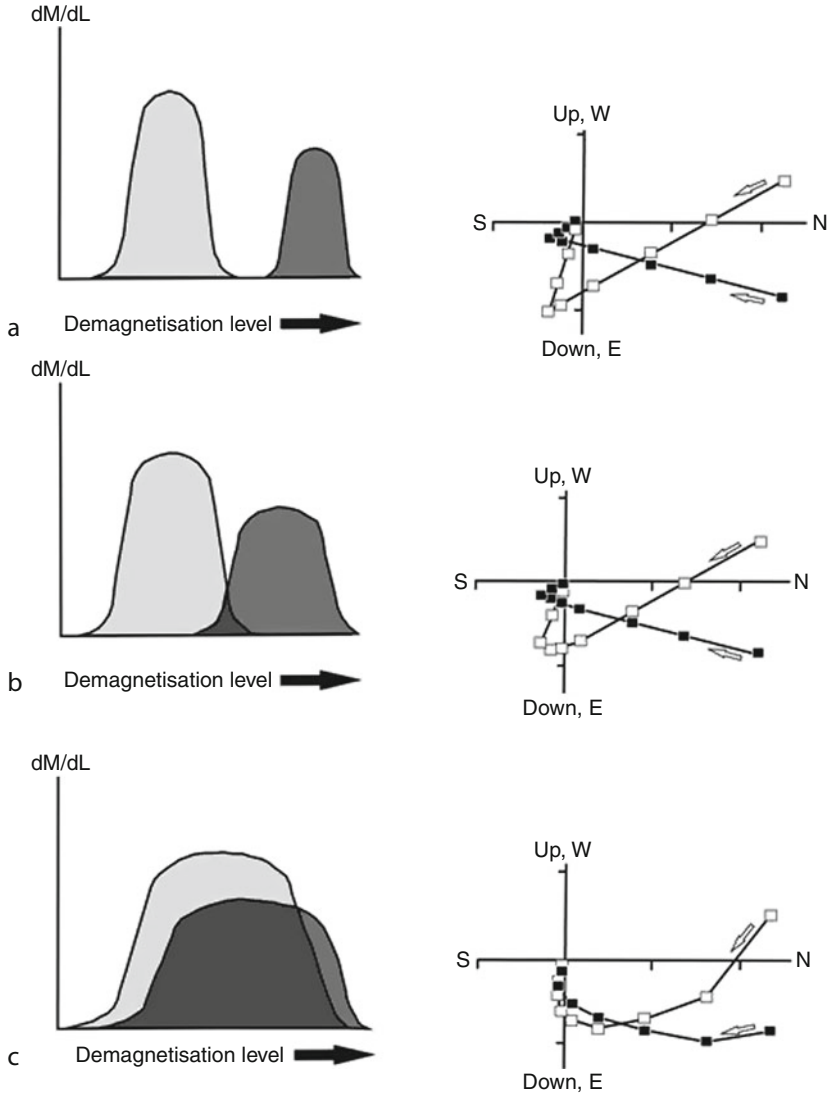
on the observation that magnetic components of different ages and modes of acquisition usually have contrasting thermal and magnetic blocking temperature spectra. Alternating field and thermal demagnetization techniques are now a routine part of paleomagnetic investigations and depend on the relationship of relaxation time to coercivity and temperature to subtract (demagnetize) the lower coercivity or blocking temperature components. Alternating field (AF) demagnetization selectively removes components with short relaxation times that typically have low coercivities. The basis of the thermal demagnetization technique is that these grains also have low unblocking temperatures: the lower the relaxation time, τ, the more likely the grain will carry a later secondary magnetization. All ferromagnetic grains are subject to a number of competing internal forces (see, e.g., Butler, 1992 and Tauxe, 1998) and larger grains tend to subdivide into zones of homogeneous magnetization in order to minimize the total magnetic energy. These *domains* are separated by narrow domain walls typically up to 100 atoms thick where the magnetic dipoles are canted around from one orientation to the other. In magnetite (Fe_3O_4)-bearing rocks, the secondary NRM tends to be carried mostly by multidomain (MD) grains with lower relaxation times while the primary characteristic remanence (ChRM) tends to be retained by single domain (SD) or pseudo-single domain (PSD) grains; the latter have sizes larger than SD but have shape or defect properties that enable them to retain remanence like SD grains. MD grains have coercivities predominantly $<$20 mT, whereas SD and PSD grains have higher coercivities. AF demagnetization can thus selectively remove secondary NRM and leave the primary magnetization unaffected. Rocks containing the less common ferromagnetic minerals pyrrhotite ($Fe_{1-x}S$) and maghemite have properties that are fairly comparable to magnetite but hematite (αFe_2O_3), which tends to be the commonest ferromagnetic constituent in sedimentary rocks, has much higher coercivity and cannot be effectively subtracted by AF demagnetization. Since hematite has a higher Curie point ($\sim$670°C) than the other common ferromagnetic minerals, it requires demagnetization to higher temperatures. Since hematite can also be an oxidation product of magnetite in igneous and metamorphic, and sometimes in sedimentary rocks, its magnetic remanence may only be subtracted by thermal demagnetization after the magnetite remanence has been removed. In this specific case, the primary magnetization in magnetite may be unblocked below a secondary magnetization residing in hematite.

AF demagnetization is unable to completely subtract the magnetism in any rock – the applied alternating fields required to do this are simply unattainable in the laboratory and would in any case, present their own problems. Thermal demagnetization, however, is capable of fully subtracting magnetization if it is continued to the Curie point. It is applied by heating the sample to a specified temperature and cooling the sample in a zero magnetic field so that all magnetization blocked below the assigned temperature is then unblocked and removed. Demagnetization proceeds in increasing temperature steps until the Curie point is passed and all remanence in the rock has been subtracted. The experimental procedure is best conducted in a field-free space so that magnetization cannot readily be imparted from the ambient field before the treated samples have been measured.

Analysis

A stereographic plot of magnetization directions at each stage of demagnetization treatment, although generally used in older studies (see Collinson, 1983 for details of plotting), is not a satisfactory way of resolving the components of remanence because these directions will likely record the resultant of two or more components. Instead it is usual to illustrate the vector (with three-dimensional properties) in two-dimensional space by projecting it onto two planes at right angles. These projections can be combined together on a single projection and are described as "orthogonal plots." They were first applied to a paleomagnetic study by Wilson (1961) and the display technique was formalized by Zijderveld (1967). The *D*, *I*, and *M* data of the progressive demagnetization experiments may be resolved into north, east, and downward (or upward) components to construct a vector component diagram (Figure 4). The base of the NRM vector is placed at the origin of the Cartesian coordinate system and the tip of the vector is projected onto two orthogonal planes. The distance of each data point from the origin is proportional to the intensity of the NRM vector projected onto the plane. The projections of the NRM vectors onto the horizontal plane are constructed by plotting N versus E and the second projection plots progressive NRM data onto a vertical plane. A vertical component of the NRM vector at each demagnetization level is plotted against the north (or east) component. It is a common practice to denote projections on the horizontal plane and vertical planes by solid and open symbols, respectively.

An important observation is that a linear trend of projected points defines the progressive removal of one component only (Figure 4a). If this line migrates toward the origin of the projection it demonstrates that only the high unblocking temperature or coercivity magnetization is left to be removed. Thus the successive removal of the lower unblocking temperature or coercivity magnetizations, and the isolation of the highest unblocking temperature/coercivity component, can be achieved by the recognition of successive linear trajectories. The last component to be resolved is often designated as the Characteristic Remanent Magnetization (ChRM) and is usually the most interesting component for interpretive purposes, although the secondary components removed below this may be of interest for resolving the later history of the rock, especially if they can be linked to a later event such as a thermal pulse or a diagenetic episode. The direction of any component represented by a straight-line segment on an orthogonal plot can be recovered by extracting that



Paleomagnetism, Measurement Techniques and Instrumentation, Figure 4 The orthogonal projection of demagnetization data during progressive demagnetization. When (**a**) there is no overlap between the blocking temperature/coercivity spectra of the sample, the lower and higher components are defined by discrete straight-line segments as they are unblocked by thermal demagnetization or subtracted by AF demagnetization. As the overlap of the spectra increases (**b, c**), the orthogonal projection becomes progressively more curved and linear segments are no longer observed when both spectra are being subtracted at the same time (**c**). Note that declinations can be read directly from the horizontal projection of the vector although a direct reading of inclination is not possible. (After Collinson, 1983.)

component from the data above and below and treating it as a unique component.

The shape of the trajectory of vector projections depends upon the degree of overlap of the coercivity or blocking temperature spectra of the components (Figure 4). When the spectra do not overlap, the vector diagram displays successive linear trajectories, each one recording the subtraction of a component. If overlap is only partial, straight-line trajectories are still identified but intermediate points corresponding to the overlap display a curved trajectory (Figure 4b). If there is complete overlap between the spectra the vector component diagram does not possess linear segments (Figure 4c) but the trajectories may sometimes be used to isolate the components if they define a great circle, a "circle of remagnetization." A single great circle on its own provides insufficient information to estimate the ChRM direction, but if more than one circle is available from different specimens and these circles converge, then the convergence point, or its antiparallel equivalent, can yield an estimate of the ChRM. Halls (1979) reports a procedure for calculating the best-fitting convergence point of several great circles. The majority of convincing paleomagnetic results come from one and two component structures, although paleomagnetic workers

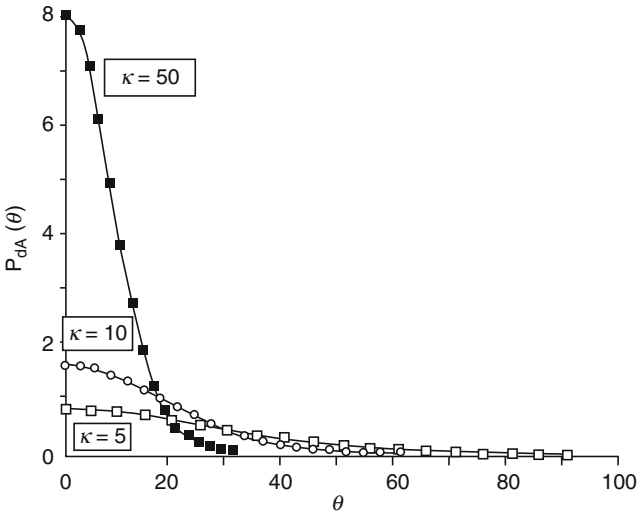
have ventured into the study of rocks with complex magnetic histories comprising multicomponent NRMs, and combinations of AF and thermal demagnetization have been used to isolate complex remanence structures.

The procedure for separating and resolving the directions of individual components is Principal Component Analysis (PCA) and comprises a method for determining the direction of the lines or planes that best fit the data described by the orthogonal projections (Kirschvink, 1980); essentially a component segment is isolated from the orthogonal projection and isolated as though it is the only component present in the rock. An advantage of this method is that it compensates for errors due to signal to noise ratio, and provides a quantitative measure of the precision of the direction. The precision of the direction determined from the best-fit line is described in terms of a Maximum Angular Deviation (MAD) and MAD values <15 are usually considered to be acceptable.

Statistics

As with all experimental data, the directions resolved by PCA will be associated with a number of random errors arising from factors such as instrument noise, inaccuracies in sample orientation, imperfections in demagnetization, and secular variation of the recorded geomagnetic field. The net result of all these factors is a dispersion from which the researcher requires the best estimate of the mean direction. Determining a mean and confidence limit from any set of values by a statistical method is based on a probability density function. A function applicable to paleomagnetic directions was developed by Fisher (1953) and provides a simple procedure for treating paleomagnetic data. Fisher's analysis treats each accepted direction in the population as having a unit weight and represents it as a point on a sphere of unit radius. The dispersion of these points on the sphere is assumed to have a circular Gaussian distribution (Figure 5) and the mean of the set of directions is calculated by vector addition: each unit vector is resolved into three orthogonal components in Cartesian coordinates and the components are summed to obtain the length of the resultant vector (R) and the mean direction (D and I). D and I define the direction of the best estimate of the mean while R is used to assess confidence in the result.

Two simple parameters, k and α_{95}, are used to illustrate the quality of the calculated mean in paleomagnetic studies. The probability of finding a direction at an angle (θ) from the calculated mean is expressed in terms of a probability function involving a precision parameter κ. Fisherian statistics use an approximation for κ defined by a parameter denoted by $k = (N-1)/(N-R)$ where N is the number of directions and R is the length of the resultant vector. The α_{95} value in degrees defines the angular radius of the cone of confidence projected from the center of the unit sphere within which we have 95% confidence that the true direction actually lies. It is simply calculated from $\alpha_{95} = 140/(k \times N)^{1/2}$ and is comparable to the standard



Paleomagnetism, Measurement Techniques and Instrumentation, Figure 5 The Fisher circular distribution derived from the Gaussian probability function. $P_{dA}(\theta)$ is the probability per unit angular area of finding a direction within an angular area, dA, centered at an angle θ from the true mean. Distributions are shown for values of the precision parameter κ, of 50, 10, and 5.

estimate error of the mean in Gaussian statistics; 5% of the observed directions are expected to fall outside of this circle. High reliability in paleomagnetic analysis is therefore expressed by large k and small α_{95}. As with all statistical analysis, precision estimates are improved by increasing the sample population although in terms of experimental effort the increase becomes progressively less worthwhile for large values of N. Sample populations from a single unit such as a lava flow are generally considered satisfactory if N is 7 or more, while k values <10 are unsatisfactory.

Determination of paleomagnetic poles

The resolved mean direction of magnetization is used directly in many analyses and interpretations – in regional, small- to medium-scale tectonic problems. However, for larger scale analysis such as the determination of past global geometries and analysis of the geomagnetic field it is necessary to convert it into an equivalent pole position. This also provides a meaningful way of comparing ChRM directions from rock formations of same age, but widely separated on the same continent or tectonic plate; for this purpose a common reference system is necessary and is provided by the paleomagnetic pole. The pole position is the position where the geomagnetic field axis responsible for the observed paleomagnetic field direction meets the surface of the Earth. A model is required to perform this calculation. Since more than 90% of the present geomagnetic field can be explained in terms of an axial geocentric dipole source, this is the model normally used to calculate paleomagnetic poles and the position is

expressed in the present geographic longitude – latitude grid. For a paleomagnetic field of inclination I, the ancient latitude (λ) of the site is given by the simple formula Tan $I = 2$ Tan λ. The equations required to calculate the position of the paleomagnetic pole require the declination D and the coordinates of the sample locality in addition to the inclination. They are given in all paleomagnetic text books (see, e.g., Tauxe, 1998).

The geomagnetic pole calculated from a single geomagnetic field observation (e.g., from a single lava flow) yields a Virtual Geomagnetic Pole (VGP) and will include components of the non-dipole field incorporating the secular variation. A paleomagnetic pole is calculated from a number of VGPs derived, for example, from several lava flows or levels through a sedimentary section and is anticipated to have averaged non-dipole field components so that it represents the Earth's rotation axis at the time that the ChRM was acquired by the rocks. The angular dispersion of the VGPs constituting the collection can be used to test whether this is effectively achieved by comparison with the dispersions achieved by secular variation during historic and recent geological time (McFadden et al., 1991). The expected angular dispersion is a function of latitude although the comparison is presently of limited value because the comparative database is sparse in the southern hemisphere and temporal coverage is poor. Confidence limits for a paleomagnetic pole are derived from α_{95}, the radius of the cone of 95% confidence about the mean direction. These translate into an oval of confidence within which we have 95% confidence that the pole actually lies. The maximum and minimum radii of this oval are given by $dp = 2\ \alpha_{95}\ (1/(1+ 3\text{Cos}^2 I))$ and $dm = \alpha_{95}$ (Sin p/Cos I) where p is the magnetic colatitude or the great-circle distance from the sampling location to the pole.

Instrumentation

The magnetization intensity can vary by several orders of magnitude between different rock types. Strong magnetizations can be rapidly measured with instruments of low sensitivity while weak magnetizations require more sensitive instruments and the measurements may need to be integrated over longer periods of time. The magnetometer developed by Blackett (1952) utilized the deflection of a suspended astatic magnetic system. Since this system is sensitive to vibration and measurements are relatively slow, it is now obsolete. Spinner magnetometers are used to measure magnetizations of strong to intermediate intensities, including those found in many igneous and metamorphic rocks. These magnetometers are less suitable for sedimentary rocks, which can often be weakly magnetized, and superconducting magnetometers (superconducting quantum interference devices-SQUIDs) are then required.

Spinner magnetometers

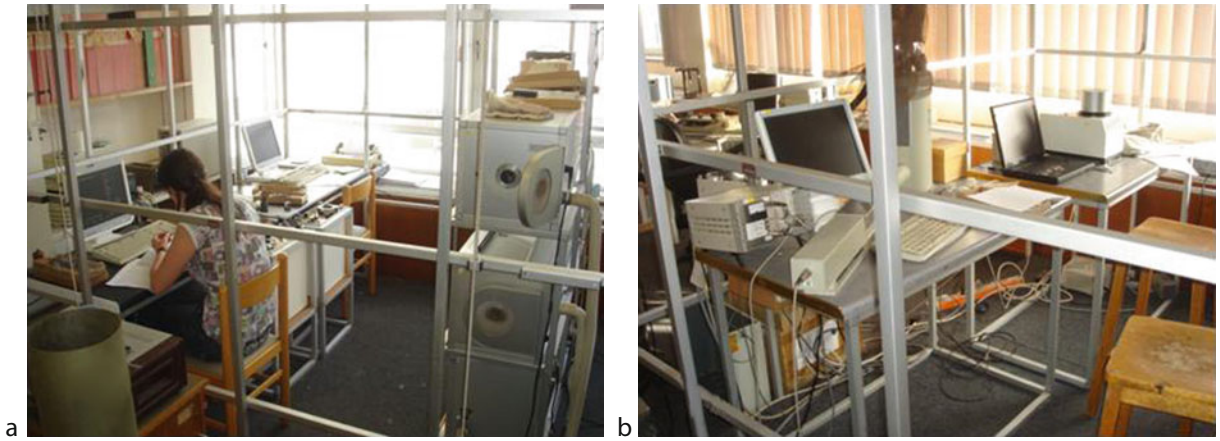
In the spinner magnetometer the sample is spun adjacent to a detecting coil. A fluctuating electromotive force (emf) is induced proportional to the magnetization with the amplitude of the output voltage proportional to the component of magnetic moment perpendicular to the rotation axis ($P_\perp$). The phase of the voltage is utilized to relate the direction of the measured component to a reference direction in the sample. The sample is rotated successively about three axes to obtain average values of the NRM components and reduce the effect of inhomogeneity to $\sim 2^\circ$ in direction and $\sim \pm 5\%$ in intensity. During the early development of spinner magnetometers, measurement of weak magnetizations was achieved by increasing the rotation speed and by careful design of the pick-up coil system. Since electric motors operating at a frequency of ≈ 100 Hz are required for rotating the samples, a challenge to the design has been the requirement to shield this unavoidable source of electromagnetic noise from the measuring assembly. This problem can be reduced by using an air turbine, and in modern magnetometers, the frequencies used are in the range 5–80 HZ with signal discrimination circuits employed to reduce the effects of noise.

The usual procedure for NRM measurement is to spin each sample in six mutually orthogonal orientations so that any two of X, Y, and Z are in turn perpendicular to the spin axis. Since two orthogonal components of magnetization are obtained from each spin, the orientations are chosen to provide four determinations each of X, Y, and Z, usually two of each sign for each component. This procedure tends to average out any random noise on the signals, the effects of inhomogeneity of NRM, and any remanent magnetism in that part of the sample holder permanently attached to the shaft. The six sample orientation used should ideally satisfy the following: (a) provide two values each of $+x$, $+y$, and $+z$, (b) distribute the displaced dipole caused by inhomogeneity of the NRM as uniformly as possible in space, (c) average the possible error arising from imperfect calibration of the NRM direction of the magnetometer, and (d) measure each NRM component in each "channel" of the magnetometer, that is, the sample is placed in the holder with X, Y, and Z each in turn parallel and perpendicular to the reference direction.

Some commercial spinner magnetometers (Figure 6b) can now achieve sensitivities close to those attainable with SQUID magnetometers, but since they need to be run at high speed they are unsuitable for friable or poorly shaped samples.

Cryogenic magnetometers

Developments in cryogenic technology have had important implications for paleomagnetic analysis. Firstly they have permitted an increase in sensitivity by one to three orders of magnitude and the rapidity of measurement has permitted study of a wider range of rock types than has been possible hitherto. Secondly it is possible for magnetism in a sample to be measured by a single insertion into the sensing coils because only one axis of the sample needs to be presented to the magnetometer. Magnetic



Paleomagnetism, Measurement Techniques and Instrumentation, Figure 6 Instrumentation in a typical paleomagnetic laboratory. Measurements and demagnetization procedures take place within large sets of Rubens coils designed to continuously nullify the ambient geomagnetic field. In (**a**), two thermal demagnetizers are stacked on the right; these are designed for the treatment of trays of multiple cores to specified temperatures for programmed time intervals. On the left, the operator is using one of two interfaced spinner magnetometers for measurement of relatively strongly magnetized rock samples. (**b**) Two magnetometers used for the measurement of weakly magnetized rock samples are an FIT hydrogen SQUID magnetometer on the left and a JR6 high speed spinner magnetometer on the right.

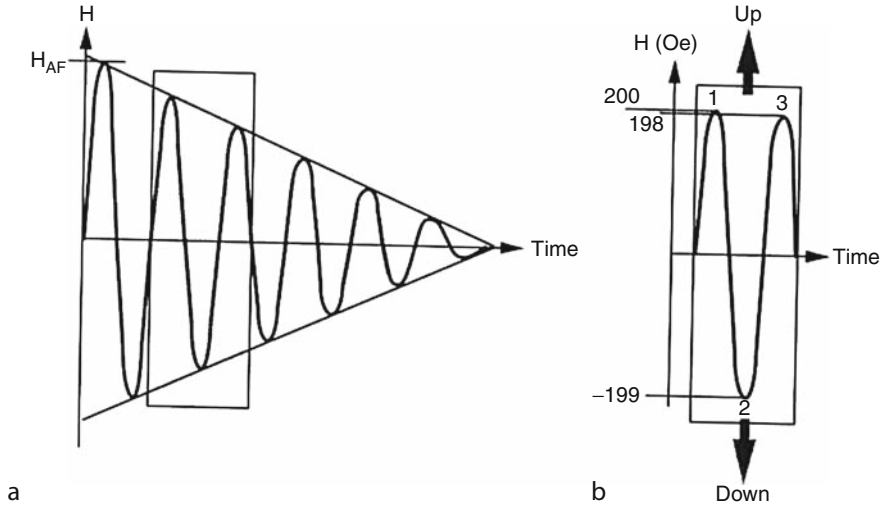
and thermal cleaning can then potentially be automated with the measuring procedure. Cryogenic magnetometers use the properties of a superconducting ring made of a metal with perfect diamagnetism, which causes the expulsion of all magnetic flux from the ring below a certain temperature. When an external field is applied in the superconducting state all flux is expelled from the interior of the metal but not from the hole within the ring; this means that induced currents flow in one direction on the outer face of the ring and in the opposite direction on the inner face. If the applied field is removed the currents on the outside of the ring disappear but the current on the inside face persists to maintain a field within the ring.

The ability of the ring to trap and maintain magnetic fields to better than one part in 10^9 can be used in magnetometry by trapping a zero field within the loop and then using this volume for measurement. These magnetometers are operated at the superconducting: resistive boundary. The ring current is quantized so any flux entering the ring at this transition state is also quantized and is measured in terms of a feed-back current. The magnetometer is surrounded by an insulating evacuated space cooled by liquid helium or nitrogen and pick-up coils connected to SQUID detectors are employed to measure the NRM along one axis or simultaneously along two or three mutually perpendicular axes. Mumetal shields are employed to blanket external field variations and some automated systems allow complete demagnetization within this field-free environment. Cryogenic magnetometers are faster and typically more sensitive than spinner magnetometers but cost much more to purchase and operate; the liquid nitrogen represents an ongoing cost, and while helium can achieve lower temperatures it is more expensive and less commonly used these days. For further details on these magnetometers the reader is referred to Collinson (1983) and Tauxe (1998).

Alternating field demagnetizers

In AF demagnetization, an oscillating field is applied to a paleomagnetic specimen in a nullified magnetic field environment. The equipment comprises a coil, a capacity bank for tuning the coil, a power supply and current reduction mechanism, a coil system or magnetic shield for providing a low ambient field over the sample, and a sample tumbler. The rock specimens are rotated within the center of the coil in a tumbling system incorporating simultaneous rotation about horizontal and vertical axes. The ratio of the two tumbling rates is designed to expose as many configurations of the sample as possible to the applied field acting along the axis. The applied current is then smoothly and gradually reduced to zero as the specimen continues to rotate. Most modern AF demagnetizers are designed to achieve initial fields in excess of 100 mT. It is essential to ensure that the geomagnetic field within the demagnetizer is completely cancelled or the specimen may acquire an Anhysteretic Remanent Magnetization (ARM), and an alternating field with a very pure waveform is essential for the best results than avoid rotational and gyro magnetic effects.

The theory of AF demagnetization is explained by Butler (1992). The waveform of the applied alternate magnetic field is a sinusoid with linear decrease in magnitude with time (Figure 7). The expanded figure (b) emphasizes the smooth decrease required. All the grain moments with coercivities below the peak AF will track the field. These entrained moments will become stranded, however, as the peak field drops below the coercivities of individual magnetic domains. The directions of stranding will be



Paleomagnetism, Measurement Techniques and Instrumentation, Figure 7 (**a**) The generalized wave form of the magnetic field used during AF demagnetization and (**b**) expanded version of a small portion of AF demagnetization between two successive peaks. (After Butler, 1992.)

effectively random if the tumbler has been appropriately designed to present as many configurations as possible of the sample to the declining applied field. By progressively increasing the applied field, the domains of successively higher coercive force are randomized or subtracted from the total measured remanence. The coercive spectra of the sample can then be resolved up to the maximum field of demagnetization and contributions of successive components to the NRM resolved by application of orthogonal projections and PCA. As noted above, AF demagnetization is unable to fully subtract the NRM in a rock and is ineffectual with hematite-bearing rocks due to the high coercivity of this mineral.

Thermal demagnetizers

Thermal demagnetizers can serve the purpose of both demagnetizing the NRM in paleomagnetic specimens and applying a partial thermal remanent magnetization (pTRM); the latter procedure is used for investigating the record of the ancient intensity (paleointensity) preserved in some rocks. If the temperature of the rock is raised until the relaxation time of some fraction of the particles carrying NRM has been reduced to a few minutes or less, the NRM of these particles will be unblocked. Their contribution to the NRM of the rock will be lost if they are cooled to the ambient temperature in a zero field. In this way, the contribution of lower stability grains to the NRM can be randomized. Alternatively, if a DC field is applied during cooling, the grains whose unblocking temperatures have been exceeded will be realigned into the new applied field direction; they will then have acquired a pTRM. If the rock sample is subjected to successively higher temperature treatments, the lower blocking temperature components are progressively removed. The components contributing to the NRM are then progressively subtracted and can be resolved by projecting the successive magnetizations on an orthogonal projection and applying PCA.

Thermal demagnetizers comprise a magnetic shielding system to exclude the ambient field, a furnace, a thermocouple, and a temperature control unit. A prime concern is the control external magnetic field, while the furnace should be of sufficient size to hold a reasonable number of samples (10–50) and to give a uniform temperature through them ($<\pm 10^{\circ}$C at 600°C). The winding of the heating coil onto the curved surface of a silica tube forming the inside wall of the furnace is noninductive to reduce stray magnetic fields. It is required to be capable of heating samples to a temperature ($\sim$700°C) in excess of the highest Curie points of the ferromagnetic minerals over a reasonable time ($\sim$1 h). The available maximum voltage is usually that of the electrical mains. The maximum current is dictated by that of the temperature controller being used, or of a variable transformer, and thus the resistance of the furnace winding is determined. Between 20°C and 700°C the resistance of the winding will increase (by 5–10%). If the resistance determined from the available voltage and current is the cold resistance, the current (and heating rate) decreases at high temperatures, whereas if it is the hot resistance the cold current will be slightly above that calculated. The wire diameter depends on the size of the furnace and the number of turns with a minimum separation of the turns set by the requirement for sufficient insulation between them; a wide separation is detrimental to temperature uniformity.

Although large furnaces are useful for dealing with many samples at once, their thermal inertia is considerable and may cause problems with temperature control. A suitable thermocouple material is Pt/13%Pt-Rh, with an output of $\sim$6.7 mV at 700°C. The thermocouple tip may be covered with a standard rock sample to the center of which an axial hole has been drilled. It is then likely that

the rock samples will be uniformly heated throughout the indicated temperature, by ensuring that the thermal inertia of rock and thermocouple are similar. Several commercial temperature controllers are available for automatically raising and holding the furnace temperature to a preselected value. The controller senses the furnace temperature via a thermocouple placed close to the furnace winding.

Some furnaces are designed so that it is possible to conduct heating/cooling cycles in an inert atmosphere or in a vacuum to minimize oxidation. Although thermal demagnetizers are in principle, capable of completely removing the NRM in a rock and thereby recovering the entire component structure in a way that may not be resolvable by AF demagnetization, this is seldom fully achievable in practice. The limitations are the difficulty of completely canceling the ambient magnetic field without excessive shielding and the possibility of chemical alteration during the successive heating and cooling cycles. To surmount the latter problem, microwave systems are in the process of development. They have been successively applied to paleointensity studies by a few laboratories (Walton et al., 1992) but have not yet been produced with a capability for routine NRM demagnetization.

Summary

A record of the past magnetic field, known as magnetic remanence, is preserved by ferromagnetic mineral grains in rocks and other natural materials. These minerals are mostly oxides of iron (magnetite, hematite, maghemite) and some types of sulfide (pyrrhotite). Although they usually comprise no more than a few percent of the total rock volume, they provide key information for geology and geophysics, and for the wider fields of the environmental sciences and archeology. The material for study is collected in the form of small oriented samples in sufficient numbers and distributed amounts to be representative of a sample of the ancient magnetic field for short periods of time (study of secular variation and short-term geomagnetic field behavior, archeological applications) or long periods of time (geology and geophysics). The magnetizations are measured using magnetometers designed for determining a range of strong to weak natural magnetizations that comprise spinner magnetometers based on the current induced in a detector system as the sample is spun near to a coil, or SQUID magnetometers based on cryogenic technology.

The magnetizations in most materials are composite effects comprising the vector sum of a primary magnetization imparted when the rock was formed and secondary magnetizations acquired during later events that may have influenced the rock. These component magnetizations are separated and resolved by demagnetization procedures that progressively subtract the magnetization resolved either in terms of the coercivity spectrum of the magnetization (AF demagnetization) or the blocking temperature spectrum (thermal demagnetization). The magnetizations are resolved by projecting the successive values of the vector during this progressive treatment onto a two-dimensional orthogonal plot and identifying the constituent components from their contributions to the coercivity/blocking temperature spectra. The populations of magnetic directions resolved from a paleomagnetic study are statistically analyzed using a system of (Fisherian) statistics assuming that each direction is of equal importance and the population can be represented in terms of a circular Gaussian distribution. Two simple parameters comprising a precision parameter k, and a cone of 95% confidence α_{95} are used to express the quality of the result. The mean direction can be converted into an equivalent geomagnetic of paleomagnetic pole by assuming that the source of the field direction resolved at the surface of the Earth originates in a geocentric dipole source in the Earth's core. In the long-term application, this dipole may also be assumed to be axial and constrained to the rotation axis of the Earth.

Definition and introduction

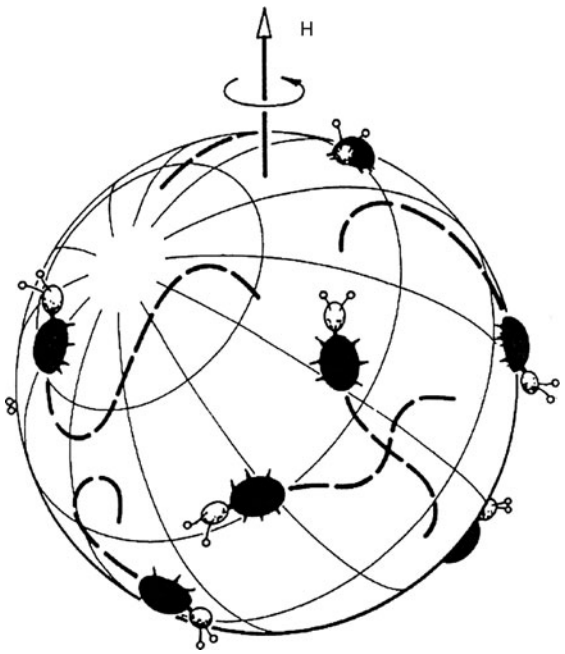
For more than two centuries, geoscientists have suggested, based on geological field observations (reconstruction of paleoclimate belts based on fossils or certain rock types), that the past Earth's equator (and Equatorial conditions) must have at some time been located far from its present position. In the early 1950s, paleomagnetists such as Runcorn (1956) provided quantitative evidence that the instantaneous geographic or rotation pole had moved with respect to certain continents. The paths followed by the poles in the geological past were termed "apparent" polar wander paths (APWPs), because it was not clear whether it was the pole or the continent that had moved. Since then, we have learned that oceanic and continental plates have moved with respect to each other and that a significant part of APW was actually due to these relative motions. A remaining fraction in polar wander, which would be a characteristic of "Earth as a whole" and which would not be accounted for by plate tectonics, is called "true" polar wander (TPW). True polar wander refers thus to the large-scale motions of the Earth's rotation axis through geological time. External forces driving shorter-term changes such as precession are not taken into account here.

True polar wander could result from centrifugal forces acting on mass anomalies distributed on or inside the Earth: excess mass, for instance, will lead to slow deformation of the Earth and change its rotation axis, causing the mass to move towards the equator without being displaced with respect to the solid Earth. The problem is to define precisely in a deformable Earth which part wanders with respect to which reference frame. What is defined (e.g., Steinberger and O'Connell, 2002) is the axis of rotation of a reference frame (RF) relative to an inertial frame of reference (i.e., determined by the angular momentum vector of Earth). The reference frame can be selected as the one that has zero net rotation when motions are integrated over the entire mantle, called the "mean mantle" reference frame. Or one can also define a "mean lithosphere" frame, in which the lithospheric plates have no net rotation. These frames in general do not coincide (Ricard et al., 1991; O'Connell et al., 1991). The "mean mantle" frame can be computed in numerical simulations in which the density distribution is given over the entire mantle. However, if one attempts to constrain it with actual paleomagnetic observations, one has to assume that the "mean mantle" frame is identical to some frame based on observations: the "hotspot reference frame" will most often be the one involved. Steinberger and O'Connell (2000) show that the approximation (discussed later in this paper) is quite good even if hotspots move in the convecting mantle.

The crust and mantle actually deform actively at the typical velocities of plate tectonics (~10–100 mm/year). Thus, polar wander involves (relative) motions of the rotation axis with respect to the Earth's mantle.

Goldreich and Toomre (1969) hypothesized that large-scale polar wandering and continental drift shared a common explanation through mantle convection and the resulting redistribution of masses within the mantle. Goldreich and Toomre (1969) started their analysis of the motions of the rotation axis of a quasi-rigid Earth with the classical figure, where a colony of beetles (the continents or other mass anomalies) moves slowly at the surface of a rigid rotating sphere (Figure 1). They simulated very large polar wander, with particularly intense and rapid swings.

The physics of TPW is explained among others by Ricard et al. (1993a): TPW is seen as the result of conservation of angular momentum of a rotating, deformable body, whose inertia tensor slowly changes with time. The reasons for the changes are mass redistributions linked to mantle convection. In simple terms, the inertia tensor component that affects polar wander is related to subducting slabs, upwelling



Paleomagnetism, Polar Wander, Figure 1 Diagram illustrating polar wander on a quasi-rigid planet (After Goldreich and Toomre, 1969). The beetles represent mass anomalies that change with time (drifting plates or mantle heterogeneities), inducing changes in the principal non-hydrostatic moments of inertia. The coordinate system attached to the (slowly deforming) solid planet moves with respect to the rotation (or spin) axis.

plumes, and more generally thermal and chemical mass heterogeneities resulting from a long history of mantle convection. With estimates of degree 2 components of the geopotential derived from satellite data, it can be shown that the non-hydrostatic part of the Earth's inertia ellipsoid is triaxial, the present rotation axis coinciding with the largest of the non-hydrostatic moments of inertia. The rotation axis tracks the maximum principal inertia axis (PIA) of the non-hydrostatic inertia tensor as fast as adjustment of the hydrostatic bulge allows.

Measure of true polar wander

The position of the rotation axis depends on the time scale. According to astronomers and geodesists, polar wandering is occurring at present. For instance, a determination by Gross and Vondrak (1999) uses the star catalog established from satellites during the past century. The result is a mean drift of the Earth's rotation pole over the period 1900–1992 of ~107 mm/year along the direction of the 79°W meridian.

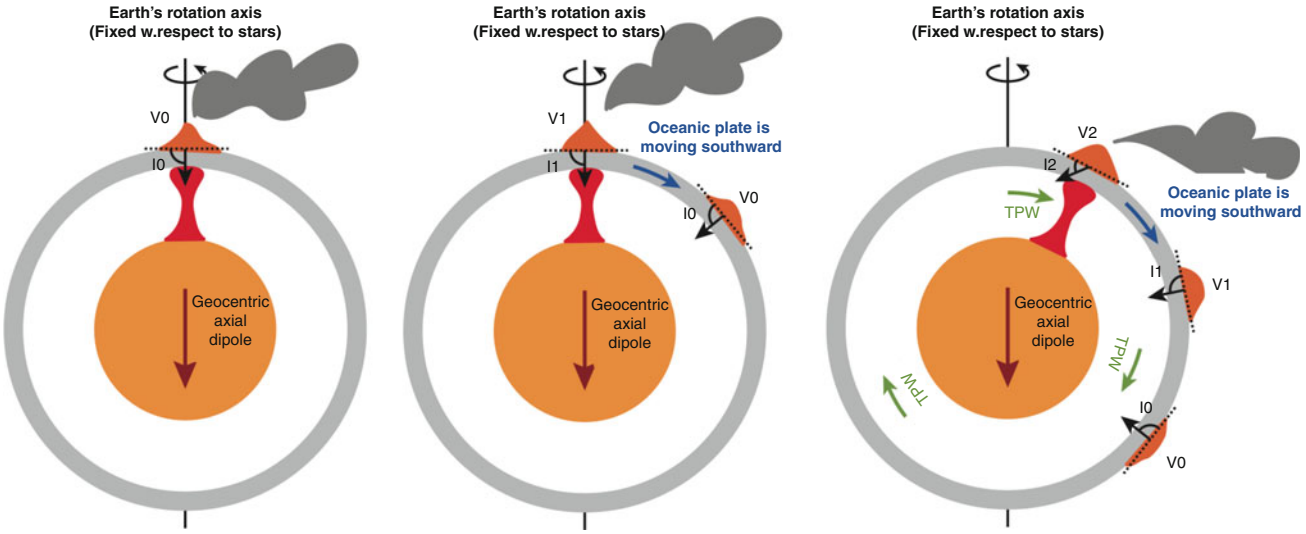
It has also been proposed that this long-term polar wander is largely due to post-glacial rebound, i.e., lithospheric and mantle response to melting of ice (e.g., Sabadini and Peltier, 1981; Mitrovica and Milne, 1998). The pole is moving towards Hudson Bay, where a large ice mass melted and the lithosphere is currently rising.

On time scales longer than 10^6 years, TPW most likely reflects convection of the whole mantle expressed at the surface by horizontal plate motions Steinberger and O'Connell (2002), and paleomagnetism has become the primary source of information. The apparent polar wander paths from all the major plates are being defined with increasing accuracy, and their differences reflect continental drift and plate tectonics. This demonstration of the reality of "apparent" polar wander seen from any plate has led some to propose that the concept of "true" polar wandering might be irrelevant or unnecessary. Are remaining fractions in polar wander, which would be a characteristic of "Earth as a whole," and which would not be accounted for by plate tectonics, actually resolvable? The concept is worthwhile if a reference frame external to the plates themselves can be defined, in which there was significant motion of the pole. Most studies performed in the last 2 decades followed an approach, based on the possibility, originally suggested by Morgan (1972, 1981), that hotspots could provide a valid reference frame for the mantle. Its meaning and existence has been the subject of continued debate, up to this day.

Hotspots are active volcanoes apparently unrelated to plate boundaries, which have been active for tens of millions of years. Hotspots are supposed to be the surface manifestation of plumes, which have left traces in the form of nearly linear chains of extinct volcanoes on the plate(s), which passed over them. Morgan (1972, 1981) proposed that these plumes have a "deep" mantle origin: these convective instabilities may be anchored at least down to the transition zone and possibly all the way down to the core-mantle boundary. As a plate moves over such a plume, the relative motion can be described by a rotation about a pole. If hotspots are indeed fixed with respect to each other and are fixed within the mantle, then hotspot apparent polar wander describes the wander of the Earth's rotation axis with respect to the mantle. It is this motion of the pole with respect to the hotspots, assumed to act as a reference frame for the mantle, which has been taken as an estimate of true polar wander. Determining TPW requires the best possible knowledge of APWPs of all plates (i.e., the best possible data base of paleomagnetic poles to determine the paleolatitudes and orientations of plates with respect to the rotation axis), of their relative motions (determined by marine magnetic anomalies and azimuths of transform faults), and finally the positions and ages of individual volcanoes along hotspot tracks on plates. Paleolatitudes of these seamounts are used for comparison to test model predictions.

APWPs and kinematic models were developed from the 1960s to the 1980s under the key assumption that when averaged over a sufficient amount of time, in excess of a few thousand years, the Earth's magnetic field could be described accurately by a geocentric axial dipole (so-called GAD hypothesis). Besse and Courtillot (1991, 2002), among others, proposed to blend two data sets: the paleomagnetic poles used to derive the APWPs and the oceanic data used to derive plate kinematic models. They used then available paleomagnetic and kinematic models and produced a "synthetic" APWP, which was defined with respect to South Africa and then transferred to all other plates. Motion of hotspots with respect to the plates (Müller et al., 1993) was then integrated to derive an estimate of TPW (Figure 2).

The resulting TPW curve is shown in Figure 3 with a 20 Myr time resolution (each point corresponds to the successive positions with respect to time of a hotspot presently situated at the North geographic pole). Points are shown with their 95% confidence circles every 10 Myr and every other point is statistically independent (estimates at 5 Myr intervals are also available in that study). The first points, corresponding to the period 8–59 Ma, are all in the same quadrant, between 3.3° and 5.9° away from the present rotation pole, with 95% uncertainties ranging from 2° to 3.8°. They are not statistically distinct from each other and therefore could correspond to a standstill. A mean position can be calculated from all data points in that time window: It is found to lie significantly displaced from the pole. The youngest mean pole at ~5 Ma is also significantly displaced from the pole but not statistically different from the 55 Ma overall mean. It seems that TPW may have been negligible for an extended period of about 50 Myr, but accelerated a few million years ago, with a velocity on the order of 100 km/Myr. Prior to that, the path displays a succession of a standstill at 160–130 Ma, a quasi-circular track from 130 to 70 Ma, then the standstill at 50–10 Ma and the



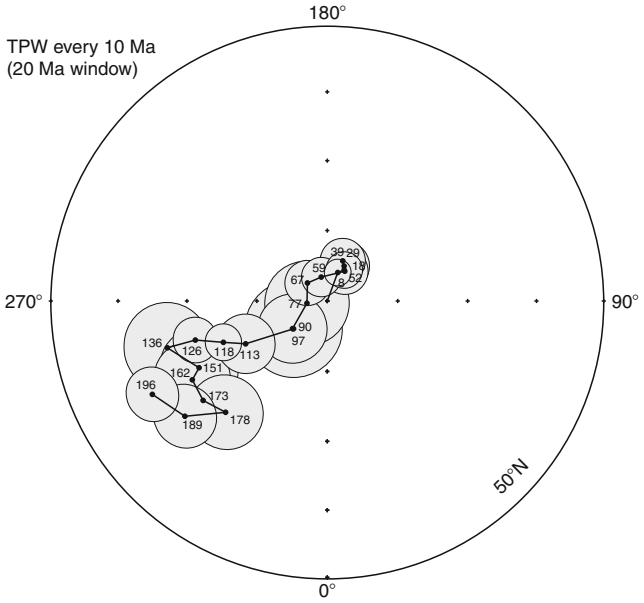
Paleomagnetism, Polar Wander, Figure 2 How mantle TPW is determined: At Time T0, a deep plume (located arbitrarily under the North Geographic Pole) produces a volcano V0 on an oceanic plate. In the hypothesis of a Geocentric Axial Dipole field, a magnetization of inclination I0 = 90° is fossilized in the lavas (the inclination (I) depends on the colatitude (l) such as TgITgθ = 2). Time T1: the oceanic plate has moved southward and a hotspot trace is formed, but the Plume remains at the same position (i.e., no mantle TPW). A new volcano (V1) is fed and records the same 90° inclination (I1) as in the volcano V0. Time T2: an episode of TPW occurs: the plume is tilted southward (with the rest of the mantle). The third volcano V2 will fossilize a lower inclination than V0 and V1. Later on, a paleomagnetist will measure past inclinations in lavas: as lithosphere only moves on the mantle, volcanoes will record the same inclination; the plume remains stationary. In case of TPW, the difference of paleolatitudes deduced from measured inclination will indicate the amount of motion.

faster motion up to the present. The true polar wander rate between 130 and 70 Ma averages 30 km/Myr. True polar wander appears episodic in nature, with periods of (quasi) standstill alternating with periods of faster TPW. The typical duration of these standstill periods is on the order of a few tens of millions of years (50 Myr). Because of all the uncertainties in models of hotspot kinematics prior to ~130 Ma, it is not safe to place too much weight on behavior prior to that time. The major event since then is therefore the end of the 130–60 Ma period of relatively fast polar wander, with a standstill (i.e., no or little TPW) from 50 Ma (actually because of larger 95% confidence circles, possibly 80 Ma) to 10 Ma.

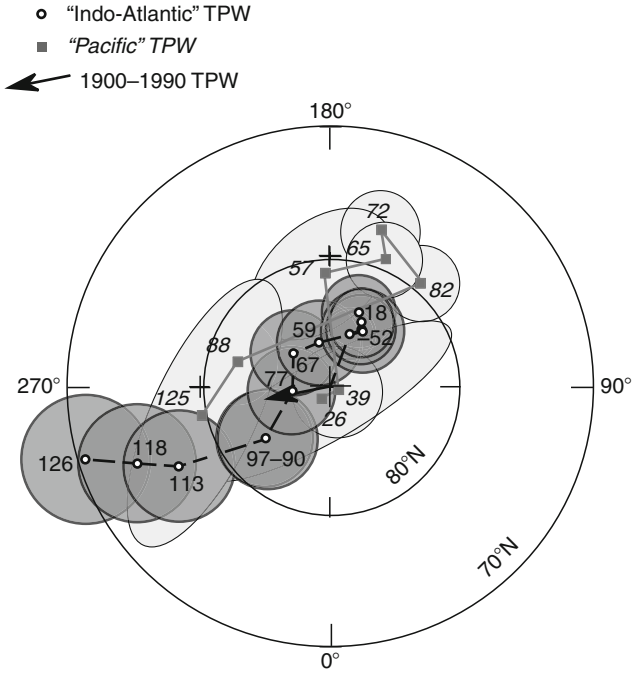
However uncertain, evidence for the fact that Earth emerged from a long standstill to enter a new period of faster polar wander in a different direction 10 Ma ago (~5 Ma at the higher resolution) is particularly interesting. That period would then still be going on. The youngest pole at ~5 Ma, taken at face value, would imply a TPW rate of 130 km/Myr in the direction ~15°W (with a large azimuthal uncertainty from 10°E to 40°W, due to proximity of the 5 Ma pole to the present rotation axis). The reasonable agreement with recent astronomical determinations (107 km/Myr in the direction 79°W, with a possible range from 65°W to 85°W) has reinforced the idea that this might be a valid estimate and that TPW direction and rate might have been rather stable over the last 5 million years corresponding to significant, large-scale changes in ice cover. Ice is not considered to have played a significant role before. It was absent prior to ~30 Ma.

A legitimate concern regarding the above conclusions is due to the fact that the analysis is not truly global, in that it fails to encompass the Pacific plate. Petronotis and Gordon (1999) have compiled an APW path (nine poles from 125 to 26 Ma) for the Pacific plate, based on the analysis of skewness of ocean crust magnetic anomalies and on seamount magnetic anomaly modeling. Using the Pacific plate versus hotspot kinematic model of Engebretson et al. (1985), based on dating of volcanoes that are part of hotspot tracks such as Hawaii, Louisville, or MacDonald, Besse and Courtillot (2002) have determined a corresponding 125–26 Ma "Pacific hotspot only" TPW curve. The "Pacific" and "Indo-Atlantic" TPW curves are compared in Figure 4. This comparison is interesting because the data sets they are based on are entirely different and independent.

Despite some significant differences, it is worth emphasizing that the two curves are altogether similar in shape (tracks, amplitudes, azimuths), particularly the 300° longitude trending track from 130 to 70 Ma, though the two are offset (in the same general direction) by about 7°. More precisely, the confidence intervals intersect (though means are not in the intersection) near 125, 90, 60, 40, and 30 Ma. The main differences occur between 80 and 70 Ma: the 82



Paleomagnetism, Polar Wander, Figure 3 True polar wander paths deduced from the hotspot model of Müller et al. (1993) going from the Present back to 130 Ma, and that of Morgan (1981) going from 130 back to 200 Ma, with associated 95% confidence ellipses (shaded *light gray*); 20 Ma sliding window. Ages are in Ma and correspond to the actual mean age of the data in the corresponding window, which is why they are not regularly distributed when the original time windows were. Note that the external circle is at 50° latitude (After Besse and Courtillot, 2002).



Paleomagnetism, Polar Wander, Figure 4 Comparison between the "Indo-Atlantic" (*open dots* and *dashed line*) and "Pacific" (*squares* and *solid line*) TPW Paths. The *arrow* shows the mean pole motion between 1900 and 1990 (After Besse and Courtillot, 2002).

and 65–72 Ma poles derived from Petronotis and Gordon (1999) and the 77 and 67 Ma poles derived by Besse and Courtillot (2002) are clearly distinct. Tarduno and Cottrell (1997) and Tarduno et al. (2003), however, expressed doubts on the reliability of APWPs for an oceanic plate, such as the Pacific, when they are based solely from inversions of magnetic surveys over seamounts and/or analysis of skewness of marine magnetic profiles. They have determined the paleolatitude (based on inclination-only data from cores) of the 81 Ma old Detroit Seamount, which is part of the Emperor chain, and noticed that the paleolatitude is distinct from that based on the 81 Ma pole of the Pacific APWP (Sager and Pringle, 1988) based on seamount anomaly poles. Tarduno and Cottrell (1997) exclude the possibilities of inadequate sampling of secular variation, bias due to unremoved overprints or off-vertical drilling. Di Venere and Kent (1999) and Cottrell and Tarduno (2000) argue that the reliability of the Pacific paleopoles based on either modeling of seamount magnetic anomalies or determination of skewness of marine magnetic anomalies should be considered suspect. Both are prone to numerous biases and could yield errors in excess of 10° in the position of the mean poles derived from them. This debate is not closed.

Is a reference frame based on hotspots valid?

Another question discussed in the last decade is Pacific hotspot fixity with respect to one another and to the "Indo-Atlantic" hotspots. Norton (1995) has suggested that the famous 43 Ma Hawaiian bend in the Hawaiian–Emperor hotspot track was actually a "nonevent," i.e., indicated a change in motion of the Hawaiian hotspot with respect to the mantle rather than a change in Pacific plate motion. Koppers et al. (2001) find that the 0–43 Ma Hawaiian and Foundation seamount trail pair is the only one compatible with the fixed hotspot hypothesis. The 43–80 Ma Emperor/Line pair shows particularly large discrepancies, requiring motions of at least 30 km/Myr. Koppers et al. (2004) studied 40Ar/39Ar age progressions of the Hawaiian and Louisville hotspot tracks. They showed that the progression is nonlinear and can be better fitted with a moving hotspot model rather than a fixed hotspot frame of reference. The primary Hawaiian and Louisville hotspots did not move in concert, showing significant inter-hotspot motion between 80 and 47 Ma. While the Hawaiian hotspot experienced a substantial 15° southward motion prior to 47 Ma (Tarduno et al., 2003), the Louisville hotspot is predicted to have experienced an eastward motion of 5° during the same geological period, followed by a minor 2° latitudinal shift over the last 30 Myr. Clouard and Bonneville (2001) showed

that Pacific seamounts are actually created by different processes, many being short-lived. Only the Hawaii and Louisville chains qualify as long-lived hotspots that can robustly be tested for fixity. Their preferred explanation for this is southward drift of Atlantic hotspots prior to ~95 Ma. Courtillot et al. (2003) reanalyzed the characteristics of the world catalog of some 50 hotspots. They suggest that surface hotspots on Earth may have three distinct origins with only seven "primary" hotspots (Hawaii, Easter, Louisville, Iceland, Afar, Reunion, and Tristan da Cunha) originating from the deepest part of the lower mantle, possibly anchored on chemical heterogeneities deposited in the D″ layer. Courtillot et al. (2003) found no evidence for inter-hotspot motion significantly larger than 5 km/Myr either within the Pacific hemisphere or the Indo-Atlantic hemisphere hotspots. Such rms velocities of 5 km/Myr or less, i.e., an order of magnitude less than rms plate velocities, are to first order "small." So, some primary hotspots indeed seem to provide a quasi-fixed frame in each hemisphere over the past 80–100 Myr.

Was there then any motion between the two hotspot ensembles? This raises the well-known difficulty of establishing a reliable kinematic connection between the two hemispheres through Antarctica. This has been addressed by Raymond et al. (2000). Based on updated kinematics (assuming that there is no missing plate boundary or unaccounted for motion between East and West Antarctica), these authors predict the location of the Hawaiian hotspot back in time, under the hypothesis that Reunion and Hawaii have remained fixed with respect to each other; for this, they use the dated tracks left on the African and Indian plates by the Reunion hotspot since it started as the Deccan traps 65 Ma ago. The plot of misfit between the predicted and observed positions for Hawaii as a function of time indicates that the two hotspots have actually drifted slowly, at ~10 km/Myr, for the last 45 Myr, but at a much faster rate (~50 km/Myr) prior to that, vindicating conclusions of Pacific hotspot motion reached by Tarduno and Cottrell (1997) or Tarduno (2007). Courtillot et al. (2003) conclude that the primary hotspots may form two distinct subsets in each one of the two geodynamically distinct hemispheres. Each subset would deform an order of magnitude slower than typical plate velocities. The two subsets would have been in slow motion for the last 45 Myr, but in faster motion prior to that.

Using their paleomagnetic results from Marie Byrd Land in West Antarctica, Di Venere and Kent (1999) demonstrated that some motion must have taken place since 100 Ma between West (Marie Byrd Land) and East Antarctica; they concluded that this motion cannot account for more than 20%, and possibly as little as 4% of the 14.5° offset between the observed and predicted positions of the 65 Ma Suiko seamount on the Emperor continuation of the Hawaiian hotspot track. They also discussed the integrity of the Pacific plate and the role of missing plate boundaries and errors in kinematic plate circuits, and find that they play a small role. Di Venere and Kent (1999) concluded that most of the apparent motion between the two main groups of hotspots is real, with an average drift of about 25 km/Myr since 65 Ma. Steinberger et al. (2004) have combined hotspot motion in the large-scale flow field of the mantle and intraplate deformation to account for most of the post-65 Ma misfits between computed and observed hotspot tracks. Only a combination of the two effects (hotspot motion and intraplate deformation) successfully predicts the geometry of the four selected seamount chains in the Pacific and Indo-Atlantic hemispheres. If correct, this analysis at the same time invalidates the notion of a reference frame or of separate hemispheres and replaces it with limited, predictable, inter-hotspot motion. But TPW can still be calculated. The Hawaiian hotspot would have moved faster between 80 and 50 Ma, and at the same time TPW would have been faster prior to 50 Ma. TPW alone would account for paleolatitudinal changes of the Reunion hotspot, whereas the two effects would be required for the Hawaiian hotspot.

The estimate of true polar wander (TPW) over the last 200 Myr is thus still a matter of strong debates, as recalled above, being based only on hotspots from the Indo-Atlantic hemisphere. The TPW curve estimated using Pacific-only data is similar to the Indo-Atlantic TPW, seemingly validating to first order the concept that TPW is a global phenomenon. On the other hand, Besse and Courtillot (2002) suggest that TPW pole positions for the two hemispheres are significantly displaced between ~50 and ~90 Ma. Hotspot tracks become fewer and more uncertain as one goes back in the past and pre-130 Ma TPW estimates should be regarded with caution. However, there are strong indications (Besse and Courtillot, 2002) that the phase of true polar wander, which ended around 50 Ma, may have started ~130 Ma ago.

Modeling of true polar wander

In an early attempt, Ricard et al. (1993b) and Richards et al. (1997) derived a model of mantle density heterogeneities based on plate motions recorded by the ocean floor, including slabs crossing the upper/lower mantle transition zone slowing down by a factor between 2 and 5. Based on this, they computed a synthetic geoid, which agreed rather well with observations, provided viscosity increased by a factor 40 going from the upper to the lower mantle. Changes in the degree 2 geoid should reflect the history of the inertia tensor and therefore TPW as revealed by paleomagnetism. They predicted TPW velocities on the order of 300 km/Myr in the direction 130°W, much larger than observed rates. Their three-layer model could not account simultaneously for the present-day geoid and observed TPW.

In other studies, seismic tomography has been used to infer 3D maps of density heterogeneities that drive flow in the viscous mantle. Steinberger and O'Connell (1997, 2002) have developed an algorithm to calculate changes in the Earth's rotation axis for rather general viscoelastic Earth models. Their model combines hotspot motion, polar wander, and plate motions in a single dynamically consistent model, allowing all effects to be simultaneously

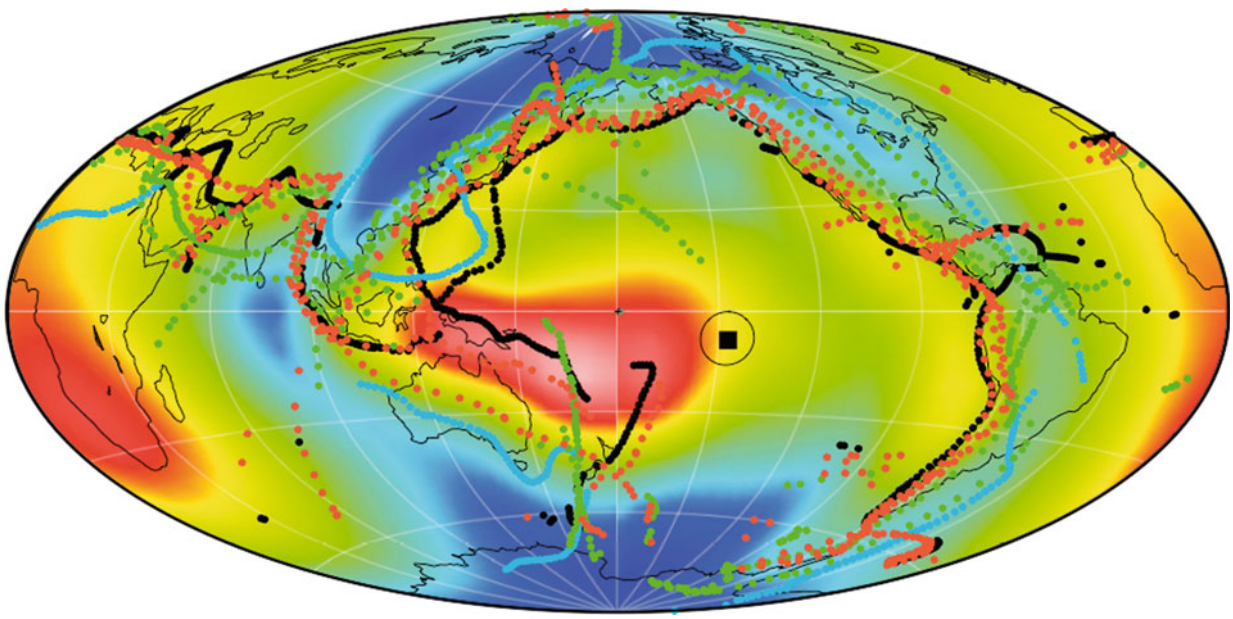
determined and their relative effects sorted out. Changes in rotation are due to advection of "realistic" density anomaly distributions inferred from a number of seismic tomography models in a "realistic" flow field constrained by observed plate kinematics at the surface. Steinberger and O'Connell (2002) compare their model results for a number of tomographic models and discuss the effects of compressibility, deep mantle viscosity, thickness of a high viscosity layer in the deep mantle, and chemical boundaries on rates of TPW. Their TPW estimates are in qualitative agreement with observations for the last 100 Ma. Steinberger and Torsvik (2010) modeled the present-day non-hydrostatic inertia tensor by combining contributions due to large low-shear velocity provinces in the lowermost mantle and due to subduction and found a spin axis at 67°N, 96°E (north Siberia). The distribution of recent subduction, with largest amounts in the northwest Pacific (beneath East Asia) and the southeast Pacific (beneath South America), adds a secondary contribution that moves the spin axis toward the observed poles.

Rouby et al. (2010) also investigated the effect of internal mass redistributions on the position of the Earth's rotational pole for the last 120 Myr. They also used a geodynamic model based on plate reconstructions and estimated the location and rate of subducted slabs under the assumption that they sink vertically into the mantle (Figure 5). The new model takes into account the effect of large-scale mantle upwellings derived from tomography (one is situated under Africa, the other, nearly antipodal under the Pacific Ocean). The temporal variation of the mantle density heterogeneities was essentially found to reflect changes in subduction history. Because the tomographic images seem to show that subducted plates do not systematically reach the CMB, they investigated the influence of the depth down to which these plates retain significant density contrast with respect to the surrounding mantle on the present-day geoid and on the temporal evolution of the Earth's PIA (we recall the rotational axis is aligned to the maximum PIA). They proposed a model, which yields to a present-day geoid in good agreement with the observed one. The associated minimum principal inertia axis seems to be relatively stable since 120 Ma and close to Africa, within the upwelling (Figure 6). Their model displays that some of the features of the computed TPW, which are directly linked to the temporal evolution of the subductions, are reminiscent of observed phases of slow and fast true polar wander, with similar peak velocities. Although their computed TPW is almost in the same meridian as the observed one, the poles are still drifting in the opposite direction, as was already the case for Ricard et al. (1997).

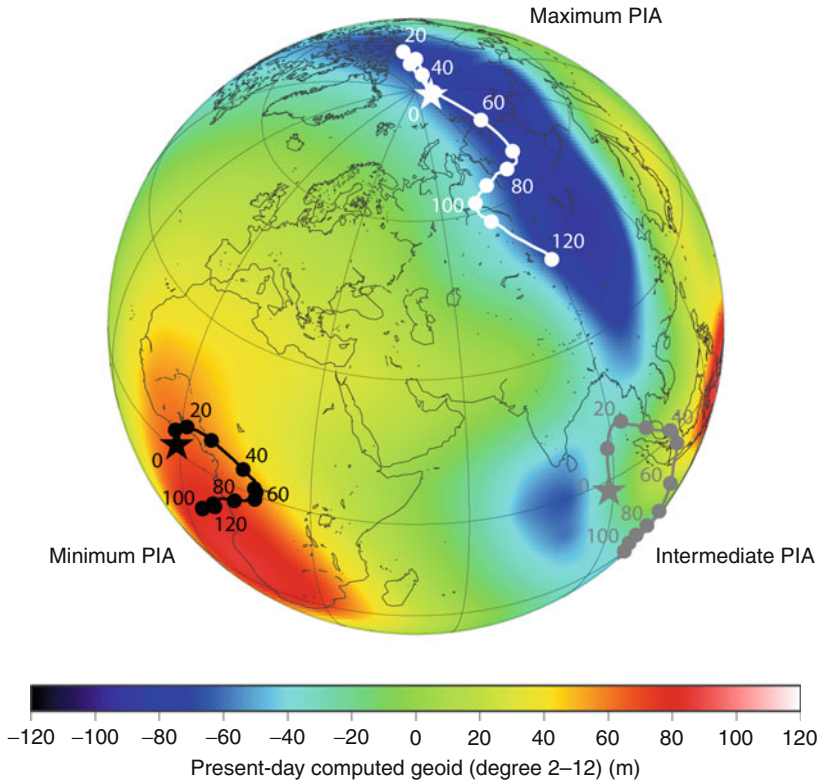
An integrated explanation for polar wander?

Let us now put this study in the broader context of the history of the Earth's rotation.

Paleomagnetic indications that would support rather fast true polar wander in pre-Mesozoic time have been put forward by Van der Voo (1994; with rates between 70 and 110 km/Myr) and for very fast true polar wander by Kirschvink et al. (1997; with rates in excess of



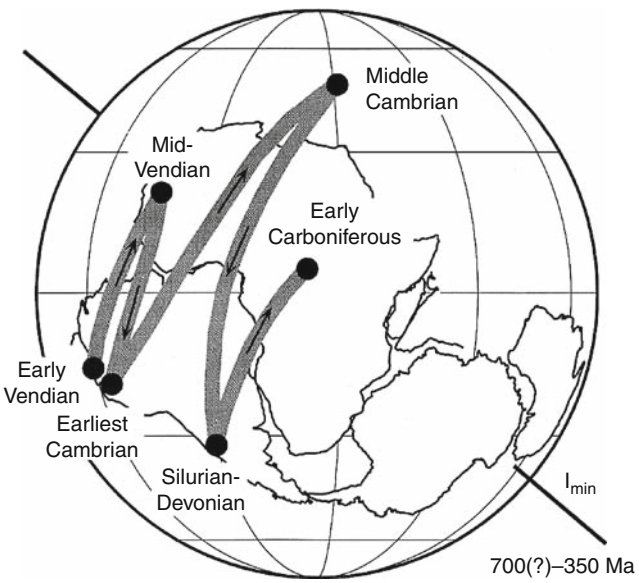
Paleomagnetism, Polar Wander, Figure 5 Subduction zones at the Earth surface, every 40 Myr, since 200 Myr, superimposed to the present-day final computed geoid (degree 2–12). The *square* represents the mean center of small circles fitting the subductions zones (After Rouby et al., 2010).



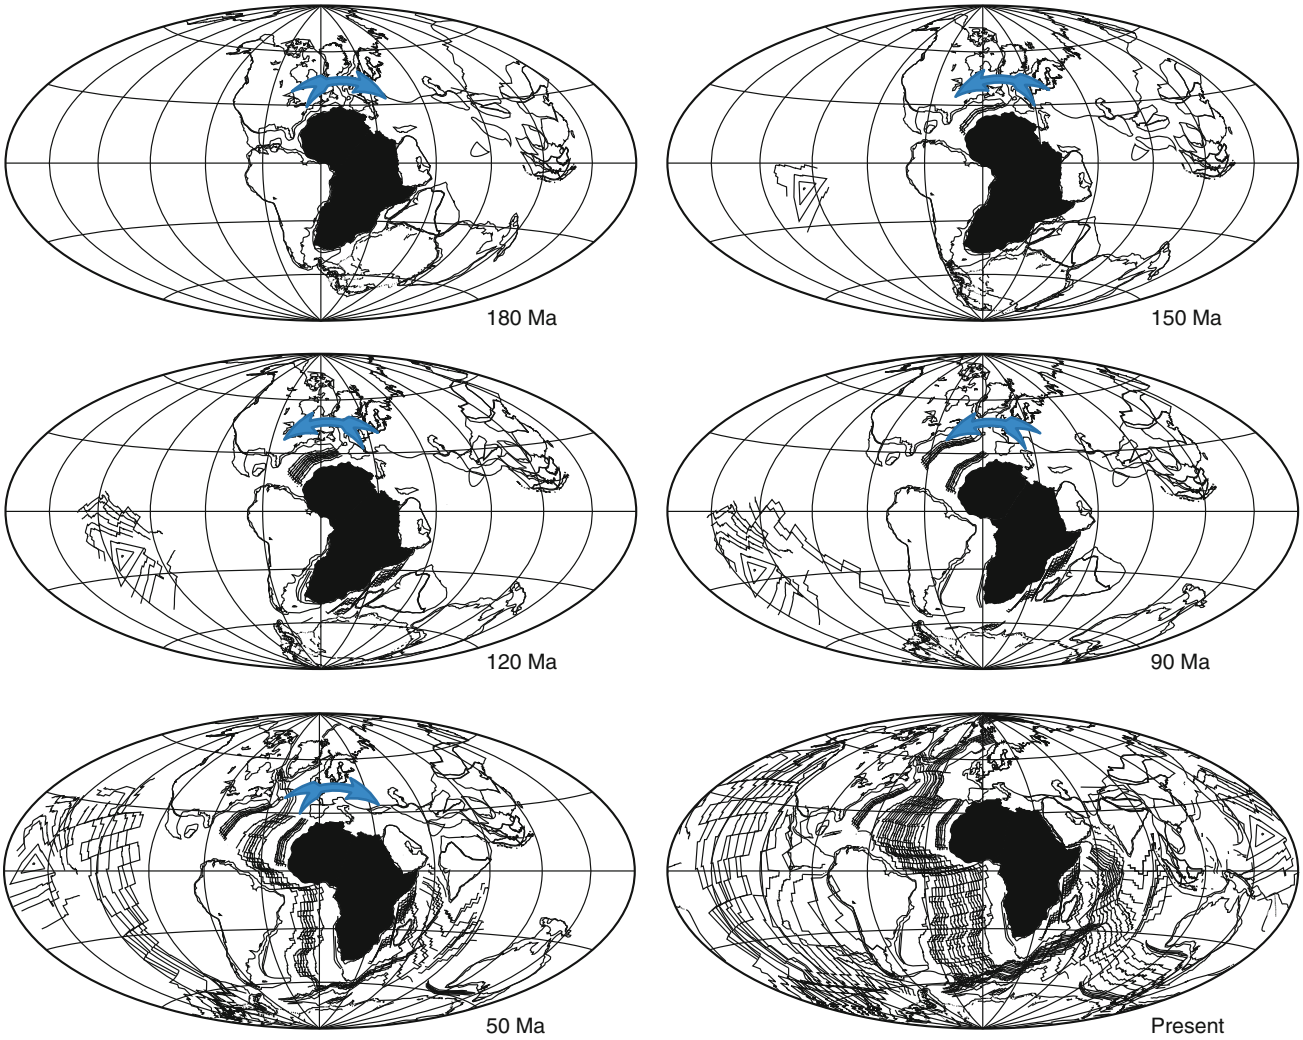
Paleomagnetism, Polar Wander, Figure 6 Principal Inertia Axes since 120 Myr (dots every 10 Myr, stars denote present-day values) for our mantle density heterogeneities model. The corresponding present-day geoid (degree 2–12) is also shown (After Rouby et al., 2010).

600 km/Myr in the early Cambrian). Recall that Steinberger and O'Connell's (2002) numerical models place an upper limit of about 100 km/Myr on TPW velocity. For pre-Jurassic time, ocean floor has been destroyed (together with evidence of plate kinematics and most hotspot traces) and TPW cannot be estimated in the way indicated above. Evans (2003) proposes to obtain a crude estimate of TPW in the case when TPW velocity would have been much faster than between-plate motions. Kirschvink et al. (1997) and Evans (2003) discussed the fact that the Earth may have in the past catastrophically exchanged two of its principle axes of inertia (inertial interchange true polar wander or IITPW), i.e., the whole lithosphere (and mantle) may have rotated by some 90° in only a few million years, bringing for instance parts of the Earth that were close to the poles at the Equator. Evans (2003) interpreted the large rotations as TPW about a common, long-lived, minimum inertial axis (Imin) near eastern Australia, which may also be regarded as the prolate axis of Earth's figure, inherited from Rodinia (Figure 7).

Satolli et al. (2007) on the basis of a high definition magnetostratigraphy in the Apennines argued that a major trend of the "mean" plate motion since at least 200 Ma can be described as large successive clockwise or counter-



Paleomagnetism, Polar Wander, Figure 7 Terminal Proterozoic to late Paleozoic apparent polar wander path for Gondwanaland. Oscillatory APW rotations are interpreted as TPW about a common, long-lived, minimum inertial axis (near eastern Australia (After Evans, 2003).



Paleomagnetism, Polar Wander, Figure 8 Global continent and ocean reconstructions, from 180 Myr to present-day, based on techniques and APWPs described in Besse and Courtillot (2002). Magnetic anomalies are from Royer et al. (1992), the 150 and 130 Myr frames from Satolli et al. (2007). A major trend of the "mean" plate motion since at least 200 Myr can be described as successive clockwise or counter-clockwise rotations (linked to TPW), and roughly centered in Africa (close to the minimum PIA, see Figure 8). The blue *arrow* indicates the direction of rotation until the next reconstruction (After Rouby et al., 2010).

clockwise rotations linked to TPW, and roughly centered on Africa, this last plate being a "central plate" from which most continents have diverged since the break-up of Pangea (Figure 8). An animated sequence derived from Besse and Courtillot (1991) APWP displays visually those features available at http://www.ipgp.fr/~besse/pw. Steinberger and Torsvik (2008) have also found that the global axis of rotation for plates since 250 Ma also roughly centered in Africa, and argued that they may also correspond to maxima of the degree 2 non-hydrostatic geoid, corresponding to the mantle upwellings.

Le Pichon and Huchon (1984) already remarked that during Late Triassic about 200 Ma ago, the outlines of Pangea lay along a great circle passing through the paleopoles of rotation and also noticed that the present geoid also displays hemispheric symmetry with an axis located in the equatorial plane. The stability of subduction zones back to the middle of the Paleozoic in a nearly N-S plane was also recognized by Collins (2003). All these studies pointed out a strong link between pole positions and the geometry of the convection: this coincidence might be explained by a deep-seated, quadrupolar convection as was first advocated by Busse (1983). Rouby et al. (2010) addressed this question by computing a present geoid day (degree 2–12) using the plate model described above (Figures 5 and 6).

The persistent location of subductions in the western Tethyan and Pacific regions for at least 250 Ma (and

possibly earlier according to Collins) have generated a ring of downwelling material inducing hot return flows (the upwellings mentioned above) confined to two main regions (presently Indo-Atlantic and Pacific). This geometry defines the location of PIAs and pins the minimum PIA in the region of upwelling. This large zone is roughly centered on the equator also close to the maxima of the degree 2 non-hydrostatic geoid. The minimum PIA has been relatively stable since 120 Ma and close to Africa. On the contrary, both the maximum and intermediate PIAs have moved in a plane perpendicular to Africa along a meridian corresponding to the large-scale pattern low of the geoid. This meridian seems to be stable with time, similar to the large-scale pattern of subduction around the Pacific and western Tethyan zone of subductions.

The temporal evolution of the rotation axis is that of the maximum PIA. Oscillatory polar wander is attributed to TPW about a common, long-lived minimum inertial axis, which would be the prolate axis of Earth figure, inherited from the past plates/continent configurations and following the quadrupolar convection model of Busse (1983).

This peculiar pattern may constitute a long-lived feature of our planet, at least since 200–250 Ma, which forces continents to be roughly in an EW position, on a single hemisphere bounded by a plane containing the rotation axis, with the Earth's rotational pole not far from the main ring of subduction zones. TPW (and possibly APW) may occur around a nearly equatorial euler pole (axis) of rotation, driven by slight changes of magnitude between the maximum and intermediate PIAs, principally caused by subduction locations and rate changes with time. This view is coherent with the successive CW and CCW rotations of all continents (including the Pacific Ocean) observed by Evans (2003), Satolli et al. (2007), and Steinberger and Torsvik (2008) around a point located somewhere in Africa and close to the equator for these last two authors.

Conclusions

For the time being, the hypothesis that TPW is a go-stop-go phenomenon, with long standstills in the tens of millions of years, and periods of faster, rather uniform polar wander at velocities often not exceeding 30 km/Myr, cannot be discounted. Evidences for superfast events at any time in the past remain to be demonstrated.

The similarity between TPW estimates for the Pacific plate and the rest of the world, which are based on completely different and independent data sets, may be taken as support to the idea that small yet significant TPW, on the order of 10°, occurred since the Cretaceous, though it still requires careful verification.

Most current modeling still fails to some extent to account for the slow values of typical TPW velocity (0–30, and rarely up to 100 km/Myr), and even more so to account for the prolonged (~50 Myr) periods with almost no TPW (standstills). Steinberger and O'Connell (2002) give reasonable velocities but predict smooth evolutions, rather than the alternating episodes, revealed by paleomagnetic data. Rouby et al.'s (2010) model restores the present geoid, displays some of the features of computed TPW that are directly linked to the temporal evolution of subductions, reminiscent of observed phases of slow and fast true polar wander, with similar peak velocities, but the poles are still drifting in the wrong direction, as was also the case for Ricard et al. (1997).

TPW seems to be linked to a pattern of quadrupolar convection permanent (at least on periods of time in excess of 200 Ma). If the two upwellings remain more or less in the same locations, the pole may move on the great circle perpendicular to the axis they form, the system being stabilized by subductions not far from the pole. These concepts remain to be tested for earlier periods of time.

The importance of the Pacific plate and severe limitations on presently available data from that plate, the fact that the global paleomagnetic database still is quite scant for certain continents and time windows, the fact that many hotspot traces are not yet sufficiently constrained in terms of age and paleolatitude, all point to the need for many more direct (paleomagnetic) measurements as opposed to indirect/remote sensing determinations of magnetization direction (i.e., "skewness" or "seamount" data).

The reason for the discrepancies between models and data could be due to the quality of reconstruction of the Pacific Ocean (specially before 130 Ma) and its relationship with bordering continents, and hence, the poor knowledge of the exact amount of subduction at a given time (to which these kind models are so sensitive). Some of this information is unfortunately lost forever, since large parts of the Pacific Ocean have been subducted.

Future research should aim to understand the discrepancies between observation and computations in order to estimate possible uncertainties on the associated mantle mass anomalies by testing other reconstructions. It will be particularly useful to build a single reference frame for both Indo-Atlantic and Pacific hemispheres: this implies that one must be able to use Antarctica to link the two hemispheres. This will not be easy, given the poor knowledge of deformations suffered by the continent and the possibility of existence of active margins on its Pacific border.

Definition

Paleomagnetism is the study of the Earth's ancient magnetic field, based on the measurement and analysis of the *remanent* (i.e., permanent) magnetization acquired by rocks during their formation.

Introduction

Paleomagnetism provides data that are useful in the interpretation of geologic processes. For paleomagnetic results to be reliable for this purpose, several important conditions must be fulfilled. First, a rock under investigation must be able to record accurately the direction and intensity of the weak geomagnetic field during its formation or later alteration. This requires an understanding of the magnetic properties of rocks and minerals. Second, the age of the formation of the rock or its subsequent alteration must be well known. Field tests based on the local and regional geology of a sampling site are valuable in this respect. Third, the remanent magnetization of the rock must possess outstanding stability in order to be able to persist unchanged for geologic eons.

The geocentric axial dipole

The Earth's present magnetic field has been measured and analyzed systematically since Gauss and Weber established the first global network of geomagnetic observatories in 1838. The advent of Earth-orbiting satellites carrying magnetometers has resulted in a vast increase in high quality magnetic data and an improvement of the global coverage. Spherical harmonic analysis of the data shows that more than 99% of the magnetic field measured at the surface of the Earth originates inside the Earth. The potential W_i of the field of internal origin is given by

$$W_i = R\sum_{n=1}^{N}\sum_{m=0}^{n}\left(\frac{R}{r}\right)^{n+1}\left(g_n^m\cos m\phi + h_n^m \sin m\phi\right)P_n^m(\cos\theta)$$

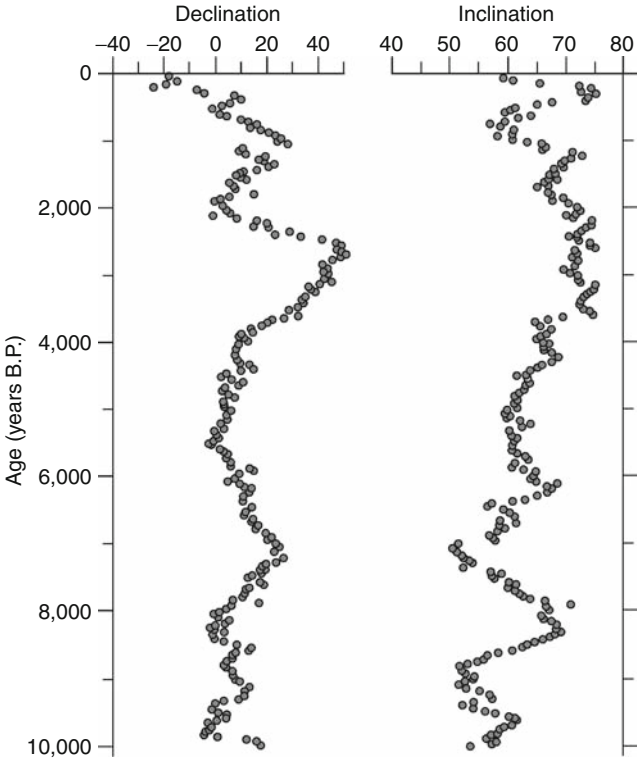
The optimum values of the Gauss coefficients g_n^m and h_n^m are revised every 5 years and define the International Geomagnetic Reference Field (IGRF). In principle, the summation consists of an infinite number of terms, but in practice it is truncated at a particular degree $n = N$ determined by the quality of the data. The recent field model IGRF-11 is defined up to $N = 13$ and contains 195 coefficients. The most important part of the magnetic field is the dipole component, which corresponds to the terms with $n = 1$. All terms with $n \geq 2$ in the spherical harmonic analysis are labeled collectively as the *non-dipole field*. The term g_1^0 is the strongest component of the field, and describes a magnetic dipole located at the center of the Earth and aligned with the rotation axis; the coefficients g_1^1 and h_1^1 correspond to orthogonal equatorial dipole components. Together, the three terms with $n = 1$ describe a geocentric dipole whose axis is inclined to the rotation axis. At present, the axial tilt is about 11°, and the geomagnetic pole does not coincide with the geographic pole. A compass needle aligns with the horizontal component of the magnetic field – the magnetic meridian – and not with the geographic meridian; the angular deviation is the *declination* (D), which varies from place to place on the Earth's surface.

The basic premise of paleomagnetism is the geocentric axial dipole (GAD) hypothesis. This hypothesis postulates that the equatorial dipole components and the non-dipole field average to zero when averaged over sufficiently long intervals of time, leaving only the GAD component as the paleomagnetic record. Consequently, the magnetic pole position calculated in a paleomagnetic investigation defines the location of the paleogeographic axis. Discrepancies from the present axis are interpreted in geologic terms. The *inclination* (I) of the magnetic field is the angle that a magnetic field line makes with the horizontal at Earth's surface. For a GAD field this angle is related to the latitude λ of the observation site by the equation

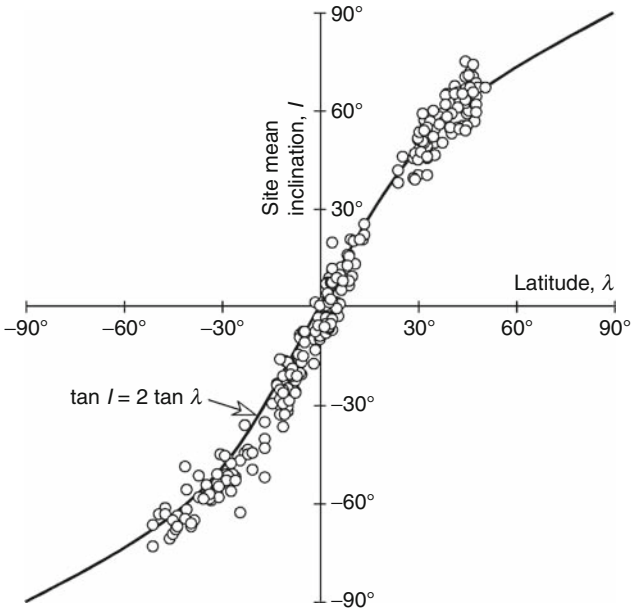
$$\tan I = 2\tan\lambda = 2\cot p \qquad (1)$$

In this equation $p = (90° - \lambda)$ is the colatitude of the observation site, i.e., the angular distance of the magnetic pole from the site.

The dipole and non-dipole fields change slowly with time, a characteristic known as *secular variation*. Time-dependent changes of the Gauss coefficients are observed in repeated analyses of the recent field. Secular variations affect both the direction and the intensity of the field. For example, the geomagnetic field has decayed by about 5% per century since direct measurements began about 160 years ago. It has been possible to reconstruct the



Paleomagnetism, Principles, Figure 1 Master curves of paleosecular variation of inclination and declination for the past 10,000 years, compiled from British lake sediments. (Turner and Thompson, 1981.)



Paleomagnetism, Principles, Figure 2 The mean inclinations of magnetization in marine sediment cores are plotted against the latitude of each sampling site. The continuous curve is the theoretical relationship given by Equation 1 for a geocentric axial dipole (GAD) field. (After Schneider and Kent, 1990.) The small deviations are partly due to paleosecular variation that has not been averaged out, but systematic bias indicates persistent long-term quadrupole and octupole components.

changing strength of the axial dipole from the magnetic observations of mariners since the late sixteenth century; these document a slower, perhaps indeterminate change prior to 1840 (Gubbins et al., 2006).

On a longer timescale, fluctuations in magnetization direction and intensity that are not due to mineralogical variations have been documented in paleomagnetic analyses of sedimentary records. The changes take place over centuries and millennia and are called *paleosecular variations* to distinguish them from changes in the present and historic field. The fluctuations are evident in intensity and direction of the magnetization. For example, oscillations in both inclination and declination measured in cores of sediments from British lakes could be correlated from lake to lake. The sediments were dated using radiocarbon and palynological age determinations. This allowed construction of a master curve of paleosecular variation in Britain for the past 10,000 years (Figure 1).

For the GAD hypothesis to be valid, the paleosecular variations need to average to zero over a few tens of thousands of years, leaving the inclination and declination of the GAD field as the paleomagnetic record. A test of the GAD hypothesis in marine sediments deposited in the last 2.5 Myr compares the measured inclinations with values predicted by Equation 1. The mean inclinations do indeed closely agree with the values expected for a GAD field (Figure 2). However, the agreement is not perfect, and in fact the optimum fit of a theoretical curve to the data is obtained when small geocentric axial quadrupole (g_2^0) and octupole (g_3^0) components are included, each equivalent to a few percent of the dipole. The magnetohydrodynamic theory of the origin of the geomagnetic field gives no rigorous theoretical justification for the GAD hypothesis or explanation of possible persistent zonal quadrupole and octupole components. However, experimental tests of the hypothesis indicate that it is a good first-order model for the time-averaged geomagnetic field.

Rock magnetism

Ferromagnetism is the type of magnetic behavior found in iron and similar metals. It is characterized by a Curie temperature, above which the ferromagnetism disappears. Ferromagnetic metals are strongly magnetic. They have properties such as magnetic hysteresis, saturation magnetization, and remanent magnetization. The important rock-forming minerals exhibit *diamagnetism* or *paramagnetism*, which are very weak forms of magnetism that do not show magnetic hysteresis. Because they cannot acquire a remanent magnetization, they play no part in paleomagnetism. A few minerals, consisting of iron oxides and sulfides, are classified as *ferrimagnetic*, which

is a form of ferromagnetic behavior associated with a crystal structure. Ferrimagnetic minerals are able to acquire a remanent magnetization. Although they occur in tiny concentrations in rocks (e.g., less than 0.01% in some sediments), the paleomagnetic properties of a rock are due to their presence.

The most common ferrimagnetic minerals are members of the titanomagnetite and titanohematite solid solution series, whose end-members are magnetite and hematite, respectively. Magnetite is usually, but not always, a primary magnetic mineral coeval with the origin of igneous rocks or predating the deposition of sediments. Hematite, pyrrhotite, and greigite are other important magnetic minerals, but they originate in the rock after its formation, so the timing of their magnetization can be dubious.

The magnetization of a rock is due to the partial alignment of the magnetic moments of its constituent grains. Within any particular grain the magnetic moment has a direction, conventionally called the "easy" direction of magnetization, which is determined by the magnetic anisotropy of the grain. This, in turn, depends on the intrinsic magnetic properties of the magnetic mineral. For example, magnetite has a cubic structure and a comparatively strong spontaneous magnetization ($M_s = 4.8 \times 10^5$ A m^{-1}), so a grain's shape dominates the anisotropy; the magnetic moment favors the direction of the longest axis of the grain. In contrast, hematite has a rhombohedral structure and a weak spontaneous magnetization ($M_s \sim 2.5 \times 10^3$ A m^{-1}). It has a strong magnetocrystalline anisotropy related to the crystal structure that causes the magnetic moment to lie in the basal plane of the crystal at room temperature.

In very fine grains of ferrimagnetic minerals, the anisotropic magnetic energy of the grain constrains the spontaneous magnetization direction to lie along an easy direction, and the entire grain is uniformly magnetized as a *single domain*. The high spontaneous magnetization of magnetite creates anisotropic magnetostatic energy related to the particle shape. The theoretical range of single domain sizes in magnetite is narrow, from about 0.03–0.1 μm in equant grains and up to about 1 μm in elongate grains. In contrast, hematite has a large magnetocrystalline anisotropy energy and single domain grain sizes may extend up to 15 μm. The magnetization of a single domain particle is very stable, because to change it requires rotating the entire uniform spontaneous magnetization of the grain against the grain anisotropy, which demands a strong magnetic field. The magnetic field needed to reverse the direction of magnetization of a single domain grain is its *coercivity* B_c. In magnetite, this field is commonly in the range 10–100 mT, but may be up to 0.3 T in acicular grains. The magnetic properties of hematite are variable and its maximum coercivity can exceed 2 T. Because of their stable remanent magnetizations, single domain particles play a very important role in paleomagnetism.

When the grain size of a magnetic mineral exceeds a critical value, the magnetostatic energy of the grain becomes too large for the grain to exist as a single domain and the magnetization subdivides into oppositely directed domains. *Multidomain* magnetizations can be changed by merely moving the wall between adjacent domains, so are less stable against change than single domains. As a result, coarse-grained rocks are often unsuitable for paleomagnetism. Laboratory methods have been developed to identify the magnetic minerals in a rock, and to evaluate whether the grain size is single domain, multidomain, or intermediate (the latter category being termed pseudo-single domain).

The magnetic moment of each grain in a rock aligns with a magnetizing field as closely as permitted by the magnetic anisotropy of the grain. Thermal energy acts to destroy the partial alignment of magnetic moments. As a result, a magnetization that originally has the value M_0 decays exponentially with time, so that after time t the remaining magnetization M_r is given by

$$M_r = M_0 \exp(-t/\tau)$$

The rate of decay is governed by the *relaxation time* τ, which is a function of the magnetic properties of the grain and the temperature T. For single domain grains of magnetite

$$\tau = \frac{1}{f} \exp\left(\frac{VB_cM_s}{2kT}\right) \quad (2)$$

Here f is a frequency factor ($\sim 10^9$ s^{-1}) related to the vibrational frequency of the crystal lattice; V is the volume of the grain, B_c its microscopic coercivity, and M_s its spontaneous magnetization; and k is Boltzmann's constant. A single domain grain of magnetite, 30 nm in diameter, has a relaxation time of about 10^9 year at 20°C. Other ferrimagnetic minerals can also possess this extraordinary stability against thermal decay. It allows a rock to retain the remanent magnetization it acquired during rock formation for very long intervals of geologic time. The relaxation time of the magnetization decreases with increasing temperature and with decreasing grain size. Thus, heating during tectonic deformation, or a change of grain size or mineral chemistry as a result of weathering, can modify or destroy a primary remanent magnetization.

Remanent magnetizations

The development of paleomagnetism as a scientific discipline was made possible by the invention in the early 1950s of the astatic magnetometer, a device that was sensitive enough to measure accurately the weak magnetizations of rocks. The instruments commonly used in modern paleomagnetic laboratories are spinner magnetometers and cryogenic magnetometers, which are even more sensitive and are able to measure rock samples much faster. As a result of the low concentrations of ferrimagnetic minerals, rocks have very weak remanent magnetizations, measuring typically $\sim 10^{-1}$ A m^{-1} for a basaltic lava and $\sim 10^{-3}$ A m^{-1} for a pelagic limestone. The intensity of

a remanent magnetization also reflects the mechanism by which the rock becomes magnetized in the Earth's magnetic field.

When an igneous rock forms, its temperature is initially well above the Curie temperature of ferrimagnetic minerals (e.g., 580°C in magnetite, 675°C in hematite). The magnetic behavior is paramagnetic, incapable of retaining a magnetization. As it cools below the Curie point, the magnetite or hematite becomes ferrimagnetic. At high temperature, the relaxation time is short and the magnetic behavior is classified as *superparamagnetic*. With further cooling, the relaxation time increases rapidly, and a few tens of degrees below the Curie point a *blocking temperature* is reached, at which the relaxation time is so large that the magnetization becomes blocked by the anisotropy of the grain. If this ensues in a magnetic field, the ferrimagnetic grains acquire a *thermoremanent magnetization* (TRM) in the direction of the field. Equation 2 controls this process and ensures that the TRM has a high stability. On the other hand, if subsequent chemical alteration of the grain occurs, the grain volume V or spontaneous magnetization M_s may alter, which, again according to Equation 2, can give rise to a new, stable *chemical remanent magnetization* (CRM). This is usually an undesirable secondary component.

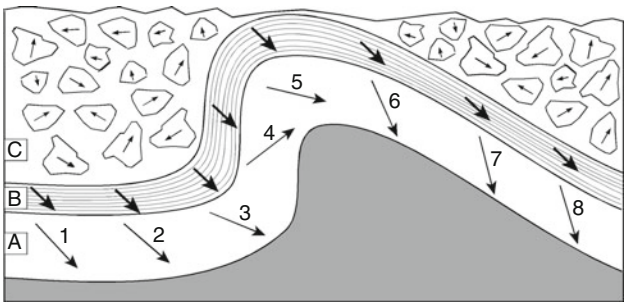
Sedimentary rocks are deposited slowly and can often be excellent archives of the ancient magnetic field. Magnetite grains form a tiny fraction of a sediment (e.g., less than 0.01% of a limestone) and are aligned partially by the magnetic field in which they settle, forming a *depositional remanent magnetization* (DRM). In some very fine-grained sediments, further magnetite alignment takes place in the waterlogged pore spaces between the nonmagnetic matrix minerals. The sedimentation rate of pelagic marine sediments is so slow that paleosecular variations are in principle averaged out within the size of a standard 1-in. paleomagnetic sample. However, in lake sediments the sedimentation rate is much higher and it is possible to study both secular variation (Figure 1) and paleoclimatic effects in these sediments. Shallow-water marine limestones also have a relatively high deposition rate, but the detrital and biogenic fractions that supply the magnetite are diluted in these limestones and they tend to have weak and unstable remanent magnetizations.

In addition to the remanent magnetizations acquired in a geological process, synthetic remanent magnetizations may be imparted to rock samples in the laboratory for the purpose of identifying and describing the carrier of a paleomagnetic signal. If a sample is placed in a magnetic field, the magnetic grains with coercivity less than the field are realigned; when the field is removed, an *isothermal remanent magnetization* (IRM) is left in the sample. If the field is strong enough to magnetically saturate the sample, a *saturation* IRM ensues. Another, important laboratory magnetization is produced by placing a sample in an alternating magnetic field in the presence of a constant bias field. When the alternating field is reduced to zero, an *anhysteretic remanent magnetization* (ARM) is produced in the sample. Both IRM and ARM can be used in various ways to gain information about the magnetic mineral and its grain size.

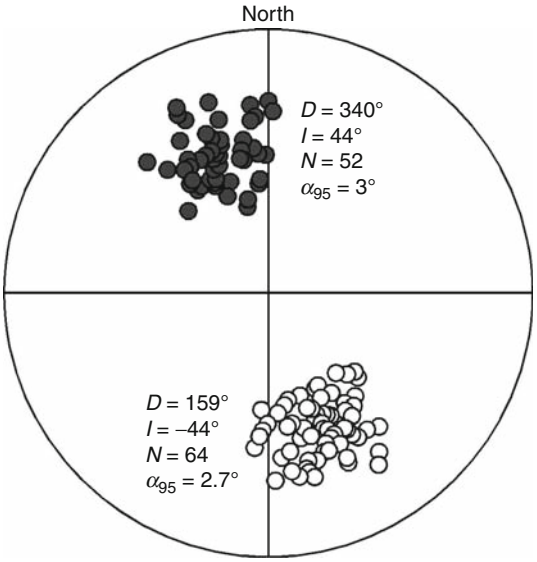
In a paleomagnetic study, special laboratory techniques are used to isolate the components of magnetization present in the rock and to identify the primary component. This is the remanent magnetization acquired during formation of the rock. The remanent magnetization of a rock in situ is called its *natural remanent magnetization* (NRM). It may contain a primary component of geological significance, but this can be accompanied by secondary components of later origin. These components can arise from geological processes, but some may also be induced during sampling. The secondary components can partially – in extreme cases, completely – overprint the primary component and must be understood for the paleomagnetic analysis to have geological significance. By progressively demagnetizing the samples, the structure of the NRM can be analyzed and stable components isolated. There are two main methods of achieving this. When a rock sample is placed in an alternating magnetic field (AF), the magnetizations of all domains with coercivity less than the peak AF field are randomized. If the peak field is slowly reduced to zero and the equipment is in a space shielded from the Earth's field, this part of the rock magnetization is demagnetized. The part that remains has been "magnetically cleaned." If the procedure is carried out in progressively increasing peak fields, the NRM decay shows the components present. Similarly, when a rock sample is heated to a given temperature T, components that have lower blocking temperatures than T are thermally randomized. If the sample is then cooled in field-free space, this part of the NRM remains demagnetized. The progressive destruction of the NRM by AF or thermal demagnetization reveals the components present in the NRM. The stable primary component is identified computationally by principal component analysis of the directions during magnetic cleaning (Kirschvink, 1980) and graphically using vector diagrams (Zijderveld, 1967).

For paleomagnetic results to be a valid record of the ancient magnetic field, it is important to know that the remanent magnetization has the same age as the rock, so identification of the magnetic mineral is important. However, this is not a sufficient criterion and field tests play a crucial role in establishing whether a magnetization component is primary or secondary. The most important are the structural fold test and the magnetic reversals test; less common, but also useful, are the conglomerate test and baked contact test.

The principles underlying the fold and conglomerate tests are illustrated in Figure 3. Layers A and B are folded rocks, and layer C is a conglomerate layer of large cobbles. The *conglomerate test* examines whether the cobble magnetizations have random directions, which would indicate that the magnetization of the parent formation from which the cobbles derive is stable. The *fold test* examines the direction of magnetization around a fold.



Paleomagnetism, Principles, Figure 3 The fold and conglomerate tests of the paleomagnetic stability of magnetization directions. The cobbles in the conglomerate (layer C) have random directions of magnetization, which indicates these are stable. The directions are also stable in layer A, changing around the fold, but in layer B their uniformity indicates they have been remagnetized after folding. (After Lowrie, 2007.)



Paleomagnetism, Principles, Figure 4 Positive reversals test in a section of the *Scaglia cinerea* formation in Umbria, Italy. The mean of 52 normal directions (*solid points*) has declination 340°, inclination 44° (α_{95} = 3.0°), and differs by less than 1° from the antipode of the mean of 64 reversed directions (open points), which has declination 159°, inclination –44° (α_{95} = 2.7°).

If the magnetization of a formation is stable, as in layer A, its direction will change from site to site around the fold; if it is unstable, as in layer B, all sites in the layer will have a common magnetization direction.

If a sedimentary formation is deposited over a long time interval, or if a collection of similarly aged igneous rocks covers enough time so that both normal and reversed intervals of geomagnetic polarity are represented, the *reversals test* may be applied. If secular variation is adequately averaged out, the reversed directions should be antipodal to the normal directions, as in Figure 4. The *baked contact test* is applied to igneous flows and intrusions. The heat of a lava dike can remagnetize the contact zone of a rock it intrudes, or on which it flows. If the paleomagnetic directions in the baked contact zone agree with those of the lava and differ from the rest of the host rock, the lava has a primary magnetic direction. In each of these tests, rigorous statistical methods are used to decide the significance of the magnetization directions.

Statistical testing of paleomagnetic data

Paleomagnetic studies are based on a hierarchical sampling system. A comparatively small number of samples, n, is taken at each of N sampling sites in the geological formation of interest; N and n are each commonly around 10–20. Statistical tests are carried out on the measured data at each hierarchical level. Testing the significance of the results is based on a method developed by Fisher (1953) that represents the paleomagnetic directions as unit vectors. These can be visualized as a distribution of points on a sphere, represented by a stereographic plot. The vector mean of the unit vectors is the best estimate of the population mean direction. Fisher suggested that the probability density P of the deviations θ between the individual sample directions and their mean direction is given by

$$P(\theta, \kappa) = \frac{\kappa}{4\pi \sinh \kappa} \exp(\kappa \cos \theta)$$

The "precision parameter" κ describes the dispersion of the points. If $\kappa = 0$, the directions are uniformly or randomly distributed; if κ is large, the points cluster tightly about their mean direction. The best estimate of κ is k, defined as

$$k = \frac{N - 1}{N - R}$$

in which R is the vector sum of the N unit vectors. In paleomagnetism the level of 95% confidence is used to define a circle with radius α_{95} around the estimated mean direction; there is a 95% probability that the true mean of the distribution lies within this circle. An approximate formula (McElhinny and McFadden, 2000) for the radius of the circle of confidence, especially appropriate for the small numbers of samples or sites in a paleomagnetic study, is

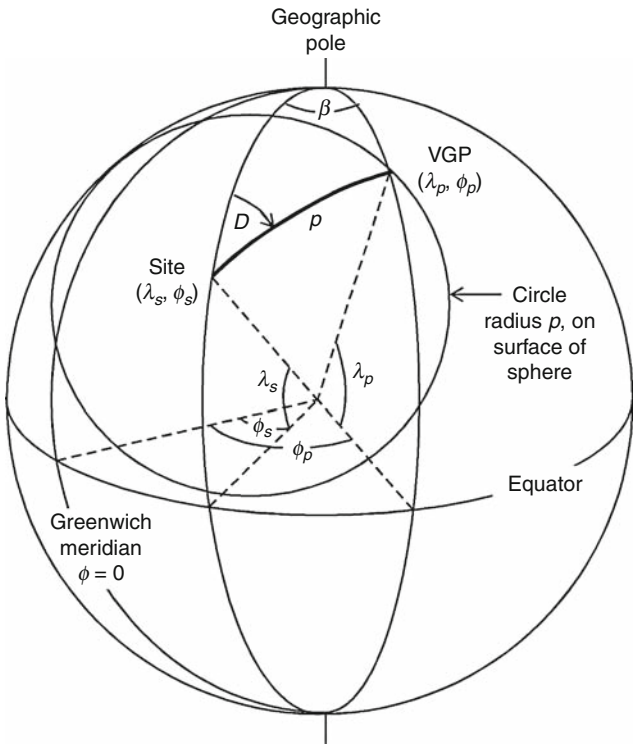
$$\alpha_{95} = \frac{140}{\sqrt{kR}}$$

The statistical definition of a confidence circle around the mean direction allows comparison of a paleomagnetic result with other data of the same age and from the same region. It allows critical evaluation of the directions before and after tectonic corrections (the fold test), as well as the equivalence of antipodal directions in a reversals test.

Statistical analysis lends credence to the results and is an important aspect of all paleomagnetic investigations. The statistical methods can be applied to paleomagnetic directions, and also to distributions of paleomagnetic pole positions.

Virtual geomagnetic poles and apparent polar wander paths

Assuming the GAD hypothesis, the location of the magnetic pole at the time of formation of a given rock formation is coincident with the geographic pole. As a result of subsequent plate tectonic motions, the location of the paleomagnetic pole becomes displaced and rotated. When the magnetizations of the rocks are measured, they appear to have been magnetized by a pole at the displaced location, which is accordingly designated the *virtual geomagnetic pole* (VGP). The principle of locating a VGP from the measured declination and inclination of the stable component of remanent magnetization in a rock is illustrated in Figure 5. First, the inclination is used to calculate the angular distance p to the magnetic pole, employing Equation 1. This defines a circle with radius p centered on the sampling site; it is the locus of possible pole locations. The VGP is located at the intersection of this circle and the great circle defined by the declination; a magnetic pole at this location gives the measured inclination and declination at the sampling site.



Paleomagnetism, Principles, Figure 5 Method for locating the virtual geomagnetic pole in a paleomagnetic study. The distance p to the pole is computed from the paleomagnetic inclination I; the virtual geomagnetic pole (VGP) is located at the intersection of the circle with radius p and the great circle with declination D.

The VGP positions of samples from geologically young rocks cluster near to the geographic pole, corresponding to the GAD hypothesis. Older rocks from the same continent give VGP positions that group well away from the present rotation axis. They plot systematically along a curved path, called an apparent polar wander (APW) path, which appears to trace the motion of the paleomagnetic pole relative to that continent. However, a different APW path is defined by the paleomagnetic data for each continent. Assuming the GAD hypothesis, the paleomagnetic pole at any time lies on the rotation axis. The Earth has only one rotation axis, so it follows that each APW path is a record of the motion of its continent relative to the rotation axis. The APW paths for different continents diverge because the continents have been displaced relative to each other. This motion of the continents was originally called "continental drift" and is the result of plate tectonics.

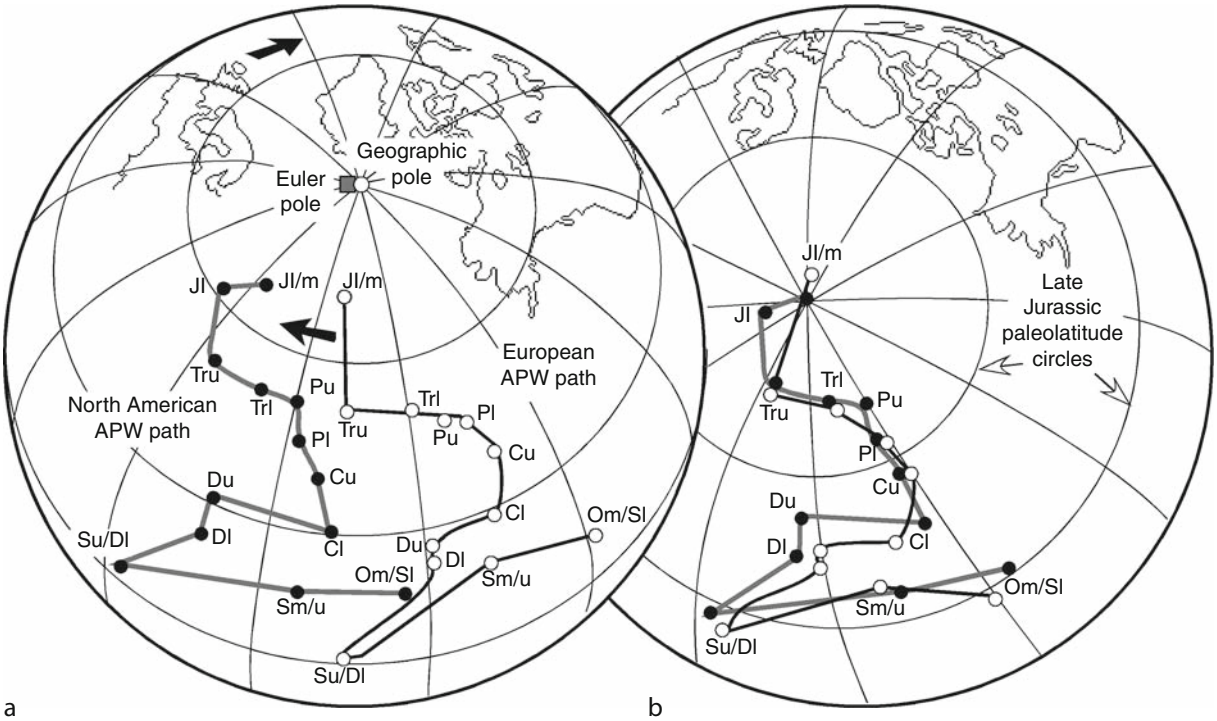
The use of paleomagnetic data for tracing continental movements is illustrated by comparing the APW paths for Europe and North America prior to the Jurassic. Their shapes are similar (Figure 6a), particularly for the Upper Carboniferous (Cu) to the Upper Triassic (Tru). The relative motion of plates on the surface of the spherical Earth is equivalent to a relative rotation about an *Euler pole* of rotation. The APW path of a continent is constrained to move with the continent. The Cu-Tru segments of the two APW paths can be made to overlap by a clockwise rotation of Europe through 38° (Figure 6b) about an Euler pole close to the present-day geographical pole (Figure 6a). Later segments of the APW paths diverge, indicating relative motion between Europe and North America since the Early Jurassic.

Continental reconstruction based on paleomagnetic data requires that the APW paths are securely defined. In order to ensure this, stringent selection criteria have been developed to ensure that the paleomagnetic data accepted for incorporation into the reference database are of satisfactory quality (Table 1).

Magnetic polarity reversals

The geomagnetic field has reversed polarity numerous times, apparently spontaneously and randomly. The record of polarity reversals has been studied in detail in igneous and sedimentary rocks, and in sediments. Beginning in the 1950s, systematic studies of paleomagnetic direction were made in radiometrically dated lavas for the most recent 5 Myr of Earth history. The polarity sequence was confirmed by investigations in slowly deposited marine sediments covering the same time interval, which established that the reversals are a geomagnetic phenomenon and not merely a rock magnetic artifact.

Intervals of constant normal or reverse polarity are called polarity *chrons*; they last typically for 10^5–10^6 year.



Paleomagnetism, Principles, Figure 6 Reconstruction of earlier positions of Europe and North America based on apparent polar wander (APW) paths. (After Van der Voo, 1990a.) In (**a**) the APW paths are shown in present coordinates; in (**b**) the European continent has been rotated by 38° clockwise about the Euler pole shown in (**a**) to bring the Cu-Tru segments of the APW paths into coincidence.

Paleomagnetism, Principles, Table 1 Reliability criteria for paleomagnetic data. Van der Voo (1990b) suggested that acceptable paleomagnetic data should meet at least three of the following criteria

No.	Brief description of reliability criterion
1	Well-determined rock age and a presumption that the magnetization has the same age.
2	Sufficient number of samples ($N \geq 24$), adequate precision of directional grouping ($k \geq 10$), and confidence angle $\alpha_{95} \leq 16°$.
3	Progressive demagnetization that demonstrably includes vector subtraction information.
4	Field tests that constrain the age of magnetization.
5	Structural control and tectonic coherence with the craton or block involved.
6	The presence of reversals.
7	No resemblance to paleomagnetic poles of younger age (by more than a period).

The chrons may be interrupted at irregular intervals by polarity *subchrons* that last on the order of 10^4–10^5 year. The *transition* from one polarity to the opposite one is estimated to take about 3–10 kyr, which is much shorter than a polarity chron or subchron. The polarity transition is accompanied by a decrease in intensity of the paleofield, which may last up to twice as long as the directional change. The polarity record also shows occasional large *excursions*, in which the magnetic pole spends 10^3–10^4 year in equatorial latitudes, but instead of completing a reversal it returns to its initial location on the rotation axis.

The irregular pattern of polarity intervals provides a kind of geological fingerprint, which can be used to date and correlate other magnetic polarity sequences in both igneous and sedimentary rocks, and sediments. The most important application has been the interpretation and dating of marine magnetic anomalies. New oceanic lithosphere forms at oceanic ridge systems and is then transported away from the ridges by the seafloor spreading process. As the basaltic lava of the ocean crust cools, it acquires a TRM parallel to the Earth's magnetic field. Seafloor spreading persists for millions of years at a ridge, during which the magnetic field changes polarity many times. This leaves some blocks of oceanic crust normally magnetized parallel to the field while their neighbors are reversely magnetized. A sequence of positive and negative magnetic anomalies, corresponding to normal and reverse polarities of the oceanic crust, is observed over the ridges, from which the sequence of polarity of the Earth's magnetic field is obtained. The oceanic polarity pattern correlates with the polarity sequence in lavas that have been dated radiometrically, thus the ages of magnetized blocks of the ocean floor can be determined.

Knowing the distances of the polarity changes from the oceanic ridge, the rate of seafloor spreading can be calculated.

Older reversal patterns have been dated by magnetostratigraphy. This entails stratigraphic sampling of a sedimentary section characterized by a uniform lithology and deposited at a uniform rate. Standard paleomagnetic techniques are used to evaluate the paleomagnetic direction of each sample and establish the existence of *magnetozones* of constant polarity. As is the case with paleomagnetic data, strict reliability criteria regulate the acceptance of a magnetic stratigraphy into a global database (Table 2).

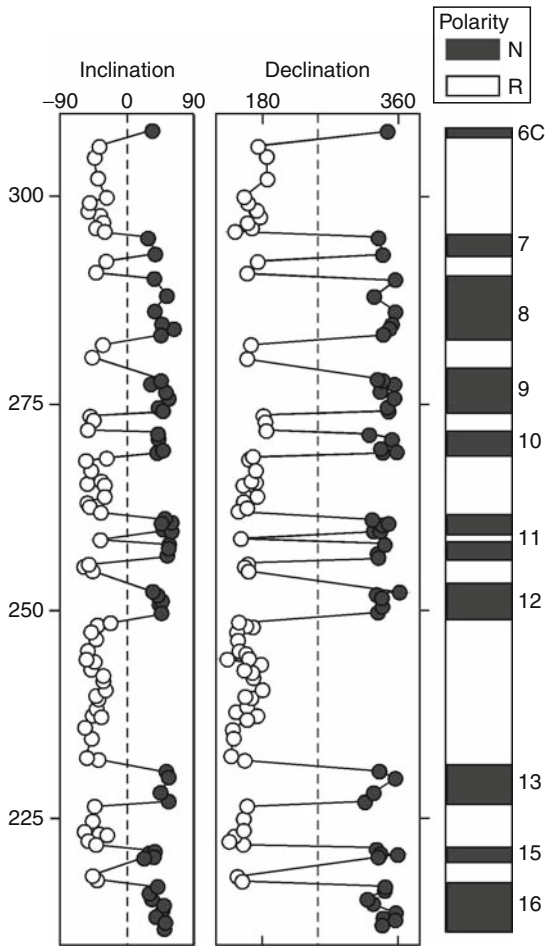
An example of coordinated magnetostratigraphy and biostratigraphy that correlates well with marine magnetic reversal history is shown in Figure 7. The *Scaglia cinerea*, a marly limestone in Umbria, Italy, was deposited in the Late Paleogene and acquired a DRM that preserves the direction and polarity reversals of the geomagnetic field during deposition. Paleontological dating of the limestones enabled correlation of major stage boundaries with the polarity sequence. The absolute ages of many stage boundaries are known independently, so the reversal pattern could be dated. Correlation with marine magnetic anomalies allowed the corresponding regions of the oceanic crust to be dated. The polarity sequence correlates well with the history of geomagnetic polarity derived from marine magnetic anomalies for chrons numbered 6C to 16 (Cande and Kent, 1992).

Magnetic polarity stratigraphy has served in this way to correlate and date the oceanic magnetic record in many paleomagnetic sections, on land and in cores from the ocean bottom. The ages of key parts of the geomagnetic polarity record have thus been determined at many correlation levels. The ages of magnetic reversals between dated tie-points can be computed by interpolation or extrapolation. The dated polarity sequence is called a geomagnetic polarity timescale (GPTS).

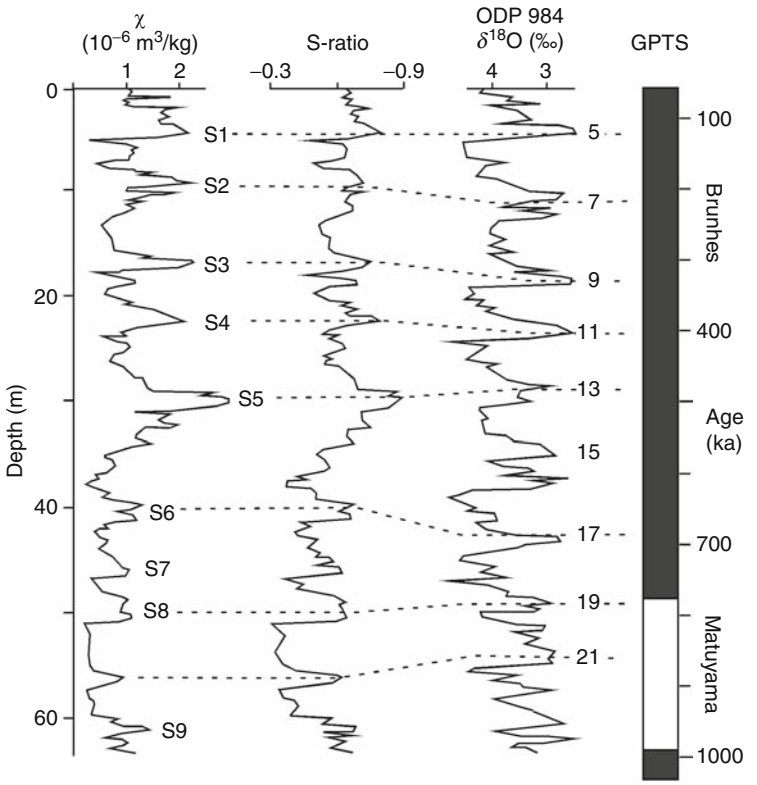
The record of geomagnetic polarity is well established from the present back to the Late Jurassic (Oxfordian), equivalent to the last 160 Myr of geological time. Three distinct episodes of reversal behavior are identified in this time interval. The oldest episode, comprising frequent reversals in the Late Jurassic and Early Cretaceous, is referred to as the M-sequence. The youngest episode, comprising the Late Cretaceous and Cenozoic, consists of frequent reversals known as the C-sequence. The M-sequence and C-sequence are separated by an interval, 38 Ma in length, called the Cretaceous Normal Polarity Superchron (CNPS), in which correlated magnetic anomalies are absent; evidently the Earth's magnetic field did not reverse polarity during this time. The episodes of

Paleomagnetism, Principles, Table 2 Reliability criteria for magnetostratigraphy. Opdyke and Channell (1996) proposed that an acceptable magnetostratigraphic section should pass at least five of the following ten tests

No.	Brief description of reliability criterion
1	Stratigraphic age known to the level of the stage, and associated paleontology presented adequately.
2	Sampling localities placed in a measured stratigraphic section.
3	Complete thermal or alternating field demagnetization performed, and analysis of magnetization components carried out using orthogonal vector projections.
4	Stable paleomagnetic directions determined from principal component analysis.
5	Data published completely as plots of VGP latitudes and/or of declination and inclination against stratigraphic position. The statistical parameters should be fully documented.
6	Magnetic mineralogy determined.
7	Field tests to constrain the age of magnetization undertaken where possible.
8	A positive reversals test should be carried out.
9	Radiometric ages, especially $^{40}A/^{39}Ar$ or U-Pb ages from volcanic ashes or bentonites, available in the stratigraphic section.
10	Multiple overlapping sections confirm the polarity sequence.



Paleomagnetism, Principles, Figure 7 Declination and inclination profiles in the Late Paleogene *Scaglia cinerea* formation, whose directions are shown in Figure 4, correlated to the history of geomagnetic polarity derived from marine magnetic anomalies for chrons numbered 6C to 16.



Paleomagnetism, Principles, Figure 8 Profiles of magnetic susceptibility (χ), hardness of remanent magnetization (S-ratio), and paleomagnetic polarity in a loess section at Sanmenxia, China, correlated to the marine oxygen-isotope ratio ($\delta^{18}O$) at Ocean Drilling Program (ODP) site 984. (Data source: Wang et al., 2006.) The peaks marked S1, S2, etc., correspond to paleosols; the lows between them are loess beds.

reversing behavior are long enough to make tentative interpretations about the reversal process. It is evident from the patterns of reversals that they do not occur cyclically. Making allowance for the time spent in transition between opposite polarity states, statistical analysis indicates that the reversals in the C- and M-sequences occur randomly. There is as yet no convincing evidence to refute identification of the CNPS as an uninterrupted period of constant normal polarity. There are competing interpretations of its origin. Whereas some investigators consider that the CNPS represents a special behavior of the geodynamo, others regard it as an exceptionally long feature in a continuous reversal process.

The breakup of Pangea and the onset of seafloor spreading date from the Early Jurassic, for which magnetostratigraphic confirmation of the marine polarity record is fragmentary. For earlier eras there is no marine polarity record to which a measured magnetostratigraphy can be correlated. Consequently, despite many magnetostratigraphic investigations in ancient rocks, there is no consistent dated polarity record older than Late Triassic. To establish a GPTS for earlier times will require verifying the same polarity sequence in multiple overlapping sections. This presents a large but important task for paleomagnetists and biostratigraphers.

Environmental magnetism

In recent years, knowledge of the magnetic properties of minerals, the grain-size dependence of parameters of magnetic hysteresis, and the use of magnetic stratigraphy have been combined in applications to a wide range of environmental problems. For example, regional environmental pollution by heavy industry and traffic has been investigated by using ferromagnetic properties to trace heavy metal contamination. However, most environmental studies have been made in sedimentary archives. The magnetic susceptibility of a sediment reflects both the concentration and type of the magnetic minerals, whereas variations in grain size may be revealed in the stratigraphic variations of magnetic coercivity and remanent magnetizations produced in the laboratory. The proportion of an IRM carried by grains with coercivity above a certain value (the so-called S-ratio) can be an indicator of the relative size of the fine-grain fraction of the ferromagnetic grains. Lake sediments and wind-blown loess deposits have comparatively high deposition rates. Detailed evaluation of the magnetic signal in these sedimentary archives can reveal variations in environmental conditions during deposition. The magnetic properties of Chinese loess deposits illustrate the way in which magnetic parameters can act as proxy for paleoclimatic indicators.

The boundary between the Brunhes and Matuyama polarity chrons (age 780 ka), and the upper and lower boundaries of the Jaramillo normal polarity subchron (990 and 1,070 ka, respectively), tie the loess section at Sanmenxia, China, to deep-sea sediments cored at Ocean Drilling Program (ODP) Site 694 (Figure 8). The wind-blown loess sediments in central China were deposited in cold climatic conditions. Paleosols formed under warmer, moister conditions were conducive to enhancement of the magnetic susceptibility. Alternations of loess deposits and paleosols are accompanied by fluctuations in magnetic susceptibility, with low values marking the loess and higher values in the paleosols. Oxygen-isotope results at the ODP site reveal cycles of climatic variation, which correlate well with the magnetic susceptibility and S-ratio data from the Sanmenxia section. The results demonstrate the usefulness of magnetic mineralogy parameters as proxies for isotopic data that document paleoclimatic variation.

Summary

Apart from isolated but important pioneering studies, in which the characteristics of the geomagnetic field and the rudiments of rock magnetism were explored, paleomagnetism originated as a scientific discipline in the 1950s. As a result of the continuous development and refinement of instrumentation and analytic techniques, it has made many notable contributions to geological knowledge. Initially it focused on the tectonic problem of "continental drift" and by developing apparent polar wander paths for the different continents it documented incontrovertibly the mobility of the continents. Matching of APW paths led to the reconstruction of supercontinents such as Rodinia, Pangea, and Gondwana. In parallel to this work, paleomagnetic analysis in conjunction with geological dating worked out the history of geomagnetic reversals. On the basis of the established reversal history and the rock magnetic properties of oceanic basalts, the hypothesis of seafloor spreading was developed. This development provided the key to the mechanism of plate tectonics and allowed the documentation and dating of plate motions, and explained how "continental drift" took place. In turn, the pattern of magnetic reversals in the oceanic crust along with magnetostratigraphy established a dated sequence of geomagnetic polarity history for the past 160 Ma. The methods of paleomagnetism and rock magnetism have found wider application in addressing environmental problems and in contributing to an understanding of paleoclimatic history.

Earthquake archaeology; Earthquake geology

Definition

Paleoseismology. An interdisciplinary field dealing with prehistoric or pre-instrumental earthquakes, in particular, their location, timing, and magnitude.

Paleoseismology

Introduction

Modern instrumental records of earthquakes cover only a little more than a century since 1890s (see *Seismic Instrumentation*). Historic accounts in several countries

such as China, Japan, and Mediterranean regions allow us to extend the records of large earthquakes up to more than a couple of thousand years. However, for most parts of the globe, no earthquake data are available for the time periods of even the past hundreds to thousands of years that are comparable to repeat time of large earthquakes on a fault. Nevertheless, geologic sedimentary strata and geomorphic features preserve evidences for strong shaking, ground breaks, and landscape changes associated with large earthquakes. Although geologic and geomorphic records are incomplete and poorly constrained in time and space, they greatly help to understand faulting process and recurrence of earthquakes that are unavailable to seismologists due to the brevity of historic documents. We have defined this discipline as "paleoseismology" and such individual earthquakes are referred to as "paleoearthquakes."

Paleoseismology is not a subbranch of seismology, but rather it is an interdisciplinary field of research, which borrows many concepts from structural geology and active tectonics. Methodology and techniques in paleoseismology are derived primarily from Quaternary geology and related disciplines such as geomorphology, soil mechanics, sedimentology, archaeology, paleoecology, photogrammetry, radioisotope dating or pedology (Grant, 2007; McCalpin, 2009).

The history of paleoseismology is as short as that of instrumental seismology. Although several pioneer geologists described surface faulting accompanying earthquakes in the late 1800s, geology and seismology at that time were separated (Yeats and Prentice, 1996). But a few leading geologists, e.g., R. E. Wallace, C. R. Allen, and D. B. Slemmons, who studied San Andreas fault and active scarps in Nevada, and radiocarbon dating technique pervasive since about 1960s–1970s, played prominent roles in bridging the gulf between instrumental seismology and geology (Yeats and Prentice, 1996). Since the 1970s, paleoseismic investigations have been yielding information about the paleo-movements on faults, dates of previous earthquakes, recurrence times, average slip rate, and earthquake effects over time intervals ranging from decades to thousands of years (Grant, 2002). Consequently, numerous paleoseismic data (e.g., Sieh, 1978) and fundamental concepts of recurrent large earthquakes (e.g., Schwartz and Coppersmith, 1984) derived from field observations have largely contributed to progress in understanding the mechanics of earthquakes and faulting.

Unlike many subbranches of geology, the uniqueness of paleoseismology lies in its potential to decipher the future from the past and present. The traditional geological doctrine of "uniformitarianism," which is used to reconstruct the past events from phenomena observable in the present, can be stretched to the future in paleoseismology to perform seismic hazard estimates and earthquake forecasting. The final goal and major contribution of paleoseismology is to not only understand long-term faulting processes, but also to provide fundamental data and speculations to mitigate seismic hazard.

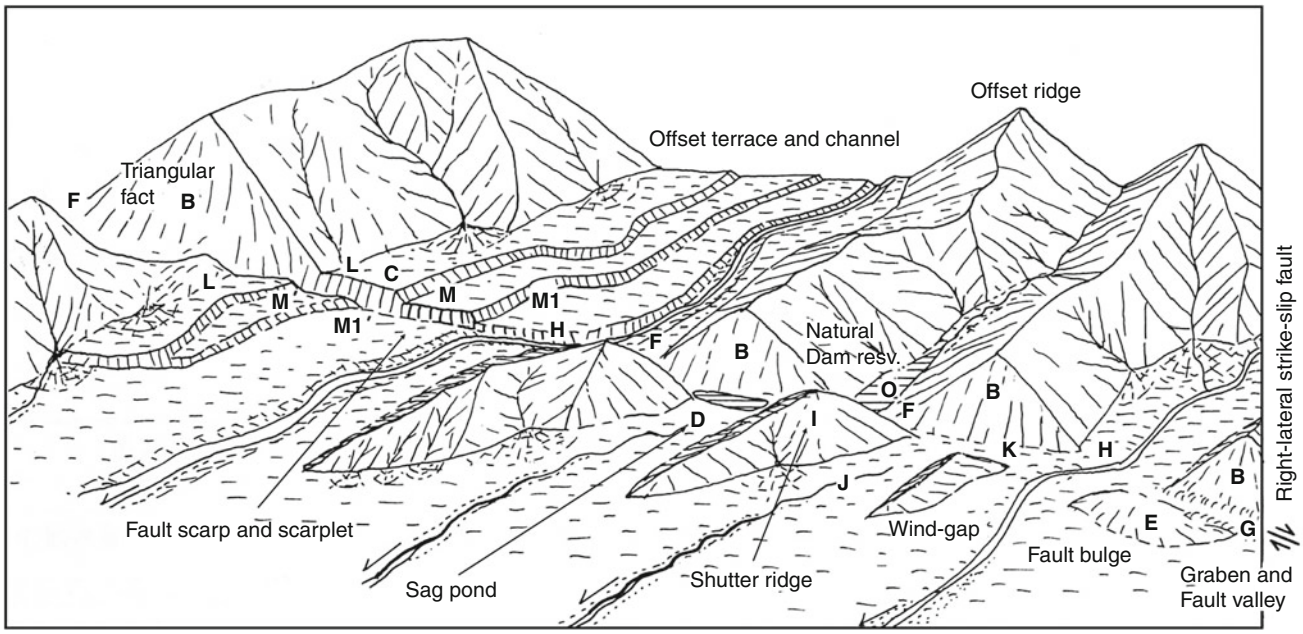
Paleoseismic records

In seismology, estimation of earthquake magnitude depends on the performance of seismometers and on network coverage (see *Seismological Networks*; *Statistical Seismology*). Geomorphic markers, surface soil, and sediments are like poorly performing strong-motion seismograms. If an earthquake is large and shallow enough, the seismogenic faulting normally reaches the Earth's surface. For inland intraplate and interplate earthquakes occurring shallower than ~20 km ("seismogenic layer," see entries on *Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat* and *Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity*), $M \geq 6$ earthquakes may leave tectonic surface breaks and permanent ground offsets (Wells and Coppersmith, 1994). The minimum magnitude of a paleoearthquake we can identify in strata and landscape is about $M \sim 6$ or higher (discussed later). For offshore earthquakes, including subduction associated mega-thrust events, $M \geq 7.5$ earthquakes leave records of significant coastal uplift and subsidence (e.g., Berryman et al., 1989). However, the paleoseismic record is spatially and temporally incomplete. Unlike instrumental seismology, recording processes by sedimentary layers are intermittent, and erosion often destroys the evidence for paleoearthquakes.

Fault identification and slip rate

Identifying an active fault is the first step for paleoseismology. As described above, a large earthquake often leaves surface breaks and warping with significant offset when the faulting reaches the Earth's surface. Detailed excavation studies often reveal evidence for each individual earthquake at an individual site. However, recognizing active traces relies on identification of geomorphic expression due to repetition of surface-faulting earthquakes as "fault landforms" for which deformation rate must be higher than local rates of erosion and deposition. Although the definition of "active fault" partly depends on the purposes (engineering or scientific) and on the usage of the terminology in different countries, it is usually identified by its association with tectonically deformed Quaternary-age materials or surfaces and by its potential to cause a large earthquake in near future.

To identify active faults and associated active landforms, aerial photographs and/or satellite images are commonly used ("aerial photographic interpretation"). High-resolution satellite images may be used to identify faulted landforms, even finding coseismic surface ruptures, around the globe, particularly in hardly accessible areas (e.g., Lin et al., 2006). The most frequently encountered feature is topographic lineaments. But lineaments are often developed by a combination of constructive geologic features and erosion. Therefore, other characteristics associated with faulting such as triangular facets, fault scarps, sag ponds, and bulges should be found along



Paleoseismology, Figure 1 Topographic features formed by right-lateral offset (modified from Okada, 1991 and Research Group for Active Faults of Japan, 1992). B, triangular facet; C, fault scarplet; D, sag pond; E, tectonic bulge; F, fault saddle; G, graben; H, offset stream; I, shutter ridge; J, beheaded stream; K, wind gap; L-L′, offset of piedmont line; M-M′, offset of terrace edge; Q, fault pond.

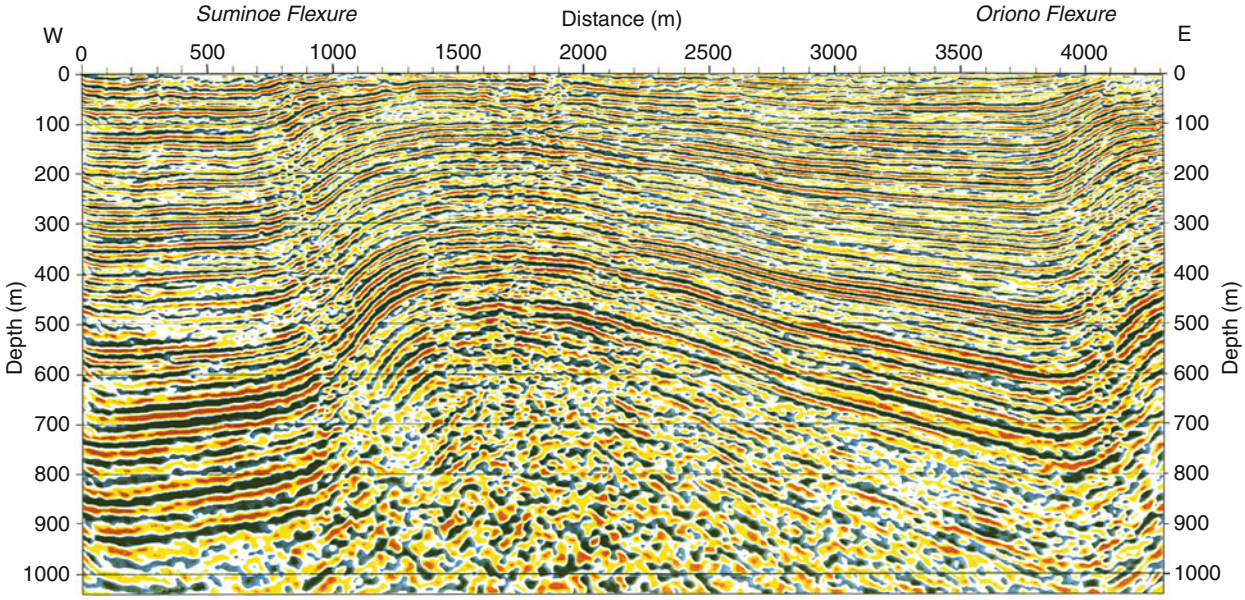
a fault lineament (Figure 1). Strike-slip faults accompany offset streams, shutter ridges, beheaded streams, wind gaps, and offset terrace risers. Multiple and systematic fault landforms along a single trace increase the reliability of its identification as an active fault trace. Most of such traces tend to be roughly along geologic faults juxtaposing different geologic units so that a traditional geologic reconnaissance is also useful to constrain an active fault zone. Fresh fault gouge (clay) and/or fault breccia are often exposed on outcrop along geomorphic traces. Geologic drilling and shallow coring are auxiliary approaches to constrain the location of a fault trace and sometimes help to estimate vertical offsets of stratigraphic units, particularly much deeper than trench excavation (e.g., Dolan et al., 2003). Deeper geologic information down to a few kilometers depth from industry oil wells provides a larger picture of fault structure and associated folds (e.g., Tsutsumi and Yeats, 1999). Several other methods reveal subsurface geologic structures for the areas having shallow water table and urban areas with limited open space. For example, cone penetrometer testing (CPT) and large diameter borings can be applied for these conditions (Grant et al., 1997). The "Geoslicer" (Nakata and Shimazaki, 1997), which consists of a sample tray and a shutter plate, can be inserted into the ground by a weighted vibrator to extract a sliced soil sample of larger than a few meters dimension (Takada and Atwater, 2004). Geoslicer can directly sample a fault itself without losing information of strike, dip, and geologic context of the fault.

Spatial resolution and accuracy in aerial photographic images are limited. Recently, airborne Light Detection And Ranging (LiDAR) surveys, which measure bare topography irradiating a laser beam from an airplane or helicopter, have been widely used to image very detailed fault-zone topography beneath dense vegetation cover (e.g., Sherrod et al., 2004) and urbanized areas (e.g., Kondo et al., 2008). These data are at the appropriate scale (meters) and accuracy (decimeter) to provide useful measurements of the fine features of fault landforms (Arrowsmith and Zielke, 2009). Airborne Laser Swath Mapping (ALSM) is also expected to find hidden active faults.

To locate an active fault trace and to confirm deformed subsurface structure various geophysical imaging techniques such as seismic reflection and refraction, ground-penetrating radar (GPR), aeromagnetic surveys, and gravity surveys are employed. The advantage of these techniques is that these are nondestructive methods for seeking deeper structures (Bond et al., 2007). High-resolution seismic reflection surveys are most pervasive to visualize shallow geologic structure associated with details of fault activity, even to reveal blind fault and fault-related fold (Figure 2).

These geomorphic, geologic, and geophysical explorations for fault identification also provide information about long-term slip rates. The slip rate on a fault, S, is calculated by dividing cumulative displacement (D) across the fault by time interval T (Figure 3),

$$S = D/T. \quad (1)$$



Paleoseismology, Figure 2 An example of fault-related fold revealed by a seismic reflection survey. Depth-converted P-wave seismic reflection profile across two flexures in south Osaka, Japan (Sugiyama et al., 2003). The strata are composed of Plio-Pleistocene non-marine and marine sediments.

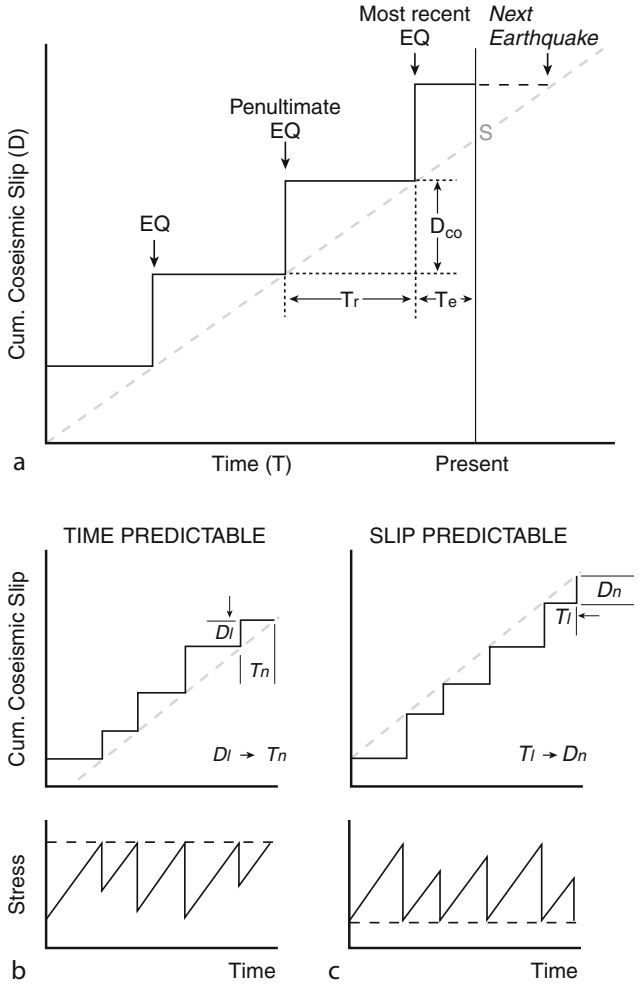
To obtain *S*, we need to find "piercing lines" or "piercing points" which intersect a fault zone as a line or a point. The piercing lines and points should be formed before the subsequent faulting events occurred. Geomorphologically, offset ridges, streams, and gullies become piercing lines, but more often well-reconstructed and dateable terraces and terrace risers are employed as the best piercing lines to estimate slip rates (e.g., L-L', M-M', M1-M1' in Figure 1). If offsets increase with terrace ages, the fault is considered to have been continuously active. Offset bedrock geology is also used as piercing lines and points to roughly estimate the very long-term slip rate. Cultural features such as roads, fences, walls, buried pipes, and rice paddy boundaries across a fault line are often used to measure the amount of coseismic slip for very recent earthquakes and historic events. In coastal and fluvial areas, where uplifted terraces are commonly seen, the vertical component of the slip rate *S*, is more easily obtained than the lateral component. Such slip rate estimates are used for classifying the fault activity (e.g., in Japan, class A: order of m/1,000 years; class B: order of 0.1 m/1,000 years; class C: order of 0.01 m/1,000 years), which is an important index for the estimation of the recurrence time of major earthquakes or for future seismic activity (Research Group for Active Faults of Japan, 1992).

Evidence for paleoearthquake

Paleoseismic evidence is either primary or secondary (McCalpin, 2009). Primary evidence is formed by tectonic deformation resulting from coseismic slip along a source fault plane. Secondary evidence is produced by earthquake shaking. Paleoseismic features are also distinguished as being on or above fault trace (on-fault or near-field features), or away from or far above a fault trace (off-fault or far-field features) (McCalpin, 2009). Because off-fault evidence for a paleoearthquake is mostly associated with strong shaking, the problem with the off-fault evidence is its difficulty in finding the corresponding seismic source. Thus, the majority of paleoseismic studies focus only on "on-fault" evidence.

Encountering a natural exposure of faulted young sediment is extremely rare. We thus excavate trenches across a fault zone (sometimes parallel to the fault zone) to expose faults and young strata that record evidence of paleoearthquakes. The site for trenches is chosen based on the fault location, land usage, sediments preservation, paleoearthquake records, and abundant dating material. The best trench site is considered as the one where: (1) deformation zone is narrow, or fault strand is single and representative of the entire fault zone; (2) frequent but dilute sedimentation processes occur with numerous dateable materials. The trench walls are not long-lived exposures and mostly not reproducible so that detailed observations and objective records by as many observers as possible are required (Grant, 2007). A trench log, which is a geologic sketch, is used for defining and mapping sedimentary units and recording evidence for surface-rupturing earthquakes, which we call an "event horizon."

An event horizon is used as the ground surface at the time of a paleoearthquake (Pantosti et al., 1993). The event horizon may be preserved as scarp-derived colluvial wedge deposits, unconformities that terminate faults, and warping (Figure 4), each of which is defined as an "event



Paleoseismology, Figure 3 (**a**) Schematic diagram showing the cumulative displacement (D) at a site along a fault as a function of time (T). D_{co} coseismic displacement, T_r recurrence interval, T_e elapsed time since the most recent earthquake, S slip rate estimated from D/T. (**b**) Time-predictable model. (**c**) Slip predictable model. After Shimazaki and Nakata (1980).

indicator" (Scharer et al., 2007). It is most likely to conclude that surface rupture and significant deformation such as folding and tilting along active traces are the direct products of seismogenic faulting. There are various kinds of evidences for paleoearthquakes which can be rated for their reliability.

Upward fault termination: This is the most common and easily identified event indicator in which faults and faulted strata are overlain by a non-deformed horizon (Figure 4a). But one tends to misinterpret an event horizon in special situations where fault slip near the ground surface tapers and dies out upward (Bonilla and Lienkaemper, 1990). Thus the quality and confidence level of this indicator depend on the amount of slip and stratigraphic conditions between different exposures at a site.

Fissure fills: Fissures and fissure fills are a sort of open crack associated with faulting and younger material filled during postseismic process (Figure 4b). They are commonly seen as a wide zone of alternating tension gashes and compressional mole tracks immediately after a large surface-rupturing earthquake due to strike-slip faulting.

Colluvial wedge: The colluvial wedge is formed on the footwall side as a result of collapse of the fault scarp exposed at the time of a scarp-forming earthquake (Figure 4c and d). A trench wall across a fault normally exposes a wedge-shaped section tapering toward or away from the fault scarp, often showing upward-coarsening structure, similar to talus deposition. When a bedrock fault plane is exposed at the earthquake, the collapsed sequence of gouge, breccia, and intact bedrock block are sequentially observed in the wedge. When it occurs within the loose sediments, scarp degradation is involved. Colluvial wedges are not only seen along normal faults but also along strike-slip and thrust faults.

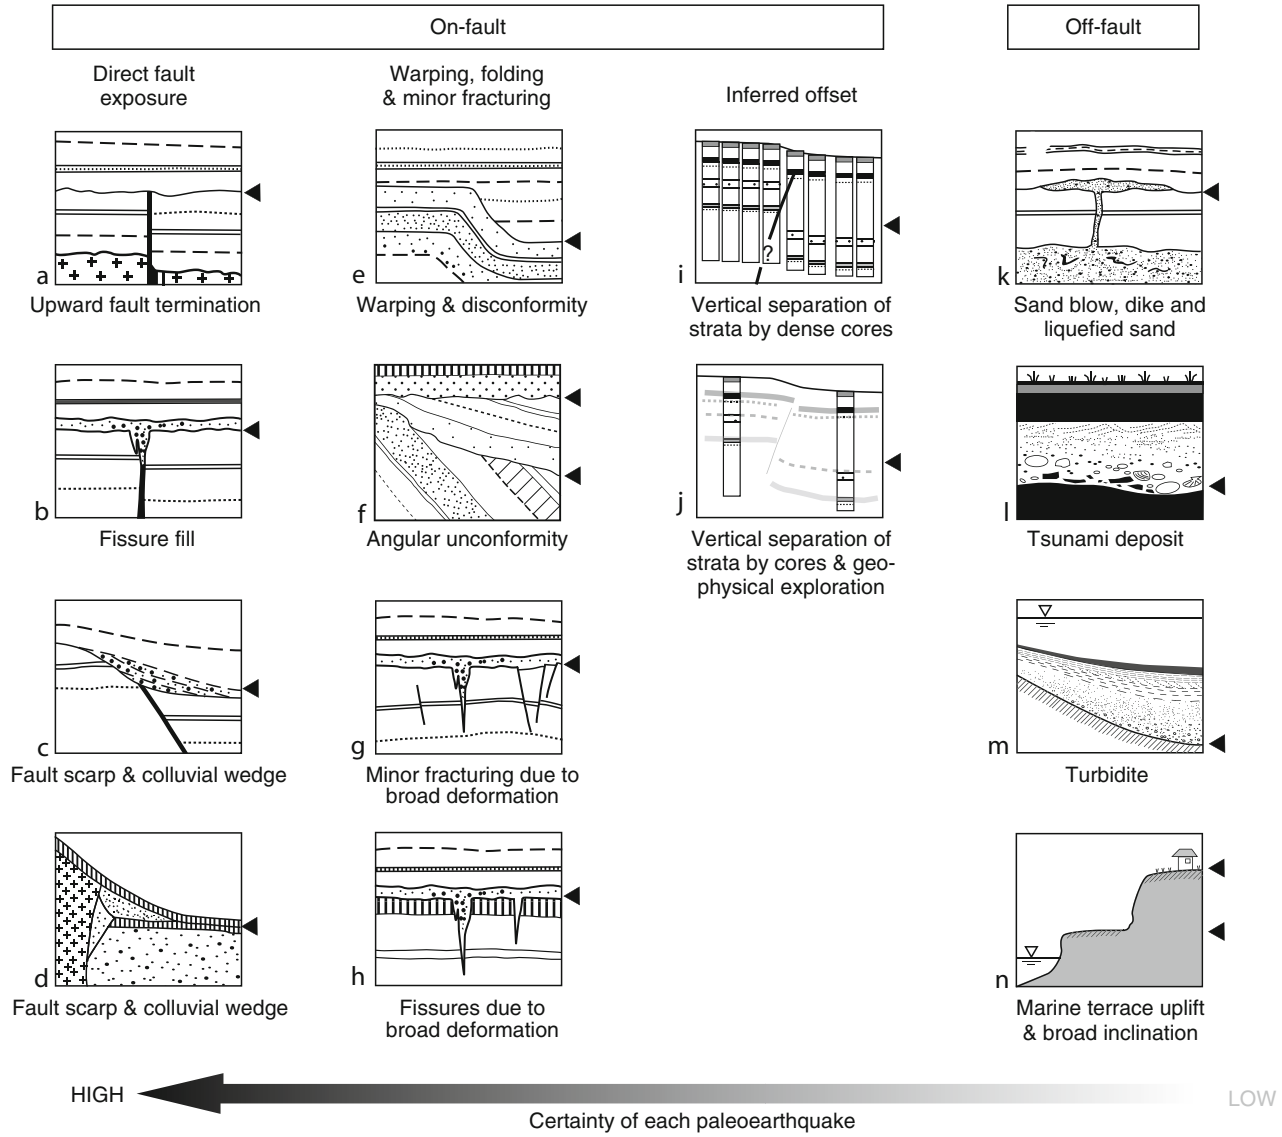
Angular unconformity associated with tilted and folded strata: An angular unconformity is produced by broad deformation of subsurface sediments due to faulting and subsequent erosion and sedimentation (Figure 4e and f). If a fault plane is simple and it is hard to find an upward termination, angular unconformity would be a substitutive criterion to identify an event horizon. But, except for significant inclination of strata, horizontal sedimentation must be guaranteed. Adhesive composition with clay and silt often shows a veneer deposit along a slope, which often mimics crustal deformation.

Minor cracks and faults associated with subtle deformation: Where the amount of displacement is small, and/or surface condition is dry, numerous minor cracks or tension fissures associated with deformation can be produced (Figure 4g and h).

The deeper we expose stratigraphic units, the more events and associated structures are likely to be exposed. Since evidence associated with older events tends to be destroyed and obscured by the most recent event, we must restore the stratigraphy and structures prior to the most recent event and then reinterpret the older events to identify multiple paleoearthquakes at a site ("Retrodeformation analysis," McCalpin, 2009). It means that reliability of the paleoearthquake tends to be reduced when we go farther back in the past. To have higher confidence for a paleoearthquake, multiple exposures of a fault and/or significant deformation (event indicators) in the same stratigraphic horizon should be confirmed at a site (Scharer et al., 2007).

Time constraints of paleoearthquakes

Although there are several methods to directly determine ages of fault activities from fault gouges (e.g., Fukuchi, 2001), timing of each paleoearthquake is commonly constrained by ages of deformed stratigraphic units and overlying undeformed strata, for which many dating



Paleoseismology, Figure 4 Schematic diagrams of typical stratigraphic event indicators of paleoearthquakes in both on-fault and off-fault regions. Solid triangle beside each panel indicates an event horizon. Several on-fault diagrams are based on Allen (1986) and Okada (1991). Note that confidence level of paleoearthquakes increases from the diagrams in off-fault regions to the ones showing direct fault exposure.

approaches using different isotopes have been used (see details in Grant, 2002 and references therein).

Among them, radiocarbon dating is the most powerful and pervasive technique in paleoseismic studies. In this technique, the time since the death of a plant or animal is estimated by measuring the sample's residual ^{14}C content relative to modern standards and the half-life decay constant of ^{14}C (5,568 years). The beta particle counting method conventionally requires 2–200 g of carbon and allows us to date back to ~40,000 years before present (yBP; actually years before 1950 AD). Meanwhile, newly developed Accelerator Mass Spectrometry (AMS) dating requires samples as small as a few milligrams and extends the measurable date back to 50,000–60,000 yBP. Since the ratio of ^{14}C to ^{12}C has varied with time due to variations in number of cosmic rays associated with the strength of the Earth's magnetic shield, measured radiocarbon age needs to be converted to calendar date. From dendrochronological approaches with tree rings, glacial varves, corals that annually record the amount of ^{14}C in the atmosphere, radiocarbon ages are calibrated to corresponding calendar dates back to about 24,000 years before present (Stuiver et al., 1998).

Such dendrochronological approaches to constrain timing of a paleoearthquake have been commonly employed since Jacoby (1989). Time constraint of

a paleoearthquake requires at least two radiocarbon dates that bracket an event horizon, in which probabilistic density is calculated from the calibrated dates of both samples. To have better constraints for paleoearthquakes, there are several calibration programs, one of which "OxCal" (Bronk Ramsey, 2001; Lienkaemper and Bronk Ramsey, 2009) not only calibrates the radiocarbon ages to the calendar years but also implements rigorous means of estimating these event ages and their uncertainties using Bayesian statistics.

As mentioned before, several countries have historical accounts longer than a thousand years or more and thus may cover more than a few seismic cycles of very active faults. However, the longer we go back in the past, the fewer and less reliable the historical accounts are. In addition, most of the historical earthquakes roughly control isoseismal areas from documents of earthquake damage, but not the specific source of each earthquake. Thus a combination of such historical documents and paleoseismic evidence with well-determined dates are used to confirm the source fault for such historical earthquakes (e.g., Armijo et al., 2005).

Archaeoseismology reaches further back in the past to reveal prehistoric earthquakes based on their effects on man-made objects, usually buildings or other monuments (Karcz and Kafri, 1978, see entry on *Archaeoseismology*). The time range depends on history and archaeology in each country. Historic accounts are often available and tied with ruins due to devastating shaking, paleo-liquefactions, and paleo-landslides (rock-slides) at archaeological sites. The advantage of archaeoseismology is narrow time constraints of earthquake occurrence by archaeological and historical knowledge. Characteristic off-fault damage types include horizontal shifting of large building blocks, downward sliding of one or several blocks from masoned arches, collapse of heavy, stably-built walls, chipping of corners of building blocks, and aligned falling of walls and columns (Marco, 2008). In some rare cases, faults intersect with archaeological sites, which enables us to measure sense and size of slip and constrain its occurrence time. Several recent archaeoseismological studies in the Eastern Mediterranean region in particular have been unveiling the detailed slip history and rupture behavior of the Dead Sea fault (e.g., Meghraoui et al., 2003), and large earthquakes associated with mythology along the Aegean Extensional province, Cyprus, and Hellenic Arcs (e.g., Stiros, 2001).

Magnitude and frequency of paleoearthquakes

Like "uniformitarianism," no paleoearthquakes can be inferred without detailed knowledge of recent observed earthquakes that left important clues between subsurface seismic processes and surface deformation. Since paleoseismology relies on paleo-surface information preserved in geology and landforms, seismic and geologic data compilations of recent large shocks associated with surface-ruptures, tilt, warping, and other earthquake-related deformation are necessary.

As seismologists found simple self-similar scaling laws for source faults, dimension and magnitude, surface ruptures compiled from worldwide data have similar scaling relations (Wells and Coppersmith, 1994). For example, the empirical relation between surface rupture length (L in km) and magnitude (M) is expressed as $M = 5.16 + 1.12 \log L$ for strike-slip fault. For seismic hazard assessment, such an empirical relation is increasingly applied to estimate magnitude from the length of an identified fault trace. Similar empirical scaling relations are found between coseismic surface displacement and magnitude. For maximum displacement D_{max} in meter, $M = 6.69 + 0.74 \log D_{max}$. For average displacement, D_{ave} in meters, $M = 6.93 + 0.82 \log D_{ave}$. Besides fault length, coseismic slip, either D_{max} or D_{ave}, is also increasingly used to estimate the magnitude of a paleoearthquake. There are two ways to have such coseismic slip from paleoseismic data. One gives an indirect estimate from slip rate (S) and average recurrence interval (T_r) of paleoearthquakes along a fault as $D = S \times T_r$. The other provides direct measurement from vertical separation of faulted strata on trench walls in particular for reverse faults and three-dimensional reconstruction of lateral offset of piercing points for strike-slip faults.

In terms of magnitude and frequency estimates for an active fault, one of the greatest impacts of geology on seismology is the "characteristic earthquake model" (Schwartz and Coppersmith, 1984, see entry on *Characteristic Earthquakes and Seismic Gaps*). This model illustrates the concept of the repetitions of similar size of large earthquakes with a similar amount of slip, rupture length, and magnitude along a fault. The model also emphasizes that paleoseismic records from a fault suggest more frequent occurrence of large earthquakes compared to the ones extrapolated from the Gutenberg–Richter relation of regional seismicity (Wesnousky, 1994). If only scanty paleoseismic information on a fault is available, one simply uses the characteristic earthquake model to estimate the size of earthquakes potentially caused by the fault.

If the characteristic earthquakes on a fault occur periodically or quasi-periodically with characteristic slip, we would not have any difficulty to approximately forecast the time and magnitude for the next large earthquake (Figure 3a). However, as summarized below, most of the recurrences of earthquakes are not periodic and may be influenced by recent rupture history. Regarding the slip-time relation at a site along a fault, under the assumption of constant long-term slip rate, two conceptual models are proposed (Shimazaki and Nakata, 1980). The "time-predictable model" can predict the time of the next earthquake from a knowledge of the previous slip (Figure 3b), whereas "slip predictable model" cannot predict the time but amount of slip, taking the slip deficit since the last one into account (Figure 3c). In reality, however, at least 30 prehistoric earthquakes in a 6,000-year-long record at Wrightwood along the San Andreas fault, southern California, follow neither time-predictable nor slip-predictable model (Weldon et al., 2004). The

paleoseismic history might prove that slip occurs at a wide range of stress levels and does not return to the same postseismic stress level, keeping quasi-periodic recurrence behaviors (Scharer et al., 2010).

To furnish the magnitude estimate using the length of a fault, one must define the extent of a fault. In nature, we rarely encounter an isolated long single fault trace. Instead, we more often map a group of faults or a network of faults, which require us to define each seismogenic fault. To subdivide faults into portions, the concept of "fault segmentation" is employed. "Fault segment" is a general term for the portions of a fault or fault system or fault zone. There are several types of fault segments ordered in terms of earthquake occurrence; *earthquake segment*, *behavioral segment*, *structural segment*, *geologic segment*, and *geometric segment* (McCalpin, 2009). Identifying and defining earthquake segments that directly determine the size of earthquakes is the ultimate goal. However, numerous studies started to focus on changes in fault orientation and boundaries of fault traces (branches, intersections, separations, and step-overs) to identify each structural and geometric fault segment. There are also varieties of scale of segment and "discontinuous gaps." But since we assess seismogenic fault, kilometer-scale traces are generally taken into account. To identify each seismogenic fault among many complex mapped fault traces, "5-km separation criteria" are now broadly employed for the hazard assessment (e.g., Earthquake Research Committee in Japan (ERC), 2005). Several studies done in the late 1980s and early 1990s compiled the surface ruptures, associated historic earthquakes, and mapped active traces around the globe and then concluded that rupture propagation beyond the 5-km step width is highly unlikely (Barka and Kadinsky-Cade, 1988; Wesnousky, 1988; Wesnousky, 2006). Although these should be case-dependent with many factors, "5 km" is still a standard separation distance to identify each seismogenic fault segment.

A long continuous fault (system) cannot be simply divided by the 5-km separation criterion instead. It generates a variety of rupture patterns and sizes of earthquakes. Several conceptual models are proposed with slip rates and event age constraints at several sites along a single fault or a single fault system. The characteristic earthquake model is one of the several conceptual models. In reality, a space-time diagram of fault rupture patterns estimated from intensive paleoseismic surveys is not so simple to apply the conceptual model. Detailed examples from the southern San Andreas fault (Figure 5, Weldon et al., 2004) and the North Anatolian fault, Turkey (Hartleb et al., 2003) show the complicated rupture patterns on a fault system.

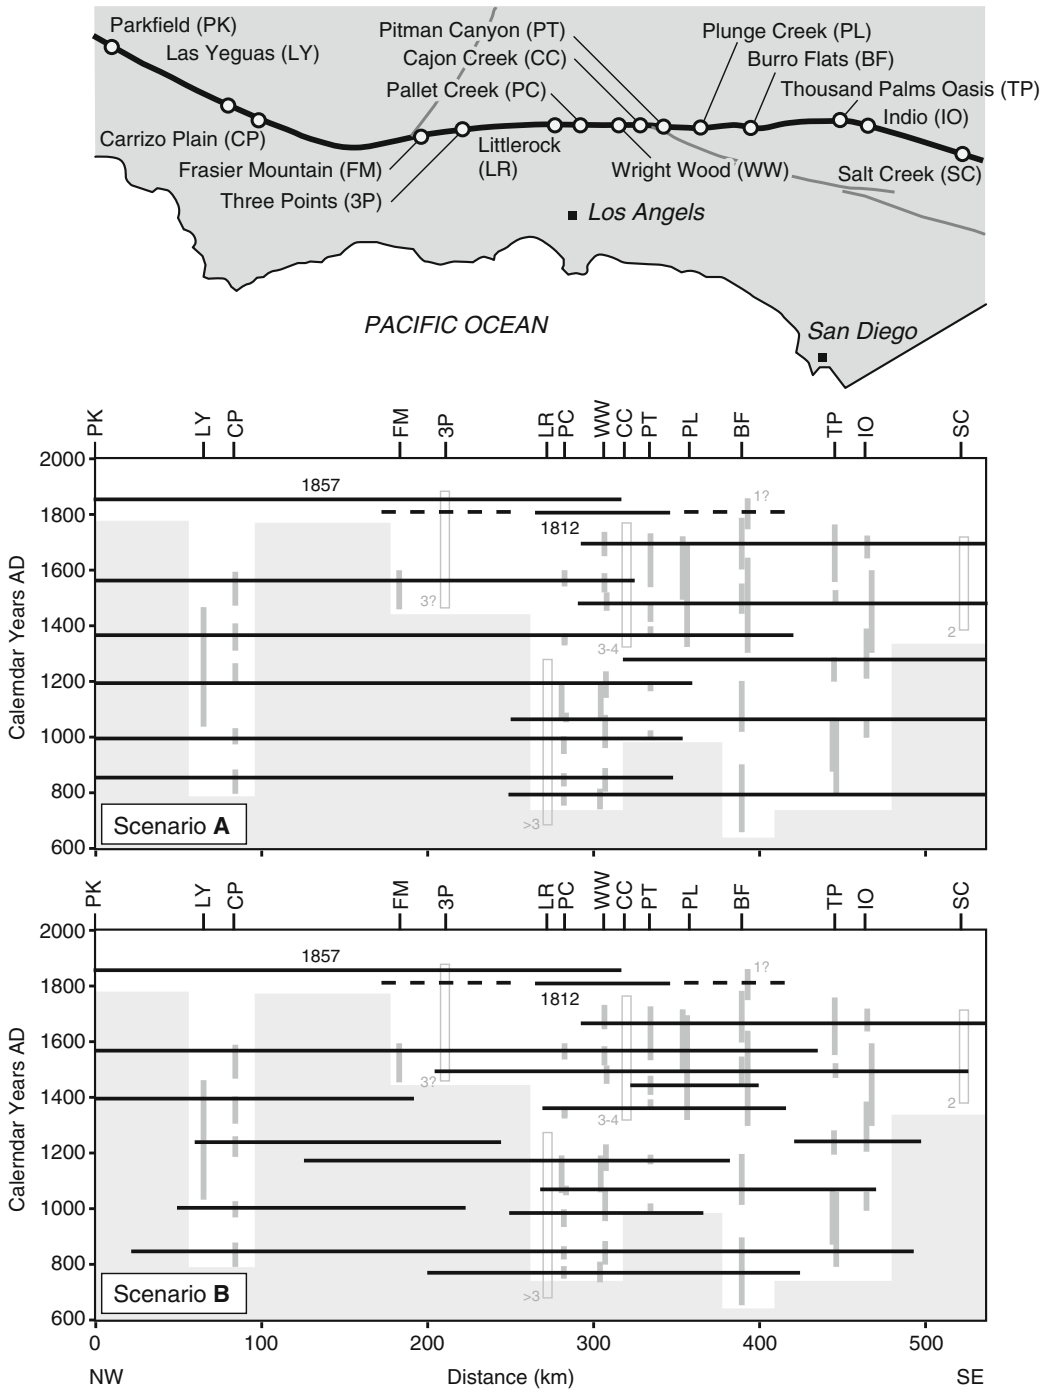
Off-fault paleoseismology

Although a limitation of off-fault evidence is its difficulty in identifying the seismic source, it becomes supportive evidence for paleoearthquakes, together with on-fault evidence. There are mainly two types of off-fault evidence for paleoearthquakes: one is due to strong shaking, and the other is related to features associated with broadly distributed coseismic and postseismic deformation (see *Earthquakes and Crustal Deformation*). The former triggers liquefaction, terrestrial and submarine landslides, and tsunami. The latter leaves uplifted, tilted, and subsided ground surfaces recorded on shorelines and marine and river terraces, where paleo-altitude can be estimated and a flat surface is guaranteed. Besides on-fault geology and geomorphology, preservation of such paleoseismic evidence is necessary. In addition, synchronicity and spatial extent of off-fault events are keys to distinguish paleoearthquakes from other causes of such secondary geologic features.

Liquefaction and associated features such as sand blows, sand boils, sand volcanoes, lateral spreading, clastic dikes, hydraulic fracturing, and rarely gravel blows and gravel dikes are the products of strong ground acceleration due to a large earthquake. Worldwide data on historical earthquakes show that the features having a liquefaction origin can be developed at earthquake magnitudes as low as about 5, but that a magnitude of about 5.5–6 is the lower limit at which liquefaction effects become relatively common (Ambraseys, 1988; Obermeier, 2009). Therefore, paleo-liquefaction is strong evidence for large earthquakes in the past. Although it is difficult to excavate trenches or pits targeted only for paleo-liquefaction, we often encounter evidence for paleo-liquefaction at archaeological sites, which can constrain the earthquake occurrence time much better than ^{14}C date due to cover-up by the non-damaged younger ruins and horizons (e.g., Figure 6, Sangawa, 2010). Since liquefaction can be commonly repeated at the same site where the recent large earthquake occurred, we can sometimes find the paleo-liquefaction on trench walls and confirm the recurrence of strong shaking at the site (e.g., Wesnousky and Leffler, 1992).

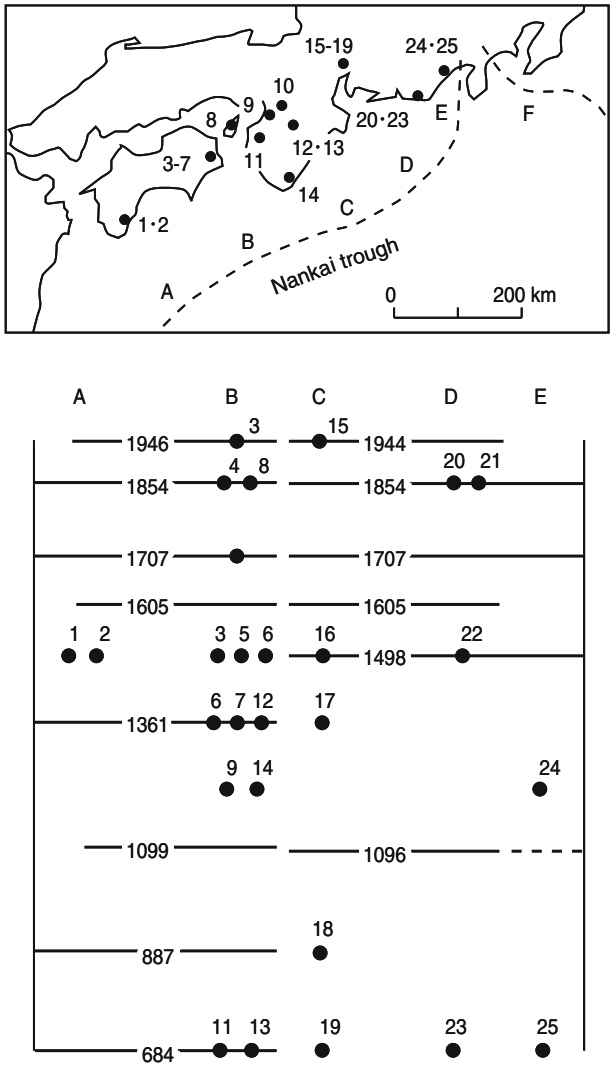
Strong ground motions in mountainous regions often trigger slope failures. In the regions characterized by steep unstable topography, we can identify massive landslides and scarps occurred in the past in aerial photographs. However, interpreting an earthquake-induced landslide or group of landslides excluding other factors like heavy rainfall is particularly hard, and levels of confidence in the resulting interpretation vary widely. Comprehensive geologic surveys with dating of landslides and several criteria (Jibson, 2009) that discriminate landslides from other factors are required.

Widespread thin sediments in coastal regions reveal occurrence of paleo-tsunamis. Sand layer often containing pebble and shell deposit is extensively deposited by tsunami waves and its inundation on the coastal areas (see *Tsunami*). Although there is no single convenient feature to distinguish tsunami deposits from those generated by other events, sedimentary facies analysis with several key features is indispensable for identifying tsunami deposit (Shiki et al., 2008). To better identify paleo-tsunami deposits, there are limited conditions to preserve



Paleoseismology, Figure 5 Two possible rupture sequences on the southern San Andreas fault (Weldon et al., 2004). Vertical grey bars are ranges in age for earthquakes at the sites listed at the lower margin and horizontal bars are rupture lengths. Open boxes represent multiple events age ranges; the individual event ages are unknown. Grey shading indicates regions and times with no data.

such sand layers; paleo-tsunami deposits are distinguished from black humus and mud deposits if the paleo-tsunami reaches the areas in swales, marsh and other calm environments where no sand sources can normally flow. Numerous studies, which employed shallow coring, pits, and trenches, exposed tsunami sand sheets intervened by finer and datable organic soils (e.g., Atwater, 1987). The recent significant contribution of the tsunami deposit studies to the subduction process is to find prehistoric M9 class earthquakes and their recurrence intervals along the 2004



Paleoseismology, Figure 6 History of mega-thrust earthquakes along the Nankai trough, Japan (Sangawa, 2010). The subduction zone is divided into five rupture segments A–E (F is the source of 1923 $M = 7.9$ Kanto earthquake along the Sagami trough). The horizontal lines with number in lower panel indicate the rupture extents and occurrence years of large earthquakes. Dots with number denote archaeological sites with exposed significant liquefactions at specific ruins and their calendar years. Recent archaeo-seismological data filled gaps in long recurrence intervals originally estimated by only historic accounts (e.g., possible rupture on A and B segments at the 1,498 earthquake), and making the Nankai subduction earthquake cycles more regular and frequent. Tsunami deposits recovered from coastal lakes, lagoons, swamps, and lowlands are also filling the gaps (e.g., Takada et al., 2002) and also provide much longer rupture history back to the entire Holocene period (Komatsubara and Fujiwara, 2007).

Sumatra-Andaman (Jankaew et al., 2008), and along the Kuril trench (Nanayama et al., 2003), and relation with the M8 class predecessors of the 1960 M9.5 Chile earthquake (Cisternas et al., 2005), which breaks through the conventional idea on regular occurrences of subduction earthquakes (see *Great Earthquakes*).

Besides paleo-tsunami deposits, submarine turbidites are another geologic clue to reveal large submarine and coastal earthquakes. Goldfinger et al. (2007) demonstrated their validity and significance of sediments associated with earthquake-triggered turbidity currents by analyzing numerous piston cores collected from submarine channels and canyon systems draining the northern California continental margin. By studying synchronous triggering of the turbidity currents, they found 15 turbidites during the last ~2,800 years, equivalent to an average repeat time of ~200 years which is similar to the onshore value of ~230 years along the northern San Andreas fault. Along-strike correlation also suggests the ~320-km rupture extent of the most of the younger events.

Broad deformation of off-fault areas is another indicator for paleoearthquakes (see *Earthquakes and Crustal Deformation*). Vertical deformation can induce changes in local rates of deposition and erosion that provide evidence of a paleoearthquake, particularly in fluvial and coastal environment (McCalpin and Carver, 2009). Subduction associated mega-thrust earthquakes and dip-slip intraplate earthquakes largely change horizontal markers such as shorelines prior to an earthquake and record off-fault coseismic uplift (e.g., Meghraoui et al., 2004) which are preserved as uplifted terraces and shorelines. Coastal areas facing subduction zones, such as southwest Japan, Taiwan, New Zealand, and Crete in Greece, have several steps of elevated terraces and shorelines associated with the mega-thrust earthquakes (see *Seismicity, Subduction Zone*). But significant coseismic uplifts are also inferred to have been formed by shallow near-coast offshore active faults that might be branched from subduction interface (e.g., Maemoku, 2001). Although dating paleo-marine terraces and shorelines is not easy, coral reefs, coral microatolls (e.g., Zachariasen et al., 1999), fossils of sessile organisms inhabit intertidal level and become both paleo-shoreline markers and indicators of timing of earthquake occurrences. For older terraces over 50 ka, other dating techniques and regional tephra fallouts are used to estimate the emergent dates. In Japan, altitudes of uplifted marine terraces formed at marine oxygen isotope stage 5e (~120 ka) often provide us with the best estimates of long-term uplift rates associated with interplate events (Koide and Machida, 2001). In contrast to coseismic uplift, studies for paleoseismic subsidence are much fewer. Subsidence associated with a subduction earthquake normally occurs inland from the rebounded uplift zone. Here, buried soil of subsided marsh and forest records the sudden vertical deformation (e.g., Atwater et al., 1995).

Permanent deformation of landscapes associated with seismogenic faulting is sometimes modified or amplified by postseismic crustal movement. Recent mega-thrust subduction events caused not only coseismic uplift, but also postseismic transient deformation that lasts more than

a few decades (see *Earthquakes and Crustal Deformation*). Although contribution of postseismic deformation associated with paleoearthquakes is hardly measured in the uplifted terraces, Sawai et al. (2004) used fossil diatom assemblages to infer the gradual changes in sedimentary environments corresponding to the transient postseismic deep creep that occurred in the seventeenth century along the Kuril subduction zone.

Seismic hazard assessment based on paleoseismology

Paleoseismic data are directly used for making probabilistic seismic hazard maps (see *Seismic Hazard*) which incorporate information on fault location, dimension, geometry, largest earthquake from such dimension, slip rates, and recurrence intervals (e.g., Working Group on California Earthquake Probabilities, 1995). Two types of statistical models of earthquake occurrence are commonly used to estimate earthquake probability: a stationary Poisson model and a conditional quasi-periodic model (see *Statistical Seismology*). The former is used for active faults or active seismic regions where only frequency of large earthquakes is available. The latter considers fluctuations of repeat times (coefficient of variation in recurrence time) and elapsed time since the most recent event (see Figure 3), which is time-dependent and compatible with the strain accumulation process. Several probability density functions such as normal, lognormal, Weibull, or gamma distributions are used for the recurrence process. Among them, the Brownian Passage Time function (Matthews et al., 2002) is evaluated as so far the best function because of its capability to account for the stress perturbations and has been adopted for the probabilistic seismic hazard studies in California and Japan (Field et al., 2009; ERC, 2005). Time-dependent seismic hazard considering conditional probabilities on most major active faults provides us with more realistic estimates (Fujiwara et al., 2009).

If further detailed paleoseismic information is available for a specific fault, a "scenario earthquake model (seismic hazard maps for specified seismic sources)" is often proposed to show the strong shaking for the areas being assessed when the specific earthquake occurs (ERC, 2005). When providing paleoseismic data to seismic engineers, possible rupture patterns for the next earthquake, slip distribution, and plausible locations of asperities becomes additional information (Somerville et al., 1999).

In addition to the shaking damage, surface rupture and displacement associated with a large earthquake often destroy man-made structures. Structures for human occupancy (e.g., hospital and school) and critical buildings (e.g., nuclear power plant) can be so located to avoid the traces of active faults (e.g., the Alquist-Priolo Earthquake Fault Zoning Act in California, see entry on *Seismic Zonation*). To mitigate direct damage due to surface-faulting, detailed positions of active faults and their paleoseismological properties are progressively been opened to the public through the internet.

Issues in paleoseismology and perspectives

There are fundamental limitations of the geologic approach to infer paleoearthquakes in time and space. The following are major caveats in using paleoseismological information:

1. Surface ruptures are commonly associated with $M > 6$ earthquakes (Wells and Coppersmith, 1994) that occur at shallow depths (mostly <20 km), even though $M \sim 5$ earthquakes may also leave surface ruptures in the case of extremely shallow hypocenter (<5 km) and volcanic environments (Payne et al., 2009, see entry on *Earthquakes, Volcanogenic*). However, we must know that geomorphic and stratigraphic evidence for all $M > 6$ paleoearthquakes is not always produced. It totally depends on regional tectonic setting, depth of hypocenter (thickness of seismogenic crust), fault slip sense, and surface geologic conditions. For example, revisiting the inland earthquakes in Japan since 1923, no more than half of the $M \sim 7$ earthquakes left the surface breaks comparable to the seismic faults, which obviously underestimates the probabilities of even $M \sim 7$ shocks (Toda and Awata, 2008). Even along major strike-slip faults, we experienced enigmatic large earthquakes that did not leave clear surface rupture (e.g., 1989 Loma Prieta earthquake and 2010 Haiti earthquake).
2. Rates of erosion and sedimentation at regional and local scales control preservations of fault landforms and evidence for paleoearthquakes at excavation sites. Human destruction of the surface geology and topography due to urbanization or farming often destroys evidence of very recent paleoseismic events. Furthermore, obtaining better time constraints for paleoearthquakes is rare due to the lack of abundant dating material.
3. Geologic and topographic evidence normally includes interpretation with epistemic uncertainties. Complete agreement is rare in aerial photographic interpretation. "Trench parties" (Grant, 2007) often create indecisive debate that is not visible in the final publication in which simple trench logs are only illustrated. Photos and detailed sketches are objective records, but they are infrequently opened to the public and are hardly accessible. Therefore one should be aware that publications often underestimate or overestimate numbers of paleoearthquakes and need extra effort to clarify quality measurements and other paleoseismic interpretations.
4. Paleoseismic study cannot precisely reveal rupture extent, thus magnitude of an earthquake without any help of historic accounts. Space-time diagrams of paleoseismic events on a fault or fault system may only conclude the cases adjacent segments did not simultaneously rupture through. Displacement data of a paleoearthquake would be useful information to estimate magnitude based on the empirical scaling law (Wells and Coppersmith, 1994). But at least five to ten measurements are stochastically required to

characterize magnitude of a paleoearthquake (Hemphill-Haley and Weldon, 1999).

5. Although we simply apply the characteristic earthquake model or extended segmentation model under the elastic rebound framework (see *Earthquakes and Crustal Deformation*), there may be intrinsic uncertainties of repeated faulting processes, for example, nonlinear strain accumulation and complex rupture process. This might be a subject seismologists have to reveal. But paleoseismology instead can be suggestive with data that also conquer "uniformitarianism." For example, the 2004 $M = 9.2$ Sumatra-Andaman earthquake was an extraordinary earthquake which can be hardly expected from historic accounts. However, intensive detailed studies about coral microatolls (Zachariasen et al., 1999) and tsunami deposits (Jankaew et al., 2008) suggested there were frequent huge events in the past, even if we do not see them in historic ages. This is an important role of paleoseismology.

Summary

Paleoseismology, which is the study of prehistoric or pre-instrumental earthquakes, is an interdisciplinary field of research mainly encompassing seismology, geology and geomorphology. Starting from identifying active faults, various field and laboratory techniques such as aerial photography interpretation, trench excavation, and radiocarbon dating are used to reveal the spatial extent and occurrence times of paleoearthquakes, and associated long-term movements of active faults. Evidence for paleoearthquakes is not only preserved in strata across a fault but also found far from the source as paleo-liquefaction, paleo-landslide, and paleo-tsunami deposits. Empirical relations between rupture length and slip versus earthquake magnitude from recent instrumentally recorded shocks enable us to estimate the size of future earthquakes on a fault or fault zone. Detailed rupture history of a fault also allows us to estimate time-dependent probabilistic seismic hazard. Although there are fundamental limitations and incompleteness in field data, contribution of paleoseismology in understanding the long-term faulting process is enormous and indispensable. Recent progress in paleoseismic data accumulations also allows seismologists and seismic engineers to make better seismic hazard maps to mitigate seismic damage in the future.

PLATE DRIVING FORCES

Definition

Plate driving forces. The forces exerted on Earth's tectonic plates that produce the observable horizontal motions of these plates.

Introduction

Since the advent of the theory of plate tectonics in the 1960s, it has been postulated that the forces that drive the observed horizontal motions of Earth's tectonic plates are produced by the process of thermal convection in the mantle. The proposition that such motions could be produced and sustained over very long geological time scales in a rocky shell, comprising the lithosphere and underlying deep mantle, that also behaves as a solid through which elastic earthquake waves travel, was initially viewed as a serious obstacle to the acceptance of the mantle convection hypothesis of plate motions. This obstacle was definitively eliminated with the recognition, amply confirmed by high-temperature deformation experiments on minerals (Evans and Kohlstedt, 1995), that the rheology of the mantle allows steady-state creeping flow when subjected to long-term shearing stresses, provided the ambient temperature is sufficiently high (Poirier, 1985).

The relationship between the mantle shear stress and deformation (measured in terms of strain rate), is

characterized by an effective viscosity whose value is strongly dependent on temperature and, if the stress is sufficiently high, also on the stress magnitude (Karato and Wu, 1993). The temperature dependence of mantle viscosity gives rise to a lithospheric layer that is stiffer and less deformable than the much hotter and hence less viscous upper mantle. Indeed, the very existence of the tectonic plates as effectively rigid bodies, with little surface deformation except for that occurring along their boundaries, is generally explained in terms of the strong temperature dependence of mantle viscosity. The creation of weak plate boundaries, characterized by very low effective viscosity, requires other mechanisms such as strain (or stress) weakening (e.g., Tackley, 2000). The rheological contrast between the lithosphere and the underlying mantle is often used as the basis for models of plate driving forces that treat the lithospheric plates and their descending limbs (subducted slabs) under the oceanic trenches (Figure 1a) separately from the mantle (Elsasser, 1969; McKenzie, 1969; Solomon and Sleep, 1974; Harper, 1975; Forsyth and Uyeda, 1975; Richardson et al., 1976; Chapple and Tullis, 1977; Richter, 1977; Davies, 1978; Bird et al., 2008).

The vertical viscosity gradient in the lithospheric plates, from an effectively undeformable, high-viscosity surface to a more deformable, low-viscosity region at the base of the plates is a consequence of the thermal structure of the lithosphere. The oceanic lithosphere can be viewed as the upper thermal boundary layer of mantle convection, in which the heat transported across the deep mantle by rising and sinking convective flow is finally transmitted to the Earth's surface by vertical conduction of heat across the lithosphere (Turcotte and Oxburgh, 1967). This boundary-layer interpretation provides an alternative context for understanding the plate driving forces, in which the horizontal motions of Earth's oceanic lithospheric plates (Figure 1a) are regarded as an integral component of the mantle convective circulation (Turcotte and Oxburgh, 1967; Richter, 1973; Jarvis and Peltier, 1982; Davies, 1988). According to this view, the horizontal plate motions are assumed to be coupled to the underlying thermal convective circulation and they are maintained by the dynamic stresses in the mantle generated by descending and ascending thermal plumes (Hager and O'Connell, 1981; Forte and Peltier, 1987, 1994; Ricard and Vigny, 1989; Gable et al., 1991; Vigny et al., 1991; Lithgow-Bertelloni and Richards, 1998; Becker and O'Connell, 2001; Lowman et al., 2008; Forte et al., 2009).

Balance between buoyancy forces and viscous dissipation

There are thus two distinct approaches that have been taken to develop models of plate driving forces where, on the one hand, the plate forces are analyzed separately from the dynamics of the underlying mantle and, on the other, the plate motions are modeled as an integral part of the convecting mantle. Both approaches must satisfy a fundamental constraint that expresses how work done by the body forces throughout the mantle are dissipated by the viscous deformation associated with the tectonic plate motions and flow in the underlying mantle.

A mathematical expression of the balance between buoyancy and dissipation (e.g., Malvern, 1969) over the entire volume, V_m, of the mantle (including the lithosphere) is:

$$-\int_{V_m} u_r\,\delta\rho\,g_0\,dV = \int_{V_m} \tau_{ij}\epsilon_{ij}\,dV - \int_{S_d} t_i\,\Delta u_i\,dS \qquad (1)$$

in which τ_{ij} and ϵ_{ij} are the deviatoric stress and strain-rate tensors, respectively, t_i is a traction vector acting on surfaces S_d across which there is a discontinuity in motion Δu_i, u_r is the vertical (radial) component of mantle flow, $\delta\rho$ are lateral perturbations in density, and g_0 is the radial gravitational field. All indices i and j represent components in each of the three Cartesian coordinate directions, and repeated indices (in the terms on the right-hand side of Equation 1) denote summation over all values (1–3) of the indices. The traction vector t_i acting on the discontinuity surface S_d depends on the deviatoric stress as follows: $t_i = \tau_{ij}n_j$, in which the n_j are the Cartesian components of the local normal vector on S_d. Although the motion along S_d is discontinuous, the traction t_i must be continuous by Newton's third law (equal and opposite actions and reactions).

The left-hand side of Equation 1 is the (positive) rate of work done by the buoyancy forces $\delta\rho g_0$ inside the regions of the mantle where there is vertical flow, as in hot plumes where $\delta\rho < 0$ and $u_r > 0$, and in cold descending slabs where $\delta\rho > 0$ and $u_r < 0$ (Figure 1a). The first term on the right-hand side of Equation 1 is the rate at which the energy released by the buoyancy forces is dissipated by the internal stresses as they continuously deform the mantle. Since the mantle rheology on plate-tectonic timescales is viscous, this energy dissipation is simply the viscous friction that converts mechanical work into heat. The second term on the right-hand side represents the rate of frictional dissipation of energy on internal discontinuity surfaces or faults and hence this term is only relevant in the upper mantle, and especially the crust, where significant earthquake faulting occurs. Since the frictional tractions t_i will always oppose the discontinuous fault motion Δu_i, the integral over the fault surfaces S_d must be negative (e.g., Malvern, 1969).

As noted above, a large number of models have evaluated the plate driving forces by specifically focusing on the lithosphere itself, distinct from the mantle. In this context, a buoyancy-dissipation balance analogous to Equation 1 can be developed:

$$\begin{aligned} -\int_{V_l} u_r\,\delta\rho\,g_0\,dV - \int_{S_l} [\delta P - \rho_0\delta\phi]\,u_i n_i\,dS \\ + \int_{S_l} u_j\tau_{ji}n_i\,dS = \int_{V_l} \tau_{ij}\epsilon_{ij}\,dV - \int_{S_d} t_i\,\Delta u_i\,dS \end{aligned} \qquad (2)$$

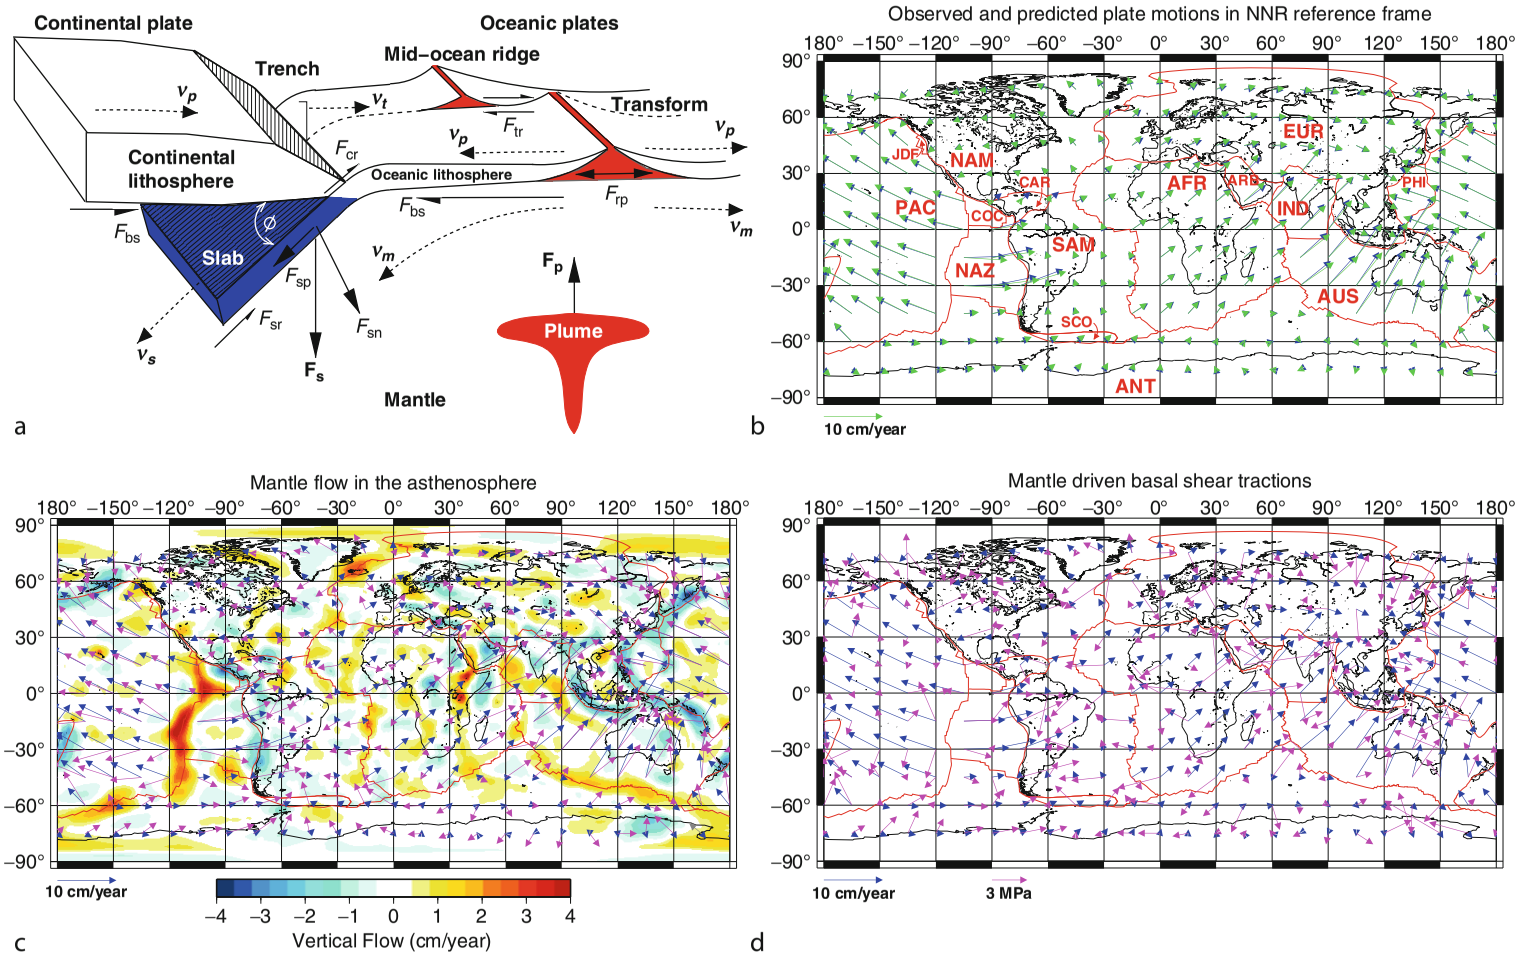

Plate Driving Forces, Figure 1 (**a**) Schematic illustration of forces acting on lithospheric plates. All plate driving forces ultimately arise from the buoyancy forces in the convecting mantle, namely, the force $\mathbf{F_p}$ due to hotter and less dense upwelling plumes and the force $\mathbf{F_s}$ due to the colder and denser sinking slabs. These sublithospheric buoyancy forces generate the plate driving forces $\mathbf{F_{sp}}$ (slab pull) and $\mathbf{F_{rp}}$ (ridge push). Whether the force $\mathbf{F_{bs}}$ (basal shear) is a plate driving or resisting force depends on the relationship of the surface plate velocity $\boldsymbol{v_p}$ to the underlying mantle-flow velocity $\boldsymbol{v_m}$. The purely resistive plate forces are $\mathbf{F_{sr}}$ (slab resistance), $\mathbf{F_{cr}}$ (collision resistance), and $\mathbf{F_{tr}}$ (transform resistance). The balance between the slab-normal force $\mathbf{F_{sn}}$ and the opposing normal force generated by mantle flow will control the trench rollback or retreat velocity $\boldsymbol{v_t}$. (Figure adapted and modified from Forsyth and Uyeda, 1975.) (**b**) The observed (*green arrows*) and predicted (*blue arrows*) present-day plate velocities, where the latter are obtained from a tomography-based model of mantle convection (Forte et al., 2009). The plate motions are with respect to a global No-Net-Rotation (NNR) frame of reference. The plate names are shown by the abbreviations in red font: AFR = Africa, ANT = Antarctica, ARB = Arabia, AUS = Australia, CAR = Carribean, COC = Cocos, EUR = Eurasia, IND = India, JDF = Juan de Fuca, NAM = North America, NAZ = Nazca, PAC = Pacific, PHI = Philippine, SAM = South America, and SCO = Scotia. (**c**) The mantle flow predicted at 200 km depth using a tomography-based convection model (Forte et al., 2009). The magenta arrows show the horizontal component of the predicted flow vector and the color contours show the vertical component (*scale at bottom*). The blue arrows show the predicted surface plate motions from (**b**). (**d**) The horizontal traction vectors (*magenta arrows*) at 30 km depth (just below the mean depth of the crust) exerted by the mantle flow predicted by a tomography-based convection model (Forte et al., 2009). The blue arrows show the predicted surface plate motions from (**b**). Scale bar for vectors is at bottom.

in which V_l represents the volume occupied by the lithospheric layer, S_l defines the lower surface of the lithosphere (where the local normal vector n_i is approximately pointing in the negative radial direction $-\hat{r}$), δP and $\rho_0 \delta\phi$ are, respectively, the dynamic pressure field and self-gravitation force acting on the base of the lithosphere, and $\tau_{ij} n_j = t_j$ are the shear stresses exerted on the base of the lithosphere by the underlying mantle flow.

If the lithosphere has a sufficiently high viscosity, owing to its relatively colder temperatures compared to the mantle, the deformation rate ϵ_{ij} in plate interiors may be assumed to be negligible. If this approximation is accepted, the first term on the right-hand side of (2) may be ignored, and the primary frictional dissipation of energy occurs on the fault surfaces S_d that define the boundaries of the plates. The vertical flow u_r in the lithospheric layer is weak, owing to the proximity of the upper bounding surface, and thus the work done by the tangential shear stresses exerted by mantle flow (third term on the left-hand side of Equation 2) is approximately balanced by the frictional dissipation of energy on plate-boundary faults. Since the dissipation on the right-hand side of Equation 2) is always positive, this implies the tangential stresses on the base of the lithosphere are, on average, acting in the direction of the flow. These approximations illustrate how plate motions may be governed by a balance between basal-shear stresses, acting as plate driving forces, and resistance to motion along plate boundaries (e.g., Hanks, 1977; Davies, 1978).

Expressions (1) and (2) are obtained on the assumption that no external tangential stresses are applied to the upper and lower bounding surfaces of the mantle and that the local vertical flow vanishes on these bounding surfaces. Some models of plate driving forces have employed prescribed plate velocities as a boundary condition, thereby implying corresponding externally applied tangential stresses on the lithosphere. This external forcing is sometimes referred to as the "hand of God" effect (e.g., Karpychev and Fleitout, 1996). To avoid the unphysical possibility that such external stresses do work on the lithosphere and underlying mantle, the models should be formulated so that compensating surface stresses, generated by the flowing mantle, are able to precisely cancel the work of externally applied stresses (e.g., Hager and O'Connell, 1981).

The principal idea that emerges from these general considerations of the plate driving forces is that plate motions are produced by the buoyancy forces $\delta\rho g_0$ in the mantle (left-hand side of Equation 1). Even when the focus is placed on the lithosphere itself, the contribution of the driving forces in the mantle is still present, but "hidden" in the basal stresses that are exerted on the lithospheric plate (left-hand side of Equation 2).

Plate driving forces: lithospheric models

Formulating the detailed physical mechanisms by which the vertically directed buoyancy forces in the mantle ($\mathbf{F}_s$ and $\mathbf{F}_p$ in Figure 1a) are ultimately expressed as horizontal forces acting on and driving the plates is the central challenge in developing models that generate realistic plate motions. The earliest models explored the dynamics of the lithosphere and its descent into the mantle under deep ocean trenches (e.g., Elsasser, 1969, 1971; McKenzie, 1969; Richter, 1973), and they suggested that the negative buoyancy forces due to the cold lithospheric slabs entering the mantle ($\mathbf{F}_s$ in Figure 1a) are the most efficient drivers of the observed tectonic plate motions.

These initial efforts set the stage for the subsequent development of *parametrized plate-force models* in which the forces driving the plate motions are represented by a limited number of discrete force vectors acting on the lithosphere (Figure 1a). One of the most influential studies of the parametrized plate-force models was carried out by Forsyth and Uyeda (1975). The forces they considered are identified in Figure 1a and they include: (1) the **slab-pull force** $\mathbf{F_{sp}} = \mathbf{F_s} \sin\phi$ acting in the down-dip direction where ϕ is the dip angle of the slab; (2) the **slab-resistance force** $\mathbf{F_{sr}}$ representing the opposing viscous shear stress acting on the sides of the descending slab; (3) the collision-resistance force $\mathbf{F_{cr}}$ representing the frictional stress acting on the upper surface of the slab as it slides past the fault surface of the shallow Benioff zone; (4) the **basal-shear force** $\mathbf{F_{bs}}$ representing the tangential shear stress generated by the flowing mantle acting on the base of the lithospheric plates; (5) the **transform-resistance force** $\mathbf{F_{tr}}$ representing the frictional stresses acting on segments of the plate boundaries where there is a component of relative motion that is tangential to the boundary, such as transform faults; and (6) the ridge-push force $\mathbf{F_{rp}}$ corresponding to the lateral force exerted on the divergent plate boundaries due to the dynamic pressure field that produces the topographic elevation of the mid-ocean ridges.

The orthogonal complement to the slab-pull force is the slab-normal force $\mathbf{F}_{sn} = \mathbf{F}_s \cos\phi$ (Figure 1a). This force component was not considered in the evaluation of the plate driving forces by Forsyth and Uyeda (1975), but the balance between this force and the opposing normal stress in the mantle will contribute to the retrograde motion (or "roll back") of the trench (e.g., Elsasser, 1971; Schellart, 2008; Funiciello et al., 2008) with the relative velocity $\boldsymbol{v_t}$ illustrated in Figure 1a.

The results obtained by Forsyth and Uyeda (1975), and earlier by Richter (1973), suggested that the balance of forces on subducting slabs are the primary control on plate motions and this view has been reiterated in a whole generation of subsequently published models (e.g., Lithgow-Bertelloni and Richards, 1998), up to the present day (e.g., Conrad and Lithgow-Bertelloni, 2004; Billen, 2008; Funiciello et al., 2008; Schellart, 2008).

A major source of uncertainty in the plate-force models is the unknown relationship between the motion of the lithospheric plates $\boldsymbol{v_p}$ and the underlying mantle flow $\boldsymbol{v_m}$ (Figure 1a), and hence the unknown local magnitude and

direction of the basal shear force $\mathbf{F_{bs}}$. The majority of models assumed the mantle is passive, and that the flow below the lithosphere is entirely generated by the subducting slabs. This is equivalent to assuming the ambient mantle temperature outside the sinking lithosphere is isothermal or adiabatic (e.g., McKenzie, 1969; Hager and O'Connell, 1981). For these passive-mantle models, the basal shear force acts in the opposite direction to the plate velocity and therefore opposes the driving force provided by slab pull.

The conclusions obtained from the parametrized plate-force models are nonunique and depend on which forces are assumed to be known. For example, whether basal shear forces contribute to driving or resisting the plate motions will depend on what forces (in Figure 1a) are prescribed as known at the outset. In the study by Forsyth and Uyeda (1975), it was assumed that basal shear forces oppose the plate motions and have a direction that is antiparallel to the plate velocity. In contrast, Davies (1978) showed that if the frictional force $\mathbf{F_{tr}}$ acting on transform boundaries is assumed to be known in advance, on the basis of earthquake stress-drop data (Hanks, 1977), then the basal shear force may act as a plate driving force. The force balance considered by Davies also showed that the collision-resistance force $\mathbf{F_{cr}}$ strongly opposes the slab-pull force $\mathbf{F_{sp}}$, greatly reducing its contribution as a plate driving force. The significance of basal shear stresses as a plate driving force has again been highlighted by Bird et al. (2008), who employed a finite-element model of the lithosphere that incorporates stress- and temperature-dependent viscosities as well as an explicit treatment of plate-boundary faults.

Plate driving forces: whole-mantle models

The popularity of parametrized plate-force models that focused on the lithosphere was based on the use of readily observed input variables derived from surface tectonics and observed plate velocities. Since the observed plate velocities were employed as an input, these models could not explain how the plate motions were generated by the internal dynamics of the mantle, nor how they would evolve over time.

Hager and O'Connell (1981) introduced 3-D spherical, whole-mantle flow models that explicitly included the interaction of the moving lithospheric plates with the underlying mantle. Although these models employed the present-day plate velocities as input, they predicted the 3-D flow throughout the mantle driven by a global distribution of subducted slabs derived from seismic catalogs of earthquake hypocenters. With the advent, in the 1980s, of seismic tomographic imaging of lateral heterogeneity in the mantle, it became feasible to apply these whole-mantle flow calculations to explore the detailed connection between surface plate motions and the 3-D flow in the mantle generated by thermal convection (e.g., Forte and Peltier, 1987; Ricard and Vigny, 1989).

Seismic tomography provides important information regarding the 3-D temperature structure of the convecting mantle and it thus constitutes a basis for developing realistic models of mantle flow dynamics that are no longer limited by the 2-D view of Earth dynamics based on surface observations of plate tectonics. The mantle flow modeling by Hager and O'Connell (1981) was therefore further extended in subsequent studies demonstrating that present-day plate motions can be successfully predicted using the 3-D distribution of buoyancy forces derived from seismic tomography (e.g., Vigny et al., 1991; Forte and Peltier, 1994; Becker and O'Connell, 2001). This confirmation that plate motions can be predicted on the basis of stresses generated in the underlying mantle by a realistic 3-D pattern of convection is a major step toward developing a complete understanding of mantle and lithosphere dynamics and how they may change over geologic time (e.g., Lithgow-Bertelloni and Richards, 1998; Conrad and Lithgow-Bertelloni, 2004; Lowman et al., 2008; Forte et al., 2009).

A recent tomography-based model of mantle convection (Forte et al., 2009) illustrates the detailed relationship between the convective circulation in the mantle and surface plate velocities. The plate velocities predicted by this model match the observed motions very well (Figure 1b). Below the lithosphere, in the underlying low-viscosity portion of the upper mantle referred to as the "asthenosphere," the predicted mantle flow velocities show significant deviations from the overlying plate motions, for example, under the western half of the North American plate and under the African plate (Figure 1c). The lack of parallelism between the surface plate velocities and the upper-mantle flow circulation in the asthenosphere is a consequence of the complex 3-D distribution of buoyancy forces in the deep mantle that are not correlated with the surface plate geometry (e.g., subduction zones and mid-ocean ridges) in any straightforward manner. It is also a consequence of the strong reduction in viscosity in the asthenosphere relative to the overlying lithosphere, thereby allowing a partial decoupling of the horizontal flow vectors in these two layers. This decoupling of the pattern of horizontal motions in the lithosphere and asthenosphere, represented by the vectors $\boldsymbol{v}_{\mathbf{p}}$ and $\boldsymbol{v}_{\mathbf{m}}$ in Figure 1a, will directly influence the local basal shear force $\mathbf{F_{bs}}$ (Figure 1a).

The basal shear force F_{bs} mapped in Figure 1d is the horizontal component of the mantle traction vector $\boldsymbol{t} = -\boldsymbol{\tau} \cdot \hat{\boldsymbol{r}}$, where τ is deviatoric stress tensor. The complex local variations in basal shear force relative to the surface plate velocities show that a simple correlation between these two, as assumed in the parametrized plate-force models (e.g., Forsyth and Uyeda, 1975), is not appropriate. It is only by considering the integrated effect of the basal shear force, measured in terms of the total torque acting on each plate, that the relationship to the surface motions becomes clearer. For example, the integrated basal torque acting on the North American plate, calculated on the basis of the tractions in Figure 1d, has

a 95% correlation to the corresponding North American plate-rotation vector.

The whole-mantle flow models thus suggest that it is the basal shear forces generated by a fully 3-D pattern of mantle convection that drive the motions of the overlying plates (e.g., Vigny et al., 1991; Forte and Peltier, 1994; Becker and O'Connell, 2001; Forte et al., 2009). The role of the plates is not entirely passive, however, because their intrinsic rigidity allows them to partially resist (and hence mask) a significant fraction of the deeper mantle flow patterns (Ricard and Vigny, 1989; Forte and Peltier, 1994). Furthermore, the buoyancy forces associated with subducted lithosphere do contribute to the basal shear forces that drive the plates. In this regard, the plates are not entirely passive because their continuous descent into the mantle, over extended periods of geologic time, ultimately generates the global distribution of subducted slabs that provide the slab buoyancy force $\mathbf{F_s}$ (Figure 1a).

Summary

Much progress has been achieved in our understanding of how mantle convection drives the surface plate motions since the earliest parametric force models were published over 3 decades ago. This progress would not have been possible without the information on 3-D mantle structure that has been obtained through seismic tomography. The interpretation of the seismic tomography models is however nonunique, owing to the imperfect sampling of the mantle by seismic waves, and also because there are other effects, in addition to lateral temperature variations, that may give rise to mantle heterogeneity.

This complexity has led to the emergence of two different views on how thermal convection in the mantle drives the tectonic plate motions. The most long held and commonly accepted view is that the buoyancy forces due to subducted slabs are the primary drivers of surface plate motions (e.g., Richter, 1973; Conrad and Lithgow-Bertelloni, 2004). According to this view the thermal evolution of the mantle is controlled almost entirely by cooling from above (i.e., subducting lithosphere), and this would arise if the mantle is almost entirely heated internally, with little or no heat entering the mantle across the core–mantle boundary.

The second view, supported by the earliest mantle convection models (e.g., Turcotte and Oxburgh, 1967) and some subsequent models (e.g., Jarvis and Peltier, 1982; Forte et al., 2009), is that a combination of active hot upwellings ("plumes") and subducted slabs is required to explain the surface plate motions. The existence of such active hot plumes requires a significant heat flux across the core-mantle boundary and it would be compatible with a mainly thermal origin for the seismic anomalies evident in the tomography models (e.g., Forte et al., 2009). The current debate on which of these two contrasting views of mantle dynamics is most compatible with the available data is not yet settled, but a resolution will be possible once the magnitude of the heat flux across the core-mantle boundary becomes more clear.

Introduction

Plate tectonics is a remarkable theory. Its central tenet, which is widely known, states that the surface of the Earth moves in a piecewise coherent fashion via a number of rigid plates (Wilson, 1965; Morgan, 1968), with most of the deformation focused along plate boundaries (Stein, 1987). The underlying dynamic mechanism responsible for plate motions has been long identified in lateral buoyancy variations within the Earth mantle (Forte, 2010). However, 40 years after the acceptance of plate tectonics, the details of how these forces may vary in time to modify plate movements remain limited, and we still fail to answer basic questions of fundamental importance: *Why do plates change their motions as shown by the geologic and geodetic records? – What are the spatial and temporal patterns of forces responsible for such changes?* The main difficulty stems from our poor knowledge of the *force balance* in plate tectonics. It is widely agreed that plate motions are driven by convection in the Earth's mantle (Hager and O'Connel, 1981; Davies and Richards, 1992). But the influence of other driving and resisting mechanisms, especially along plate margins, remains unclear. Forces concentrated along plate margins are known as plate boundary forces (Forsyth and Uyeda, 1975) and it is likely that they play an important role in modulating plate motions (Humphreys and Coblentz, 2007).

A key component of plate boundary forces is the gravitational collapse associated with large mountain belts extending along plate margins. Climate-induced variations in topography, related to uplift and erosion in orogens, have been long recognized as possible controls in tectonics (Koeppen and Wegener, 1924), and may be therefore capable to initiate variations in plate motion on regional and global scales. Conversely, geodynamicists can use inferences on topography and plate motion variations as powerful probes into the underlying force balance of plate tectonics.

Temporal variations in plate motions provide significant constraints on the budget of forces acting upon plates. This is because by virtue of Newton's first law of motion any change in plate motion is necessarily driven by variations in one or more driving or resisting forces. With the advent of space geodetic techniques (Dixon, 1991), increasingly accurate estimates of global plate motions and their temporal variations are now available (Sella et al., 2002). While geodesy measures the current rates of plate motion, one can also glean long-term constraints

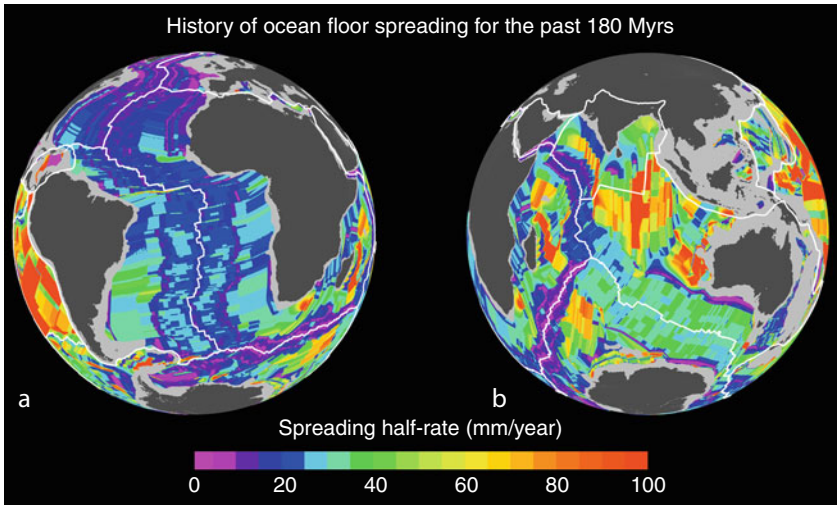

Plate Motions in Time: Inferences on Driving and Resisting Forces, Figure 1 Observed oceanic spreading half-rates for the past 180 Myrs after a recent global compilation by Müller et al. (2008). Plate boundaries are in white, continents in dark gray. Abrupt changes in spreading rates reveal short-term variations in global plate motions, particularly visible in the South Atlantic (**a**) as well as in the Indian Ocean (**b**). Such rapid variations are unlikely to originate from global changes in mantle driving forces, which occur on a longer time scale on the order of 50–100 Myrs as indicated by mantle circulation models. Instead, they are related to short-term variations in plate boundary forces caused, for example, by rapid growth of surface topography at convergent margins (see text). These observations point to the first-order importance of plate boundary forces in controlling global plate motions.

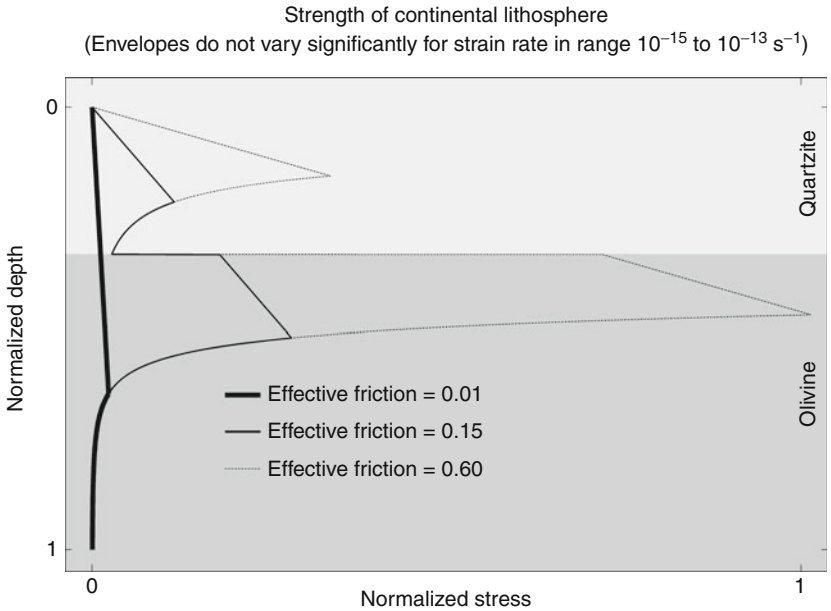

Plate Motions in Time: Inferences on Driving and Resisting Forces, Figure 2 Normalized strength/depth profiles for a simplified two-layer continental lithosphere, plotted for three different fault friction coefficients and a strain rate in the range of 10**–15 to 10**–13 1/s, typical of plate tectonics. Laboratory experiments performed mainly on quartzite and olivine (see text) indicate that lithosphere strength increases linearly with overburden pressure in the upper brittle part, and decreases exponentially with increasing temperature in the lower ductile part. Note that the brittle part contributes a significant portion (70–80%) of the total lithospheric strength, independently of the particular choice of friction coefficient and strain rate values. Experimental results suggest a friction coefficient around 0.6 (*dashed envelope*) for rocks under lithostatic pressure conditions, known as Byerlees law. However, various independent evidences for weak faults suggest much lower values between 0.01 and 0.15 (*solid envelopes*), so that plate boundaries experience considerably lower stresses even for high strain rates.

on plate motion from paleomagnetic observations derived from the magnetic isochron record of the ocean floor. In fact, recent paleomagnetic plate motion models approach temporal resolutions on the order of 1–2 Myrs and reveal a number of rapid *velocity-changes* (few cm/year) occurring over time-periods of a few Myrs or less (Müller et al., 2008). Some of these are particularly evident in the Southern Atlantic (Figure 1a) and in the Indian Ocean (Figure 1b). Their short duration makes it unlikely to attribute the changes to variations in the internal distribution of mantle buoyancies. In fact, these evolve globally on longer time scales on the order of 50–100 Myrs (Bunge et al., 1998), although locally changes may occur over some 10 Myrs (Forte et al., 2009). It is reasonable to link these rapid changes to variations in plate boundary forces.

Plate tectonics and the rheology of the lithosphere

The regime of plate tectonics requires high strain rates and low resistive stresses to coexist simultaneously along plate margins. But it is challenging to model this regime on a computer, because it is difficult to simulate shear failure along plate boundaries. To overcome this challenge some models of the lithosphere incorporate highly non-Newtonian, viscous creep, strain-rate weakening rheologies together with viscoplastic yielding. Moresi and Solomatov (1998) explored the effects of temperature-dependent viscosity in combination with a plastic yield stress: The former causes the cold upper boundary layer (lithosphere) to be strong, while the latter allows the boundary layer to fail locally in regions of high stress. The success, measured through a so-called plateness, is evident when extreme strain-softening rheologies, known as pseudo-stick-slip (Bercovici, 1995), are employed (Bercovici, 2003). Unfortunately, the rheological parameters required for pseudo-stick-slip agree poorly with laboratory experiments of ductile deformation performed on olivine (Kirby, 1983), particularly at the pressure and temperature conditions typical of the upper mantle (Karato and Jung, 2003). Figure 2 shows normalized strength envelopes of a simplified two-phase lithosphere. Depth-dependent strength is parameterized via empirical laws established through laboratory experiments performed on quartzite, abundant in the upper 20 km of continental lithosphere, and olivine, which dominates at greater depths. The laboratory results indicate that strength increases linearly with overburden pressure in the upper, brittle part of the lithosphere; it then decreases exponentially with increasing temperature in the lower, ductile part (Kohlstedt et al., 1995). High strength in the upper lithosphere reflects the resistance of rocks to failure at low temperature, or to sliding past each other when already faulted. Experimental results indicate a simple linear relationship to parameterize this behavior (Byerlee, 1978), with shear stress proportional to the normal pressure through a friction coefficient typically on the order of 0.6 (dashed envelope in Figure 2). There is, however, mounting evidence for significantly lower values (in the range 0.01–0.15, see solid envelopes in Figure 2) along faults and plate boundaries (Hickman, 1991; Bird, 1998; Suppe, 2007).

Computer models of the faulted lithosphere coupled with global mantle circulation models

Lithospheric faults exhibit low friction, as we have noted. In other words, they are mechanically weak and experience low stresses independently of the strain rate. It is therefore attractive to represent faults directly within the computational grid of numerical models of the lithosphere. This can be done, for instance, through the use of so-called contact-elements, in an approach known as neo-tectonic modeling. Neo-tectonic models have reached considerable sophistication. They solve the equations of mass and momentum conservation, and compute the instantaneous force balance and associated plate velocities. They implement empirical, depth-dependent rheologies of the

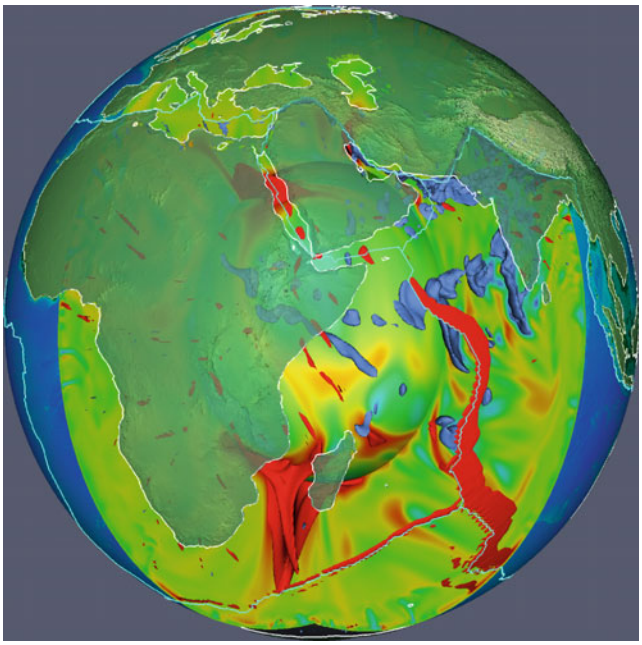

Plate Motions in Time: Inferences on Driving and Resisting Forces, Figure 3 Temperature distribution in the Earth's mantle from a recent, high-resolution 3-D global circulation model. *Blue* represents cold, denser material whereas *red* is hot and buoyant mantle. View is on Africa, coastline is in *white*, with continental topography in transparent *green color* scale. Present-day plate boundaries are outlined in *blue*. More than 100 million grid points discretize the Earth's mantle, equivalent to an average grid spacing of 20 km or less. Circulation models include radial variations in mantle viscosity (factor 40 increase from the upper to the lower mantle), internal heat generation from radioactivity, bottom heating from the core, and a history of subduction spanning the past 120 Myrs. A cold downwelling is visible beneath Tibet where the ancient Tethys Ocean subducted under Eurasia; a hot and buoyant upwelling is visible as well beneath the spreading triple-junction of the Antarctica, Africa, and Australia plates. The circulation model provides a realistic, first-order estimate of internal buoyancy forces driving global plate motions.

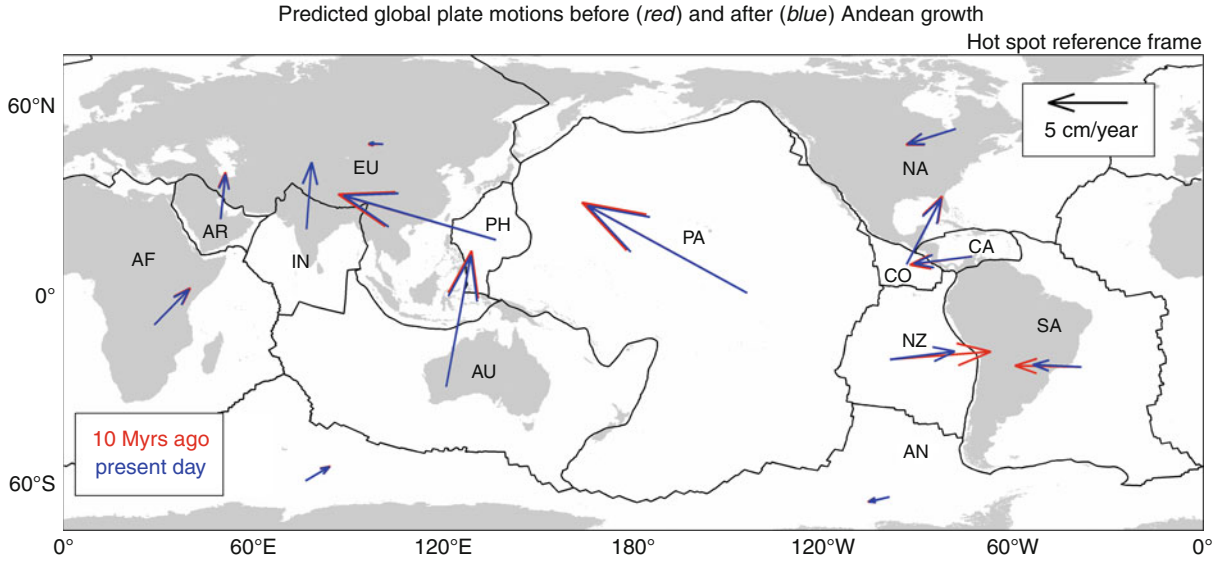

Plate Motions in Time: Inferences on Driving and Resisting Forces, Figure 4 Predicted plate motions in the Hot spot reference frame from coupled global mantle convection/lithosphere dynamics simulations, corresponding to assumed Andean paleotopography 10 Myrs ago (*red*) and present-day topography (*blue*). Plate boundaries are in *black*, continents in *gray*. AF Africa, AN Antarctica, AR Arabia, AU Australia, CA Caribbean, CO Cocos, EU Eurasia, IN India, NA North America, NZ Nazca, PA Pacific, PH Philippine, SA South America. IN and AU are treated as separate in the computational grid, based on recent evidences of plate separation (see text and Figures 6, 7). Note that a lower paleotopography assumed for the Andes 10 Myrs ago results in a predicted NZ/SA convergence of 10.1 cm/year at long 71.5°W, lat 25°S, whereas present-day topography results in a predicted convergence of 6.9 cm/year at the same position (see text). The rates compare remarkably well with observations inferred from a variety of data, which indicate a 30% reduction of NZ/SA plate convergence from 10.3 cm/year to 6.7 cm/year over the past 10 Myrs. The modeling results suggest that the reduction of NZ/SA convergence is caused by resisting plate-margin forces associated with the topographic load of Andes (see text). Similar numerical models moreover confirm that frictional variations along the boundary, arising from variations in trench sediment infill, are insufficient to explain the record of plate motion.

lithosphere and account for ductile deformation in the lower crust as well as brittle deformation along faults. In some cases, they take advantage of the so-called thin-sheet approximation to reduce the computational complexity from 3-D to 2-D (Kong and Bird, 1995) and to achieve greater computational efficiency.

Independent of advances in neo-tectonic models, there has been much progress in modeling the global circulation of the Earth's mantle (Tackley et al., 1994; Bunge et al., 1997; Zhong et al., 2000). Mantle circulation models (MCMs) account for the dynamic effects from a weak asthenosphere on the horizontal length-scales of the flow (Bunge et al., 1996), include internal heat generation from radioactivity, as well as a significant amount of heat from the core (Bunge, 2005; Quere and Forte, 2006; van der Hilst et al., 2007). Combined with constraints on the history of subduction, these models place first-order estimates on the internal mantle buoyancies driving plate motions. Figure 3 shows the temperature distribution in the mantle from one recent model with more than 100 million grid points (Oeser et al., 2006), equivalent to a grid point spacing of 20 km and less throughout the model mantle. MCMs provide first-order estimates of mantle buoyancy forces, but do not account for the complex processes in the lithosphere such the brittle failure. Similarly, neo-tectonic models include stresses originating within the lithosphere, and realistic plate boundary forces. But they rely on assumptions of the mantle buoyancy field to complete the force balance. The logical step is merging the two model classes to simulate the coupled global mantle convection/plate tectonics system. This makes it possible to account simultaneously for plate boundary forces and mantle-related components of lithospheric force balance, and to predict variations in global plate velocities that one may test explicitly against the geologic record. Several authors have recently undertaken such approach (Iaffaldano et al., 2006; Ghosh et al., 2008). Results are encouraging, and in the following, we review recent predictions of climate-related topography variations and their influence on plate velocities in the Southern Pacific, Southern Atlantic, as well as in the Indian Ocean that compare well with observations.

Recent plate motion changes

Kinematics of the Southern Pacific and Atlantic, and its relations to climate variations and topographic growth in the Andes

Paleomagnetic (Gordon and Jurdy, 1986; DeMets et al., 1994) and geodetic (Norabuena et al., 1999) data indicate a significant reduction (as high as 30%) of the Nazca/South America plate convergence over the

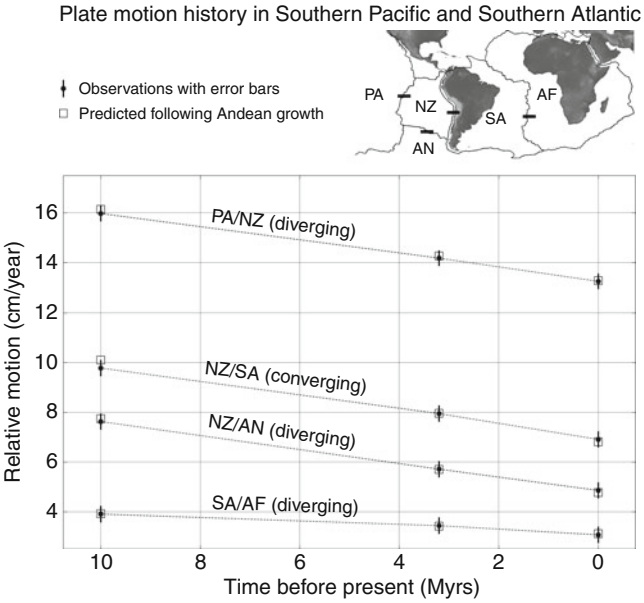

Plate Motions in Time: Inferences on Driving and Resisting Forces, Figure 5 Predicted and observed relative plate motions in the South Atlantic and South Pacific over the past 10 Myrs for a set of adjacent plate pairs: PA/NZ, NZ/SA, NZ/AN, and SA/AF (abbreviations as in Figure 6). *Black bold segments* in the small inset indicate positions along plate boundaries (*thin black*) at which relative motions have been computed. Observed plate motions (with *error bars*) inferred from paleomagnetic and geodetic data are represented by *black dots*, while *empty squares* indicate relative motions predicted from our simulations of the global coupled mantle/lithosphere system. The models explicitly account for the growth of the Andes over the past 10 Myrs, and demonstrate that the relative plate motion record can be entirely explained with the history of Andean orogeny. Our simulations thus point to the importance of far-field effects in plate tectonics, and imply that resisting plate margin forces due to Andean growth account for about 18% of global plate motion changes over the past 10 Myrs (see Figure 8).

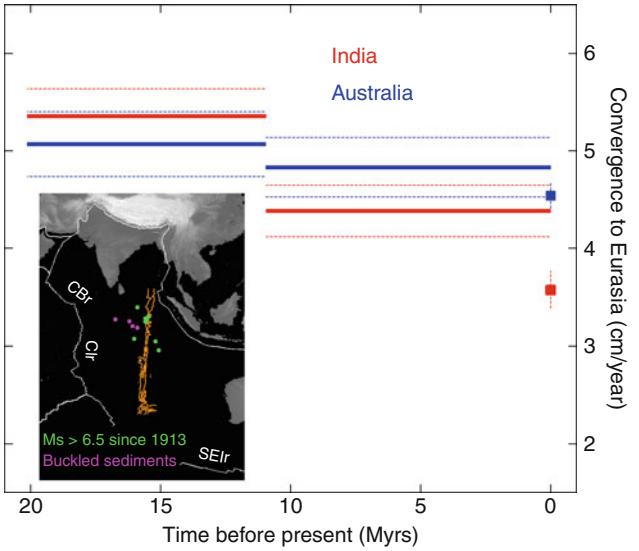

Plate Motions in Time: Inferences on Driving and Resisting Forces, Figure 6 Observed convergence of India (*red*) and Australia (*blue*) relative to fixed Eurasia over the past 20 Myrs. Convergence rates are computed through rigid-rotation Euler poles at long 86°E, lat 27°N of the India/Eurasia margin. Present-day values (*squares*) are derived from geodetic techniques while the paleomagnetic record (*solid lines*) is computed by averaging finite rotations of magnetic anomalies identified along the Carlsberg and South-East Indian ridges (labeled respectively, as CBr and SEIr in inset. Clr is Central Indian ridge). Note that convergence rates are very similar between 20 and 11 Myrs ago, when India and Australia appear to behave as one single plate with presumably little internal deformation. The convergence relative to Eurasia differs more distinctly over the last 11 Myrs, when India and Australia slowed down by almost 2 cm/year and 0.5 cm/year, respectively. Inset shows locations of identified unconformities of sediments (*magenta dots*) as well as great (Ms $>$ 6.5) earthquakes (*green dots*) indicating left-lateral strike-slip motion in the northern portion of the Ninety East Ridge (*orange contours*). Those evidences suggest diffuse deformation in the Indian Ocean particularly pronounced during late Miocene, and have been interpreted as separation between the India and Australia. Plate boundaries are in *white*, continental topography in *gray color* scale.

past 10 Myrs. The timing of the slowdown is significant in that it is coeval with major growth of the Andes (Allmendinger et al., 1997) inferred from a variety of independent data (Gregory-Wodzicki, 2000). Iaffaldano et al. (2006) tested the effect of topography on plate convergence by computing plate velocities before and after Andean topography growth, assuming mantle shear tractions from a MCM, as well as a low fault friction coefficient of 0.03 for the tectonic model. They performed two separate simulations of global plate motions, in order to estimate the increase of horizontal deviatoric force in the frictional region of the Nazca/South America interface arising from the gravitational collapse of the Andean belt, and its effect on the convergence rate. One simulation was based on present-day topography from the ETOPO 5 data set, as high as 5 km in the central Andes, to compute global plate velocities. A second simulation accounted for a lower topographic relief of continental South America, based on a reconstruction of Andean paleo-elevation 10 Myrs ago (Gregory-Wodzicki, 2000). Comparison of the two computed velocity fields predicts a 30% convergence reduction between the Nazca and South America plates (Figure 4), and agrees well with the record of present and past plate motions. More importantly, the contribution of the momentum from the gravitational collapse of the large plateau has been estimated to be of some 10**13 N/m along the central Andes. It should be pointed out that other mechanisms, such as temporal variations of friction along plate boundaries (Iaffaldano et al., 2008) and lateral buoyancy variations (Forte et al., 2009), may contribute to modify the convergence regime along the Nazca/South America margin to a minor extent. From Figure 4, it is evident that the total convergence reduction is unevenly partitioned between the Nazca and South America plates. This can be understood by recalling that mantle shear tractions exerted on the lithosphere-base scale to first order with

the basal surface area of the plate times its velocity. Because the Nazca plate is smaller than South America, a higher velocity reduction is required in the momentum balance for mantle shear tractions to equilibrate topography-generated plate-boundary forces along the margin. Iaffaldano and Bunge (2009) took a step forward and used global models to predict the history of relative motion for plates adjacent to Nazca and South America (Pacific, Africa, Antarctica), which are shown in Figure 5. Agreement between models and observations is remarkable, implying that the resisting forces along the Nazca/South America plate boundary are responsible for driving plate motion changes also in the Southern Atlantic and Southern Pacific regions.

Plate motion changes in the Indian Ocean

While instantaneous calculations of the plate tectonic momentum balance cannot be taken to model the temporal evolution of plate boundaries, they do allow us to test the effects of variations in plate geometry on global plate motions, and in particular the creation of new plate boundaries. From the principle of inertia, it follows that any such event would invariably trigger plate motion changes due to repartitions in the budget of basal drag and plate boundary forces. A recent such episode is thought to have occurred in the Indian Ocean, where a variety of evidence has been interpreted as the generation of a diffuse boundary between the India and Australia plates, dated between 8 and 20 Myrs ago (Wiens et al., 1985; Gordon et al., 1998). Ocean-floor deformation at about 8 Myrs is documented from buckling of marine sediments (Weissel et al., 1980). Ongoing deformation in the Indian Ocean is also supported by pronounced (Ms > 6.5) and localized seismicity (Stein and Okal, 1978) along the northern portion of the Ninety East Ridge (see inset in Figure 6), suggestive of left-lateral strike-slip motion. Figure 6 shows the observed convergence history of India and Australia relative to Eurasia since early Miocene based on geodetic (Sella et al., 2002) as well as paleomagnetic (Cande and Stock, 2004; DeMets et al., 1994; Gordon and Jurdy, 1986; Merkouriev and DeMets, 2006) data collected along the Carlsberg and South East Indian ridges (labeled respectively as CBr and SEIr in the inset). Within errorbars, convergence rates are almost indistinguishable between 20 and 11 Myrs ago, suggesting that India and Australia behaved as one single plate with presumably little deformation occurring in between. Over the past 11 Myrs however their convergence to Eurasia differs distinctly. While India slowed down by almost 2 cm/year, convergence of Australia to Eurasia remained almost steady, with only some 0.5 cm/year of reduction. Timing of the India/Eurasia plate-motion change coincides reasonably well with the occurrence of diffuse deformation in the Indian Ocean. More relevant is the fact that Tibet had attained most of its current elevation (Tapponnier et al., 2001) prior to the slowdown of the Indian plate and prior also to the presumed formation of the India/Australia plate boundary, implying that resistive plate

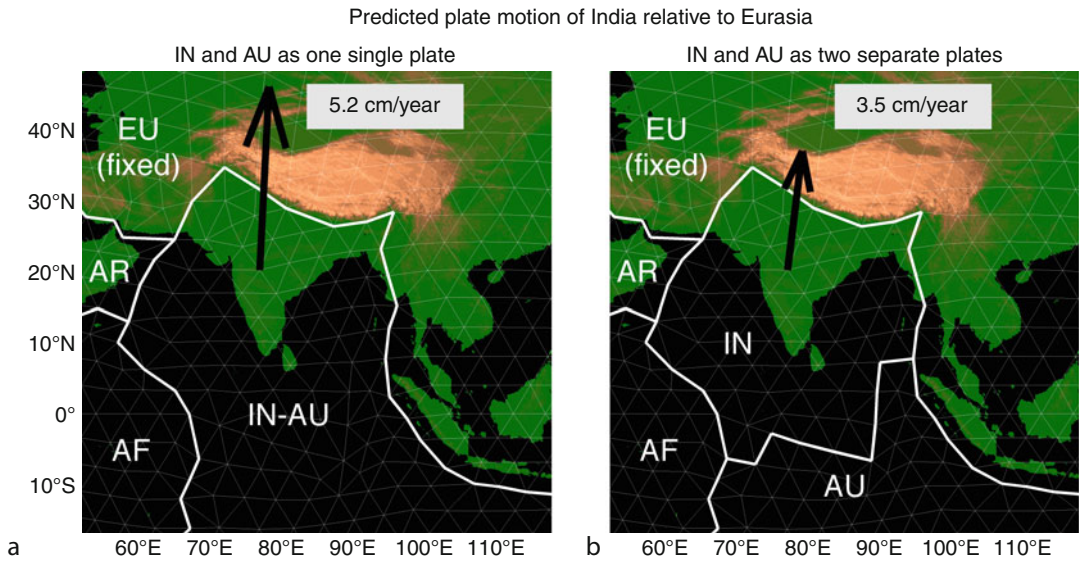

Plate Motions in Time: Inferences on Driving and Resisting Forces, Figure 7 Predicted India (IN) plate motion relative to Eurasia (EU) from two distinct simulations with India and Australia (AU) acting, respectively, (**a**) as one single and (**b**) as two separate plates, where plate boundaries in our computational mesh are shown in *bold white* and finite elements in thin white. Plate motions are computed at long 86°E, lat 27°N. Abbreviations of plate names as in Figure 6. Note that a single India/Australia plate results in a predicted convergence of 5.2 cm/year relative to EU, incompatible with the geodetic estimate (see Figure 12). Two separate plates result in a convergence of 3.5 cm/year of IN relative to EU, similar to the present-day observation. In the latter scenario, resisting forces from the gravitational load of Tibet act only against the smaller India plate, and are thus more effective in slowing the convergent motion.

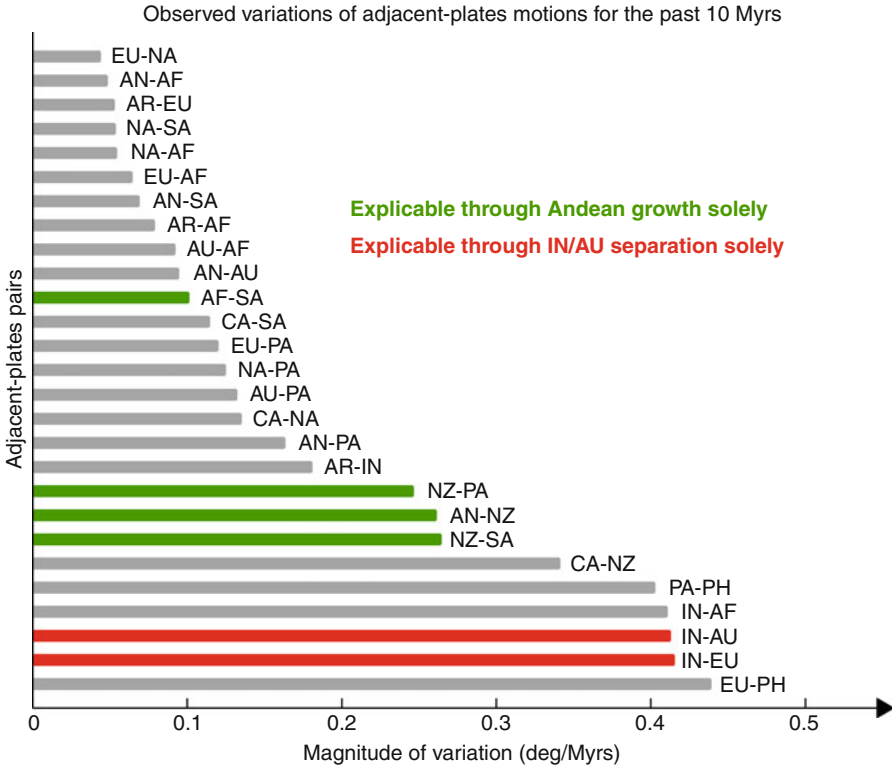

Plate Motions in Time: Inferences on Driving and Resisting Forces, Figure 8 Observed variations of adjacent-plates motions over the past 10 Myrs. Abbreviations of plate names as in Figure 6. For each couple of adjacent plates, variations are computed as magnitude of difference between relative rotation poles at 10 Myrs, derived from paleomagnetic reconstruction, and at present day, obtained through geodetic techniques (GPS). The Cocos oceanic plate is not considered, since a geodetic estimate for its rotation pole is not available. Variations of AF/SA, AN/NZ, NZ/SA, and NZ/PA adjacent-plates systems (*green bars*) can be entirely explained through the effect of Andean growth (see Figures 6 and 7). They amount to about 18% of the global relative motions changes over the past 10 Myrs. Variations of IN/EU as well as IN/AU relative motions (*red bars*) can be entirely explained through the effect of separation between India and Australia (see Figure 7). They amount to about 17% of the global relative motions changes over the past 10 Myrs. Thus, our models of mantle/lithosphere dynamics explicitly predict about 35% of the global plate motion changes observed over the past 10 Myrs from two well-identified tectonic variations.

boundary forces arising from the gravitational load of Tibet were already in place to act against convergence. Iaffaldano and Bunge (2009) tested explicitly whether plate-boundary forces from high Tibet are sufficient to explain the observed reduction of India/Eurasia plate convergence, once the former is separated from Australia by an additional plate boundary (Figure 7). Specifically, they performed two distinct simulations of global plate motions, one with India and Australia cast as one single plate and the other with two plates built into the computational finite-element grid. A single India/Australia plate results in a predicted convergence of 5.2 cm/year at long 86°E, lat 27°N (Figure 7a), whereas India being separated from Australia implies a convergence of 3.5 cm/year at the same position (Figure 7b). The latter prediction compares remarkably well with the geodetic estimate (see Figure 6). Finally, it is worth mentioning that simulations also predict an increased convergence between India and Australia, concentrated in the Indian Ocean, compatible with the aforementioned geologic and geodetic record.

Conclusions

Recent results indicate that joint modeling of the mantle/lithosphere system begins to achieve a level of maturity that allows explicit testing of a range of hypotheses on the force balance in plate tectonics, and identifying key controlling parameters. While buoyancy forces from MCMs contribute significantly to the dynamics of plate motion, it is clear that plate boundary forces are of sufficient magnitude relative to these driving forces to affect plate motions and plate deformation, and to initiate rapid plate motion changes. One key controlling parameter in regulating plate velocity is the elevation of large mountain belts, because their topographic load consumes a considerable amount of the driving forces available in plate tectonics, as much as 10**13 N/m. Along the Nazca/South America plate boundary these forces are sufficient to reduce the convergence rate over the past 10 Myrs by some 30%. This reduction is, however, not an isolated episode of a rapid plate motion slow down. Instead many such variations are documented from the global compilation of Müller et al. (2008), which points to the

importance of topography and erosion in the global tectonic system (Cloetingh et al., 2007). The fact that models accurately predict the spreading history of the Pacific/Nazca, Nazca/South America, Nazca/Antarctica, and South America/Africa plate boundaries is of equal interest. The result is not entirely surprising, and arises from the kinematic constraints of plate tectonics on the sphere. This suggests that far-field effects cannot be neglected in the geologic record at least in some cases. The strong influence of mountain belts on the plate tectonic force balance could have important implications. In an influential paper, Raymo and Ruddiman (1992) advanced the notion that Cenozoic climate change may have been caused by the uplift of Tibet. In other words, the rise of large mountain plateaus may act as a tectonic force on climate (Strecker et al., 2007). Low erosion rates have been implicated as a prerequisite for the creation of large mountain plateaus (Sobel et al., 2003; Clift and Vannucchi, 2004). This implication suggests conversely that climate can act – through large topography – as a force in plate tectonics. Overall, a significant portion of recent changes in global plate motions can be attributed to topography-related forcing along plate boundaries rather than to mantle buoyancy. These findings are summarized in Figure 8, where the relative plate motion changes observed globally over the past 10 Myrs are plotted. Green and red bars show variations in plate motion that are related, respectively, to the growth of the high Andes or to the presumed recent separation between India and Australia, and amount to about 35% of the total change over the Earth surface. This remarkable first-order result clearly demonstrates the ability of plate boundary forces to affect the global plate velocity field. The level of maturity achieved by neo-tectonic simulations coupled with 3-D MCMs thus allows geodynamicists to make explicit predictions of the plate tectonic force balance that can be tested against the geologic record of present and past plate motions.

Introduction

The plate tectonics paradigm, developed in the late 1960s, provides an excellent framework to explain the tectonics of the Earth's crust since the Cenozoic period. In general, the tectonic style reflects how the planets lose their internal heat and plate tectonics represent one of the at least three styles in which planets cool (Sleep, 2007). Intriguingly, Earth is the only planet that presently exhibits plate tectonics (Stevenson, 2003), an unusual mode of cooling. It is now widely appreciated that the excess density of the oceanic lithosphere that is sinking deeply in subduction zones drives the modern-style plate tectonics ("subduction tectonics," Stern, 2005). However, *why and when on Earth plate tectonics began* has been highly controversial and remains one of the most challenging unresolved problems in our understanding of the evolution of the planet (for a recent review on the subject see Condie and Pease, 2008 and articles therein; Ernst, 2009). While many authors propose that plate tectonics, in some form, operated since early Archaean times (Kroner, 1981; Ernst, 1983; Sleep, 1992; Parman et al., 2001; Smithies et al., 2003, 2005; Sleep, 2005; Condie, 2005; Cawood et al.,

2006; Condie and Kroner, 2008; Dilek and Polat, 2008), others favor a much later beginning in the Earth's history (Davies, 1992; Hamilton, 1998, 2003; Stern, 2005, 2007; Hamilton, 2007; Dewey, 2007; Brown, 2008; Ernst, 2009).

Demonstration that plate tectonics operated at any given time requires evidence for lithospheric subduction and independent plate motions. However, since the oldest oceans on present Earth are not older than Jurassic, one is forced to consider the geological record on continents that dates back to ~4.4 Gyr (billion years). This section summarizes the debate on the onset of modern-style plate tectonics on Earth, but before addressing this, an overview of the current perspectives on modern-style plate tectonics in terms of thermal evolution of Earth and other silicate planets is considered pertinent. Subsequently, the footprints of plate tectonics in the deep geological past, the Precambrian (covering an early part of the Earth's history, including, Hadean- prior to 3.8 Gyr, Archaean-3.8–2.5 Gyr and Proterozoic-2.5–0.54 Gyr) are traced through a consideration of empirical observations and multidisciplinary datasets that are believed to serve as proxies for modern-style plate tectonics in the ancient geologic record.

Modern-style plate tectonics: some broad perspectives

In its initial conceptualization, plate tectonics offered a purely kinematic description of how lithospheric plates move and interact with one another on the nearly spherical surface of the Earth. There was little clarity on the forces that cause plate motions. Notwithstanding the traditional view that the asthenospheric convection powers contemporary plate motions, modern geodynamicists find an increasing consensus for predominance of "top-down tectonics" (Anderson, 2001), at least during some stages in the Earth's history, and suggest that plates drive themselves as they organize the overall mantle convection (Davies, 1999; Hynes, 2005).

The thermal boundary layer – the lithosphere – is buoyant when new oceanic crust is created at the Mid Oceanic Ridges (MOR). As the lithosphere ages and moves away from the MOR, it cools (conductively), thickens, and increases in density leading to a buoyancy-crossover in the lithosphere–asthenosphere system. On the present Earth, such a crossover occurs in 20–40 Myr (million years). This "ridge-push" coupled with "gravitational descent" of the lithosphere in the subduction zones contributes to much of the plate motion, so much so that the modern plate tectonic style can be referred to as "subduction tectonics" (Stern, 2005). Based on seismic tomography, it is evident that the lithospheric slabs on Earth reach great depths, typically 1100–1300 km, and possibly down to the core-mantle boundary (Vander Hilst et al., 1997). While the "slab pull" of the sinking lithosphere and the associated "slab suction" of the entrained ambient mantle at subduction zones move the plates (Conrad and Lithgrow-Bertelloni, 2004), the viscous resistance of the asthenosphere impedes plate motion. Resistance to the sinking lithosphere is also from dissipation forces that are manifest as deformation (mainly faulting and bending) in the subducting slab and phenomena such as regional mantle down swelling. The nature and extent of equilibrium between the driving and resisting forces is indicated by the limited range of the observed plate velocities, which possibly did not exceed ~17 cm/y, for instance, during the Mesozoic drift of the Indian lithospheric plate, a case of extremely rapid plate motion.

As stated earlier, Plate tectonics seems to be an unusual way for silicate planets to cool, and perhaps represents a specific stage in the ~4.57 Gyr cooling history of the Earth (Ernst, 2009 and references cited therein). This implies a temporal change in the cooling/tectonic style of the planet. Ernst (2007) suggested that the Earth's plate tectonic history is divisible into four stages. In the early three stages, plate motions were controlled by asthenospheric convection dragging buoyant lithosphere down inwards. Contrary to this, during the fourth stage alone, the subducting lithosphere causes plate motions. The latter stage is referred to as the "Proterozoic plate tectonic regime," while the early stages comprise "Proto-plate tectonics" (Stern, 2007) broadly analogous to delamination tectonics and/or the shallow subduction mode of tectonics (Foley et al., 2003).

Evolution of earth's tectonic regimes

Numerical modeling, geochronological and isotopic results on meteorites, and the oldest known terrestrial rocks and minerals, especially ex-situ magmatic zircons in ancient sediments, offer valuable constraints on the physical conditions of the planet during its early history. A general consensus is that the condensation of the accreting hot Earth was completed by ~4.57 Gyr (Ernst, 2009 and references cited therein). Further rapid increase in its internal heat is ascribed to core-formation, radioactive decay of long-lived elements (U, Th, ^{40}K) and short-lived isotopes (e.g., ^{26}Al), bolide impacts and very early impact of a Mars-sized body and such other factors (Wetherill, 1976; Kleine et al., 2004; Cameron and Benz, 1991; Halliday, 2004). As illustrated in Figure 1 (Stage I), this phase was succeeded by the formation of a near-surface magma mush ocean several hundred kilometers thick (Abe, 1997; Boyet and Carlson, 2005; Davies, 1999), prior to 4.4 Gyr. The Earth cooled rapidly thereafter leading to the formation of a thin silicate-proto crust by ~4.4 Gyr, consistent with the well-documented occurrence of 4.2–4.4 Gyr igneous zircons from the Archaean sediments of Western Australia (Wilde et al., 2001; Watson and Harrison, 2005). It is generally perceived that such a Hadean crust may have been recycled back into the mantle by viscous drag and mantle overturn (Boyet and Carlson, 2005). Significant cooling of the Earth's crust (below the boiling point of water) by ~4.0 Gyr is inferred from preservation of the ~3.9 Gyr Isua volcano-sedimentary assemblages, western Greenland, which suggest the possibility that water-oceans marked the planet's outer rind by the Late Hadean times. Presence of microdiamond ± graphite inclusions in the detrital zircons

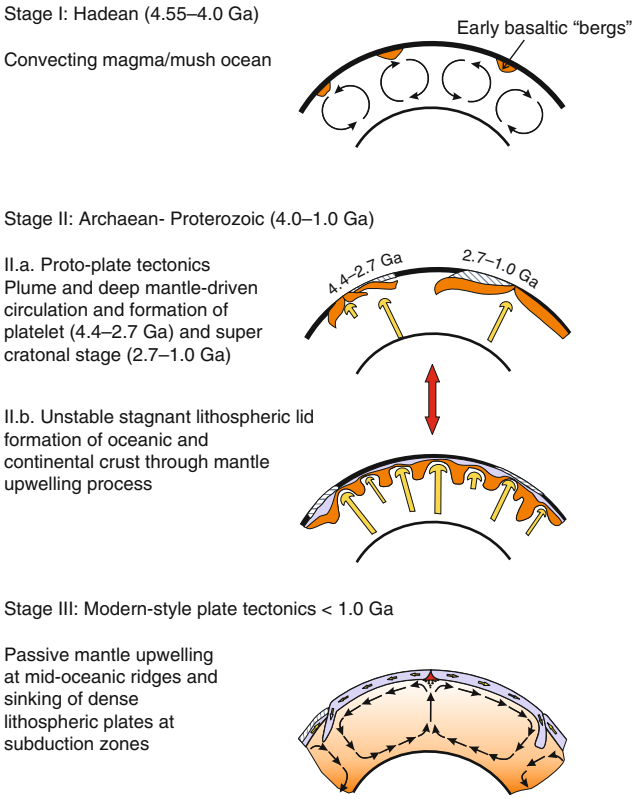

Plate Tectonics, Precambrian, Figure 1 Cartoon illustrating the evolution of global tectonic styles from the Hadean to present involving three main stages. See text for more details (Modified after Ernst, 2007; Stern, 2008 and references cited therein).

(Menneken et al., 2007) suggests thick Archaean lithosphere, at least locally. However, if these inclusions were initially graphite, but transformed to diamonds subsequently through subduction processes, the thick lithosphere can be inferred much later, during the Mid Archaean rather than Hadean/Early Archaean (Williams, 2007). Indeed, Mid Archaean diamonds have also been sourced in younger kimberlites from several cratons, suggesting thick lithosphere and possible plate motion by the Mid Archaean (Shirey et al., 2004).

Thermal models of planetary evolution suggest three principal modes of non-radiative planetary heat transfer (Sleep, 2000, 2007): (1) magma mush oceans, (2) plume and plate tectonics and (3) stagnant-lid convection (illustrated in Figure 1 in corresponding stages). The magma mush ocean mode is, by far, the most energetic mode and probably characterizes the Hadean tectonic style. The stagnant-lid convection, the least energetic mode, characterizes the present Venus and Mars and is possibly present on Earth episodically. Much of the modern, Wilson-style plate tectonics reflect convective overturn in the suboceanic lithosphere–asthenosphere system. On the other hand, the craton-capped lithosphere scenario mimics the stagnant-lid mode where the build-up of sublithospheric temperature leads to episodic break up and drift of continents (Gurnis, 1988; Lowman and Jarvis, 1996; Silver and Behn, 2008). In this process, some low-density lithosphere is returned to the mantle by viscous drag. However, the high-brittle yield strength combined with chemical and mineralogical buoyancy and high viscosity of the cratonic roots promote long-term stabilization of cratonic lithosphere compared to the oceanic lithosphere. While the latter is continuously recycled back into the mantle, the cratonic lithosphere accumulates over time and forms a time-integrated aggregate. Mantle convection is driven by both bottom-up and top-down thermal and gravitational instabilities: hot-buoyant plumes of mantle overturn and cold-dense sinking lithospheric slabs (Davies, 1999 and Anderson, 2001). It is further perceived that in the Hadean Earth, the widespread vigorous bottom-up overturn and plume ascent predominated (Condie, 1994, 2005; Sleep, 2007). High-temperature regimes and low-mantle viscosities may have led to rapidly moving plates and avalanches of lithospheric descent into the lower mantle interspersed with intervals of relative quiescence (O'Neill et al., 2007). In contrast, by the Phanerozoic time, thermal heterogeneities in the deep-mantle lessened, and progressively thicker and cooler oceanic lithospheric plates became negatively buoyant leading to the foundering and driving mantle convection from the surface downward. Craton-capped lithospheric plates being chemically and mineralogically buoyant would stabilize at the Earth's surface. Stagnant-lid tectonics is a dominant mode of other silicate bodies today, and it is likely that Earth also experienced some episodes of this mode. However, in the Hadean, stagnant-lid tectonics may have been very unstable (Hamilton, 2007).

Through a correlation between mantle potential temperatures (T_P) – a measure of mantle temperature adiabatically decompressed to pressures corresponding to the planetary surface, and the Urey ratio (heat production/heat loss) for progressively cooling silicate bodies, Sleep (2000) showed that whereas the stagnant-lid style encompasses a wide range of thermal conditions from thermally "active" to "dead" silicate bodies, the modern plate tectonics can only occur when appropriate mantle thermal conditions exist. Plate tectonics are thus an effective mode of planetary heat loss, but conditions favorable for this style may only exist for a relatively brief interval in planetary evolution. Ernst (2007) showed that a Urey ratio of ~0.3 extrapolated back in time yields a "thermal catastrophe" at ~1.0–1.5 Gyr (Korenaga, 2006).

The density of the present oceanic lithosphere is controlled largely by the thickness of its mantle component. Although a small part, the oceanic crustal thickness is controlled by T_p that determines the amount of mantle melting for a given amount of mantle upwelling (McKenzie and Bickle, 1988). The mantle potential temperature for the Archaean Earth was probably 300–500°C higher than today (Nisbet et al., 1993). Thus, decompression melting of the hotter Archaean mantle must have generated thicker oceanic crust and a more buoyant lithosphere. Presently, the oceanic lithosphere reaches neutral buoyancy in about

20 million years (Davies, 1992), while in a hotter Archaean mantle, it would take longer (approximately 80 Myr) to reach neutral buoyancy and much longer lithosphere–asthenosphere crossover times. In the Arcahean, the negatively buoyant lithosphere would have been removed much more rapidly than it could form and subduction may have been possible intermittently, considering the crust was denser and hence gravitational instability would also favor subduction. This scenario is in contrast to the protracted time through which subduction is sustained in the Phanerozoic.

The transition from stagnant-lid to plate-tectonic modes requires lithospheric rupture, subsidence and asthenosphere flow over the lithosphere. Mechanisms for efficient cooling of relatively hotter Archaean lithospheric plates may include three possible scenarios: (1) greater length of the Archaean ocean ridge system (Hargraves, 1981), about 27 times to the present length, (2) inversion of basalt to eclogite in buoyantly subducted Archaean oceanic crust, and (3) negatively buoyant oceanic mantle lithosphere because of latent heat loss associated with melt extraction at MORs.

Criteria for recognizing plate tectonics in the precambrian geological record

Recognizing the onset of modern-style plate tectonics on planet Earth involves tracking the manifestation of the processes in the geological record. For instance, evidences for the creation of new oceanic lithosphere, the existence of "ocean-plate stratigraphy," subduction processes where lithosphere is returned to the mantle, transform and transcurrent faulting at any given time. The problem of preservation of the diagnostic criteria figures prominently, as the evidence in all likelihood, can be fragmentary and incomplete owning to obliteration by tectonic and surface processes. From the theoretical considerations presented in the foregoing sections, the modern-style plate tectonics are not only unusual in a planetary perspective, but also in the Earth's evolutionary history. Thus, the Huttonian approach "The present is the key to the past" may not be entirely helpful to understand the Earth's earliest tectonic history (Rollinson, 2007; Stern, 2008). In any case, best approaches should consider multiple working hypothesis and methodological uniformitarianism emphasizing upon constancy of natural laws rather than substantive uniformitarianism invoking uniform geological processes through time (Stern, 2008). Some of the most robust criteria for recognizing the operation of the plate tectonics in the past include: ophiolites, blueschists and Ultra High-Pressure (UHP) metamorphic belts, eclogites, passive margins, transform faults, paleomagnetic evidence, igneous rocks with subduction-related geochemistry and isotopic evidences for recycling. In general, the Archaean crust is typified by granite-greenstone terrains, with characteristic rock types such as komatiitic ultramafics and basalts and TTG gneisses. Archaean terrains generally preclude mafic alkaline igneous rocks, undisputedly recognized ophiolites, widespread multicyclic sediments, UHP terrains and blueschist-eclogite metamorphic assemblages. Several of these form distinctive lithologies ascribed to Wilson-style plate-tectonic processes prevalent in the Phanerozoic times. Lithological associations such as stratigraphically intact platformal sedimentary formations do not appear unequivocally until the latest Archaean time. Such temporal distribution of rock formations are considered to reflect changes in tectonic style (Stern, 2007, 2008 and references cited therein).

Evidence for existence of paired metamorphic belts and subduction-related batholiths also form useful criteria. In general, different authors apply the criteria in different ways. For example, while some consider when a particular assemblage or property first appeared, others emphasize on when it became common. Thus, the inferences on the onset of plate tectonics on the Earth could be quite subjective, even by the same criterion. A broad description and significance of some of the important criteria are given below.

Ophiolites: Ophiolites are slices of the oceanic lithosphere tectonically emplaced onto the continental crust and could be reliable indicators of past plate tectonics. A complete ophiolite sequence (ocean-plate stratigraphy) would include pelagic sediments, pillow basalt, sheeted dykes, gabbros, and tectonised ultramafites (lherzolites and harzburgites). However, generally, fragmentary and dismembered sequences are encountered in Precambrian terrains. Well- preserved ophiolites are known from many Neoproterozoic terrains (up to ca. 1.0 Gyr old; Stern, 2008 and Ernst, 2007 and 2009). Some of the better-preserved Neoproterozoic ophiolites include, Purtuneniq ophiolites, Canada (Scott et al., 1992) and Jormua ophiolites, Finland (Peltonen et al., 1996), although ophiolites as old as ca. 3.8 Gyr (the Isua suite, Greenland; Furnes et al., 2007) have been proposed, they remain controversial (also see Bickle et al., 1994).

Blueschists: Blueschists are metamorphosed mafic rocks bearing predominantly a sodic amphibole that stabilizes at high-P, low-T typical of Pacific-type of orogenic belts. Best studied examples are the Franciscan and Sanbagwa terrains (Ernst, 2003). The oldest known blueschists are Neoproterozoic (800–700 Myr; Maruyama et al., 1996) and undisputed pre-Neoproterozoic blueschists are virtually unknown.

Eclogites: Eclogites (s.s) are metabasalts and metagabbros that equilibrated at $P > 1.2$ GPa (> 45 km) and T (> 600–$650°C$) with a characteristic pyropic-garnet and omphacitic-clinopyroxene-bearing assemblage. Different types of eclogites have been described, but Colman's group C (associated with glaucophane schists) and the "low-T eclogites" (Carswell, 1990) could be reliable indicators of subduction process.

UHP terrains: UHP terrains form when continental crust initially subducted to greater than 100 km returns to the surface through subsequent tectonic processes.

Typical assemblages include coesite and diamond, indicative of 700–900°C and 3–4 GPa, or more (Liou et al., 2004). The oldest known UHP terrain is in Mali, ca. 620 Myr (Jahn et al., 2001) and Kazakhsthan, 530 Myr (Maruyama and Liou, 1998).

Paired metamorphic belts: The occurrence of paired metamorphic belts was originally conceptualized by Miyashiro (1972). They serve as one of the diagnostic criteria for modern-style plate tectonics and typically form on the overriding plate with the high-P low-T (blueschist facies) terrane forming next to the trench, whereas the low-P high-T terrane (greenschist facies) develops near to the arc. Paired metamorphic belts represent thermal structure of a mature subduction zone (Kelemen et al., 2003 and van Keken et al., 2002). As these belts are usually very wide, tens of hundreds of kilometers, they could be robust features that survive several episodes of orogeny and erosion (Stern, 2008). As only ~30% of convergent plate boundaries are accretionary, a large proportion, remain erosional (Clift and Vannucchi, 2004). In a paired metamorphic belt, accretionary convergent margins are preserved as broad zones, whereas the erosional boundaries could be much narrower (Stern, 2008 and references cited therein).

Batholiths: Mere presence of magmatic "island arc" features suggests modern-style plate tectonics with deep subduction (100–250 km). In such a setting from older terrains, volcanic rocks are usually removed by erosion, leaving behind well-preserved mid-crustal batholiths (Stern, 2002, Hamilton and Myers, 1967). Felsic plutonic lithologies represented by TTG suites (Tonalite-Trondjhemite-Granodiorite) dominate Precambrian plutons coalesced into batholiths. Subduction-related batholiths also serve as polarity indicators when combined with other evidences such as grade of metamorphism. etc.

Composition of igneous rocks: Considerable geochemical evidence in terms of depleted mantle source signatures for mid-crustal magmatic complexes suggests relevance of plate tectonic processes by the end of Hadean and in subsequent periods (Shirey et al., 2008). Fluid mobile elements such as K, Sr, Pb, HFSE ratios such as Nb/Th, Th/U, rare earth-element chemistry and other trace element compositions are often used to establish the 'arc-like' signatures in igneous suites (Kerrich and Polat, 2006 and references cited therein), which support the general thesis of plate tectonics since the Early Archaean.

Palaeomagnetic measurements: Palaeomagnetic data indicate differential movement of continents in pre-Neoproterozoic times (Pesonen et al., 2003; Cawood et al., 2006 and references cited therein).

Isotopic compositions: So far, the strongest evidence for crust-mantle differentiation is from the isotopic record of key rock units. There is enough evidence for the recycling of early crust and sediments into the mantle since Early Archaean (Shirey et al., 2008; Wilde et al., 2001 and Valley et al., 2006 and references cited therein). Isotopic studies on diamonds, for example ^{33}S from the inclusions preserved in the Archaean diamonds, provide the best evidence that the surface materials of the early Earth were recycled into the mantle (Farquhar et al., 2002). However, such recycling could also be due to proto-plate-tectonic activity or delamination associated with stagnant lid (Stern, 2008).

Summary and conclusions

The onset of modern-style plate tectonics on Earth remains controversial. A critical evaluation of the Precambrian geological record in terms of many of the criteria considered in the foregoing reveals that plate tectonics were operational in some form in some places on the planet possibly during the Early-Meso Archaean, but became widespread since ~2.7 Gyr. The problem however, concerns three of the indicators, namely, ophiolites, UHP metamorphism, and Blue schists, which clearly suggest much later onsets of more specifically, modern-style plate tectonics around 1.0 Gyr (Stern, 2005; Ernst, 2009; Condie and Kroner, 2008 and references cited therein). A closer consideration of these three criteria in terms of the inferred physical conditions prevalent in the Hadean and Archaean assumes importance. If the Archaean oceanic crust were significantly thicker than the modern oceanic crust (Sleep and Windley, 1982 and Foley et al., 2003), the deeper layers of the oceanic crust may not get accreted to the continents in the subduction zones. Thus, the rock associations such as, layered gabbro, ultramafic cumulates could be missing from the Archaean ophiolites, which may have been recycled into the mantle (Condie and Benn, 2006). From a different perspective, obduction of thin oceanic crust also results in delamination of the middle-to lower-crustal sections and the mantle lithosphere during successive collisional tectonic events. Thus, the preservation of only the upper pillow lavas of the oceanic crust (oceanic flake tectonics of Hoffman and Ranalli, 1988) may be expected. The widespread occurrence of mafic plain type greenstones in the Archaean may be remnants of oceanic crust than oceanic plateaus (Tomlinson and Condie, 2001). The apparent absence of blueschists and UHP rocks before ca. 1.0 Gyr (especially in the Archaean rock record) could also be ascribed to the relatively hotter Archaean Earth, wherein the subduction geotherms did not pass into blueschist stability field (Peacock, 2003; Ernst, 2009; Condie and Kroner, 2008 and references cited therein). Indeed the thermo-barometric studies of Archaean metamorphic rocks suggest steeper subduction geotherms (Moyen et al., 2006). Further, it is possible that the rate of uplift of UHP rocks may have been very slow in the Archaean, such that these assemblages recrystallized and hence no longer recognized.

Although the most robust evidences (temporal distribution of ophiolites, UHP metamorphism, and blueschist terrains) lead us to the thesis that modern-style of plate tectonics was undisputedly operational in the Neoproterozoic time, there are no evidences to suggest that manifestation in the geologic records is not strictly

synchronous. As summarized by Condie and Kroner (2008), it is quite unlikely that the plate tectonics on the Earth began as single global event at a distinct time in the early Archaean rather, it is probable that it began locally and progressively became more widespread from early to the late Archaean. By the late Archaean (2.7 Gyr), steep subduction similar to modern times was widespread on the planet. O'Neill et al. (2007) suggested that subduction may have been episodic during the Precambrian, possibly explaining the peak in crustal production at 2.7 Gyr.

Plate Motions in Time: Inferences on Driving and Resisting Forces

PLATES AND PALEORECONSTRUCTIONS

Alan G. Smith
Department of Earth Sciences, University of Cambridge, Cambridge, UK

Definition

The *lithosphere* is the outer rigid part of the Earth, forming a shell whose thickness may range up to about 200 km.
A *tectonic plate* is a part of the Earth's lithosphere that is bounded by active plate margins.
A present-day *plate margin* is a seismically active zone that cuts the lithosphere.
Conservative plate boundaries are plate boundaries that separate two plates that are sliding past one another along a *transform fault* (which must cut the lithosphere).
Divergent (*extensional*) *plate boundaries* mark where the two plates are separating from one another, generally forming *passive* (*or Atlantic*) *continental margins* (though extension can also occur behind island arcs).
Convergent plate boundaries are located between a converging oceanic and continental plate forming an *active* (*Pacific*) *continental margin*, or between a converging oceanic plate and an island arc.
A *global paleoreconstruction* shows a reassembly of the major continents (and oceans) relative to one another at some time in the past. If the reassembly is made using ocean-floor spreading magnetic anomalies and fracture zones, and derives the geographic poles from paleomagnetism, it is a *global paleomap*. If only the continents are depicted, it is a *global paleocontinental reconstruction* (*or map*). If each continent is projected separately onto a global map frame (as in pre-Mesozoic maps) is it is a *global composite reconstruction.*
A *paleo-plate reconstruction* is simply a paleoreconstruction that shows the plate boundaries of the time concerned, that is, ridges, trenches, and major transform faults.

Earthquakes and plates

Earthquakes are caused by the catastrophic release of accumulated elastic strain. The strain accumulates as a result of differential movement between parts of the lithosphere. A map of earthquakes over the past 40 years or so shows that differential movement is generally confined to narrow seismic zones, particularly in the oceans (Figure 1). Elsewhere there is little or no seismicity, showing that most of the lithosphere is not undergoing differential motion and is therefore rigid. The present-day surface extent of a plate is marked by zones of active seismicity that show the plate boundaries.

Plate compositions, sizes, and shapes

Plates are made up of *Lithosphere, Continental*, with a thickness that probably averages about 200 km (Priestley and McKenzie, 2006), and *Lithosphere, Oceanic*, whose thickness varies from a small value at a mid-ocean ridge, where it is created, to about 100 km for old oceanic lithosphere (Stein and Stein, 1992; Crosby et al., 2006). Most of the plates in the Pacific Ocean are almost entirely, or entirely, made of oceanic lithosphere, but other plates are made up of varying proportions of continental and oceanic lithosphere (Figure 1). There are no wholly continental plates. The shapes of most plates are quite irregular, reflecting their past histories of growth and destruction.

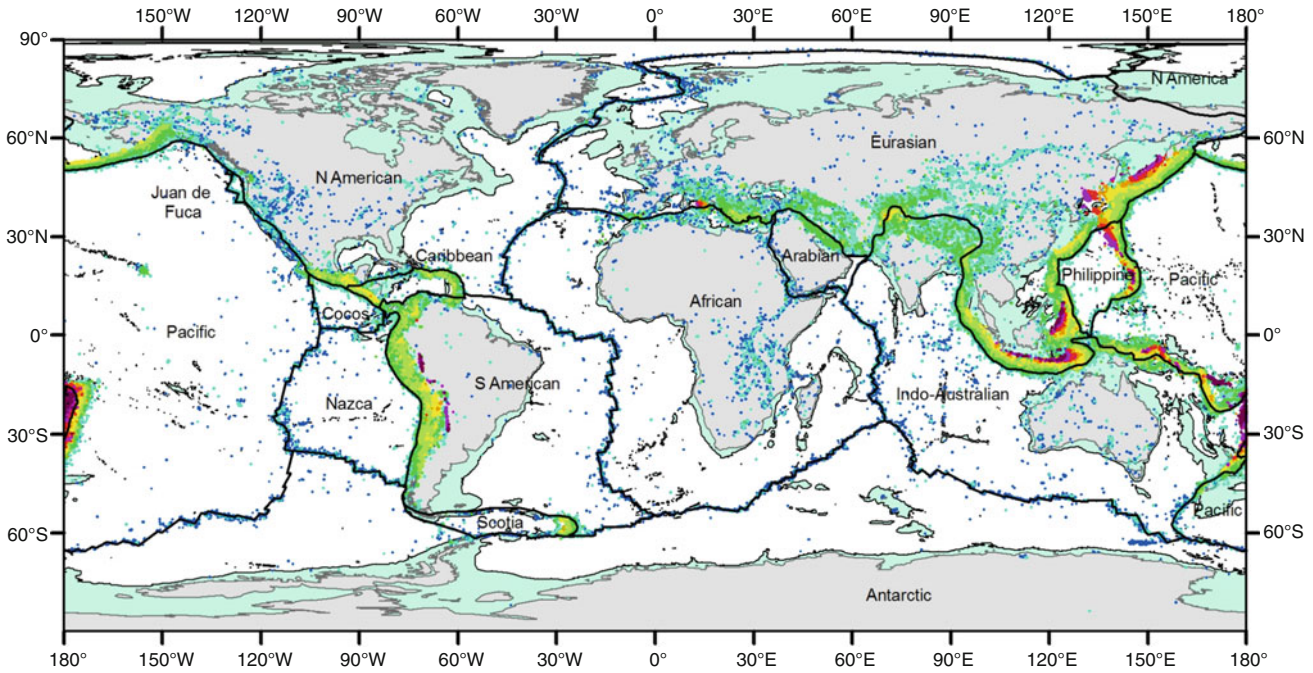
Plate tectonics

Plate tectonics describe the motions of the lithospheric plates and the effects they cause. It is now the major branch of terrestrial tectonics, which is the study of the origins of the large-scale structures of the Earth, particularly the lithosphere. The name tectonics is derived from the Greek word tektonikos (τεκτονικός) "pertaining to building."

Plate motions and Euler's theorem

Plates are rigid bodies that can move relative to one another in three ways: one, they can slide past one another; two, they can move away from one another; three, they can move toward one another.

According to a theorem attributed to Euler, the relative motion of two rigid bodies on a sphere can be described as a rotation about a line passing through the Earth's center that cuts the Earth's surface at a point known as the rotation pole. The pole will have a latitude, λ, and a longitude, φ, with the rotation that takes place in



Plates and Paleoreconstructions, Figure 1 Present-day earthquakes and simplified map of the present-day plates. The Philippine plate is also known as the Philippine Sea plate. The plate boundary between Eurasia and North America in northeast Asia is poorly defined. Cylindrical equidistant world map showing land areas as *light gray*. Areas between 2,000 m water depth and the coastline are *blue* (colored version) or *light gray* (monochrome version). Deeper oceanic areas are uncolored. Over 400,000 earthquakes are shown. In the colored map, the color code is: 0–10 km (79478) *blue*; 10–35 km (168263) *light blue*; 35–100 km (79890) *green*; 100–200 km (47056) *yellow-green*; 200–300 km (11144) *yellow*; 300–400 km (3874) *orange-brown*; 400–500 km (4674) *red*; 500–600 km (8427) *magenta*; 600–700 km (2477) *deep magenta*; >700 km (4) *black*. The monochrome version shows earthquakes ranging from *light gray* (shallow) to *black* (deepest). The rainbow-colored areas in the Australasia, together with smaller areas along the western coast of the Americas, indicate zones of seismic activity of increasing depth. The continuous *black* line is the plate network showing 14 plates, all labeled. It is unclear whether the Indo–Australian plate should be considered to be two plates with a boundary in the NW Indian Ocean. The plate margins in the oceans are very narrow and conform to ideal plate margins; those in the continents are much broader. In particular, the wide belt of active deformation in the Alpine–Himalayan belt shows that the deformation is not restricted to the narrow plate margin on the map between the African, Arabian, and Indo–Australian plates on the one hand, and the southern Eurasian plate on the other. Rigid plate tectonic descriptions of such areas may be inappropriate. (Copyright A. G. Smith). The earthquakes are those of magnitude 4 or greater listed in http://earthquake.usgs.gov/earthquakes/eqarchives/epic/

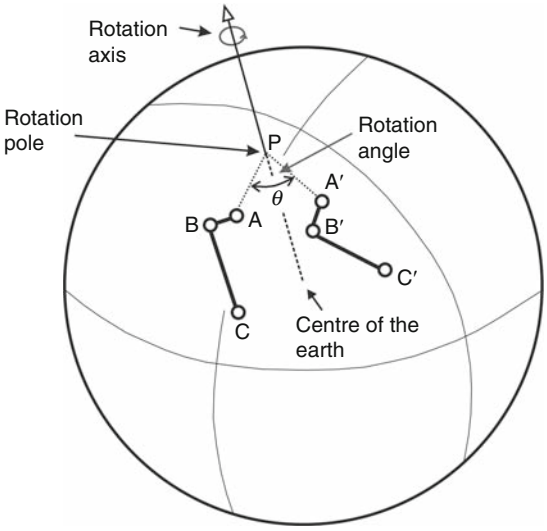
a given time given by θ (Figure 2). To a good approximation the Earth is a sphere and tectonic plates are rigid. Thus the motion of one plate relative to another in a given time interval is given by their Euler rotation (λ, φ, θ). λ varies from 90° N, the N pole, conventionally given the value of +90, to 90° S, the S pole, or −90. Longitudes are positive measured E from the Greenwich meridian, conventionally taken as 0°, or as 360°. If measured W from the Greenwich meridian, the longitudes are negative. Maps showing the whole world run from 0° E to 360° E, or 0 to −360. They could also run from 180° W, that is, −180, to 180° E, or +180. The sign of the rotation θ is found by fixing one plate as a reference and determining whether the rotation moves the second plate in an anticlockwise direction when looking down on it – a positive rotation – or moves clockwise – a negative rotation. Changing the reference plate changes the sign of the rotation.

Sliding motions

When plates slide past one another they neither create nor destroy lithosphere. They conserve the lithosphere and are described as conservative plate boundaries. On a sphere such boundaries are circular arcs forming what are known as transform faults as in the San Andreas fault. The Euler pole is the point at the center of the arc.

Divergent motions

When a continent breaks up and the pieces move away from one another the motion is divergent. At first the margins of the continents-to-be are stretched, forming what will become passive continental margins, as in the East African Rift. Eventually the stretching reaches the stage where new ocean-floor has to form, as in the Red Sea or the Gulf of Aden. The Euler rotations for each stage are given by the rotations needed to bring the different



Plates and Paleoreconstructions, Figure 2 The line ABC on a rigid body on the surface of a sphere (e.g., Earth) is moved to A′B′C′ by a rotation through the angle θ, about the rotation axis. The rotation axis passes through the center of the Earth and cuts the surface at point P with geographic coordinates of latitude λ and longitude φ (not shown), leading to an Euler rotation of (λ, φ, θ). (Copyright A. G. Smith).

markers (passive margins; anomalies of the same age) together.

Convergent motions

The local motions between present-day converging plates can be found from the slip vectors of earthquakes. If the convergent margin is long enough it is also possible to use these motions to estimate the position of the Euler pole. However, the local motions and Euler poles for ancient plate margins are difficult to estimate. In favorable circumstances it is possible to calculate them from a plate circuit. For example, the Cenozoic motion along a convergent plate boundary between India and the rest of Eurasia can be calculated by successively summing the motions from Eurasia to North America, North America to Africa, and Africa to the Indo–Australian plate (Figure 1). All of these motions are known from the ocean-floor spreading patterns in the Atlantic and Indian Oceans. Their sum gives the required result. The absence of any Paleozoic and Precambrian ocean-floor means that the motions and Euler poles at all pre-Mesozoic convergent plate boundaries are highly uncertain.

Reference frames

Three classes of reference frames are relevant to global reconstructions: any plate, the paleomagnetic reference frame, and that given by "hot-spots."

Plates as reference frames

Any plate, large or small, that can be linked to all the other plates can be used as reference frame to make a global reassembly: there is nothing fundamental in the choice of a plate. These global reassemblies are not geographic maps because they do not show the geographic latitude and longitude of the time concerned. To turn a reassembly into a map one needs to know the position of the geographic pole at the time concerned, which is given by paleomagnetism.

Paleomagnetism as a reference frame

Over a period of several tens of thousands of years or more, the Earth's magnetic field averages to what is known as a geocentric axisymmetric dipole field, or GADF. Virtually all paleomagnetic measurements use this field model to interpret the results. The field is geocentric because it behaves as if it were at the Earth's center; it is axisymmetric because the field is symmetric about the Earth's spin (or rotation) axis; and it behaves like a bar magnet and is therefore a dipole. Such a field has a very simple relationship between the angle, I, known as the inclination that the lines of magnetic force make with the horizontal, and the latitude, λ, of the point of observation:

$$\tan I = 2 \tan \lambda, \qquad (1)$$

where tan = tangent of the angle (I or λ).

As a plate moves, the latitude of a point on it changes and the orientation of the plate varies. Both these effects are recorded in the remanent magnetization – or *Paleomagnetism, Principles* – preserved in rocks. The actual position of the north magnetic pole at the time must lie along the line through the observation point that coincides with the direction of the declination. It is at a distance of ($90 - \lambda$) degrees from the observation point along that line. Thus, in principle, paleomagnetic data can be used to reposition that plate at the time that the old magnetism was superimposed on the rocks.

The determination of the age and direction of magnetization in rocks becomes progressively more difficult as one goes back in time, but these problems will not be discussed here. However, any Mesozoic or Cenozoic global reassembly can be turned into a map by finding where the mean north magnetic pole lies on the reassembly and making that point the north geographic pole of the map (Smith et al., 1994). A map of Pangea just before break-up is shown in Figure 3.

Although paleomagnetic measurements give the past latitude and orientation of a plate, they do not give its past longitude. Thus it is generally not possible to make a paleoreconstruction from paleomagnetic measurements alone. However, paleo-longitude differences between any two points on different continents will be correctly given if the relative position of the two points has been determined via a plate tectonic circuit whose individual motions are known.

Hot-spots as a reference frame

The origin of linear volcanic chains like the Hawaiian Islands has been attributed to the slow movement of

Plates and Paleoreconstructions, Figure 3 Mollweide projection of Pangea reassembled at the end of the Triassic period, ~200 Ma. The *green* areas are the present-day coastlines; the *blue* areas all lie above 2,000 m water depth, showing the approximate present-day extent of the continental crust. The latitude-longitude grid is drawn at 30° and shows in particular the estimated position of the late Triassic equator. Pangea was assembled by the collision of the southern continents (Gondwana) with the northern continents (Laurasia). A large oceanic area, known as the Tethys, separated southern Eurasia from northeast Gondwana. The distribution of continental fragments lying within the Tethys is uncertain, particularly that of China and adjacent areas (the large fragment lying east of Eurasia). Some continental slivers and/or island arcs off western North America are shown schematically. Several other slivers probably lay adjacent to other continental margins of Pangea, but no attempt has been made to depict them. (Copyright A. G. Smith).

a tectonic plate over a fixed deep plume of hot mantle, giving rise to "hot-spots" at the surface (Wilson, 1963; Morgan, 1981). A purely descriptive term for them is that they are examples of "large igneous provinces" created in the case of hot-spots by intense, generally basaltic, magnetism. From the point of view of making reconstructions they show an interesting property in that they move relative to one another at rates that are an order of magnitude slower than those of plates. Hot-spots have been used as a reference frame that is believed to provide longitudes as well as latitudes for a global reassembly, forming a so-called absolute reference frame (Duncan, 1981; Müller et al., 1993). The paleomagnetic reference and hot-spots reference frames agree within the limits of error for much of Cenozoic time, then gradually diverge for reasons that are not clear (Livermore et al., 1988).

Paleoreconstructions

Paleoreconstructions attempt to show where the oceans and continents were in the geological past. That this is possible is due to several effects: (1) conservation of continental crust during plate motions; (2) the record of Mesozoic and Cenozoic continental separation in the intervening ocean-floor; and (3) the record of changes in continental latitude and orientation in *Paleomagnetism, Principles*.

Conservation of continental shapes

The extension on passive continental margins is probably about 100 km for a margin that is 200 km wide at the present-day, such as parts of the eastern North American margin (e.g., Sawyer, 1985). In other areas, the extension may be much higher: Powell et al. (1988) estimated a total of 360 km extension across the Australia–Antarctica margin before the formation of ocean-floor (180 km) equivalent to 1.6° of latitude for each margin, assuming symmetric extension.

To a good approximation, continental shapes on a global scale are conserved during plate motions. In detail this is clearly not the case. For example, when continents separate the passive margins have been stretched. When two continents converge, the continental lithosphere of one continent overrides that of the other, which is then partially subducted. But because continental lithosphere is less dense than the underlying mantle, it cannot be subducted to any great depth. Thus the continental crust in the collisional zone becomes thickened and the area of continental crust decreases. In the case of the collision between India and Asia, the Tibetan plateau, and the Himalayas may represent a loss of continental area in a strip that may be more than 500 km wide (Coward et al., 1988; Shackleton, 1988). As one goes back in time, the subducted Indian crust should be pulled out from under Eurasia and added to the Indian continent. Similar adjustments, but on a generally smaller scale, are necessary to the shapes of all continents caught up in collision zones, but are rarely made.

The continental shapes used for reconstructions generally show the edges of continents at about 2,000 m water depth. This shape is unfamiliar where there is a wide shallow sea between the 2 km submarine bathymetry contour and the coastline. To aid in recognition, the present-day coastline is commonly shown on continents, but the coastline of the time concerned may be quite different, as well as being very difficult to pin down.

Record of continental separation in the ocean-floor

The ocean-floor generated during the break-up of Pangea and the creation *of* the Atlantic, India, Antarctic, and

Arctic Oceans is still mostly preserved. Successively older oceanic transform faults, fracture zones, and ocean-floor magnetic anomalies and the continental edges themselves can be fitted together to give the Euler rotations needed to reposition all the major continents to a high degree of precision for most of Mesozoic and all of Cenozoic time, or roughly back to 200 Ma. The net results are paleocontinental reconstructions, that is, a display of the relative positions of the continents in the past (Smith et al., 1973).

Paleozoic and Precambrian composites

For pre-Mesozoic time the only ocean-floor that remains is tectonically highly deformed. Thus Paleozoic and Precambrian global "maps" are made by geographically repositioning individual continents using paleomagnetism. The uncertainties in paleomagnetic poles are considerable, particularly for Precambrian time. Although the order in which the continents are arranged on the globe is known, at least for Paleozoic time, the longitude separations of adjacent continents are not. These separations are subjectively estimated from evidence such as the distribution of fossils, tectonic effects, and the like. The results have been called composites, rather than maps, to emphasize the fact that they include qualitative data (Smith et al., 1973). The Precambrian has few fossils that provide an accurate indication of age and only scattered age determinations. Their absence, together with the absence of ocean-floor data and the uncertainties in pole positions, means that there are no generally agreed composites for most of Precambrian time. The Precambrian is still a veritable terra incognita.

Paleo-plate reconstructions

As noted above, a *global paleoreconstruction* is a reassembly of the major continents (and oceans) relative to one another at some time in the past. To turn this into a *paleo-plate reconstruction*, one needs to add the plate margins of the time concerned. For Jurassic and younger periods the former positions of ocean ridges are known from the ocean-floor record in the Atlantic, Indian, and Southern Oceans, but much of the Pacific ocean-floor has been subducted and for these areas former ridge positions have to be estimated. For Triassic and older periods the positions of former ocean ridges is largely a matter of informed guesswork (e.g., Stampfli and Borel, 2002, 2004).

Orogenic belts, that is, those areas made up of deformed, metamorphosed, and igneous rocks, mark the former positions of convergent margins. However, the margins are commonly difficult to locate precisely and many orogenic belts include more than one former convergent margin, together with the locations of former oceans that have since been subducted. Thus although one can join former ridges to orogenic belts to make a sketch plate boundary map for the time concerned, this map is necessarily imprecise.

Precambrian *global paleoreconstructions* are generally schematic (e.g., Collins and Pisarevsky, 2005). Because paleo-plate reconstructions build on an initial global reassembly, most Paleozoic and all Precambrian paleo-plate reconstructions are essentially cartoons that show the kinds of plate boundaries that may have existed at a given time but whose locations may have considerable errors.

Conclusions

The ocean-floor magnetic anomalies, transform faults, and fracture zones, together with the paleomagnetic frame allow very precise global Cenozoic and Mesozoic maps to be made. The inferred relative longitudes of Paleozoic and Precambrian continents depend on qualitative data, giving rise to poorly defined "composites." Fossils enable precise dating of Paleozoic features that help in the construction of composites, but such precision is not obtainable from Precambrian fossils, giving rise to considerable uncertainties in all Precambrian reconstructions. How to convert these global paleoreconstructions into verifiable paleo-plate reconstructions is a largely unsolved problem for pre-Mesozoic time.

POROELASTICITY

Ran Bachrach
Geophysics and Planetary Sciences Department, Tel Aviv University, Tel Aviv, Israel

Definition

Poroelasticity is a joint formulation for the behavior of a solid–fluid coupled porous system. Poroelasticity describes the behavior of porous continuum and pore fluid with respect to applied displacements and stresses. Poroelasticity jointly treats the solid frame and pore fluid to calculate changes in pore pressure, solid displacements, and fluid displacements due to stresses and displacements associated with external or internal processes.

The theory of poroelasticity is based on the work of Terzaghi, 1941; Biot, 1941, 1956a, b, 1962; and Gassmann, 1951. Poroelasticity is often called Biot theory as the work of M. A. Biot is considered to establish the complete foundation for the theory.

Basic concepts

Consider a connected network of pores fully saturated with fluid. The following are basic concepts that form the basis for the theory of poroelasticity.

Drained and undrained deformation

For a fully saturated porous material, we consider two fundamental states (or thought experiments): *Drained* and *undrained* (sometimes these are called *jacketed* and *unjacketed* conditions).

Drained conditions are achieved when pore pressure in a representative elementary volume (REV) is in equilibrium with the surrounding throughout the deformation of the saturated porous medium. A special case (described as a lab experiment) is when pore pressure and fluid can freely defuse in and out of the sample during the deformation process. Undrained (or jacketed) conditions refer to the condition in which the boundary of the porous solid (REV) is impermeable and pore fluid cannot exit the rock during the deformation process.

Physical measurements on both states (laboratory measurements) will determine the poroelastic coefficients of the rock. Often "dry conditions" are associated with the drained experiment. In poroelasticity the term "dry" elastic modulus refers to the drained experiment and not the elastic modulus when the material is dry.

Linear stress–strain formulation for poroelastic media

Consider the displacement vector in the solid $\mathbf{u} = [u_x, u_y, u_z,]$ and the average fluid displacement vector in the pore space $\mathbf{U} = [U_x, U_y, U_z,]$.

The volume of fluid displaced through a unit area normal to the x, y, z, direction is $\phi\mathbf{U}$ and the fluid displacement field is $\mathbf{w}$. The isotropic poroelastic stress–strain relations that relate stress, σ, and pore pressure, P, to displacement and strain, e, can be written in an abbreviated notation as:

$$\sigma_{ij} = 2\mu e_{ij} + \delta_{ij}(\lambda_c\theta - \alpha M\zeta)$$
$$P = -\alpha M\theta + M\zeta$$
$$\theta = \nabla\cdot\mathbf{u}, \quad \zeta = \varphi\nabla\cdot(\mathbf{u}-\mathbf{U})$$

where λ_c is the lame's coefficient for the closed (undrained) system and μ is the shear moduli. Note that the shear strain and stress are not affected by pore pressure and fluid presence. M, α are the two poroelastic constants associated with the poroelastic stress–strain formulation. M is known as Biot modulus, or P wave modulus, and relates dry response to saturated response as follows:

$$\lambda_C = \lambda_{\text{dry}} + \alpha^2 M,$$
$$\frac{1}{M} = \frac{\alpha-\varphi}{K_0} + \frac{\varphi}{K_f}.$$

where K_f is the pore fluid bulk modulus and φ is the porosity. α is the Biot parameter and is defined as:

$$\alpha = 1 - K_{\text{dry}}/K_0$$

where K_{dry} is the bulk modulus of the rock measured under drained conditions and K_0 is the bulk modulus of the frame mineral.

Note that when the system is jacketed, that is, $\zeta = 0$ so there is no relative displacement between the fluid and matrix, the pore pressure and the total stress are related and the bulk modulus is defined in terms of "closed" elastic properties.

When the matrix is open, the assumption is that there is a constant pore pressure in the system (pore pressure is in equilibrium with the surroundings) and thus fluid can flow freely in and out of the system. One special case of such conditions is when the pore pressure is equal to zero. The term "dry" frame conditions often refers to the states of zero pore pressure.

The poroelastic linear stress–strain relation can be written in terms of pore pressure as the coupling variable rather than the relative fluid displacement (or divergence). A popular form of the linear isotropic poroelastic stress–strain relations is given by:

$$\sigma_{ij} + \alpha P\delta_{ij} = 2\mu e_{ij} + \lambda_{dry}\theta\delta_{ij}$$
$$\zeta = (1/M)P + \alpha\theta$$

Note that the pressure direction here is assumed to be negative, for example, the pore pressure resists a positive confining stress that pushes the grains together.

The above equation can be written as an equivalent linear elasticity relation by substituting the total stress with Biot effective stress $\sigma^*_{ij} = \sigma_{ij} + \alpha P\delta_{ij}$ as:

$$\sigma_{ij}* = 2\mu e_{ij} + \lambda_{dry}\theta\delta_{ij}$$
$$\zeta = (1/M)P + \alpha\theta$$

In terms of the differential pressure (also known as Terzaghi's effective stress or just the "effective" stress) defined as $\sigma'_{ij} = \sigma_{ij} + P\delta_{ij}$ the linear stress–strain relations are given by:

$$\sigma_{ij}' - (1-\alpha)P\delta_{ij} = 2\mu e_{ij} + \lambda_{dry}\theta\delta_{ij}$$
$$\zeta = (1/M)P + \alpha\theta$$

When $\alpha = 1$ (soft materials where $K_{dry} << K_0$) the Biot effective stress is equal to the differential stress (often called Tarahzagi's effective stress). Simple derivation of Biot's effective stress law is given by Nur and Byerlee, 1971.

Gassmann's equation and fluid substitution

Gassman's equation (Gassmann, 1951) relates the elastic constant of saturated material in closed or undrained state to the drained or open conditions. In its isotropic form, Gassmann's equation can be written as:

$$\frac{K_{sat}}{K_0 - K_{sat}} = \frac{K_{dry}}{K_0 - K_{dry}} + \frac{K_{fl}}{\varphi(K_0 - K_{fl})}$$
$$\mu_{sat} = \mu_{dry}$$

where K_{sat} refers to the saturated bulk modulus of the closed system. The shear modulus for the open system (dry) and the closed system are the same $\mu_{sat} = \mu_{dry}$ as fluid does not contribute to the shear stiffness of the system. Gassman's equation can be derived directly from Biot's equations or from basic elasticity considerations by accounting for mass conservation of pore fluid in a closed system. Gassmann's equation assumes that pore fluid is in equilibrium throughout the sample and that the pore fluid does not interact with the mineral frame. For more information see Mavko et al. (1998). Anisotropic extension to Gassmann's equation is derived by Brown and Korringa (1975) in terms of the elastic compliance tensor:

$$S^{dry}_{ijkl} - S^{sat}_{ijkl} = \frac{\left(S^{dry}_{ij\alpha\alpha} - S^{0}_{ij\alpha\alpha}\right)\left(S^{dry}_{kl\alpha\alpha} - S^{0}_{kl\alpha\alpha}\right)}{\left(S^{dry}_{\alpha\alpha\beta\beta} - S^{0}_{\alpha\alpha\beta\beta}\right) + (\beta_{fl} - \beta_0)}$$

where $S^{dry}_{ijkl}, S^{sat}_{ijkl}$ are the saturated and dry 4th order compliance tensors, β_{fl} is the fluid compressibility (or inverse bulk modulus), and β_0 is the compressibility of the mineral frame.

Fluid substitution

One of the many practical applications of Gassmann's equation is the ability to predict the elastic modulus of a known rock saturated with different fluids. One example is the prediction of seismic velocity of a gas-saturated sediment given the seismic velocity of the same sediment saturated with brine. This fluid substitution scheme is readily derived from Gassmann's equation:

$$\frac{K_{sat1}}{K_0 - K_{sat1}} - \frac{K_{fl1}}{\varphi(K_0 - K_{fl1})} = \frac{K_{sat2}}{K_0 - K_{sat2}} - \frac{K_{fl2}}{\varphi(K_0 - K_{fl2})}$$
$$\mu_{sat2} = \mu_{sat1}$$

Skempton coefficient

If the system is closed (jacketed), the pore pressure and the external stress are directly related as:

$$\theta = \frac{(\bar{\sigma} - \alpha P)}{K_{dry}} \rightarrow P = \frac{1}{\alpha}\left(\bar{\sigma} - K_{dry}\theta\right), \quad \bar{\sigma} = \sigma_{kk}/3$$

$$\theta = e_{kk} = \frac{\bar{\sigma}}{K_{sat}} \rightarrow P = \frac{1}{\alpha}\left(K_{sat} - K_{dry}\right)\theta \rightarrow P = B\bar{\sigma},$$
$$B = \frac{1}{K_{sat}}\left(\frac{K_{sat} - K_{dry}}{\alpha}\right)$$

B is known as the Skempton coefficient and is one of the most measured laboratory quantity.

Three-dimensional consolidation

Poroelasticity provides the analytical framework for three-dimensional consolidation of soils and sediments as follows:

Darcy's law relates fluid motion to pore pressure gradient and gradient of the gravitational potential G and can be written as

$$\partial \mathbf{w}/\partial t = \frac{-\boldsymbol{\kappa}}{\eta}\nabla P - \frac{-\boldsymbol{\kappa}}{\eta}\nabla G$$

where $\boldsymbol{\kappa}$ is the permeability tensor and η is the fluid viscosity.

The total stress field must satisfy the equilibrium equations (neglecting the inertia terms)

$$\sum \frac{\partial \sigma_{ij}}{\partial x_j} + \rho b_i = 0,$$

where b_i is the body force acting on the media (Gravity) and will be neglected in the following expressions. Combining Darcy's law with the equilibrium equation, we obtain the general consolidation equations that couple fluid and solid displacements of the vectors $\boldsymbol{u}$ and $\boldsymbol{w}$ as:

$$2\sum_{ij}\frac{\partial}{\partial x_j}(\mu e_{ij}) + \frac{\partial}{\partial x_j}(\lambda_C\theta - \alpha M\zeta) = 0$$

$$\frac{\partial \mathbf{w}}{\partial t} = \frac{\boldsymbol{\kappa}}{\eta}\nabla(\alpha M\theta - M\zeta)$$

for the special case where the poroelastic coefficients are constant, the equation of motion is written (after application of the divergence operator and some algebra) as:

$$(2\mu + \lambda_C)\nabla^2\theta - \alpha M\nabla^2\zeta = 0$$

$$\frac{\partial \zeta}{\partial t} = \frac{\boldsymbol{\kappa}}{\eta}M_C\nabla^2\zeta$$

$$M_C = M(2\mu + \lambda)/(2\mu + \lambda_C)$$

The latter equation can be written in terms of pore pressure as the familiar diffusion equation with an added volumetric solid deformation term:

$$\frac{\partial P}{\partial t} - \frac{\boldsymbol{\kappa}}{\eta}M\nabla^2 P = -\alpha M\frac{\partial \theta}{\partial t}$$

This equation is used extensively in the study of soil consolidation, compacting reservoirs, and stress–fluid coupled processes in the earth.

Dynamic poroelasticity and wave propagation in saturated porous medium

The wave equation in saturated porous media is derived by adding the inertia terms to the equation of motion. For isotropic media with isotropic permeability, it can be written in terms of fluid and solid displacement vectors:

$$2\sum_{ij}\frac{\partial}{\partial x_j}(\mu e_{ij}) + \frac{\partial}{\partial x_i}(\lambda_C\theta - \alpha M\zeta) = \frac{\partial^2}{\partial t^2}\left(\rho u_i + \rho_f w_i\right)$$

$$\frac{\partial}{\partial x_i}(\alpha M\theta - M\zeta) = \frac{\partial^2}{\partial t^2}\left(\rho_f u_i + m w_i\right) + \frac{\eta}{k}\frac{\partial w_i}{\partial t}$$

where $m = \left(\varphi\rho_f + \rho_a\right)/\varphi^2$ is the mass coupling parameters, and $\rho_a = \varphi\rho_f(a - 1)$ is the apparent density that relates the dynamic tortuosity to fluid density and rock porosity (Berryman, 1980).

The equations of motion can be written in terms of rotation-free and dilatation-free equations similar to the equation for P and S wave in linear elasticity. However, unlike linear elasticity, in isotropic linear poroelastic media, there are two P waves that travel with two different velocities and a single shear wave velocity. The two P wave velocities are known as the fast and slow Biot wave velocities and have been observed in the laboratory (Plona, 1980). When the fluid viscosity is zero, the two P waves are not attenuated but when the fluid viscosity is finite the slow Biot wave is highly attenuated and quickly decays into pore pressure diffusion. In his 1956 papers, Biot discusses many details associated with wave propagation in the low frequency range, which is the appropriate range for seismic investigation, and the high frequency range, which covers the ultrasonic case.

Definition

Dynamic elasticity allows predicting and explaining the propagation of perturbations in solids. The contributions of Newton, Hooke, Cauchy, Poisson, and Navier laid the basis of dynamic elasticity by the beginnings of the nineteenth century. It is possible to solve the equation of motion in terms of displacements using potentials which are solutions of the wave equations for longitudinal (or compression) and transverse (or shear) waves. The waves that propagate in fluids like water and air are called acoustic waves. Plane waves are the simplest solutions of wave equation as discovered by D'Alembert. In conjunction with Fourier transforms, plane waves are central in the solutions of a variety of problems like waves in layered media and surface guided waves.

Introduction

Waves are part of our existence and manifest themselves at many scales and with an enormous variety of effects. Perhaps the most familiar waves could be those generated in a pond after a pebble is thrown. Other waves that we cannot see are the sound waves that propagate in the air. They allow both hearing and speech. Elastic waves are of the same type of acoustic waves but can be also of transverse nature as they can propagate in solids. In what follows we establish the fundamental equations and delineate solution strategies. Recent findings are pointed out.

Newton's second law

During the second half of eighteenth century, Isaac Newton developed groundbreaking ideas of mechanics and optics; we can credit him the invention of calculus although this has been a matter of bitter debate with Leibnitz and his followers. Regarding the motion of bodies, his descriptions enabled the industrial revolution. Consider a particle with mass m subjected to loads. Second Newton's law establishes that:

$$\sum \mathbf{F} = m\ \mathbf{a}, \tag{1}$$

which means that the sum of forces equals the product of mass and acceleration. In this equation boldface letters represent vectors. For instance, the acceleration vector $\mathbf{a} = (a_1, a_2, a_3)^T$ has components a_j for the three directions x_j (with j = 1, 2, and 3). The upper index T means the transpose operation.

As velocity is the change of displacement with time, acceleration is the change of velocity with time. Therefore, acceleration is the second derivative of displacement **d** with respect to time and is written as:

$$\mathbf{a} = \frac{\mathrm{d}^2\mathbf{d}}{\mathrm{d}t^2}. \tag{2}$$

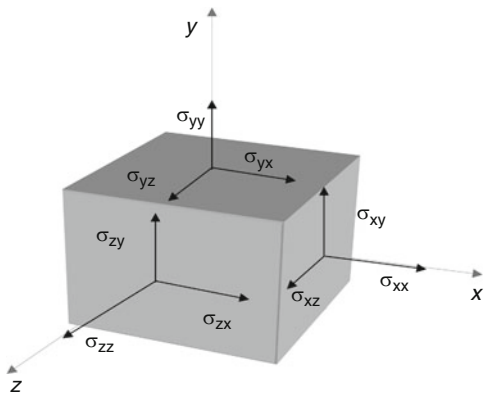
Newtonian mechanics explained the motion of both celestial bodies and everyday objects. By means of the methods of calculus, developed significantly by Newton himself, these ideas where applied to deformable solids. For a successful application a relationship between forces and displacements, a constitutive law, is needed.

Cauchy's stress and strain

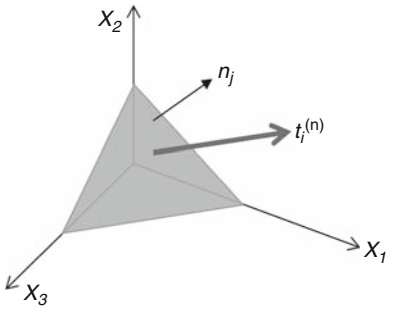
Assuming Cartesian coordinates and studying equilibrium within a continuum we can state Newton's second law per unit volume in modern form using both index notation and partial derivatives with respect to particular variables. This is possible thanks to the concept of stress tensor developed by Cauchy. Therefore we can write

$$\frac{\partial \sigma_{ji}}{\partial x_j} + f_i = \rho \frac{\partial^2 u_i}{\partial t^2}, \tag{3}$$

where $u_i(\mathbf{x},t)$ = displacement vector of point **x** (represented by x_j, with j = 1, 2, and 3, respectively, or by x, y and z) and time t, $\sigma_{ji}(\mathbf{x},t)$ = stress tensor components (force per unit area) on the faces of a particle oriented along the axis j (see Figure 1), f_i = body force pr unit volume, ρ = mass density, and the right hand term is precisely the mass per unit volume multiplied by acceleration. Moreover, it is possible to show that in order to guarantee equilibrium on moments the stress tensor must be symmetric (i.e., $\sigma_{ji} = \sigma_{ij}$). The equilibrium at a given boundary subjected to tractions or forces per unit area leads to Cauchy equation $\sigma_{ij} n_j = t_i^{(\mathbf{n})}$ which relates the stress tensor at a point with traction associated to a given normal vector as depicted in Figure 2.



Propagation of Elastic Waves: Fundamentals, Figure 1 Stress components on the faces of a particle oriented along the axes *x*, *y*, and *z*.



Propagation of Elastic Waves: Fundamentals, Figure 2 Traction vector on a plane with normal n_j.

The motion at point $\mathbf{x} + d\mathbf{x}$ allows for a first order description if it is within a small neighborhood of $\mathbf{x}$ and can be expressed in terms of values at $\mathbf{x}$ by means of:

$$\begin{aligned} u_i(\mathbf{x}+d\mathbf{x},t) &= u_i(\mathbf{x},t)+\frac{\partial u_i}{\partial x_k}dx_k \\ &= u_i(\mathbf{x},t)+\frac{1}{2}\left(\frac{\partial u_i}{\partial x_k}+\frac{\partial u_k}{\partial x_i}\right)dx_k \\ &\quad +\frac{1}{2}\left(\frac{\partial u_i}{\partial x_k}-\frac{\partial u_k}{\partial x_i}\right)dx_k. \end{aligned} \tag{4}$$

The first and third terms of last equality exhibit the motion at $\mathbf{x} + d\mathbf{x}$ as the composition of a rigid body translation and rotation, respectively, which do not produce any strains. The middle term really implies strains and is the product of the Cauchy infinitesimal strain tensor,

$$e_{ik}=\frac{1}{2}\left(\frac{\partial u_i}{\partial x_k}+\frac{\partial u_k}{\partial x_i}\right), \tag{5}$$

and the spatial differentials dx_k. This tensor is a natural candidate for a constitutive law.

Hooke's law

Solids undergo deformations when subjected to loads. If deformations are small a linear relationship can be assumed. This is what Robert Hooke did when studying springs. To secure his finding he even wrote an anagram: *ceiiinosssttuv* to hide the Latin sentence: *ut tensio sic vis* which literally means that the displacement (*vis*) is proportional to the force (*tensio*).

Nowadays, we express Hooke's law simply by writing $F = k \times \delta$ where $F =$ force, $k =$ spring constant or stiffness, and $\delta =$ displacement. Hooke and Newton were contemporary, but not very friendly to each other. Hooke claimed Newton stole from him the notion of gravitational force as proportional to inverse square of distance; Newton ignored him. Actually, such an idea was implicit in Kepler's laws and many suspected it, but only Newton gave a precise quantitative account.

For linear elastic materials the more general constitutive law is

$$\sigma_{ij}=c_{ijpq}\,e_{pq}. \tag{6}$$

This is Hooke's law expressing a linear relationship between stresses σ_{ij} and strain e_{pq} at a point. Very likely, Hooke never imagined such an extension. Technically speaking these are second order tensors. Both are due to Cauchy.

Elastic properties appear in the tensor c_{ijpq} which is of fourth order. At a given point, it represents 81 entries but after recognizing the symmetry of the stress and strain tensors we have 36 independent constants. Energy considerations allow having only 21 constants for a general anisotropic solid. If the medium is isotropic we have

$$c_{ijpq}=\lambda\delta_{ij}\delta_{pq}+\mu(\delta_{ip}\delta_{jq}+\delta_{iq}\delta_{jp}), \tag{7}$$

where $\delta_{ij} =$ Kronecker delta (=1 if $i = j$; =0 if $i \neq j$; note that $\delta_{jj} = 3$) and the parameters $\lambda, \mu =$ Lamé constants. Equation 7 shows that only two independent constants are needed to describe a linear isotropic solid.

Navier's equation

For isotropic materials Hooke's law can be written as

$$\sigma_{ij}=\lambda e_{kk}\delta_{ij}+2\mu e_{ij}. \tag{8}$$

Substituting Equation 8 in Equation 3 and considering the definition of strain in Equation 5, we can write the governing equation for motion within an elastic medium:

$$\mu\frac{\partial^2 u_i}{\partial x_j\partial x_j}+(\lambda+\mu)\frac{\partial^2 u_j}{\partial x_j\partial x_j}+f_i=\rho\frac{\partial^2 u_i}{\partial t^2}. \tag{9}$$

This is Navier's equation. It is possible to show that under very general circumstances the homogeneous solution (for $f_i = 0$) can be expressed by means of:

$$u_i=\frac{\partial\phi}{\partial x_i}+\varepsilon_{ijk}\frac{\partial\psi_k}{\partial x_j} \quad \text{with} \quad \frac{\partial\psi_k}{\partial x_k}=0. \tag{10}$$

Here $\varphi = \varphi(\mathbf{x}, t)$ and $\psi_k = \psi_k(\mathbf{x}, t)$ are functions called potentials (see Achenbach, 1973). The first is a scalar while the second is a vector. These functions must be solutions of the homogeneous wave equations:

$$\frac{\partial^2\phi}{\partial x_j\partial x_j}=\frac{1}{\alpha^2}\frac{\partial^2\phi}{\partial t^2} \quad \text{and} \quad \frac{\partial^2\psi_k}{\partial x_j\partial x_j}=\frac{1}{\beta^2}\frac{\partial^2\psi_k}{\partial t^2}, \tag{11}$$

respectively. This is supported by Lamé's theorem (for details see Aki and Richards, 1980). Here $\alpha=\sqrt{(\lambda+2\mu)/\rho}$ and $\beta=\sqrt{\mu/\rho}$ are the velocities of compressional (or P) and shear (or S) waves, respectively. The existence of two types of waves was suspected earlier thanks to experiments that show light as transversely polarized waves. Poisson employed Newtonian intermolecular elastic forces and found theoretically the existence of P and S waves. His considerations lead him to conclude that $\alpha=\sqrt{3}\beta$. This happens when $\lambda = \mu$ (or

$v = 0.25$) and therefore, a medium with this property is called a Poisson solid.

D'Alembert solution of wave equation

For the linearly elastic, isotropic, homogeneous elastic medium, Navier's equation can be solved through the superposition of solutions of wave equation called potentials (see Aki and Richards, 1980). Therefore, our capability to solve the canonical equation of dynamic elasticity rests upon the ability to solve wave equation. This is subject of significant mathematical interest and many methods exist to look for solutions. Here we follow instead a quick, intuitive approach to solve the wave equation. In our opinion, the simplest solution is the one proposed by D'Alembert, whom was a disciple of the eighteenth century French Illustration. Extending his idea we can write

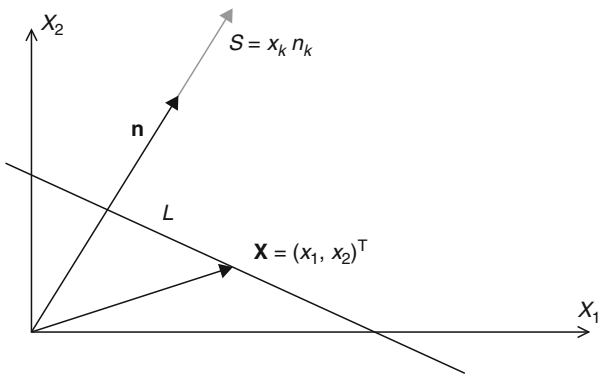
$$\phi(\mathbf{x},t) = f\left(t - \frac{x_k n_k}{\alpha}\right) + g\left(t + \frac{x_k n_k}{\alpha}\right), \tag{12}$$

which is a solution of a wave equation for almost any function f and g, propagating along the unit vectors n_k and $-n_k$, respectively. Equation 12 displays the beauty and power of D'Alembert solution. One powerful strategy is present in many methods and consists in sending explicitly plane waves in many directions.

This is what comes out after an exam of the arguments in Equation 12. Consider that $x_k n_k = s$ is the equation of a plane in 3D space with a distance s from the origin, measured along n_k. In vector notation we can write $\mathbf{x} \cdot \mathbf{n} = s$. This is the definition of a new coordinate s and is illustrated using the Cartesian system in 2D depicted in Figure 3. The line L corresponds to a constant value for s.

Fourier transforms and plane waves

In order to describe and generalize the power of the plane wave concept, consider the representation of a function



Propagation of Elastic Waves: Fundamentals,
Figure 3 Coordinate s along the vector **n**. Line L corresponds to a constant value for s.

$$f(t) = \frac{1}{2\pi}\int_{\infty}^{\infty} F(\omega)\exp(+i\omega t)\mathrm{d}\omega, \tag{13}$$

where $F(\omega)$ = Fourier transform of $f(t)$ given by

$$F(\omega) = \int_{-\infty}^{\infty} f(t)\exp(-i\omega t)\mathrm{d}t. \tag{14}$$

Equation 13 exhibits an arbitrary function in terms of continuous superposition of sines and cosines. This fundamental property can be practically exploited under the assumptions that signals are discrete and periodic. We have then a powerful tool: the Discrete Fourier Transform. Moreover, the Fast Fourier Transform (FFT) algorithm allows for efficient computation. With this powerful tool we are effectively holding infinity in our hands. As the variable t in Equation 13 is a dummy variable we can substitute it by the D'Alembert argument (t-s/c). Therefore, it is possible to write

$$\begin{aligned} f(t-s/c) &= \frac{1}{2\pi}\int_{-\infty}^{\infty} F(\omega)\exp[+i\omega(t-s/c)]\mathrm{d}\omega \\ &= \frac{1}{2\pi}\int_{-\infty}^{\infty} F(\omega)\exp[-i\omega s/c]\exp[+i\omega t]\mathrm{d}\omega. \end{aligned} \tag{15}$$

We first see D'Alembert argument at the complex exponential but then the contribution of the plane wave is given by the transfer function that multiplies the Fourier transform of signal. Let us consider the transfer function

$$\exp[-\mathrm{i}\omega s/c] = \exp[-\mathrm{i}(\omega/c)\mathbf{n}\cdot\mathbf{x}] = \exp[-\mathrm{i}\mathbf{k}\cdot\mathbf{x}], \tag{16}$$

which represents a harmonic plane wave propagating and identify that the wave vector $\mathbf{k} = (\omega/c)\mathbf{n}$ that gives the direction of propagation of the plane wave, where **n** is a unit vector ($n_1^2 + n_2^2 + n_3^2 = 1$).

It is possible to extend the idea that the unit vector **n** may have complex values then we have inhomogeneous plane waves. As an example of the significant representation power of generalized plane waves we can express a harmonic spherical wave as a superposition of both homogeneous and inhomogeneous plane waves using the Weyl integral (see Aki and Richards, 1980):

$$\frac{1}{R}\exp\left(-i\omega\frac{R}{c}\right) = \frac{1}{2\pi}\iint \frac{\exp(-ik_x x - ik_y y - \gamma|z|)}{\gamma}\mathrm{d}k_x\mathrm{d}k_y. \tag{17}$$

Here $\gamma = \sqrt{\omega^2/c^2 - k_x^2 - k_y^2}$ with the sign chosen so that Re $\gamma > 0$ and $R = \sqrt{x^2+y^2+z^2}$. Plane waves are

then building blocks to construct solutions for the half-space problems and layered media. They play a central role in seismology. Certainly, it is the success of a simple idea.

Green's function for homogeneous space

The Green's function is the displacement field produced within an elastic medium by a concentrated, impulsive unit load at a given point. For an infinite, homogeneous, isotropic, elastic medium Stokes found the analytical solution at the middle of the nineteenth century. More than 50 years later, at the eve of the twentieth century, Lamb (1904) found the solution for a vertical point load at the surface of a half-space. The solution for the horizontal load came again more than 50 years later (Chao, 1960).

If the body force is a unit concentrated impulsive it can be represented with Dirac's delta functions for space and time. Moreover, to specify the force direction we add Kronecker delta δ_{ij} (=1 if $i = j$, =0 for $i \neq j$). Therefore, we can define $f_i \equiv \delta_{ij}\delta(|\mathbf{x} - \xi|)\delta(t)$ and $u_i(\mathbf{x}, t) \equiv G_{ij}(\mathbf{x}, \xi; t)$ = Green's function for the infinite elastic domain. It is the displacement in direction i at $\mathbf{x}$ when a unit impulse is applied in direction j at point ξ.

The Green's function should satisfy Navier's equation, which can be written as

$$\mu\frac{\partial^2 G_{ij}}{\partial x_k \partial x_k} + (\lambda+\mu)\frac{\partial^2 G_{kj}}{\partial x_i \partial x_k} - \rho\frac{\partial^2 G_{ij}}{\partial t^2} = -\delta_{ij}\delta(|\mathbf{x} - \xi|)\delta(t). \tag{18}$$

On November 26th, 1849, G. G. Stokes read his paper on the Dynamical Theory of Diffraction. He intended to model a light source in the luminiferous Ether and assumed a force in an infinite domain. Based upon previous results of Poisson regarding Laplace equation, he obtained the exact solution for the displacement field due to a single force within the unbounded elastic medium. Without knowing it, he had conceived the first mathematical model of an earthquake. This solution (Stokes, 1849) can be expressed by means of

$$G_{ij}(\mathbf{x}, \xi; t) = \frac{1}{4\pi\mu r}\left\{f_1\gamma_i\gamma_j + f_2(\delta_{ij} - \gamma_i\gamma_j)\right\}, \tag{19}$$

where

$r = |\mathbf{x} - \xi| = \sqrt{(x_1 - \xi_1)^2 + (x_2 - \xi_2)^2 + (x_3 - \xi_3)^2}$

and $\gamma_j = (x_j - \xi_j)/r$ is the unit vector form ξ to $\mathbf{x}$. The functions f_1 and f_2 are given by

$$f_1(r, t) = \frac{\beta^2}{\alpha^2}\delta(t - r/\alpha) + 2\beta^2\int_{1/\alpha}^{1/\beta}\delta(t - r\kappa)\kappa d\kappa \tag{20}$$

and

$$f_2(r, t) = \delta(t - r/\beta) - \beta^2\int_{1/\alpha}^{1/\beta}\delta(t - \kappa r)\kappa d\kappa. \tag{21}$$

We can notice that Stokes' solution decays as $1/r$ and is modulated angularly by sines and cosines. It is remarkable that the longitudinal P-wave pulse has the same time dependence as the source followed by a similar transverse pulse with much larger amplitude. Between these main P and S arrivals we find a disturbance decaying more rapidly away from the source.

In the frequency domain (after applying Fourier transform) these functions can be written as follows:

$$f_1(r, \omega) = (\beta^2/\alpha^2)[1 - i2/qr - 2/q^2r^2]\exp(-iqr) + [i2/kr + 2/k^2r^2]\exp(-ikr) \tag{22}$$

and

$$f_2(r, \omega) = (\beta^2/\alpha^2)[i/qr + 1/q^2r^2]\exp(-iqr) + [1 - i/kr - 1/k^2r^2]\exp(-ikr). \tag{23}$$

Here $q = \omega/\alpha$ and $k = \omega/\beta$ are the wave numbers of P and S waves, respectively. If ω equals zero, the static case, we obtain the constants $f_1 = 1$ and $f_2 = (1 + \beta^2/\alpha^2)/2$ that correspond to the Kelvin solution for a unit static load in the full elastic space. The Stokes solution for the infinite space is frequently used in the integral BEM or IBEM formulations (see Bouchon and Sánchez-Sesma, 2007).

For a homogeneous or layered half-space, Fourier methods allow to formulate the problems in integral form. Obtaining the displacement and stress fields requires adequate discretization. A remarkable compendium of fundamental solutions is the one due to Kausel (2006).

The theory allows solving the homogeneous boundary conditions in terms of an eigenvalue problem. This lead to surface guided waves.

Green's function retrieval from correlations

If an elastic, inhomogeneous, anisotropic medium is subjected to isotropic, equipartitioned, illumination, the resulting field is said to be diffuse as its intensities are governed by a diffusion-like process. This may be easily argued if the role of multiple scattering is invoked. Under these circumstances, the Green's function can be retrieved from averaging cross-correlations of the recorded motions of such diffuse field (e.g., Weaver and Lobkis, 2004; Wapenaar, 2004; Sánchez-Sesma and Campillo, 2006; Gouédard et al., 2008).

The pioneering studies of Aki have contributed to the understanding of coda waves and seismic noise. Various scattering formulations have been developed in order to explain coda features (see Aki, 1957; Aki and Chouet, 1975; Sato and Fehler, 1998). When multiple scattering takes place, the intensities, which are related to energy densities, follow diffusion-like equations. These waves arrive at the receiver from different directions, sampling the medium along their paths.

When source and receiver are both at the same point, we have interesting consequences. From the observable side, the autocorrelation is proportional to the energy

density at a given point, and the imaginary part of the Green function at the source is finite because the singularity of the Green's function is restricted to the real part.

Thus, the directional energy densities at a point are proportional to the imaginary part of Green's function tensor components at the source itself, which is indeed the given point. The relationships among energy densities and its partitions have been recently studied by Perton et al. (2009) and Margerin et al. (2009). The Green´s function may be useful to imaging the subsurface structure at the site. In fact, the connection of the imaginary part of the Green´s function at the source with the optical theorem has been explored by Snieder et al. (2009).

For horizontally layered systems and 1D excitation, the relationship between reflection response and autocorrelation of surface motion was discovered by Claerbout (1968). An algorithm to identify reflection coefficients based upon Claerbout´s results was proposed by Scherbaum (1987). In fact, this is a single-station inversion method and, in principle, it allows imaging of the subsurface impedance structure. The idea was tested using small locally recorded earthquakes.

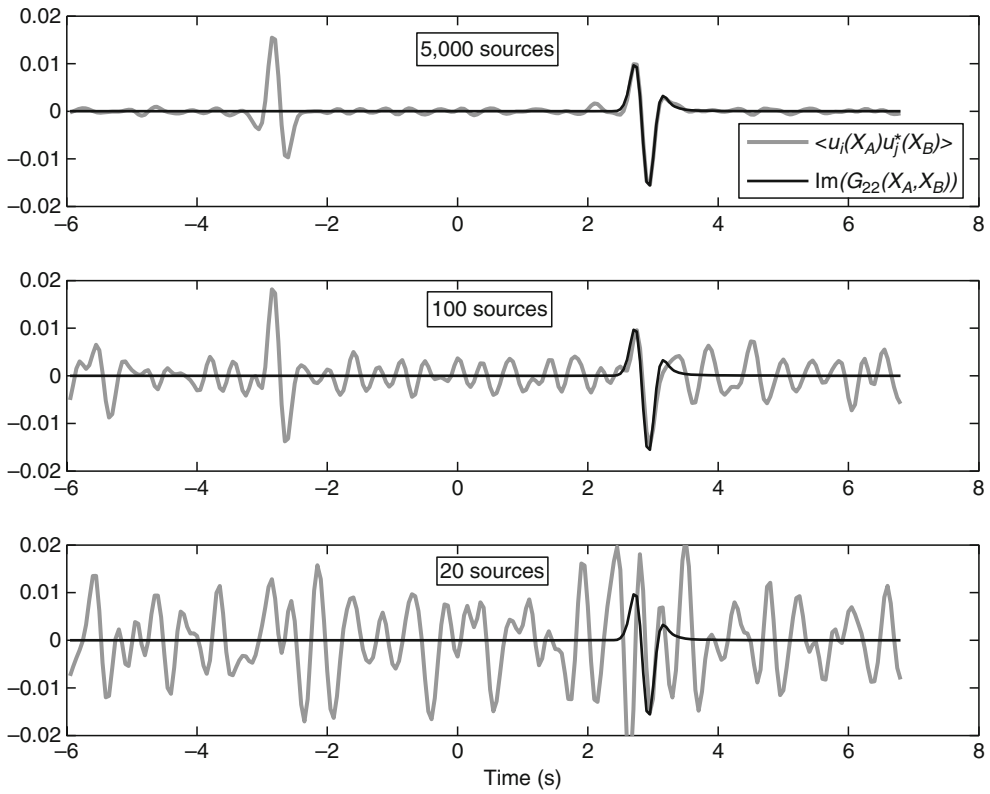
Seismic noise is produced by nearby, superficial low-strength sources that we will generically call microtremors. Noise sources are 3D in nature and have significant geometrical spreading. The relative sampling of the medium with respect to depth is considerably reduced due to this attenuation.

In what follows, we review the Green´s function retrieval from correlations of field fluctuations. For the layered medium with free surface overlaying a half-space we compute the imaginary part of the Green function when source and receiver coincide at the free surface.

It has been demonstrated (e.g., Weaver and Lobkis, 2004; Wapenaar, 2004; Sánchez-Sesma et al., 2008) that if a 3D diffuse harmonic displacement vector field $u_i(\mathbf{x}, \omega)$ is established within an elastic medium, the average cross-correlations of such motions at points $\mathbf{x_A}$ and $\mathbf{x_B}$ can be written as:

$$\left\langle u_i(\mathbf{x_A}, \omega) u_j^*(\mathbf{x_B}, \omega) \right\rangle = -2\pi E_S k^{-3} \times \mathrm{Im}\left[G_{ij}(\mathbf{x_A}, \mathbf{x_B}, \omega)\right]. \tag{24}$$

In this equation, the Green's function $G_{ij}(\mathbf{x}_\mathrm{A}, \mathbf{x}_\mathrm{B}, \omega) =$ displacement at $\mathbf{x}_\mathrm{A}$ in direction i produced by a unit harmonic point force acting at $\mathbf{x}_\mathrm{B}$ in direction j, $\omega =$ circular frequency, $k = \omega/\beta =$ shear wavenumber, $\beta =$ shear wave propagation velocity, and $E_S = \rho\omega^2 S^2 =$ average energy density of shear waves ($\rho =$ mass density,



Propagation of Elastic Waves: Fundamentals, Figure 4 Correlations are computed with 20, 100, and 5,000 sources, for the scalar case. We can see that as the number of sources considered increases the retrieval, the G_{22} function is better achieved.

S^2 = average spectral density). Note that the asterix implies the complex conjugate and the angular brackets mean azimuthal average. Equation 1 is the analytical consequence of a correlation-type elastic representation theorem and has been verified recently in canonical examples of a full space (Sánchez-Sesma and Campillo, 2006) and for an elastic inclusion embedded in a full space and for more general circumstances (Sánchez-Sesma et al., 2006, 2008). For the scalar case it is possible to compare the Green´s function retrieval from correlations. In Figure 4, we show how the G_{22} function is retrieved taking into account 20, 100, and 5,000 sources. The correlations are computed with these numbers of sources, and we can see that as the number of sources considered increases, the retrieval is better achieved.

Energy densities at given points and directions

In what follows we compute the theoretical energy density at a given point $\mathbf{x_A}$. In order to do so we rewrite Equation 24 assuming $\mathbf{x_A} = \mathbf{x_B}$:

$$E(\mathbf{x_A}) = \rho\omega^2 \langle u_m(\mathbf{x_A}) u_m^*(\mathbf{x_A}) \rangle = -2\pi\mu E_S k^{-1} \times \mathrm{Im}[G_{mm}(\mathbf{x_A}, \mathbf{x_A})], \quad (25)$$

where $\mu =$ shear modulus. The energy density of shear waves E_S is a measure of the strength of the diffuse illumination. We see that the total energy density at a point is proportional to the imaginary part of the trace of the Green tensor for coincident receiver and source.

Note that this is possible because the singularity of Green's function is restricted to the real part. The imaginary part is finite and regular and represents the rate of energy injected by the unit harmonic load at that point. This quantity "detects" the energy that goes back to the source-receiver and may be used to imaging. Equation 25 is valid even if the summation convention is ignored. In that case $E(\mathbf{x_A}) \equiv E_m(\mathbf{x_A})$and the energy density is associated to a particular direction (for discussions see Perton et al., 2009 and Snieder et al., 2009).

To illustrate these ideas from theoretical point of view let us consider again the Stokes' (1849) solution. It is possible to show that

$$\mathrm{Im}[G_{ij}(\mathbf{x}, \mathbf{x})] = -\frac{\omega}{12\pi\rho}\left(\frac{1}{\alpha^3} + \frac{2}{\beta^3}\right)\delta_{ij}. \quad (26)$$

This shows that the power injected into the infinite elastic medium by the unit harmonic load grows linearly with frequency, as expected, it is an isotropic tensor, and the energy labeled as being related to P and S waves is injected into the medium with the proportions given by the principle of equipartition for elastic waves $E_S/E_P = 2\alpha^3/\beta^3$. This is more than a fortuitous coincidence. It shows that an uncorrelated set of random forces uniformly distributed within a medium (simulating multiple scattering) can produce an equipartitioned elastic field, at least in some part of the elastic domain.

Summary

In this article dynamic elasticity fundamentals are discussed. This theory is useful to explain the propagation of elastic waves in solids. Newton's second law allowed writing the equilibrium equation within an elastic medium. Cauchy developed the concept of stress and strain while Hooke's idea to relate linearly stress and strain lead to Navier's equation which is in fact Newton's equation in terms of displacements. It can be solved using solutions of wave equations for P and S waves, discovered by Poisson. Both static and dynamic elasticity were developed in the nineteenth century. However, the first synthetic seismogram was computed at the beginning of the twentieth century. Plane waves are the simplest solutions of wave equation and are a key component to study elastic wave propagation in layered media and surface waves. The Green's functions in time or frequency domain are the solutions for an impulsive or harmonic point load, respectively. The canonical case of an infinite homogeneous space is due to Stokes (1849) and is given here.

It has been recently discovered that the Green's function can be retrieved from averaging correlations of a diffuse field. This applies for a very general medium. The relationship of energy and Green function allows establishing identities between average normalized measurements (correlations or autocorrelations) and intrinsic properties of the medium (imaginary part of Green function between two points or at the source itself) and opens the door to use noise measurements to construct virtual sources and do medium characterizations of unprecedented quality.

RADIOACTIVITY IN EARTH'S CORE

V. Rama Murthy
Department of Earth and Planetary Sciences, Institute of Meteoritics, University of New Mexico, Albuquerque, NM, USA

Definition

Lithophile. Affinity for silicates
Chalcophile. Affinity for sulfur
Siderophile. Affinity for metals
BSE. Bulk Silicate Earth refers to primitive silicate material in the Earth from which the core is separated. Corresponds to the total mantle + crust system of silicates now.
P, T. Pressure, temperature
TW. Terawatt. 1 TW = 10^{12} W
D_K. Concentration of K in Fe-alloy/Concentration of K in silicate melt.
GPa. GigaPascal =10^9 Pascals (1 GigaPascal is equivalent to 10 kilobars of pressure)
Geoneutrinos. Electron antineutrinos produced inside the Earth due to β^- decay of naturally occurring radioactive elements in the Earth.
Oxygen fugacity, fO_2. A measure of the oxidation state of a system irrespective of the presence or absence of a gas phase containing free oxygen.
IW buffer. Iron–Wustite buffer. A synthetic redox mineral reference buffer representing the oxygen fugacity of a system where Fe_{metal} is in equilibrium with FeO (wustite), according to the reaction $Fe_{metal} + ½O_2 =$ FeO (wustite). The IW buffer corresponds to log $fO_2 = -12.5$ at 1,200°C.

Introduction

The Earth is a thermal engine driven by its internal heat. The bulk of this heat is produced by the elements potassium (K), uranium (U), and thorium (Th) through the radioactive decay of their isotopes ^{40}K, ^{235}U, ^{238}U, and ^{232}Th. Table 1 lists the atomic percentages, radioactive decay constants, half-life, and heat production characteristics of these radioactive isotopes.

Because K, U, and Th are strongly lithophile, differentiation of the Earth into a metallic core and a silicate primitive mantle (BSE) will have partitioned them overwhelmingly into the BSE. A long-standing convention is that the radioactivity of the BSE represents the total radioactivity of the Earth and that the metallic core has no radioactivity (e.g., McDonough, 1999, 2003). However, radioactivity in the core has come into focus due to recent developments in three areas: (1) modern high P, T experiments on the metal-silicate partitioning behavior of K and U; (2) theoretical and experimental advances in our understanding of the electronic structure of potassium under conditions of high pressure and temperature; and (3) thermal models of the core that satisfy the size and age of the inner core and the energy to sustain geomagnetic field. Also, it is known that the heat due to radioactivity in BSE, about 19 TW (e.g., compiled in Lodders and Fegley, 1998), falls short of the surface heat flux estimated at 30–44 TW (Lee, 1970; Hofmeister and Criss, 2005; Pollack et al., 1993). This shortfall is suggestive of either a higher than BSE radioactive content of the mantle and/or radioactivity in the core (see Murthy, 2006). In the discussion below, new experimental developments are emphasized, citing where necessary the models and calculations that bear upon the radioactivity in the core.

Potassium radioactivity in the Earth's core

Potassium radioactivity in the Earth's core has been a topic of discussion for nearly four decades. Purely on geochemical grounds, Hall and Murthy (1971) and Lewis (1971) proposed that K enters the metallic core of the Earth as a consequence of the presence of sulfur in the core

Harsh K. Gupta (ed.), *Encyclopedia of Solid Earth Geophysics*, DOI 10.1007/978-90-481-8702-7,

Radioactivity in Earth's Core, Table 1 Important heat-producing radioactive isotopes in the Earth: atomic percentages, decay constants, half-lives, and heat production values (After Van Schmus, 1995)

Isotope	Atomic percentage	Decay constant λ (year^{-1})	Half-life (years)	Specific isotopic heat production (μWkg^{-1})
^{40}K	0.01167	5.54×10^{-10}	1.251×10^{9}	29.17
^{235}U	0.7200	9.85×10^{-10}	7.038×10^{8}	568.7
^{238}U	99.2743	1.551×10^{-10}	4.468×10^{9}	94.65
^{232}Th	100.00	4.95×10^{-10}	1.401×10^{10}	26.38

(Murthy and Hall, 1970). Since then, the implications of K in the Earth's core for the energetics of the core, convection and core cooling rate, growth rate of the inner core, the geomagnetic field, and thermal evolution of the Earth have been noted in several studies (e.g., Verhoogen, 1973; Goettel, 1976; Gubbins et al., 1979; Stevenson et al., 1983). Early experiments, however, concluded against the presence of K in the core (Oversby and Ringwood, 1972; Ganguly and Kennedy, 1977; Murrell and Burnett, 1986). These low pressure (1 bar to −1.5 GPa) and low temperature (1,030–1,350°C) studies yielded very low distribution coefficients, D_K for potassium. The laboratory D_K values applied to core formation led to the conclusion that K cannot be present in an S-bearing core.

Since these first-generation experiments, we have made a substantial progress in understanding the partitioning behavior of elements. For example, we know now that the partitioning of an element between metal and silicate depends on a number of variables such as pressure, temperature, oxygen fugacity (fO_2), and the composition of both the metal and silicate melts (Murthy, 1991; Hillgren et al., 1996; Jana and Walker, 1997; Righter et al., 1997; Gessmann and Rubie, 1998, 2000; Gessmann et al., 1999; Li and Agee, 2001; Bouhifd and Jephcoat, 2003; Chabot et al., 2005). In addition, core formation models suggest metal-silicate partitioning at a pressure range of 30–60 GPa and a temperature of 3,000–4,000°C (e.g., see Rubie et al., 2003 and Chabot et al., 2005 and the discussion and references cited therein). In the context of these developments, several new experiments have investigated the possibility of K-radioactivity in the core.

Chabot and Drake (1999) made the first systematic study of the effect of some of the variables on K partition into metal alloys at 1.5 GPa and 1,900°C. They showed that D_K was dependent on the S content of the metal alloy and on the composition of the silicate melt. Their experiments yielded low values of D_K ($\sim 6 \times 10^{-3}$) leading to their conclusion that the K content in an S-bearing metallic core will be trivially small (<1 ppm). The D_K values obtained by Chabot and Drake (1999) are lower by an order of magnitude and at variance with a number of later studies. This discrepancy may be due to their capsule choice (Gessman and Wood, 2002) or due to other experimental artifacts caused by the extreme lability of K under experimental conditions (Murrell and Burnett, 1986; Murthy et al., 2003).

Studies of K partitioning at high pressure and temperature (2.5–24 GPa and 1,500–1,900°C) by Gessman and Wood (2002) found a significant entry of K into Fe-S-O alloys. K partition into the metallic liquids depended strongly on S and O contents of metal alloy and increased with temperature. K had little tendency to partition into S-free metal alloys, as was noted in many previous studies. They show clearly that the partitioning behavior of K is strongly influenced by anion/cation ratio of the Fe-sulfide liquid as well as the depolymerization level of the silicate liquid noted previously by Chabot and Drake (1999). Evaluating the effect of these and other variables on D_K, Gessman and Wood (2002) suggest the possibility of 100 ppm of K content in a core containing about 10% S and possibly up to a maximum of ~250 ppm for conditions relevant to core separation from a deep magma ocean.

Murthy et al. (2003) found a significant partition of K into Fe–FeS liquids in experiments at 1–3 GPa at temperatures above the liquidus of both metal and silicate phases (1,200–1,800°C) and at fO_2 ~1.5 log units below IW buffer, corresponding to core separation conditions in a magma ocean (Walter and Thibault, 1995; Chabot and Agee, 2003; Chabot et al., 2005; Wade and Wood, 2005). D_K seemed positively correlated with temperature as noted in previous studies but not correlated with pressure in the pressure range of the experiments. Extrapolating to deep magma ocean conditions and a core with ~10% S, the inferred K content is 60–130 ppm, a little lower but comparable to that inferred by Gessman and Wood (2002).

Bouhifd et al. (2007) studied the partition of K between silicates and FeS-rich alloy and pure Fe metal at 5–15 GPa and a temperature of 1,900°C at an fO_2 between 1.5 and 3 log units below IW buffer. D_K was clearly positively correlated to S and O contents of the metal alloy and temperature as observed in previous experiments. In the pressure range of their experiments, no pressure dependence of D_K was observed both in sulfur-free and sulfur-bearing metal alloys. A parameterization of all existing D_K data showed a linear relationship between D_K and temperature, a relationship useful to predict D_K values at plausible temperature relevant to core formation if the S and O contents of the core are known. For reasonable assumptions of S and O contents, Bouhifd et al. (2007) found K content of ~250 ppm in the core. If the core is free of S and O, the K content falls as low as ~25 ppm.

Partitioning experiments between peridotite silicate liquids and Fe-Ni-S-C-O melts at pressures of 1.0–7.7 GPa and temperatures of 1,650–2,200°C by Corgne et al. (2007) did not find any relationship between D_K and temperature, as observed by Gessman and Wood (2002), Murthy et al. (2003), and Bouhifd et al. (2007). Nor did they find any dependence of D_K on the S content of metal alloy, as found in Chabot and Drake (1999), Gessman and Wood (2002), Murthy et al. (2003) and Bouhifd et al. (2007). A compositional control on D_K by the O content of the metal alloy was observed leading to their conclusion that a core containing S, C, and about 2 wt.% O could only have up to 25 ppm of K irrespective of the S and C levels. For a possible O content of ~5 wt. % (Badro et al., 2007), the K content of the core is ~80 ppm. However, the discrepancy between this work and the other recent studies is unresolved at present.

Quantum mechanical calculations predict a change in electronic structure of K at high pressures (from 4d-like orbitals to 3s-like orbitals), making K behave like a transition element (Bukowinski, 1976; Lee et al., 2004). This prediction is experimentally confirmed by the work of Lee and Jeanloz (2003) that showed the alloying of K with a high-pressure polymorph of Fe at pressures >26 GPa and temperature 2,500 K. The change in chemical bonding behavior of K under pressure is noted in several other experiments (Ito et al., 1993; Parker et al., 1996; Hirao et al., 2006; Bouhifd et al., 2007). These experiments and calculations show that K entry into a Fe-metal core is facilitated by high temperatures and high pressures, making it siderophile at extreme conditions.

Radioactivity in the core is suggested in a number of studies concerned with the age and size of the inner core, and the energy required to sustain the geomagnetic field. The estimated core–mantle boundary (CMB) heat flux is 6–12 TW (Buffett, 2003) and controls the rate of core cooling. Recent studies (Buffett, 2003; Nimmo et al., 2004; Costin and Butler, 2006) have examined the question of how best to reconcile the CMB heat flux with the size of inner core, the ~3.5 Ga history of the magnetic field, and the CMB temperature. These authors note that the presence of K in the core at ~200–400 ppm is in best accord with the present size of the inner core and the power needs of a geomagnetic dynamo. Using somewhat different parameters, similar conclusions have been reached by others (for example, Labrosse, 2003; Buffett, 2003; Butler et al., 2005; Costin and Butler, 2006). Thus, it appears that a variety of thermal models of the core call for an additional heat source in the core. In view of the recent experimental data, it is reasonable to attribute this at least in part to the radioactivity of K. However, no precise estimates are possible at present. A more definitive evaluation of the influence of temperature, pressure, and other variables on K partitioning into metal alloys is needed. There is also an uncertainty of the mantle K content at the time of core separation (Murthy, 2006) although the convention is to use the model BSE content of ~240 ppm. Nor are the S and O contents of the core known. Given these caveats, a core K content of up to 250 ppm of K seems tenable. The corresponding radioactive heat production in the core, especially with any accompanying U and Th (see discussion below) would be ~2 TW, a significant fraction of the CMB heat flux. However, the uncertainty of these figures cannot be overemphasized. Table 2 summarizes the current estimates of K-radioactivity in the core from standard geochemical models, thermal modeling of the core, and recent high P, T partition experiments.

Radioactivity in Earth's Core, Table 2 A comparison of inferred values of potassium abundance in the core from geochemical models, theoretical calculations, and recent experiments, and the corresponding heat production in terawatts (TW = 10^{12} W) today

[a]For realistic conditions of core segregation, K in core will be much less (see discussion in Lee and Jeanloz, 2003, 2004)

U (and th) radioactivity in the Earth's core

There have been some attempts to evaluate the presence of U (and Th) in the core. Earlier experiments were largely at low pressure and low temperature. Furst et al. (1982) noted that under the highly reduced conditions relevant to core formation in the Earth, U and Th tend to become chalcophile (affinity for sulfur) and might enter a sulfur-bearing core. The chalcophile tendency of U under these conditions is confirmed by Murrell and Burnett (1986) and in the recent high P, T experiments described later. Feber et al. (1984) noted the significant solubility of UO_2 in impure Fe-metal at 1 bar pressure and at temperature >3,000 K suggesting that significant U could be present in the core. In a series of detailed experiments, Murrell and Burnett (1986) measured the partitioning of K, U, and Th between silicate and sulfide liquids at low pressures (1 bar to 1.5 GPa) and found that U and Th tend to be less lithophile under reducing conditions and are markedly chalophile and partition at greater levels than K into Fe–FeS liquids.

The high P, T partitioning experiments of U described below yield somewhat ambiguous results. Bao et al. (2005, 2006) investigated the partitioning of U between silicate melt and pure Fe liquids at pressures of 3.0–14.5 GPa and temperatures of 1,660–2,500°C. They found that partition of U into the metal is dependent on whether the silicates were molten or solid and increases with both P and T. They found a similar P and T dependence of U in Fe-10 wt% S and Fe-35wt% S liquids, with a positive dependence on S content of the metal phase. Inferred values for U content in core are in the range of 1–4 ppb for pure Fe and at least 10 ppb for 10wt% S in core. At these latter levels, U alone can produce 1–2 TW of heat energy. Together with K, radioactivity in the core can then account for a significant fraction of the CMB heat flux. In contrast to these observations, Wheeler et al. (2006) found that U entry into core is not supported in their experiments for conditions up to 10 GPa, 2,300°C and 28 wt% S at fO_2 about 2 log units below IW. The discrepancy between these two studies is not understood.

Malavergne et al. (2007) found that U partitioning into core metal is dependent on S content and highly reducing conditions (fO_2 about 4–5 log units below IW buffer) and at temperatures up to 2,400°C and 20 GPa. These experiments permit a range of 0.0003–0.63 ppb U in core depending on whether the metal is S free or S rich. In experiments at temperatures of 2,200–2,400°C and pressures up to 8 GPa, under very low oxygen fugacity (~4 log units below IW), Murthy et al. (2007) found U partitioning into metal to be positively correlated with S content. The data permit U concentration in the core of 1–2 ppb with a heat production of 0.1–0.3 TW.

In a series of papers, Herndon (see for example, Herndon, 1998, 2006, and references to his work cited therein) has argued that gravitationally segregated U in the core functions as a nuclear reactor to provide substantial energy. In order to segregate uranium into the core, the core–mantle differentiation needs to have occurred at fO_2 of about 4–5 log units below IW buffer (Malavergne et al., 2007). Such a scenario would have reduced most iron in the planet to metallic form, leaving little oxidized iron in the mantle. This is not supported by the fact that the mantle contains ~8% of oxidized iron. The mantle would also have been strongly depleted in Ta under such a low oxidation, which is not the case (Mann et al., 2009). Current ideas of core formation based on siderophile element partitioning in the mantle suggest a much higher oxygen fugacity of about 2 log units below IW. Schuiling (2006) discusses other difficulties of the Herndon proposal.

Conclusions

There have been many theoretical discussions of radioactivity in the Earth's core in the past. But it is the new high P, T experiments of metal-silicate partitioning of K and U that urge a serious consideration of radioactivity in the Earth's core. The experimental data could permit up to 250 ppm of K and up to 10 ppb of U in the core at the upper end. The corresponding heat production due to K and U (and associated Th) could be ~2–4 TW, a significant fraction of the CMB heat flux. As mentioned in the section on K-radioactivity, the uncertainty in these numbers is very large. It may not be possible to precisely determine the radioactivity of the core by currently available geochemical and geophysical analyses except to note the general possibility of radioactivity in the core.

A way out of this impasse may now be available. Radioactive β^- decays of K, U, and Th in the interior of the Earth produce electron antineutrinos ($\overline{\nu_e}$).

These are termed geoneutrinos, and can serve as probes to directly measure the radioactivity of the Earth's mantle and core (e.g., Raghavan et al., 1998; Rothschild et al., 1998; Mantovani et al., 2004; Enomoto et al., 2005; Fiorentini et al., 2005; Giammarchi and Miramonti, 2006). Geoneutrino flux measurements use the antineutrino inverse β-decay reaction with protons, $\overline{\nu}_e + p \rightarrow e^+ + n$ in an appropriate liquid in a scintillator chamber. The resulting positron and neutron emissions are then measured by usual scintillation techniques. Geoneutrinos from each radioactive isotope can be distinguished by their characteristic energy spectrum. Neutrino detectors exist now in several countries, and new ones less susceptible to interference by nuclear reactors and other near surface radioactive sources are planned. These developments in neutrino geophysics should be able to measure the U and Th abundances in the deep Earth and the core. Present detection techniques do not allow measurement of K due to the lower energy of its antineutrinos compared to those from U and Th decay. Further developments are needed for K determination. Geoneutrino measurements are likely to provide a definitive answer about the level of radioactivity in the core and in addition clarify several questions regarding the Earth's formation, differentiation, chemical composition, heat budget, and geodynamics (Sleep, 2006).

Definition

Radiogenic heat production rate. Physical property defining the amount of heat liberated in unit time in a unit volume of rock by the decay of unstable radiogenic isotopes; dimension: W m^{-3}.

Geoneutrino. An electron antineutrino emitted in β-decay of nuclei during radiogenic heat production caused by the decay of the unstable isotopes ^{238}U, ^{232}Th, and ^{40}K.

eV (electron Volt). A non-SI unit of energy in nuclear physics, defined as the kinetic energy gained by an electron of elementary charge when accelerating through an electric potential difference of 1 V. Thus, one electron Volt equals one Volt, which is one Joule per Coulomb, multiplied by the electron charge of $e = 1.602\,176\,487(40) \times 10^{-19}$ C. Therefore, $1\ eV = 1.602\,176\,487 \times 10^{-19}$ J.

ppm (parts per million). A non-SI unit of relative frequency (or abundance) in 10^{-6}, similar to % (percent) or ‰ (per mil) in 10^{-2} and 10^{-3}, respectively.

Radiogenic heat generation

The main interior sources of heat in the Earth are the heat content of the infant Earth immediately after formation due to gravitational contraction and the decay of unstable, radioactive isotopes. The potential energy released as heat during the gravitational accretion of the infant Earth dwarfs all other heat sources. This energy is calculated from gravitational contraction. The mass accumulated in a spheroidal planet of constant density ρ and radius r equals $m = (4\pi/3)\, r^3\rho$. Addition of a further shell of thickness dr and mass $dm = 4\pi\, r^2\rho\, dr$ results in the release of additional potential gravitational energy $dE_p = G\, m\, dm/r = (16/3)\, \pi^2\, G\, \rho^2\, r^4\, dr$, where $G = 6\,673 \times 10^{-11}\ m^3\ kg^{-1}\ s^{-2}$ is the universal gravitational constant. Integration yields:

$$E_p = \int_0^{r_E} dE_p = \int_0^{r_E} \frac{G\,m}{r}\,dm = \frac{16\,\pi^2\,\rho^2\,G}{3}\int_0^{r_E} r^4\,dr = \frac{16\,\pi^2\,\rho^2\,G}{3}\,\frac{r^5}{5} = \underbrace{\left(\frac{4\pi\,r_E^3\,\rho}{3}\right)}_{M_E}^{2}\,\frac{3\,G}{5\,r_E} = \frac{3}{5}\,\frac{G\,M_E^2}{r_E}, \quad (1)$$

where $M_E = 5.976 \times 10^{24}$ kg and $r_E = 6.371 \times 10^6$ m are mass and radius of the Earth, respectively. Accordingly, the accretion of the Earth results in the release of heat on the order of $E_p = 2.24 \times 10^{32}$ J. A refined analysis considering the radial variation of density in the Earth modifies this value by only about 10% to $E_p = 2.49 \times 10^{32}$ J (Stacey and Davis, 2008).

An additional, similarly large energy input is assumed to have occurred in the wake of an impact into the young infant Earth by a Mars-sized protoplanet orbiting the sun close to the Earth's orbit. The terrestrial Moon is generally believed to be the result of this impact, which released energy on the order of 10^{31} J (Melosh, 1990; Canup and Righter, 2000; Canup and Asphaug, 2001). However, most of the vast energy liberated during accretion of the Earth or by this impact was radiated back into space already during accretion or immediately after the impact (Stacey and Davis, 2008).

For an average specific heat capacity of 1 088 J kg^{-1} K^{-1} and a cooling by 650 K over a lifetime of 4.6 billion years, the mean rate by which the Earth is losing its original heat is 29 TW (Vacquier, 1991, 1992). This corresponds to a thermal energy of 4.2×10^{30} J. As the heat loss of the young and hot infant Earth was larger than today, the contribution of original heat to today's heat loss is certainly smaller. A larger cooling by 1 175 K would result in a mean cooling rate of 52 TW corresponding to a thermal energy of 7.6×10^{30} J (Stacey and Davis, 2008).

The annual production of radiogenic heat in the Earth, 6.3×10^{20} J (Jaupart et al., 2007), corresponds to more than twice the global production of primary energy in the year 2000. This huge energy source by itself clearly exceeds the world's energy annual demands predicted through the year 2030 (IEA, 2008). If it were used at great scale, it may satisfy a large proportion of the primary energy demand of the entire twenty-first century.

Apart from the heat content of the infant Earth immediately after formation, the radiogenic decay of the unstable isotopes of uranium (^{238}U; ^{235}U), thorium (^{232}Th), and potassium (^{40}K) provides the largest internal source of heat. Most of these isotopes are enriched in the Earth's crust and mantle (Table 1). During radioactive decay, mass is converted into energy. Except for the tiny amount associated with the antineutrinos and neutrinos generated in β^-- and β^+-decay or electron capture, respectively, all of this energy is converted into heat. Certain peaks in the corresponding γ-spectra are characteristic for the different decay series while the continuous background spectrum is due to Compton scattering and photoelectric absorption.

The two uranium isotopes, ^{238}U and ^{235}U, decay into lead, ^{206}Pb and ^{207}Pb, with a half-life of 4.5 and 0.71 billion years, respectively. Characteristic lines for the γ-spectrum of the ^{238}U decay series, for example, are produced by the daughter element bismuth, ^{214}Bi, at 609 keV, 1 120 keV, and 1 764 keV. Uranium is an abundant mobile trace element in many rocks. With a half-life of 14.1 billion years, thorium ^{232}Th decays also into lead ^{208}Pb. Characteristic lines for the γ-spectrum of the thorium decay series are produced by the daughter elements thallium, ^{208}Tl, or actinium, ^{228}Ac, at 584 keV and 2 615 keV or 912 keV and 966 keV, respectively. Thorium also occurs as a trace element, is relatively inactive chemically and frequently bound to clay minerals. The only unstable isotope of potassium is ^{40}K. It disintegrates by electron capture or emission into argon, ^{40}Ar, or calcium, ^{40}Ca, respectively, with a corresponding characteristic line in the

Radiogenic Heat Production of Rocks, Table 1 Average radiogenic heat generation rate per mass, A′, in geologic materials (data: McDonough and Sun, 1995; Stacey and Davis, 2008; Jaupart et al., 2007)

Material		Concentration (ppm by mass)				Heat generation (10^{-12} W kg^{-1})
		C_U	C_{Th}	C_K	C_K/C_U	A′
Igneous rocks	Granites	4.6	18	33 000	7 000	1 050
	Alkali basalt	0.75	2.5	12 000	16 000	180

γ-spectrum of the potassium decay at 1 460 keV. Potassium occurs in many clay minerals at concentrations of several percent.

Tabulated data

The compilations of measured radiogenic heat generation rate which are reported in several research papers and reference books will not be duplicated here. Čermák and Rybach (1982) present a large collection of data arranged according to rock type. Van Schmus (1984, 1995) presents data on the abundance of radiogenic isotopes in various minerals and rocks of the Earth's crust and mantle and discusses the variation of radiogenic heat generation over the lifetime of the Earth. Stacey and Davis (2008) present data on average mass specific heat generation rates for various geologic materials, and Jaupart et al. (2007) discuss radiogenic heat sources in the Earth's crust and mantle. They provide an in-depth discussion on current models for the composition of a bulk silicate Earth (BSE), that is, the Earth's crust and mantle without the core: These are based on data from samples of either (1) meteorites considered representative for the starting material and high-temperature processes in the early solar nebula when the Earth accreted or (2) upper mantle rocks formed by low-temperature processes. As can be expected, both show large variations in composition due to their different provenance and history.

Chondrites are considered representative of undifferentiated silicate material from the solar system prior to melting and the formation of a (mainly) iron core. Different classes of chondrites correspond to perturbations in elemental abundance in the gas state caused mainly by volatility or condensation temperature. The important elements with respect to radiogenic heat generation are uranium, thorium, and potassium. As elaborated by Jaupart et al. (2007), the first two condensate at very high temperature, why they are called "refractory lithophile" elements. They show the same ratio in all types of chondritic meteorites, which demonstrates that they behave similarly in the early solar system. In contrast, potassium is a "moderately volatile" element with a lower condensation temperature. The best agreement with solar concentration ratios is found for carbonaceous chondrites of the CI type of which, however, McDonough and Sun (1995) report only five finds. Compositional data exist only for three of them, in particular for the 700 g meteorite found near Ivuna in Tanzania in 1938 from which the name "CI" is derived for this type of carbonaceous chondrite. However, chondrites are known to be more enriched in volatiles such as H_2O and CO_2 than the Earth.

Samples from the Earth's mantle are called pyrolites, a contraction of the names of two principal mantle minerals, *pyr*oxene and *oli*vine, making up the complementary rocks peridotite and basalt. Because the former is the solid residue of the partial melting event which produced basalts, a mixture between the two was considered a suitable starting material, the pyrolytic mantle. Generally, pyrolite data suffer from leaching of uranium during low-temperature alteration. As most samples derive from the upper mantle, it has been questioned whether the pyrolytic composition adequately represents a bulk silicate Earth.

A third approach discussed by Jaupart et al. (2007) avoids a specific choice of a starting composition but determines it from the intersection of the two compositional trends of chondritic meteorites and peridotites. A source of error in this approach derives from the scatter in the two trends.

A fourth method proceeds from the elemental ratios of uranium and thorium and determines the primitive bulk Earth abundances from measurements on peridotites. Again, Jaupart et al. (2007) provide a concise introduction into this method. Table 1 summarizes mass-specific radiogenic heat generation rates for terrestrial rocks, meteorites, Moon surface samples, and average values for the Earth's crust, mantle, and a bulk silicate Earth (BSE).

Calculated heat generation rate

The energy emitted by all of these decay processes comprises the kinetic energy of the emitted particles and the γ-radiation associated with the different decay processes. It is absorbed in the rocks and finally transformed into heat. In general, the total heat generation rate A of a rock is the sum of the individual contributions A_U, A_{Th}, and A_K by uranium, thorium, and potassium, respectively:

$$A = \rho\left(C_U A'_U + C_{Th} A'_{Th} + C_K A'_K\right), \quad (2)$$

where ρ is rock density, and A′ and C are heat generation rate per mass and concentration, respectively, of the corresponding element in the rock. Table 2 shows values for A′ reported by different authors. The variation is less than 3 %, at most.

Thus, if a rock's density ρ and its concentrations in uranium (C_U), thorium (C_{Th}), and potassium (C_K) are known, its radiogenic heat generation rate A can be determined. Inserting the values, for example, of Rybach (1988) from Table 2 into Equation 2 yields:

$$A\left[\mu W\,m^{-3}\right] = 10^{-5} \times \rho\left[kg\,m^{-3}\right] \times (9.52 \times C_U[ppm] + 2.56 \times C_{Th}[ppm] + 3.48 \times C_K[\%]), \quad (3)$$

where concentrations are given in weight-ppm (i.e., 10^{-6} kg kg^{-1}) for uranium and thorium and in weight-% for potassium.

The natural γ-radiation of rocks can be measured, for instance, by spectrometry on rock samples in the laboratory (see Measuring Techniques). An alternative source of γ-spectra is the natural gamma spectrometer (NGS) borehole tool which yields as output the three logs URAN [weight-ppm uranium], THOR [weight-ppm thorium], and POTA [weight-% potassium]. In combination with density RHOB from the compensated density log [g cm^{-3}], this information can be used directly to obtain the bulk heat generation rate A from Equation 2 using any of the values for A'_U, A'_{Th}, and A'_K from Table 2.

Alternatively, for lack of spectra, the total γ-ray emission GR may be used, measured either in the laboratory or by suitable logging tools in boreholes. A γ-ray (GR) log is often included in most logging runs as one of the basic geophysical measurements in boreholes. Its reading reflects the combined radioactive decay of uranium, thorium, and potassium. However, it does not yield information on the individual contributions as it records the total number of γ-rays detected by the tool during a time interval. The relative gamma activities of uranium, thorium, and potassium, that is, the relative number of γ-rays emitted by the same mass during the same time interval are shown in Table 3.

Therefore, if POTA, THOR, and URAN are recorded as percent, ppm, and ppm, respectively, the gamma ray log's reading GR is proportional to the corresponding contents (Beardsmore and Cull, 2001):

$$GR = X \times (POTA + 0.13 \times THOR + 0.36 \times URAN), \quad (4)$$

where the proportionality X varies with the radius of sensitivity of the log for detecting γ-rays. This varies with a number of factors, but lies within a few decimeters, at most, and can be approximated as constant for a given borehole (Beardsmore and Cull, 2001). Then, bulk heat generation rate A can be related to GR by combining Equations 2 and 4 using the data of, for example, Rybach (1988) from Table 2:

$$\frac{A[\mu W m^{-3}]}{GR[API]} = \frac{10^{-3} \times RHOB[g cm^{-3}] \times (34.8 \times POTA[\%] + 25.6 \times THOR[ppm] + 95.2 \times URAN[ppm])}{X[API] \times (POTA[\%] + 0.13 \times THOR[ppm] + 0.36 \times URAN[ppm])},$$

that is:

$$A[\mu W m^{-3}] = \frac{0.0348}{X[API]} \times RHOB[g cm^{-3}] \times GR[API] \underbrace{\frac{(POTA[\%] + 0.736 \times THOR[ppm] + 2.736 \times URAN[ppm])}{(POTA[\%] + 0.130 \times THOR[ppm] + 0.360 \times URAN[ppm])}}_{Y} = 0.0348\left(RHOB \times GR \times \frac{Y}{X}\right). \quad (5)$$

Y in Equation 5 still contains the unknown relative elemental abundances. However, it turns out that the range for Y is limited between $1 \leq Y < 7.6$ for the two extreme cases when either 0 = THOR = URAN and POTA > 0, or 0 = POTA = THOR and URAN > 0. Beardsmore and Cull (2001) argue that in regions in which sediments have been derived from a common source through time the relative proportions of the elements in Equation 5, and hence Y, should remain relatively constant with depth. Thus, Beardsmore and Cull (2001) maintain that a plot of A (derived, e.g., from a NGS log) versus RHOB × GR should yield a gradient, which depends only on the relative

Radiogenic Heat Production of Rocks, Table 2 Heat generation rate per mass, A′, for uranium, thorium, and potassium (Clauser, 2009)

A'_U (μW kg^{-1})	A'_{Th} (μW kg^{-1})	A'_K (μW kg^{-1})	Data source

Radiogenic Heat Production of Rocks, Table 3 Relative gamma activity of uranium, thorium, and potassium (data source: Adams and Weaver (1958) and Emsley (1989) referred to in Beardsmore and Cull (2001))

Element	^{238}U	^{232}Th	^{40}K
Half-life (Ga)	4.47	14.1	1.28
Relative γ-activity	3 600	1 300	1

proportions of the radioactive elements in the sediments and should be similar over any region containing sediment derived from the same source.

An alternative empirical relationship was published by Bücker and Rybach (1996), which does not require information on the relative proportions of the radioactive elements in the rock. It relates bulk heat generation rate A to total γ-ray emission GR recorded by borehole tools as

$$A\left[\mu W\,m^{-3}\right] = 0.0158(GR[API] - 0.8). \quad (6)$$

This relation has been successfully tested on a number of data sets where both NGS and GR logs were available. As the relations in Equations 3 and 6 are based on measurements mostly on igneous rocks, caution is required when applying them to sedimentary rocks.

Measuring techniques

A number of different analytical methods are available for determining the concentrations of uranium, thorium, and potassium. An inter-laboratory comparison of different methods on selected materials yielded consistent results within a few percent (Rybach, 1988). However, among all other methods, γ-ray spectroscopy is the only one which enables determining all three concentrations simultaneously. It implies secular equilibrium within the uranium and thorium decay series and a constant ^{40}K/K ratio, both of which are satisfied for most rock types (Rybach, 1988). The method is based on counting the number of decays per energy channel. Commercial spectrometers will offer, for instance, 2 048 channels for measuring decays in the energy range of 0–3 000 keV, yielding a resolution, in this particular case, of 1.46 keV per channel. In performing measurements, it is important to realize that radioactive decay is a stochastic process. Therefore, decays need to be recorded over a sufficiently long time. In view of the minute U-, Th-, and K-concentrations, and depending on crystal size and sensitivity, this may imply recording times on the order of several hours. Additionally, a possible sampling bias needs to be considered when selecting samples for measurements.

The interpretation of γ-ray spectroscopy relates the elemental concentrations C linearly to the corresponding counting rates N in the energy channel x by the corresponding coefficient h(x): N(x) = h(x) C. Thus, the total count rate due to the decay of uranium, thorium, and potassium in the energy channel x is given by:

$$N(x) = h_U(x)\,C_U(x) + h_{Th}(x)\,C_{Th}(x) + h_K(x)\,C_K. \quad (7)$$

The coefficients h depend mainly on the characteristic spectra of the radioactive elements, but also on the geometry of the sample, the geometric configuration of the measurement, and on the efficiency and sensitivity of the detectors. Thus, γ-spectroscopic measurements require calibration based on samples of known elemental concentrations. This enables accounting for the influence of the geometry of the detectors. Additionally, possibly variable sample geometry needs to be addressed separately. Three different effects require attention (Adams and Gasparini, 1970): (1) *Variation of the continuous background spectrum* may occur if the background radiation was determined with an empty sample chamber in which no absorption of the natural background radiation occurs. This can be avoided by measuring the background radiation using a nonradioactive sample of equal size and similar density, such as water-filled plastic tubes; (2) *Deformation of the spectrum* may occur if a larger sample volume increases the likelihood for internal Compton scattering. Thus, larger samples are characterized by a decreased peak size and an increased level of the continuous spectrum; (3) *Radiation self-absorption* of a fraction of the γ-radiation emitted within the sample reduces the γ-radiation recorded at the detector. Self-absorption increases with sample thickness d and reduces the count rate N by a factor

$$F = \left(1 - e^{-\mu d}\right)/\mu\,d, \quad (8)$$

where μ is the absorption coefficient (Watt and Ramsden, 1964). The joint effect of spectrum deformation and self-absorption is quantified by measurements on potash salt standards. While the absolute ^{40}K-concentrations are unknown, the relative variations reveal the influence of variable sample diameters. Theoretically, the total activity is proportional to the sample cross section, that is, to the square of the sample diameter. In plotting the count rate versus sample diameter one finds, however, a smaller exponent of only 1.5. Thus, the remainder of the radiation is either absorbed within the sample or transferred to other energy bands.

The energy peaks in the spectrum are analyzed for finding the elemental concentrations. Theory predicts a Gaussian normal distribution for the energy peaks. The count rate N at energy x in the local neighborhood of such a Gauß peak comprises a contribution of the Gauß peak itself, G(x), and a linear trend ax + b, describing the background radiation and the Compton scattering (Adams and Gasparini, 1970):

$$N(x) = G(x) + ax + b. \quad (9)$$

Such linear trends need to be removed prior to further interpretation, for example, by linear regression. Then,

the area under the peak above the base line corresponds to the sought total energy. In practice, the count rates within this area are summed up, or a Gaussian distribution function

$$G(x) = A\, e^{-(x-x_0)^2/2\sigma^2} \quad (10)$$

is fitted to the corrected peak, where x_0 and σ are mean energy and standard deviation of the peak, and A is a calibration constant. For a Gauß distribution, the peak's full width at half maximum (FWHM) is related to σ by

$$FWHM = 2\sigma\sqrt{\log 2}. \quad (11)$$

The summed up count rates analyzed this way then need to be calibrated by corresponding measurements on samples of known concentrations. Finally, this yields the concentrations of the radiogenic isotopes of uranium, thorium, and potassium.

Heat generation and geoneutrinos

Currently, general hypotheses on possible distributions of radiogenic heat generating elements in the mantle and core of the Earth are mainly based on analogies with chondritic material and direct evidence is lacking. However, as radiogenic sources produce heat, electron antineutrinos $\bar{\nu}$ are emitted in β^--decay of nuclei in the decay chains of ^{238}U, ^{232}Th, and ^{40}K. Thus, the heat produced in nuclear decay is directly related to the antineutrino flux, as shown in Table 4 (Fiorentini et al., 2003).

Neutrinos are elementary particles that travel close to the speed of light, are electrically neutral, and can pass through ordinary matter almost undisturbed. They have a very small, but nonzero mass. Therefore, neutrinos are extremely difficult to detect. As the emission of geoneutrinos is coupled to radiogenic heat generation, this enables, at least theoretically, a geoneutrino tomography of radiogenic heat distribution within the Earth. But this concept is as difficult to implement as it is intriguing. First, there is a huge flux of cosmic neutrinos which traverses the Earth from which geoneutrinos need to be distinguished: The neutrino flux at the Earth's surface from the sun alone is estimated at about 60×10^9 s^{-1} cm^{-2} (e.g., Bahcall, 1969). The flux of geoneutrinos is still on the order of $(60–15) \times 10^6$ s^{-1} cm^{-2} (Fiorentini et al., 2003).

In spite of this immense flux density, the vanishing mass of neutrinos requires exceptional sensors for their detection: (1) At the Gran Sasso observatory in Italy, the detector is a tank of 100 t of liquid gallium trichloride ($GaCl_3$) containing the equivalent of 30 t of gallium at a subsurface laboratory. Here, antineutrinos are observed indirectly through the conversion of a gallium nucleus into a germanium isotope by neutrino capture. For all the high neutrino flux through the tank, an interaction of a neutrino and a gallium nucleus occurs only every 35 h. (2) In the *Kamioka Liquid Scintillator Antineutrino Detector* (*KamLAND*) experiment (Araki et al., 2005), the detector comprises of a 13 m diameter nylon balloon filled with 1 kt of liquid scintillator consisting of mineral oil, benzene and fluorescent chemicals. KamLAND is an experiment at the Kamioka Observatory, an underground neutrino observatory near Toyama, Japan, built to detect electron antineutrinos. The experiment is located in the old Kamiokande cavity in a horizontal mine drift in the Japanese Alps. The detector is housed in an 18 m diameter stainless steel spherical vessel with 1 879 photomultiplier tubes mounted on the inner surface. KamLAND is the first detector to conduct an investigation on geoneutrinos and may yield important geophysical information. It has the sensitivity to detect electron antineutrinos produced by the decay of ^{238}U and ^{232}Th within the Earth. Earth composition models suggest that the radiogenic power from these isotope decays is 16 TW, approximately half of the total measured heat dissipation rate from the Earth.

A successful antineutrino tomography requires global sampling and distinguishing between cosmic neutrinos traversing the Earth and geoneutrinos generated within the Earth. Recently, a project was proposed to deploy considerably smaller neutrino detection sensors in a network of boreholes around the globe (de Meijer et al., 2006). Time will show whether the significant technical challenges associated with the construction of smaller sensors than those in the experiments at the Gran Sasso and Kamioka observatories can be overcome and a road opened for an antineutrino tomography of the Earth.

Radiogenic Heat Production of Rocks, Table 4 Maximum antineutrino energy and heat production rates in natural decay processes (de Meijer et al., 2006; Fiorentini et al., 2005)

Decay reaction	E_{max} (MeV)	Heat (μW kg^{-1})
$^{238}U \rightarrow {}^{206}Pb + 8\,{}^4He + 6\,e + 6\bar{\nu}$	3.25	95
$^{232}Th \rightarrow {}^{208}Pb + 6\,{}^4He + 4\,e + 4\bar{\nu}$	2.25	27
$^{40}K \rightarrow {}^{40}Ca + e + \bar{\nu}$	1.31	0.0036

Summary

The heat produced in the radioactive decay of the unstable isotopes of uranium (^{238}U; ^{235}U), thorium (^{232}Th), and potassium (^{40}K) is the largest internal heat source of the Earth. During radioactive decay, mass is converted into energy. Except for the tiny amount associated with the antineutrino and neutrinos generated in β^-- and β^+-decay or electron capture, respectively, all of this energy ends up as heat. The annual production of radiogenic heat in the Earth equals 8.6×10^{20} J, which is more than twice the global production of primary energy in the year 2000. The distribution of radiogenic isotopes in the Earth controls to a large extent the thermal regime of the Earth. Unfortunately, this distribution is known only with great uncertainty. Recently, it has become possible to detect geoneutrinos, that is, antineutrinos emitted during

radioactive decay of unstable isotopes, in large detectors. With decreased size and improved accuracy of detectors together with directional resolution power, an antineutrino tomography of the Earth appears to become possible. Ideally, this would enable locating and quantifying the distribution of unstable isotopes in the Earth, thus helping to resolve a number of open questions with regard to the state and evolution of the Earth's thermal regime.

Definition

Remanent magnetization. Permanent magnetization held in rocks and other earth materials, commonly, though not always, dating from cooling to below the Curie temperature (Tc) or Néel temperature (Tn) of the magnetic minerals in the rock, or the time of formation of the rock unit.

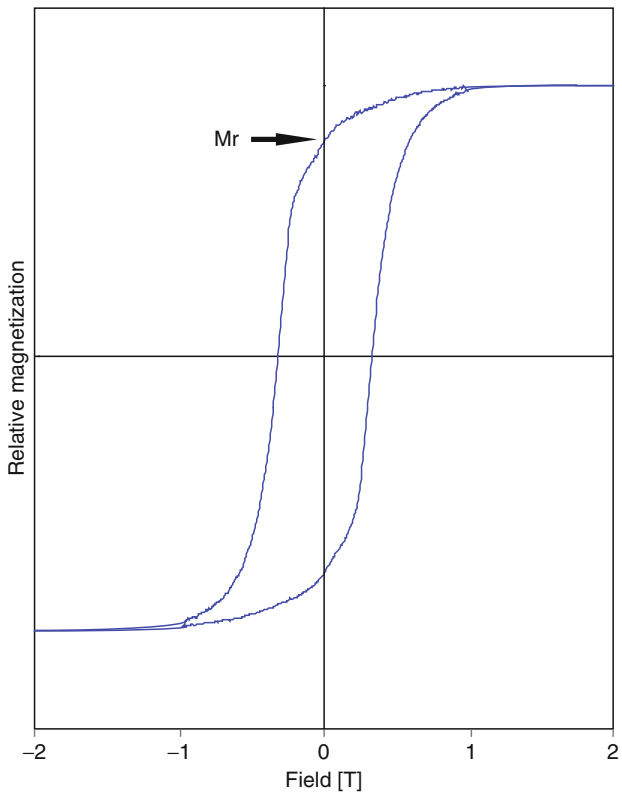
Introduction

The fact that earth materials, particularly rocks, possess a permanent magnetization has been known for some time. Early observations of rocks producing large anomalies were commonly ascribed to lightning strikes. By the mid-nineteenth century remanence was accepted as a property of some rocks, and by the early twentieth century crude measurements of the direction of magnetization were possible. During the second half of the twentieth century, the measurement of remanent magnetization (RM) became a well-established research field (see entries under *Paleomagnetism, Principles*). RM is a vector quantity,

having both direction, usually related to the direction of the Earth's field at the time of origin, and intensity, related to both mineral phase and the external field. Descriptions of remanent magnetization, associated paleomagnetic techniques, and results are detailed in standard paleomagnetic textbooks such as Butler (1992), McElhinny and McFadden (2000), and Tauxe (2010). More detailed discussion of the theory and development of remanent magnetization can be found in rock magnetism books, including those by Nagata (1961), Stacey and Banerjee (1974), O'Reilly (1984), and Dunlop and Özdemir (1997).

Source of RM

Remanence is a property unique to a small group of minerals possessing ferromagnetic or antiferromagnetic properties, mostly iron oxides and iron sulfides. Remanence is observable in hysteresis behavior, when, after saturation, the applied field is reversed and decreased to zero. If the magnetization does not also return to zero, but retains a measurable quantity, a remanent magnetization is present (Figure 1). This characteristic is temperature dependent, with only some of the mineral phases possessing remanence at earth surface temperatures.



Remanent Magnetism, Figure 1 Hysteresis loop of hematite-dominated sample of the El Laco deposit, northern Chile. Horizontal axis is the external field, in Tesla; vertical axis is relative magnetization. Mr indicates the remanent magnetization left after the sample is saturated and returned to a zero field.

The most common and important magnetic minerals on Earth belong to the cubic oxide series magnetite ($Fe^{2+}Fe_2^{3+}O_4$) – ulvöspinel ($Fe_2^{2+}Ti^{4+}O_4$), and the rhombohedral oxide series hematite ($Fe_2^{3+}O_3$) – ilmenite ($Fe^{2+}Ti^{4+}O_3$). Both series have important solid solution versus temperature relationships, as well as magnetic complexities of key interest in the rock magnetism. Additionally, both series show remanence properties that vary with composition. Furthermore, the oxide bulk compositions in the vicinity of equilibrium tie lines between ilmenite and magnetite are found in a majority of igneous and metamorphic rocks, especially basalts. In these assemblages, the slopes of the tie lines are a function temperature, whereas tie line positions are a function of the oxygen fugacity of equilibration according to the oxygen thermobarometer (Buddington and Lindsley, 1964).

End-member hematite is antiferromagnetically ordered with equal and opposite magnetic moments in alternate cation layers. However, at room temperature, a weak ferromagnetic moment is produced because the alternate moments are ~0.13° away from being perfectly antiparallel (Dzialoshinskii, 1957). This effect is commonly referred to as "spin-canting" and such hematite is termed "canted-antiferromagnetic." Many oxidized sediments contain hematite, and carry this weak, but very stable magnetization, which is mainly due to its high coercivity.

The temperature and composition phase relations of the hematite-ilmenite series are a result of a complex interaction of Fe-Ti ordering and magnetic ordering at high temperature. Slow cooling to intermediate to low temperatures produces exsolution of discrete ilmenite and hematite (Burton, 1991; Harrison et al., 2000; Ghiorso and Evans, 2008). Exsolved grains contain two phases, a host (hematite or ilmenite) and lamellae of the second phase. Ilmeno-hematite (hematite with ilmenite exsolution), or hemo-ilmenite (ilmenite with hematite exsolution) commonly have a strong, and very stable magnetization, referred to as "lamellar magnetism." Lamellar magnetism is due to a defect magnetic moment at the interface (or contact layer) between the two phases (Robinson et al., 2002, 2004) where a ferrimagnetic substructure is present because of the different quantity of Fe^{2+} and Fe^{3+} ions in contact Fe layers, as compared to standard Fe^{3+} layers in adjacent hematite.

Intermediate members of this series rapidly cooled from high temperature produce intermediate metastable phases that are ferrimagnetic and show complicated magnetic properties near and below room temperature (Ishikawa and Akimoto, 1957; Burton et al., 2008; Robinson et al., 2010) with some compositions with varied Fe-Ti ordering showing magnetic self-reversal (Harrison et al., 2005; Ishikawa and Syono, 1963).

Natural remanent magnetization (NRM)

The magnetization held by a rock sample prior to subjection to any laboratory procedures is referred to as Natural Remanent Magnetization (NRM). It is the sum total of all

remanences held in the rock and may include primary as well as secondary remanences arising from different processes. The NRM is differentiated from induced magnetization, which a rock may acquire as it sits in an external field, and loses when the field is removed. Induced magnetization is dependent on the magnetic susceptibility of the material as well as the strength of the external field. NRM is traditionally described by the manner of acquisition of the remanences involved, leading to a number of both natural and laboratory magnetizations, as described below.

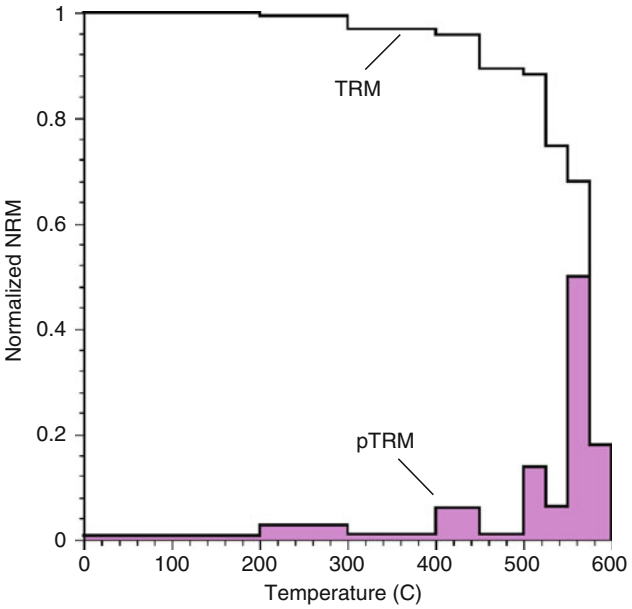
Thermoremanent magnetization (TRM)

Igneous rocks, cooling down from a molten state through the Curie or Néel temperature (Tc or Tn), obtain a thermoremanent magnetization (TRM) parallel to the ambient field. For magnetite this temperature is 580°C while for hematite it is 675°C. At these temperatures the spontaneous nature of the ferromagnetic material occurs and remanence is blocked just below this temperature. The material must cool slightly further to the blocking temperature (Tb) before this magnetization becomes locked in with a relaxation time equivalent to geologic time spans. The direction of remanence, so important to the whole field of paleomagnetism, becomes permanent at this point, with a net direction parallel to the ambient field. The intensity of the magnetization is influenced by the size of the external field, and by the phase, composition, and grain size of the ferromagnetic minerals present.

The TRM preserved in igneous rocks is a summation of the remanences of all the ferromagnetic grains present. This means there may be a range of Curie temperatures and related blocking temperatures, giving rise to partial thermal remanence (pTRM). As a simple case, if a rock had both pure hematite and pure magnetite grains present, the hematite grains would lock in the field slightly below 675°C while the magnetite grains would provide additional remanence once the rock cooled to below 580°C. Commonly, a combination of oxide minerals of varying composition provide for remanence acquired at a range of temperatures. In Figure 2, a plot of pTRM is shown for a basalt with low Ti-magnetite. Metamorphic rocks heated to above their Curie temperatures will have the remanence reset as the material cools down. High grade metamorphic rocks, such as granulite- and amphibolite facies rocks, heated to above 600–700°C will have all the existing magnetic minerals remagnetized in the external field at the time of cooling, whereas rocks of lower metamorphic grade will have only minerals with Tc below the peak metamorphic temperature completely reset. Néel (1955) introduced the theory of thermoremanence; Dunlop (1977) and Dunlop and Özdemir (1997) provide detailed treatment of the theory.

Detrital remanent magnetization (DRM)

Sedimentary rocks obtain a remanent magnetization in a very different way. Here the detrital grains settling in a water column are influenced by the external magnetic field producing a depositional remanent magnetization (DRM). These grains are also influenced by procedures in the sedimentary environment imparting a post-depositional remanence (pDRM). The general term of detrital remanent magnetization includes both processes of depositional as well as post-depositional magnetization.



Remanent Magnetism, Figure 2 Thermoremanent magnetization plot from a Tertiary basalt, Meseta Lago Buenos Aires, Argentina. *Upper curve* labeled TRM represents the amount of magnetization left after increasing heatings up to 600°C, with nearly 75% of the remanence being removed between 550°C and 600°C. *Lower curve* (pTRM) indicates the percentage of TRM residing within certain blocking temperatures.

When eroded ferromagnetic grains enter the sedimentary regime, they retain their magnetic moments even though the original orientation of that moment is lost. These grains, as they settle through a water column, respond to the external field, and in a mechanical response, become aligned with the influencing field over a very short time period. As redeposition experiments in the laboratory have shown, this theory is not so simple as projected (Verosub, 1977). There are a number of changes that can occur once the grain is deposited, but before magnetization is locked in. These effects lead to a pDRM, or post-depositional remanent magnetization, a prevalent but complicated process (Shcherbakov and Shcherbakova, 1983). Common effects are the dewatering of the sediment, compaction of the grains, and bioturbation, all of which allow for ferromagnetic particles, particularly small ones, to realign. Magnetization is not considered final until the grains are no longer able to move about or realign, occurring at a depth referred to as the lock-in depth. This gives grain size an importance in DRM, with smaller grains more susceptible to realignment, but also

yielding stronger and more stable remanence. To this end fine-grained sediments, as mudstones and siltstones, retain a remanence better than coarser-grained rocks such as sandstones or conglomerates.

The notion of individual grains settling in a water body has recently been investigated (Tauxe et al., 2006) and found to be more complicated. In marine environments in particular, fine-grained sediments do not sink as discrete particles, but rather flocculate with coexisting nonmagnetic particles. The entire floc needs to be aligned with the external field, leading to variations in remanence, especially with respect to intensity, from that predicted by theory and redeposition experiments.

Chemical remanent magnetization (CRM)

Commonly rocks undergo chemical changes after formation, usually at temperatures below the Curie temperature of the minerals involved. These changes can be alterations to existing magnetic minerals and/or the creation of new iron oxides within the rock unit. These changes can result in new or altered remanences; this process is commonly referred to chemical remanent magnetization (CRM).

A classic example of CRM is "red beds" or sedimentary rocks with strong reddish hues due to the ubiquitous presence of hematite. Such rocks may have a DRM from the time of formation, due to the presence of detrital grains of magnetite and/or hematite. After deposition, changes brought on by differing environments, a range of aqueous solutions, or variations in oxidation state may result in weathering of existing ferromagnetic minerals, or in the deposition by precipitation of new ferromagnetic minerals. Existing magnetic minerals may break down to weaker or nonmagnetic minerals, such as hematite altering to goethite or pyrrhotite to pyrite. Ferromagnetic minerals may also alter to other magnetic minerals with different remanence characteristics. One example is the oxidation of magnetite to maghemite. Another alteration common is that of nonmagnetic grains to magnetic ones, such as the case of Fe-bearing silicate grains altering to discrete hematite grains. New ferromagnetic minerals develop, such as the formation of hematite cements and coatings, which is pervasive in red beds develops.

CRM can also be produced during progressive metamorphism, for example, when Fe-silicates breakdown to produce magnetite, in hematite-ilmenite solid solutions, or when Fe-bearing silicates react with pyrite (nonmagnetic FeS_2) to produce pyrrhotite (magnetic FeS). Lamellar magnetism mentioned earlier is a CRM because it is produced during the chemical reaction of exsolution and not at the Curie temperature of the minerals; with slow cooling this can occur hundreds of degrees below the Tc.

CRM is also recognized in igneous rocks, such as in the formation of secondary hematite in cracks and factures in basalts or around the rims of discrete magnetite grains. In this case, the CRM is often hard to distinguish from the original TRM, as the CRM is quite stable and many of the magnetic properties of the two remanences are similar.

Viscous remanent magnetization (VRM)

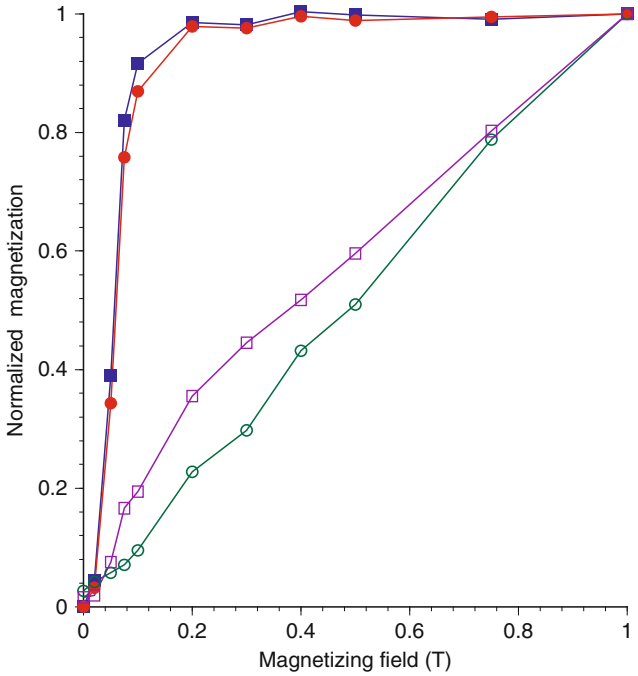
At room temperature, in low ambient fields, rocks may acquire a component of magnetization in the direction of the "present" field. This remanence acquired over long time periods in low fields, such as the Earth's field, is referred to as viscous remanent magnetization (VRM). It is generally assumed that the strength of the VRM is related to the log of the time involved, although this is a gross simplification of the situation. The importance of other factors, including grain size, initial magnetic state, and the angle of the ambient field relative to the original remanence vector have recently been investigated and shown to also affect the strength of VRM (Yu and Tauxe, 2006). Although VRM is ubiquitous in geologic examples and is found associated with many different rocks types, in many cases it is small and can easily be removed by demagnetization techniques. Due to its soft nature, VRM is often referred to as an "overprint" commonly representing the present magnetic field and must be removed prior to investigating the primary remanence.

In natural situations where temperatures may be elevated for a considerable time, as in low-grade metamorphism, or in young oceanic lithosphere, there is commonly a thermal viscous remanent magnetization (TVRM) acquired. Here, increased temperature over extended time periods enhance the viscous remanence and produce a magnetization that may eventually replace the original NRM. Pullaiah et al. (1975) have investigated such magnetization changes over a range of temperatures and timescales, with additional discussion provided by Dunlop and Özdemir (1997).

Isothermal remanent magnetization (IRM)

The presence of a large magnetic field over a short time period may also produce a remanent magnetization, referred to as isothermal remanent magnetization (IRM). An IRM can be imparted in the laboratory and used to help identify properties of magnetic materials. Samples are subjected to increasingly large external fields, usually to 1 T or larger, and the resulting magnetization recorded. Differences in composition, concentration, grain size, and saturation state effect the acquisition of IRM. For example, magnetite-bearing samples will saturate in fields of 0.1–0.3 mT, while hematite-dominated rocks will require fields larger than 1 T to reach saturation (Figure 3).

In the natural environment, a typically cited example of an IRM is the magnetization gained in a rock after being struck by lightning. The large magnetization produced by the electric currents in lightning imparts an intense, but chaotic remanence on surface rocks. First studied by Cox (1961), IRM is common in regions subject to intense thunderstorms, such as the desert southwest of the North America. In some cases, the effect of the IRM can be removed by demagnetization; in other samples, the



Remanent Magnetism, Figure 3 Normalized IRM acquisition in fields up to 1 T; *closed symbols* are Jurassic diabase dikes with magnetite; *open circles* are Jurassic mudstones with hematite.

magnetization has been totally reset, giving rise to paleomagnetic sites with random directions (Tauxe et al., 2003).

However, this type of IRM is commonly accompanied by high heat; therefore, the term is slightly misused.

Applications of remanent magnetization

RM is used extensively in the disciplines of magnetism, including paleomagnetism, rock magnetism, and the study of magnetic anomalies. The study of paleomagnetism centers on the identification and description of the remanent field held in rocks. Results from the measurement of RM are used widely in the study of plate tectonics, structure, regional tectonics, stratigraphy, volcanology, and archeology. Positions of the earth's magnetic field at specific times in the geologic past provide us invaluable information on the position of continental bodies in the past, the interrelationship between different continents, and the paths they have followed in subsequent motions across the earth's surface. RM can provide age information by comparison to established reversal timescales, as well as relative ages within a region. Regional tectonics, local rotations, and timing of folding can all be investigated using the remanence recorded in suitable rock units. Stratigraphic studies, especially in the wealth of deep-sea sediment cores from international drilling projects, lake sediments, or in thick sedimentary sequences on land, can be established and compared using the recorded remanence.

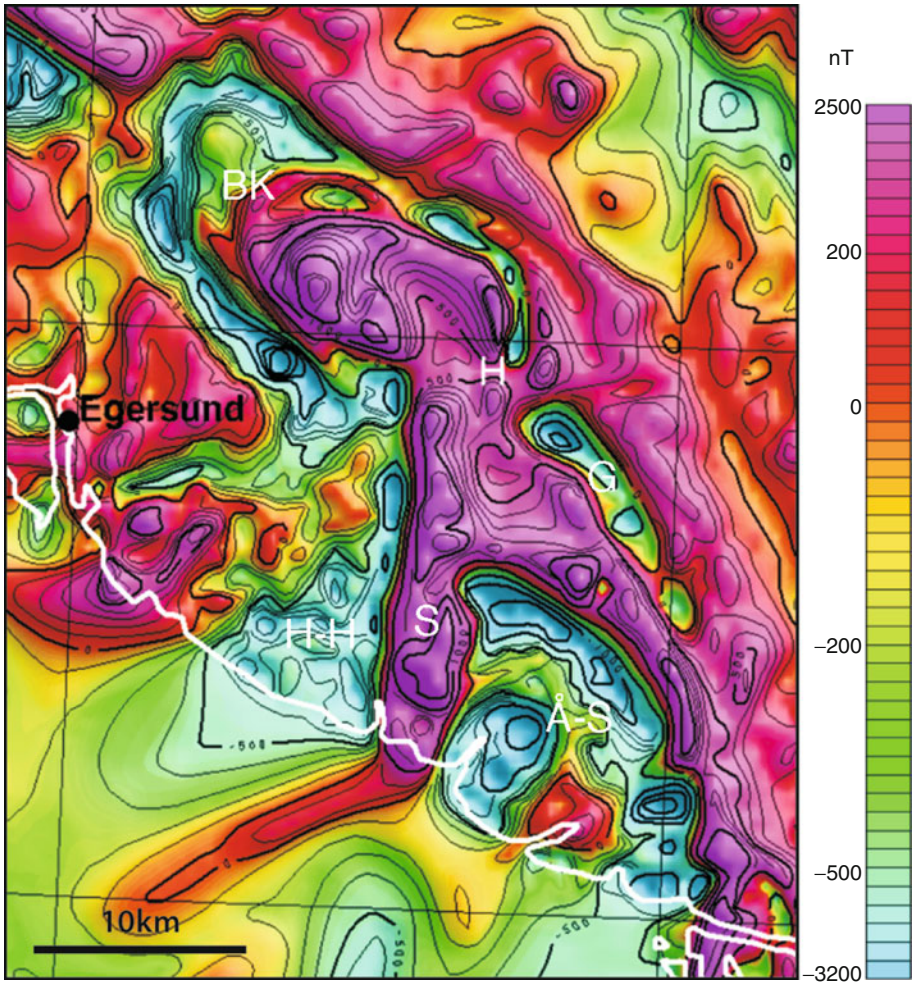
Experimental studies in rock magnetism make excellent use of the remanent magnetization properties of rocks and minerals. Studies of hysteresis behavior, magnetization at high and low temperatures, and responses to acquisition and removal of laboratory remanences all provide important information on oxide composition, grain size, and magnetic properties of a wide range of natural and synthetic materials.

Remanent magnetism plays an important part in the interpretation of magnetic anomalies. Well established in the 1960s in the study of marine magnetic anomalies from the seafloor, remanent polarity of extruded basalts played a pivotal role in the interpretation of observed anomalies (Vine and Matthews, 1963; Heirtzler et al., 1963). The use of the polarity sequence preserved in the ocean crust allows for dating of the seafloor as well as calculations of spreading rates and investigations of plate histories. Anomalies on land show considerable complexities and many are assumed to be entirely related to induced fields due to the present magnetic field. But, in many cases, there is a significant component of remanent magnetization interacting with the induced field, and depending on the remanent direction and intensity, enhancing or at times annihilating the induced field (McEnroe et al., 2009). An excellent case of remanent magnetization producing strong aeromagnetic anomalies comes from the Rogaland Igneous Complex in southern Norway (McEnroe et al., 2008), where anorthosites and a layered intrusion have intense remanence roughly antiparallel to the present field, producing large negative anomalies (Figure 4).

Exploration for natural resources by aeromagnetic surveys has been widely used since the 1950s. The classic work by Balsley and Buddington (1958) and later by McEnroe and Brown (2000) in the oxide rich area of the Adirondack Mountains of New York required a detailed knowledge of the RM for accurate interpretation of the data. Understanding the contribution of RM to magnetic anomalies will be crucial for future exploration as the accuracy and resolution of these surveys increase. Magnetic surveys will also be at the forefront for geological mapping of Earth and other planets.

Summary

Remanent magnetization is a permanent magnetization residing in earth materials that is gained when the material is formed or altered in the presence of the Earth's magnetic field. Measurable RM is founding in most rocks, ranging from metamorphic gneisses to lava flows to marine and lake sediments. The remanence is carried by iron oxides and sulfides, but magnetite and hematite are by far the most common and the most important remanence carriers. RM is categorized and described by various methods of acquisition; TRM for remanence produced as minerals cool through their Curie temperatures, DRM for the remanence obtained as detrital grains of magnetic minerals align during the deposition process, and CRM for the process where remanence develops from chemical changes in



Remanent Magnetism, Figure 4 Aeromagnetic anomaly map from a fixed-wing survey over the Rogaland region in southwestern Norway. The magnetic total field was reduced to anomaly values by subtracting the International Geomagnetic Reference Field from the total field of 1965. the rock. RM forms the basis for research in paleomagnetism, where the direction, intensity, and age of the remanence are determined and interpreted. It is also useful in experimental studies of rock magnetism, and in the investigation of anomalies in global, regional, and local magnetic field measurements.

Remote sensing data; Space imagery

Definition

Remote sensing. Refers to small- or large-scale acquisition of information of an object or phenomenon (e.g., earth surface features), by the use of either recording or real-time sensing device(s) such as by way of aircraft, spacecraft, satellite, buoy, or ship that are not in physical contact with the object.

Geographic information system. Refers to spatial data management and analysis tools that can assist users in organizing, storing, editing, analyzing, and displaying positional and attribute information about geographical data.

Lineaments. Any linear features that can be picked out as lines (appearing as such or evident because of contrasts in terrain or ground cover, tone, pattern, size, etc.) in aerial or space imagery.

Tectonics. A field of study within geology concerned generally with the structures within the lithosphere of the Earth (or other planets) and particularly with the forces and movements that have operated in a region to create these structures.

Neotectonics. A subdiscipline of tectonics which deals with the current or recent geologic deformations.
Active fault. A planar fracture in rocks with visible displacement or seismic activity that has occurred during the geologically recent period, as opposed to passive faults that show no movements since their formation.
Lithology. The scientific study and description of rocks/rock types in terms of compositional and physical character of the rock.
Geomorphic features. Landform features such as rivers and peneplains formed by geomorphic processes (e.g., erosion and mass-wasting) that shape them.
Strain meter. An instrument used by geophysicists to measure the deformation of the Earth in the field.

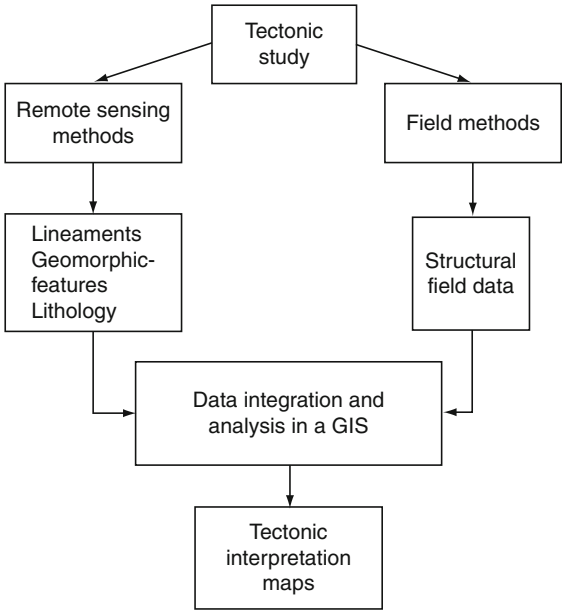
Introduction

Mapping of lineaments from various space imagery are a commonly used initial step in tectonic studies. The surface expression of geological structures such as faults, joints, dykes, veins, and straight routes of rivers are often displayed or represented in the form of lineaments in aerial photographs or on remotely sensed images. In addition, remote sensing data are useful for detecting lithology and geomorphic features, which are, in turn, important in assessing the mechanisms of faulting. The most common and widely used remote sensing techniques include: Satellite Pour l'Observation de la Terre (SPOT), which is a high-resolution optical imaging Earth Observation Satellite (EOS), Landsat satellite both multispectral scanner (MSS), and thematic mapper (TM) including enhanced thematic mapper (ETM), Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER), Shuttle Radar Topographic Mission (SRTM) and/or *SAR Interferometry* (InSAR), and Global Positioning System (GPS). Data acquired from optical, thermal, radar images or digital terrain elevation at the same or different sensor platforms or devices are all useful for tectonic studies.

Lineament mapping and analysis is a combined effort of technology and field evidence (Figure 1). The availability of multispectral and multi-sensor data with synoptic coverage and use of different image enhancement techniques provides an opportunity to prepare more reliable and comprehensive lineament maps useful for tectonic studies. Field studies or ground truthing of orientation measurements of structural features and identifying rock types provide support for verifying remote sensing derived tectonic interpretation. Geographic information system (GIS) facilitates integration of all data types and provides a strong basis for tectonic interpretation of structural features.

Data and method

Mapping of geological structures from various space imageries is a commonly used initial step in tectonic studies. The routine procedure for extracting tectonic features from digital remote sensing data usually involves initial digital image enhancement followed by manual interpretation (Suzen and Toprak, 1998). There have been significant approaches for the evaluation and automatic detection of lineaments and curvilinear features from satellite images (Karnieli et al., 1996). However, the human expert judgment still remains to be an asset for lineament detection and interpretation.



Remote Sensing and GIS Techniques for Tectonic Studies, Figure 1 A simplified flow chart showing the methodology of tectonic study using remote sensing and field data in a GIS framework.

Satellite-based remote sensing data may be optical image (e.g., SPOT and Landsat), which usually senses the behavior of visible, ultraviolet, and infrared light components of the electromagnetic energy used in imaging. The data could also be thermal image in which the devices sense the thermal energy of the electromagnetic spectrum. The Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) is an example of modern remote sensing device that senses the behavior of visible, ultraviolet, infrared light, and thermal infrared components of the electromagnetic energy spectrum. The remote sensing satellite may also acquire radar images such as the Shuttle Radar Topographic Mission (SRTM) and/or Interferometric Synthetic Aperture Radar (InSAR) in which the system has a transmitter that emits microwaves or radio waves of the electromagnetic energy to detect objects. The Global Positioning System (GPS) is a US space-based global navigation satellite system. GPS is made up of three parts: satellites orbiting the Earth; controlling and monitoring stations on Earth; and the GPS receiver that reads broadcasted signals from space sent by GPS satellites. Each GPS receiver then provides three-dimensional location based on latitude, longitude, and altitude, and the time that are useful for tectonic studies.

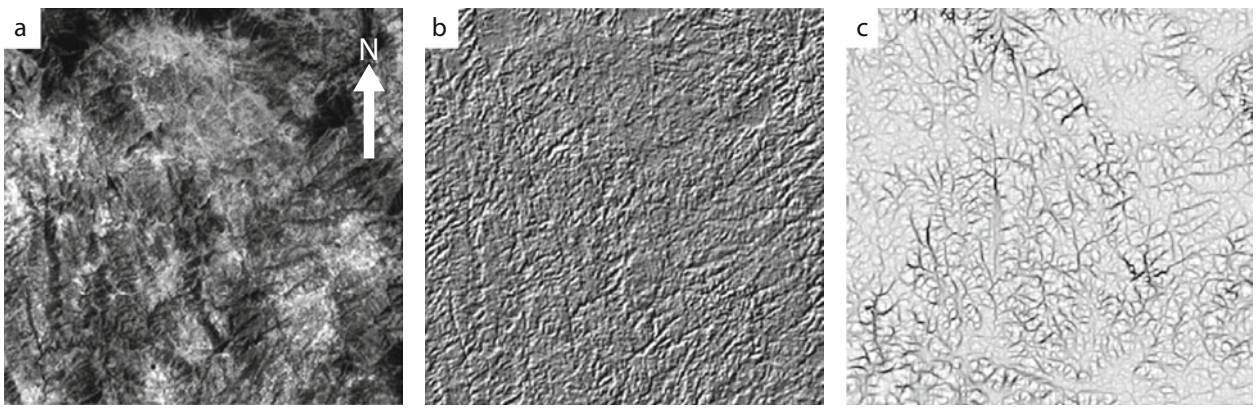
Digital elevation models (DEM) may be prepared in a number of ways, but they are frequently obtained by remote sensing rather than by direct survey. One powerful technique for generating digital elevation models is InSAR: two passes of a radar satellite (such as RADARSAT-1 or TerraSAR-X), or a single pass if the satellite is equipped with two antennas (like the SRTM instrumentation), suffice to generate a digital elevation map with extensive areal coverage and high resolution (10–30 m). Alternatively, other kinds of stereoscopic pairs can be employed using routine photogrammetric techniques, where two optical images acquired with different angles taken from the same pass of an airplane or an EOS such as the high-resolution stereo of SPOT5 or the visible and near-infrared band of ASTER (e.g., Hiranoa et al., 2003).

Remote sensing

The surface expression of lineaments displayed in aerial photographs or remote sensing data (Figure 2) may be passive faults, showing no movements since their formation or may be active faults with movements created by either earthquakes or ongoing uplifting. Earthquakes and uplifts are related to tectonic movements in the subsurface. The surface expression of these movements as structures visible on satellite imageries can be mapped and used to investigate the tectonic movements. Time series thermal satellite remote sensing datasets were used to detect pressure built-up due to tectonic activities and associated subsurface degassing that created changes in the thermal regime prior to an earthquake event (Saraf and Choudhury, 2005). Such studies are useful in locating earthquakes' epicenters and understanding the fault mechanics involved in the deformation during earthquake occurrences and uplifting processes.

DEM acquired from satellites such as SRTM data or optical images are useful for derivation of topographic parameters such as slope and surface curvatures (geomorphic indices) for mapping drainage networks and lineament extraction (Zizioli, 2008; Demirkesen, 2008). These morphotectonic parameters can be used as indicators of active tectonics in a region. For instance, rivers are sensitive to changes in tectonic deformation, adjusting their routes over different periods of time depending on the physical properties of the host rocks, climatic effects, and tectonic activity. Thus, the drainage system of a region records the evolution of tectonic deformation. Quantitative measurements of a number of geomorphic indices are commonly used as a reconnaissance tool in tectonic geomorphology studies to identify areas experiencing tectonic deformation. Combinations of different geomorphic indices derived from DEM data allow the quantification of surface deformation both on maps and on stream profiles. It is possible to assess and quantify the rate of uplift by studying the influence of faults on stream geometry and changes in direction as a result of neo-tectonic activity (Gloaguen et al., 2008). Such thematic geomorphic indices can easily be incorporated into a GIS tool for further analysis and interpretation.

Interferometric synthetic aperture radar (InSAR) is a radar technique used in geodesy and remote sensing. This geodetic method measures the line-of-sight displacements and uses two or more synthetic aperture radar (SAR) images to generate maps of surface deformation or digital elevation, using differences in the phase of the waves returning to the satellite, or aircraft. The technique can potentially measure millimeter-scale or even lower changes in deformation over time spans of days to years. InSAR can be used to measure ground movements due to earthquakes and to monitor creep and strain accumulation on faults (e.g., Stramondo et al., 2005). Due to its easy integration within a GIS environment, DEM data is important in such analyses. Time series data, a sequence of space imagery shots taken at different times, is a requirement in such studies. Then the changes are detected at observation points that have a fixed geographical location for later comparison and monitoring purposes.



Remote Sensing and GIS Techniques for Tectonic Studies, Figure 2 Different types of remote sensing data showing conspicuous NE-SW trending lineaments from 12 km × 12 km area (**a**) SPOT band 3, (**b**) digitally enhanced Landsat TM band 5, and (**c**) minimum curvature image derived from SRTM digital elevation model. The lineaments represent both extensional and strike-slip tectonics.

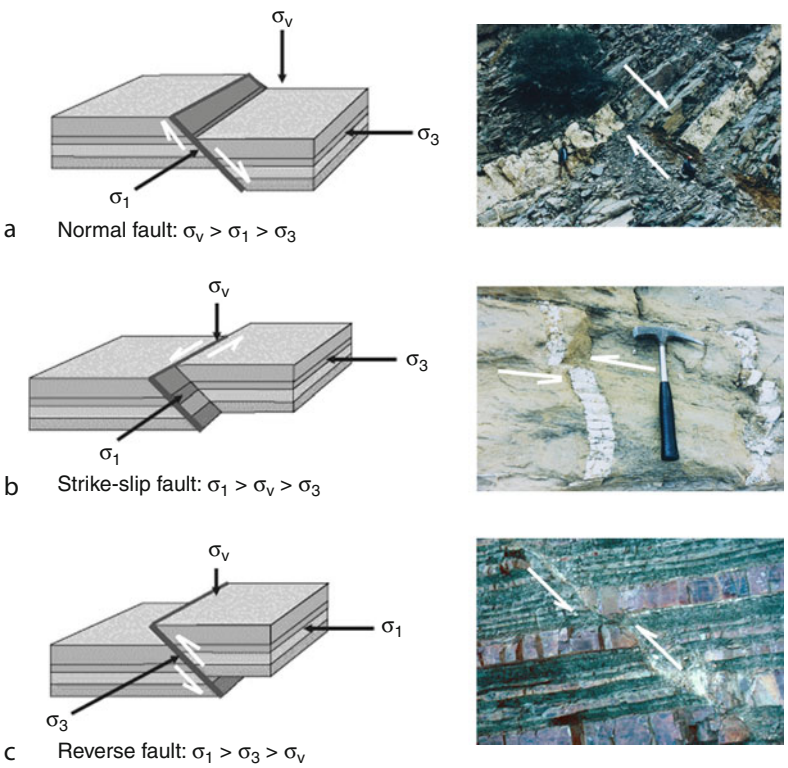
GPS measurements, among other applications, are now in use to determine the motion of the Earth's tectonic plates and deformation around active faults and volcanoes. It provides a powerful means to directly measure the kinematic pattern of present-day crustal deformation by setting up several regional GPS network stations and monitoring the changes in geographical locations and heights at the control points (Jouanne et al., 1998). GPS can measure movement of faults or tectonic plates to within the precision of a few millimeters to approximately one centimeter over baseline separations of hundreds of meters to thousands of kilometers (Segall and Davis, 1997). The three-dimensional nature of GPS measurements allows one to determine vertical as well as horizontal displacement at the same time and place. Field methods such as the use of strain meters can provide far greater strain sensitivity than does GPS. However, strain meters cannot offer the spatial coverage and long-term stability as GPS do. InSAR measurements are tremendously exciting because of their unparalleled spatial coverage. InSAR and GPS are complementary in that GPS provides long-term stability, vector displacements, and better temporal coverage as compared to the extensive spatial coverage provided by SAR/InSAR and thus results from one system are directly relevant to the others (Segall and Davis, 1997).

Tectonic studies

Tectonics deals with large-scale deformations of the Earth's lithosphere. The lithosphere is broken up into several tectonic plates that move relative to one another. Plate tectonics theory explains the formation of the plates and the origin of the forces responsible for the motion of these plates. There are three types of plate boundaries characterized by their relative motion: each having different types of surface phenomena including volcanic activities, earthquakes, and faults. The tectonic styles at the different plate boundaries are:

- Extensional tectonics that results in the formation of normal faults (Figure 3a) and associated tectonic processes due to the thinning/stretching of the lithosphere.
- Strike-slip tectonics that results in strike-slip faults (Figure 3b) in zones of lateral displacement within the lithosphere.
- Compressional tectonics that results in the formation of thrust faults (Figure 3c) and associated tectonic activities due to the shortening and thickening of the lithosphere.

The difference between structural geology and tectonics is the scale of observation. Structural geology deals with small-scale rock deformation, while tectonics is more concerned with larger features. Thus, remote sensing



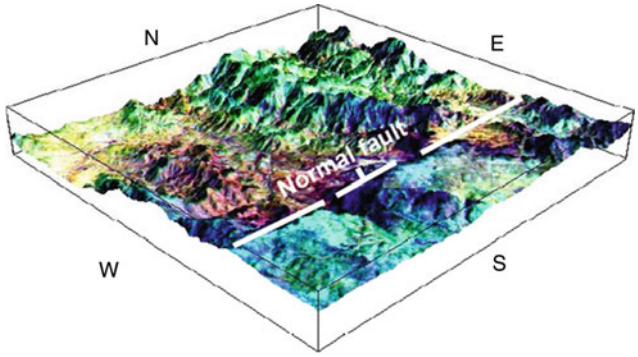
Remote Sensing and GIS Techniques for Tectonic Studies, Figure 3 Fault block models and their equivalent outcrop-scale structural features from field study formed by different tectonic processes: (**a**) Normal faults, (**b**) strike-slip faults, and (**c**) thrust faults. In the sketches the maximum principal stress (σ_1), the vertical stress (σ_v), and minimum principal stress, (σ_3) are shown. Field structures in (**a**) and (**c**) are cross-sectional views and (**b**) is plain view.

methods help in detecting large-scale tectonic features while field studies are necessary in investigating how the mapped lineaments control the tectonics of a region by looking into the details at mesoscopic-scale. All remote sensing methods used for lineament extraction cannot describe the nature of the tectonics in a region without ground truthing. It is generally recognized that lineament or fracture trace analysis used in conjunction with tectonic investigations is not credible without field verification. In regional scale studies, although field checking of each lineament is impossible due to significant cost and time involved (Mabee et al., 1994), systematic field checking is still necessary to decipher and derive confidence estimates of the nature of lineaments. The field data include observation and measurement of orientations of joints, dykes, and faults. Field evidences presented in the form of figures and sketches (e.g., Figure 3a–c) can provide good support for tectonic interpretation. The structural data collected from the field need to be grouped according to rock type and proximity of sampling points to take into account the geographic locations of observation points. In order to understand the structural–geological significance of fracture arrays, it is a common practice to subdivide them into separate sets on the basis of orientation. Rose diagrams are commonly used to reveal the orientations of vertical and steeply dipping joints, faults, and dykes observed at different scales. Many workers (e.g., Arlegui and Soriano, 1998; Solomon and Ghebreab, 2006) have effectively used remote sensing data supported by field studies to map regional spatial distributions of lineaments toward understanding their tectonic origin.

Geographic information system (GIS)

GIS is a tool in spatial data management and analysis that can assist users in organizing, storing, editing, analyzing, and displaying positional and attribute information about geographical data. GIS facilitates integration of all data types and allows a better understanding of the tectonic interpretation of a region under study. The full potential of remote sensing and GIS can be utilized when an integrated approach is adopted. Integration of the two technologies has proven to be an efficient tool in many studies, specifically in tectonic studies (e.g., Ratzinger et al., 2006; Gloaguen et al., 2008).

For instance, different geomorphic indices derived from DEM and a number of factors influencing each index can be integrated in a GIS that will allow a better interpretation of the results. Backed with remote sensing data and ground-checking, it is possible to outline the deformed area and the local strain intensity (relative uplift rates) and thus infer the neotectonic history of a region. Jain and Verma (2006) applied a combination of remote sensing and GIS for mapping active tectonic intensity zone in India. Superimposing a lineament map over a lithological map in a GIS environment provides an insight into the nature of tectonics of a region. Visible horizontal displacement along lineaments (e.g., Figure 3b) as evidenced from movement in rock units can be used to depict strike-slip fault tectonism.



Remote Sensing and GIS Techniques for Tectonic Studies, Figure 4 Three-dimensional synoptic view of a digitally processed remote sensing data created by draping from ASTER bands (13, 5, and 3) in red green and blue order over the SRTM DEM data in a GIS environment. Note the east–west normal fault that dips to the north.

Draping the lithological map or digitally enhanced color image over a three-dimensional DEM data in a GIS environment can also reveal the faulting mechanisms such as normal faulting due to visible subvertical displacement of lithological units (Figure 4). In order to classify the fault mechanics involved in deformation, an overlay of historical earthquake data on mapped tectonic features or lineaments can be integrated in a model derived from remote sensing data with results such as from differential radar interferometry in a GIS environment. A GPS-derived parameters can be easily integrated in a GIS framework to provide a powerful means of directly measuring the dynamics of present-day crustal deformation by monitoring the changes in geographical (horizontal) locations and heights (vertical displacements) at well-positioned control points. All these examples demonstrate the application of remote sensing and GIS techniques for mapping both active and passive faults. However, to better understand the types of faults involved, field checking still remains a requirement.

Summary

Remote sensing and GIS are complementary to each other and efficient techniques for lineament mapping, and hence for tectonic studies. Advanced remote sensing techniques such as InSAR and GPS have revolutionized tectonic studies by directly measuring the motion of faults associated with earthquakes and rates of uplifts. Field studies are, however, needed to identify the types of lineaments and correlate them to the remotely acquired data. Comparison of orientations of major structures or lineaments such as joints, dykes, and faults obtained from field measurements, and plotted on rose diagrams facilitates their tectonic interpretation. GIS is a very time-saving and cost-effective tool once the database is established. Integrating data of different layers such as lineament and lithological maps, and geomorphic indices

acquired, for example, from DEM, GPS measurements and field studies in a GIS environment followed by spatial analysis of the data allows correlation between different parameters for unraveling the nature of the tectonics of a region. Moreover, integrating historical dataset from past earthquake events, if any, including an understanding of the regional tectonic setting is essential in facilitating interpretation of results. Overall, combining remote sensing, GIS, and field techniques provides a powerful tool for understanding the tectonic framework of a region, and assessing the resulting fault mechanisms.

REMOTE SENSING, APPLICATIONS TO GEOPHYSICS

Hojjatollah Ranjbar
Department of Mining Engineering, Shahid Bahonar University of Kerman, Kerman, Iran

Definition

Remote sensing is defined as the acquisition of data using a remotely located sensing device, that relies on the measurements of electromagnetic energy (EM) in the range of 0.4 μm to 1 m, and extraction of information from the data (Gupta, 2003; McCloy, 2006). Remote sensing can be multilevel (i.e., sensing the surface of material from a distance of few centimeters to millions of kilometers). Taking a spectrum of a leaf by using a spectroradiometer to taking an image by Hubble telescope from a star at a distance of few light years fall in the realm of remote sensing. However, here, we mean the imaging of the Earth's surface.

Introduction

The remote sensing systems can acquire images from the surface of the Earth by either passive or active methods. Passive systems use the electromagnetic energy that is produced by the sun or any other process like anomalous heat buildup within the Earth. Active remote sensing systems create their own electromagnetic energy that (1) is transmitted from the sensor toward the terrain, (2) interacts with the terrain producing a backscatter of energy, and (3) is recorded by the remote sensor's receiver (Jensen, 2000). The sending and receiving of signals are largely unaffected by atmospheric conditions. Therefore, radar satellites can record the details of the Earth's surface in cloudy weather condition and any time of the day and night. LIDAR (LIght Detection and Ranging) and SONAR (SOund NAvigation Ranging) are also the active remote sensing systems. It should be noted that remote sensing is a geophysical method as it uses the electromagnetic spectrum as a medium for surveying the Earth's surface. It is now recognized as a separate branch of science and engineering.

The electromagnetic spectrum that is used by remote sensing systems is named according to the wavelength ranges. Gupta (2003) has classified the electromagnetic spectrum into visible (0.4–0.7 μm), near infrared (0.7–1.0 μm), Shortwave infrared (1.0–3.0 μm),

mid-infrared (3.0–35 μm), far-infrared (35–1.0 mm), and RADAR (1–100 cm).

A remote sensing system that allows sensing the Earth in any wavelength and in any time makes an ideal remote sensing system. An ideal remote sensing system cannot be achieved due to the absorptions of the electromagnetic energy from the Earth's atmosphere.

Each object has unique sets of absorption and reflectance features concerning the wavelengths. The plot is known as spectral signature. Figure 1 shows the spectra of the common surface materials. Although each material at the surface of the Earth has many absorption and reflection features, the present remote sensing systems can only image these materials in limited wavelengths because the atmosphere is not clear for all the wavelengths.

There are different sensors that are used onboard the satellites or in an aeroplane. The present remote sensing systems that orbit the Earth are imaging the Earth's surface in visible, near infrared, shortwave infrared, thermal infrared, and RADAR regions of EM spectrum. The reader can refer to Jensen (2000) and Lillesand et al., (2004) for different sensors and platforms specifications.

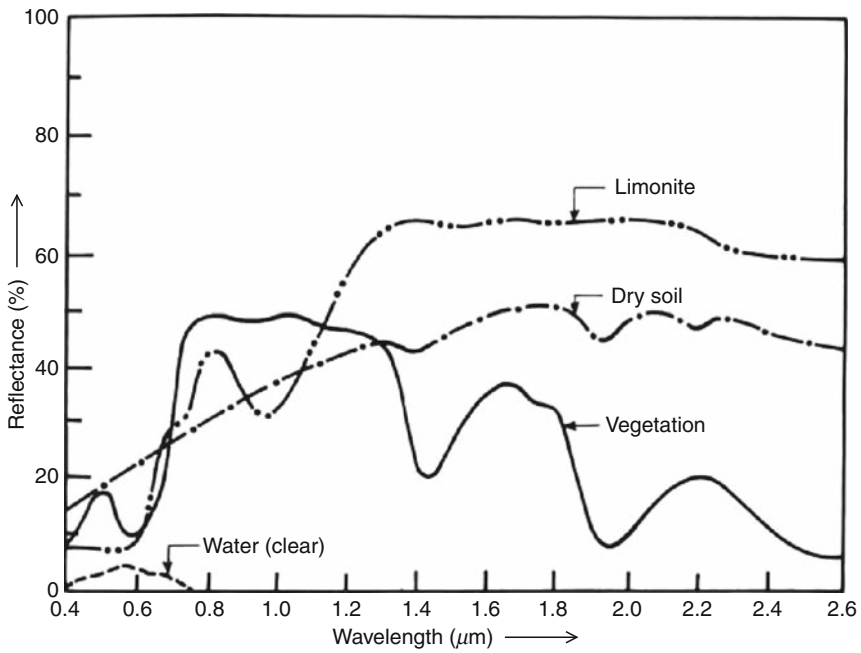
A digital image consists of pixels. Each pixel is representative of a surface area that defines the spatial resolution of the system. Enhanced Thematic Mapper Plus (ETM^+) multispectral data has a resolution of 30 m (each pixel is equivalent to 900 m^2 ground area), while Quickbird has a resolution of 60 cm for its panchromatic image (each pixel is equivalent to 0.36 m^2 on the ground).

As these images are in digital formats, several simple or complex mathematical operations can be applied on them in order to enhance specific features from these images. This is called image processing operation. Image filtering (Mather, 2001) is a common image processing technique that enhances the linear features. Figure 2 shows the enhanced faults in the southern part of Iran in a filtered image.

Application of remote sensing to geophysics

Remote sensing data can be used for designing the survey grid and line in geophysical surveys, verifying, and helping a better interpretation of the geophysical methods. Remote sensing images can be combined to form color images in various scales that depend on the spatial resolution of the remote sensing system. These color images can be draped over a digital elevation model (DEM) to give a three-dimensional (3-D) model of the area (Figure 3). These 3-D models can be used in both land and airborne geophysical surveys for designing the survey lines. The 3-D model can provide information such as the terrain ruggedness, man-made installations, surface conditions, transportation routes, etc.

The surface of the Earth is continuously deformed due to the tectonic activities over geological time that causes the formation of structures such as fold and fault. Geophysical methods such as magnetic, magneto-telluric, gravity, and seismic methods are used for studying these structures. These methods are subsurface methods.



Remote Sensing, Applications to Geophysics, Figure 1 Typical spectral reflectance curves for selected common natural objects (Gupta, 2003).

Remote sensing techniques are useful in order to study these structures and to interpret the tectonic activities in the regional and local scale at the surface of the Earth. In order to obtain a clear picture of the structures, the combined interpretation of remote sensing and geophysical data is helpful, if the geological structures have any trace in the satellite images. Remote sensing applications to tectonic and structural studies are reported by many researchers (e.g., Harris, 1991; Philip, 1996; Saintot et al., 1999; Chernicoff et al., 2002; Chatterjee, 2003; Raharimahefa and Kusky, 2006; Walker, 2006). Figure 3 shows a part of Zagros simply folded belt that the folds axis directions indicate a force direction because of the subduction of Arabian plate beneath the Iranian plate. These structures are also studied by using gravitational, magnetic, and seismic methods.

Remote sensing is also useful for interpretation of geophysical data. Alteration process causes the changes in mineralogical content of rocks due to the reaction of hot solution with the rocks. Porphyry copper mineralization is associated with these alteration zones (Evans, 1993). Both radiometric and remote sensing methods can be used for alteration detection (Ranjbar et al., 2001; Ranjbar and Honarmand, 2004; Ranjbar et al., 2010). The minerals present in sericite and k-feldspar have a higher gamma radiation. We cannot differentiate these minerals by geophysical methods. Remote sensing method is capable of recognizing the minerals responsible for the higher

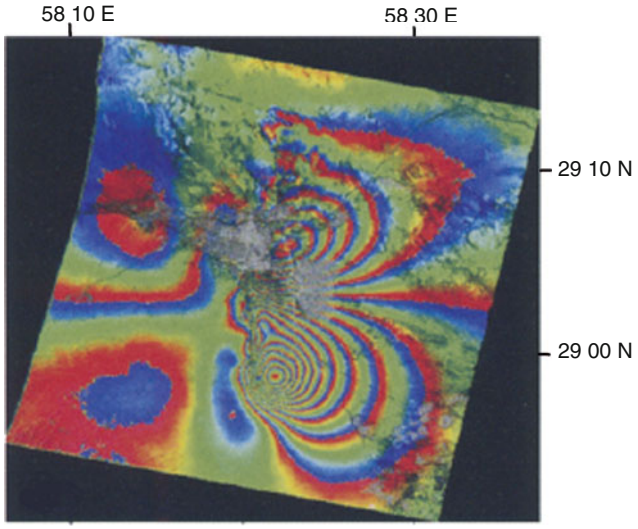
Remote Sensing, Applications to Geophysics, Figure 3 3-D view of folding due to the movement of Arabian plate against Iranian microplate. The force direction is shown by an *arrow*. Landsat color image (Band7 in *red*, band 4 in *green*, and band 2 in *blue*) is draped over DEM of the area.



Remote Sensing, Applications to Geophysics, Figure 4 An interferogram that shows the deformation along a fault due to the Bam earthquake in Iran. The rings that are closer, indicating more deformation (After Ye, 2005).

radiation in geophysical data. There are also minerals in the alteration zones that have very low radiation to be detected by geophysical methods. Kaolinite, Calcite, epidote, and chlorite are such minerals. These minerals are recognized by remote sensing methods. Remote sensing techniques can also be used in combination with other geophysical methods such as magnetic, electromagnetic, and electrical methods in helping with the interpretation.

Another area that received much attention is the field of active faults study by the combined use of interferometry and geophysical data. RADAR (Radio Detection And Ranging) images are more useful for detection of the geological structures than the images acquired in the optical ranges of EM spectrum, because the RADAR pulses are illuminating the ground from a specific direction. The RADAR wavelengths are in order of few tens of centimeters. Synthetic Aperture Radar interferometry (INSAR) is a branch of remote sensing that has emerged in the recent years that deals with the deformation in the Earth's crust. There are several papers published about INSAR method in structural and tectonic fields (e.g., Klees and Massonnet, 1999; Wright et al., 2001, 2004; Ye, 2005; Bürgmann et al., 2006; Taylor and Peltzer, 2006). Figure 4 shows an interferogram of a fault in Bam area that triggered an earthquake in 2003. This fault is detected by remote sensing and geophysical methods.

Summary

Remote sensing images due to their multi-temporal, multispectral, and synoptic views are extensively used for solving problems related to mineral exploration, tectonics, vegetation cover studies, surface changes, earthquake studies, weather and volcanic eruption forecasting, etc. The images can be acquired in different wavelength ranges such as visible, near infrared, thermal, and Radar ranges of electromagnetic spectrum. We are now able to recognize many minerals from the space by using their spectral properties. Remote sensing data can be used for designing the survey grid and line in geophysical surveys, verifying, and helping a better interpretation of the geophysical methods. Small and large structures are easily recognizable in the images, although we often need to enhance the images for recognizing these structures.

Synonyms

Differential InSAR (abbreviated as D-InSAR); Interferometric SAR (abbreviated as InSAR); Radar interferometry; SAR interferometry

Definition

Radar. Acronym standing for Radio Detection and Ranging. A technique to detect any targets and measure the distance to them, based on the round-trip time of microwave (radio wave) pulses between the antenna and the targets.
SAR. Acronym standing for Synthetic Aperture Radar. A technique to image any ground surfaces, using airborne or spaceborne radar sensor. Its high spatial resolution is achieved by collecting numerous return pulses from each target in sight and by effectively synthesizing large antenna size.
InSAR. Acronym standing for Interferometric SAR. A technique to image surface topography and ground displacements, using phase values of two or more SAR images.

Introduction

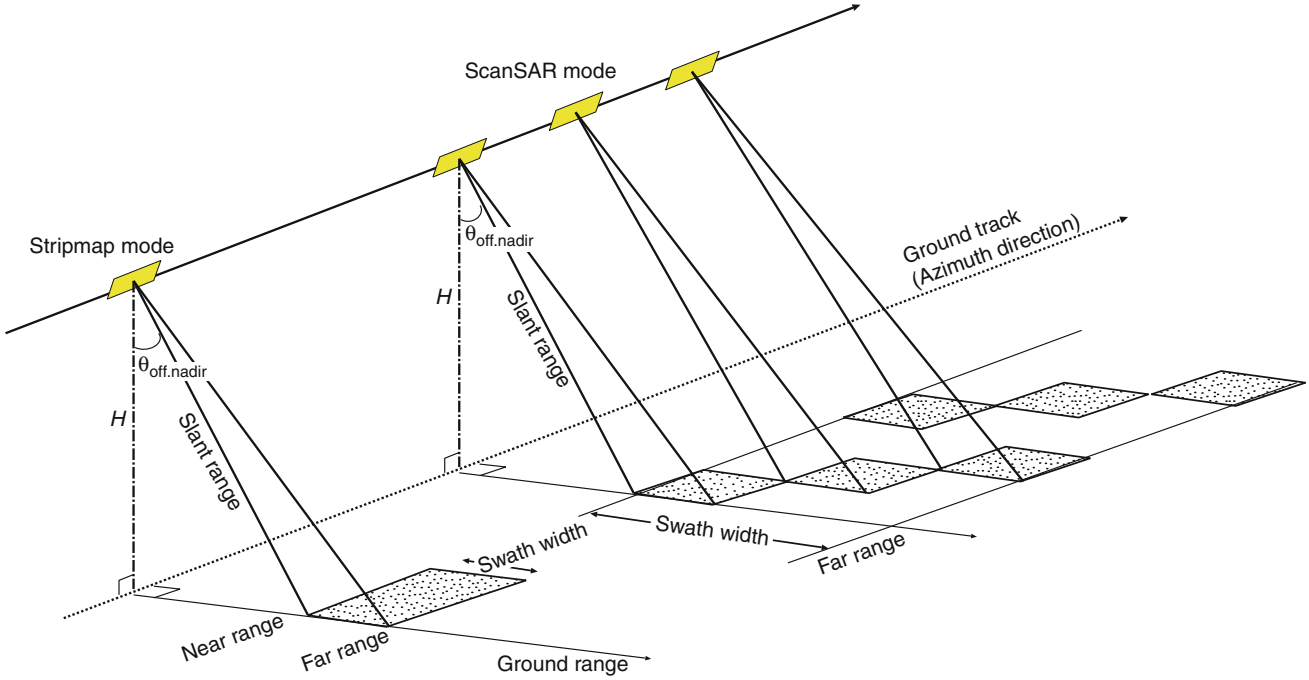
Crustal deformation data have been traditionally acquired by ground-based geodetic techniques such as leveling, triangulation, and electro-optic distance measurement. More recently, global positioning system (GPS) has become a standard tool for high-precision crustal deformation measurement, and provided us with a wealth of data to study plate tectonics, earthquakes, volcanic activities, and atmospheric and hydrological loading deformation. All these techniques, however, require in situ benchmarks, and thus prevent us from observing inaccessible areas. Interferometric SAR (InSAR) was, therefore, regarded as a surprising and revolutionary technique when Massonnet et al. (1993) first showed an image of the co-seismic deformation associated with the 1992 M7.3 Landers earthquake, because the raw data was completely acquired on a spaceborne sensor. Another big surprise for the community was its incredibly high spatial resolution, which no other geodetic techniques were possible to achieve in practice.

Nowadays, InSAR users have proliferated in a worldwide community and applied to a variety of geophysical problems. A number of excellent and extensive reviews for advanced students and researchers are already published (Bamler and Hartl, 1998; Massonnet and Feigl, 1998; Burgmann et al., 2000; Hanssen, 2001; Pritchard, 2006; Simons and Rosen, 2007; Zhou et al., 2009). I therefore tried to make this article much shorter and more introductory, but it still includes necessary and useful concepts, ranging from the fundamentals of SAR/InSAR imagery to more up-to-date topics.

Fundamentals of SAR imaging and SAR data

SAR satellite flies over at an altitude of hundreds of km, repeating transmission and reception of microwave pulses. The along-track and across-track axes are almost identical to the *azimuth* and *range* axis in the acquired radar image. The area illuminated on the ground is called *swath*, whose width spans roughly 50–100 km in the standard *stripmap* (or *strip*) mode with an incidence angle of 20–50° (Figure 1). While previous SAR applications are mostly derived from the stripmap mode, another imaging mode, *ScanSAR*, is also promising because it covers much wider swath width, 300–500 km, by illuminating multiple swaths at the expense of reducing the resolution. ScanSAR is useful for imaging long-wavelength signals

Harsh K. Gupta (ed.), *Encyclopedia of Solid Earth Geophysics*, DOI 10.1007/978-90-481-8702-7,



SAR Interferometry, Figure 1 Geometry of SAR imaging. SAR sensor transmits microwave pulses in slant range direction, and receives their reflected pulses. While stripmap mode achieves high spatial resolution with a fixed off-nadir angle, ScanSAR mode achieves wider imaged area (swath) with multiple off-nadir angles at the expense of the resolution.

associated with, for instance, a magnitude-8-class earthquake (Motagh et al., 2008).

Although it was not strictly necessary, satellite-based SAR system has been often placed on a sun-synchronous and near-polar orbit with an inclination angle of slightly greater than 90°. When the satellite moves to the north (south), we call it is in *ascending* (*descending*) orbit.

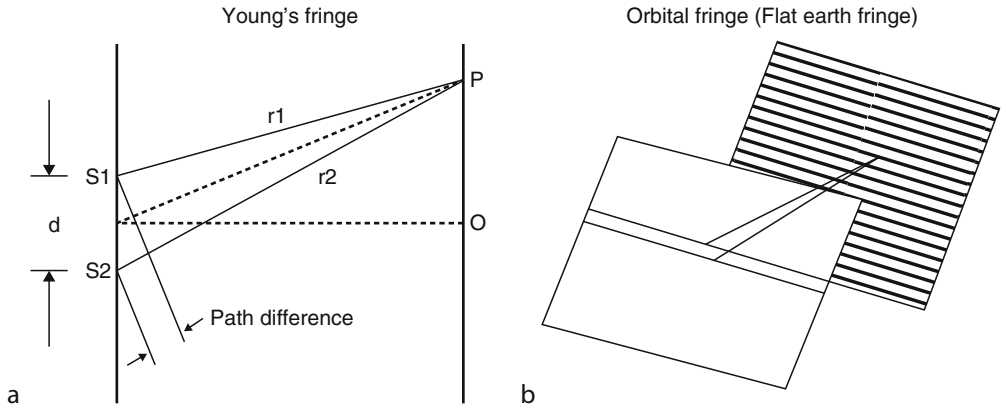
The raw data acquired on SAR sensor are impossible to visually interpret, and require a bit involved processing algorithms; those algorithms are detailed in a couple of text books (e.g., Curlander and McDonough, 1991; Cumming and Wong, 2005). The first interpretable SAR image is a single-look-complex (SLC) image, whose important difference from other optical images is that each pixel consists of a complex (real and imaginary) value, i.e., amplitude and phase. This is because the waveform of each repeated pulse is precisely controlled to be identical, and hence the received pulse provides us with not only a scattering (reflection) *intensity* but also a *phase*. The phase data do contain the geometric information from the antenna to the ground targets, and are fully exploited in generating InSAR image as discussed later. However, the phase image itself is usually not as useful as the intensity image because it is again impossible to visually interpret the physical meaning. Meanwhile, the intensity image is often useful and derived from a square-root magnitude of SLC data with spatial averaging called *multi-looking*. By single-look, it means the finest spatial resolution for both range and azimuth axis. In the standard stripmap mode, the range and azimuth resolutions are derived as,

$$\Delta r = \frac{c}{2B}, \quad and \quad \Delta a = \frac{L}{2}, \tag{1}$$

respectively; the c, B, and L are the speed of light, the frequency bandwidth of the microwave pulse, and the antenna length along azimuth axis, respectively (Curlander and McDonough, 1991; Cumming and Wong, 2005). The waveform of each microwave pulse is called *chirp signal*, whose instantaneous frequency linearly changes by as much as the frequency bandwidth B over the duration of each pulse. It should be noted that the spatial resolution depends neither on the sensor altitude nor the carrier frequency of microwave. Intensity images are often shown in gray scale images, in which strongly (weakly) reflected objects/areas are usually colored as bright (dark). Although they simply look like black-and-white photographs, we should keep in mind that they could be acquired regardless of weather and time because SAR is actively transmitting and receiving microwaves. Also, intensity images are indispensable for high-precision image matching prior to a generation of InSAR image.

Fundamental principles of InSAR

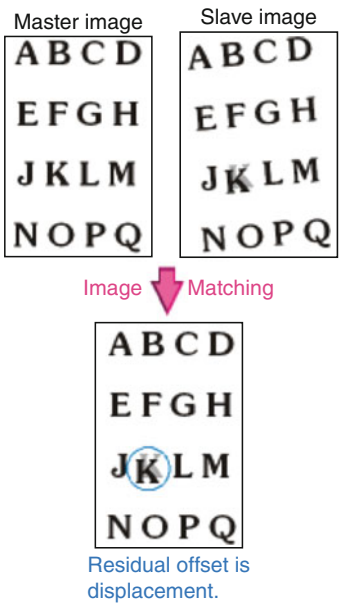
Interferometric SAR (InSAR) is a technique to generate a digital elevation model (DEM) or a ground displacement



SAR Interferometry, Figure 2 (**a**) Geometry of the Young's experiment. Depending on the path difference, the two coherent waves from the slit, S1 and S2, are in-phase or out-of-phase on the screen, and interference fringes are observed on the right screen. (**b**) Orbital fringe (flat earth fringe) can be regarded as a 3-D analogue of the Young's experiment.

image from a *pair* of SLC images. The term *interferogram* is often used to represent InSAR image. We can understand the principle of InSAR, recalling the classical Young's experiment that is known to be a proof of the wave characteristics of the light (Ghilia and Pritt, 1998). Two coherent waves out of the slits will generate "stripes" on the wall, called interference *fringe* (Figure 2a). We can simulate the fringe if we know the separation of the slits, the distance from each slit to the wall, and the wavelength of the coherent wave. Depending on the path difference, the two coherent waves are in-phase or out-of-phase when they reach the screen. Namely, the difference of the phases generates the interference fringe. We may regard the imaging geometry of InSAR as the 3-D Young's experiment (Figure 2b). The repeat orbit tracks, the ground surface, and the microwave correspond to the double slits, the screen, and the coherent wave, respectively. Once we get two SLC images, we can generate an initial interferogram, multiplying one SLC image with the complex conjugate of the other SLC image. We then observe similar fringes in the initial interferogram as illustrated in Figure 2b, which is literally a map of the difference of two SLC phases. For descriptive purposes, the former SLC image is often denoted as *master*, and the latter SLC image is called *slave*. At this moment, the slave image must be precisely co-registered (or matched) to the master image (Figure 3); we will come back to this *image co-registration* (or *image matching*) procedure later on.

While Figure 2b shows an initial interferogram over flat areas with parallel orbits, the fringe will appear undulated if the areas are not flat. The fringe over flat areas is called *flat Earth fringe* (or, *orbital fringe*), and can be precisely simulated from the pair of orbit data. If we subtract the flat Earth fringes from the initial interferogram, we can extract *topographic fringe* that can be used to generate DEM. The Shuttle Radar Topography Mission (SRTM) was carried out along this idea in 2001, and generated 3-s resolution DEM over +/− 60° latitudes (Farr et al., 2007). In the case



SAR Interferometry, Figure 3 Image registration (matching) of the master and slave images prior to interferogram generation, and the principle of pixel-offset technique to derive large displacements. While long-wavelength distortion can be corrected, localized huge displacement remains as residual offset. Courtesy of Tobita et al. (2001a).

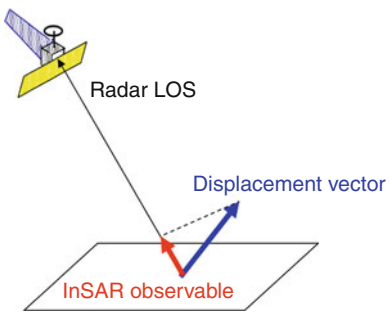
of SRTM, they carried two SAR antennas on the same platform, and thus were able to generate DEM without repeating the previous orbit track. In contrast, all the present SAR satellite systems carry only one antenna with a repeat-pass period of several weeks, which are 11 days for TerraSAR-X, 16 days for COSMO-SkyMed, 24 days for Radarsat-1/2, 35 days for Envisat, and 46 days for ALOS. Therefore, if ground surface undergoes significant deformation during the repeat orbit cycles due, for

instance, to earthquake and volcanic eruption, the interferogram will include *deformation fringe* as well. To extract deformation fringe, we must take out both orbital fringe and topographic fringe, which can be simulated from satellite orbit data and DEM. The deformation fringes represent slant range changes along the radar line-of-sight (LOS), and thus projections of the 3-D displacement vector on the ground along the unitary vectors toward the radar LOS (Figure 4). The range changes should be interpreted as relative displacements to the reference point(s) inside each interferogram. Depending on literatures, they denote differential interferometric SAR (D-InSAR) when the technique is used to detect deformation signals. Recently, however, the term InSAR is often and simply used to represent D-InSAR.

Even if no significant ground displacements take place during the repeat-pass period, however, we usually encounter other non-negligible fringes due to the spatial heterogeneities in the propagation delay of microwaves through the atmosphere, the errors in satellite orbit data, and those in DEM. Because these fringes limit the precision and accuracy of SAR-based crustal deformation measurement, a couple of correction approaches have been proposed. More advanced time-series analysis techniques have also been developed to overcome the issues, which will be introduced in the last section.

InSAR processing

Image registration (Matching): Before we get an initial interferogram, we must register (or, match) each imaged target in one SLC image to the same target in the other SLC image with a sub-pixel level accuracy, because any ground objects do not usually locate at the same pixel coordinates in each SLC image. This pre-processing is called *image registration* (or *image matching*) and prerequisite to be performed prior to generating an initial interferogram. Although a simple polynomial transformation between the range and azimuth coordinates of two SLC images is sufficient in most cases, we need to take into account the effects of 3-D topography when the terrain surface is rugged to eliminate a stereoscopic effect (Michel et al., 1999).



SAR Interferometry, Figure 4 InSAR observable is a projection of the displacement vector along the radar line-of-sight (LOS) direction.

When large ground displacements on the order of meters or more take place locally, and if we correct for the long-wavelength image distortion using the polynomial transformation, we can detect and quantify those localized displacements as a by-product of image registration without viewing InSAR image (Figure 3; Tobita et al., 2001a). This approach to detect large displacements is called *pixel offset* or *feature tracking* technique, and has been applied to earthquakes, volcanic eruptions, and glacier movements. The advantages of pixel-offset data are twofolds. First, pixel-offset data can quantify large displacements even in such areas that completely loses interferometric coherence, where InSAR data cannot be unwrapped; we describe *coherence* and *unwrapping* later below. Secondly, in contrast to InSAR data, pixel-offset data provide us with not only range offset but also azimuth offset component. While the range offset has the same sensitivity to the 3-D displacement vector as InSAR data (Figure 4), the azimuth offset is a projection of the displacement vector onto the unitary vector perpendicular to the LOS. Hence, the azimuth offset data are complementary to the range offset or InSAR data. Taking advantage of this property, Fialko et al. (2001) derived a full 3-D displacement map for the 1999 M7.1 Hector Mine earthquake, combining the InSAR data from both ascending and descending track with the azimuth offset data. Using pixel-offset data from both descending and ascending track, Tobita et al. (2001a, b) inferred a 3-D displacement map associated with the 2,000 eruption episode at Usu volcano.

Interferometric phase and its relation to geometry: Suppose we have two co-registered SLC images, E_1 and E_2, acquired from different ranges r_1 and r_2:

$$E_1 = e^{j\phi_{Scatter}} e^{-\frac{4\pi r_1}{\lambda}} \tag{2a}$$

$$E_2 = e^{j\phi_{Scatter}} e^{-\frac{4\pi r_2}{\lambda}} \tag{2b}$$

Here we assume that the reflection magnitude and scattering phase are constant during the data acquisition time. Then, the interferometric phase ϕ is derived as

$$E_1 E_2^* = e^{-\frac{4\pi(r_1 - r_2)}{\lambda}} \tag{3}$$

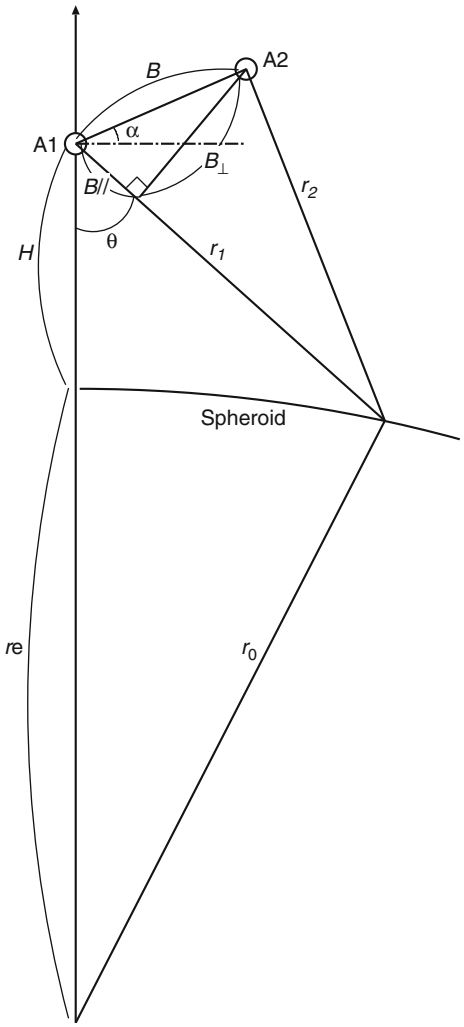
or

$$\phi = \frac{4\pi}{\lambda}(r_1 - r_2) \tag{4}$$

The last one is the fundamental equation for InSAR, which describes "unwrapped" phase in the initial interferogram. The actual phase in the initial interferogram is "wrapped" into an interval $[-\pi, \pi]$, and thus has ambiguities of $2\pi N$; N is integer. In order to quantify the ground displacement along radar LOS, we have to perform 2-D *phase unwrapping* on the interferogram, which is not necessarily straightforward (Bamler and Hartl, 1998; Ghilia and Pritt, 1998). While the interferometric phase is strictly a phase "difference" of two SLC phases, it is conventional

to simply call phase. The factor 4 is to take into account the round-trip distances.

Figure 5 is a cross section that is perpendicular to the satellite repeat tracks and passes through the Earth's center, and shows a geometry of InSAR data acquisition. The spatial separation of the repeating orbits is termed *baseline* (or *spatial baseline*), B; the temporal separation of data acquisition is sometimes called *temporal baseline*. Because the baseline B is usually much shorter than the ground range distance R, a parallel ray approximation holds (Zebker et al., 1994) and the fundamental Equation 4 can be approximated as follows:



SAR Interferometry, Figure 5 Geometry of InSAR data acquisition and its relation to the baseline. The A1 and A2 are the satellite's repeat orbits, and the spatial distance between the A1 and A2 is the baseline B. The initial InSAR phase is proportional to the difference between the ranges, r_1 and r_2, and hence the B_{para} (eq. 5). The fringe rate (density) along the range axis is proportional to the B_{perp} (eq. 6).

$$\phi = \frac{4\pi}{\lambda}(r_1 - r_2) \approx -\frac{4\pi}{\lambda}B_{//} = B\sin(\theta - \alpha), \qquad (5)$$

where θ and α are defined in Figure 5, and $B_{//}$ (or B_{para}) is a baseline component parallel to the radar LOS. The angle θ is called *off-nadir angle*, and is identical to incidence angle if the Earth's curvature is negligible. The other baseline component $B_\perp$ (or B_{perp}) is perpendicular to radar LOS and gives us an important criterion for successful InSAR processing as we discuss below.

Decorrelation (Coherence): In the actual InSAR data processing, we do not necessarily get clear fringes over the entire area. Depending on the data pairs and places, it is not uncommon that no fringes are observed. To detect clear fringes, the reflected waves received at master and slave acquisitions must be more or less correlated to each other. The degree of correlation is quantified as *coherence*, and there are two independent decorrelation sources.

The first source of decorrelation originates in the imaging geometry. As Figure 6 indicates, we observed higher (fewer) fringe density as becomes longer (shorter); imagine the case of zero baseline length. The fringe density can be derived from the gradient of phase (Equation 5) along the range axis:

$$\frac{\partial\phi}{\partial R} = -\frac{4\pi B_\perp}{\lambda R\tan\theta} + \frac{4\pi B_\perp}{\lambda(r_e + H)\sin\theta} \approx -\frac{4\pi B_\perp}{\lambda R\tan\theta}. \qquad (6)$$

Namely, the fringe density is proportional to the perpendicular baseline $B_\perp$, and inversely proportional to the wavelength λ; see Simons and Rosen (2007) for the case with topography. If the fringe density becomes too high to be counted within a range resolution of SAR image, we will not be able to identify any orbital fringes. This type of decorrelation is termed *baseline decorrelation* (or *spatial decorrelation*). The *critical baseline* is given as such a perpendicular baseline that gives a phase gradient 2π over the range resolution Δr;

$$B_\perp^c = \frac{\lambda R\tan\theta}{2\Delta r}.$$

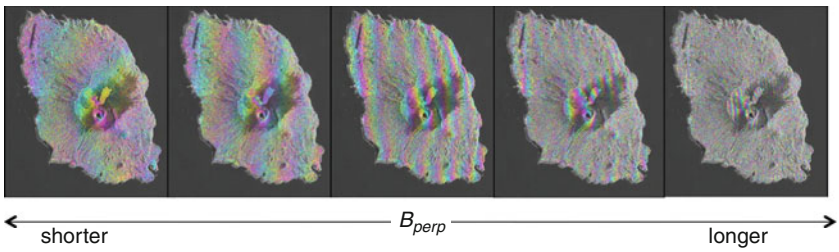
For a typical value of ALOS/PALSAR with $\lambda = 23(cm)$, $R = 870(km)$, $\theta = 34°$, $\Delta r = 5(m)$, the critical baseline becomes $B_\perp^c = 135,000(m)$, which gives an upper limit of $B_\perp$. However, we practically prefer much shorter $B_\perp$, generally less than ~2,000 m for ALOS/PALSAR, because in more realistic situations the effect of topography also comes in. The longer the $B_\perp$, the more sensitive to rugged terrain as Figure 6 indicates. To eliminate topographic fringes, we need more accurate and higher resolution DEM if the $B_\perp$ becomes longer. Massonnet et al. (1996) proposed an alternative approach that could effectively reduce the $B_\perp$ by a combination of integer multiplied (wrapped) interferograms. For instance, if one interferogram with perpendicular baseline of 300 m is combined with the other interferogram with perpendicular baseline of 290 m with factors 1 and −1, the effective perpendicular baseline becomes 10 m.

The scaling operation, however, also scales the amount of noise, and thus the approach is limited to small integer numbers.

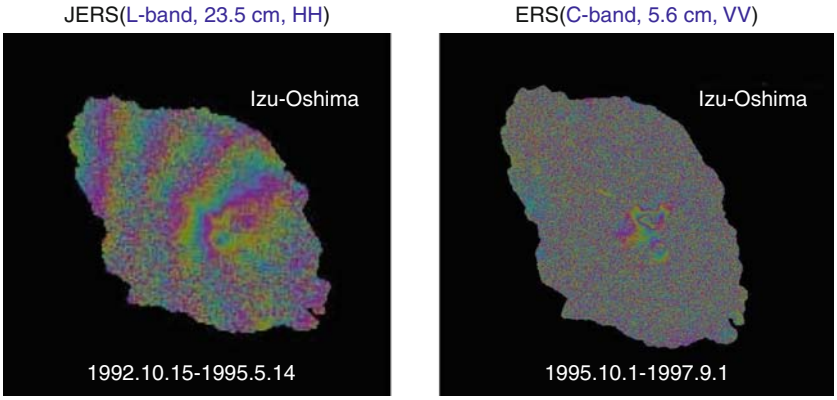
The second type of decorrelation is termed *temporal decorrelation*, which is related to the scattering phase in the Equation 2a, and originates in how the microwave pulses interact with the physical objects near the ground. We often encounter the temporal decorrelation problem over vegetated areas with C-band (shorter-wavelength) SAR data and/or snow-covered areas; see Figure 7. It should be recalled that each pixel value in SLC image is a superposition of all the reflected microwaves from all scatterers inside each resolution cell ($\sim 5 \times \sim 10$ m). Short-wavelength microwave pulses tend to be reflected on the vegetation canopies before reaching the ground surface, and their random motion will result in different scattering phases at different acquisition time, causing temporal decorrelation. On the contrary, long-wavelength microwave pulses can more easily reach the ground, which does not move as rapidly as vegetations, and thus the resulting scattering phases will be also stable over time. Besides the selection of wavelength, the polarization of microwave is also essential for better coherence over time. While, most presently, operated satellite-SAR sensors are capable of multi-polarization modes, it was shown that HH-polarization gives better coherence than VV-polarization (Cloude and Papathanassiou, 1998). This is because the HH-polarized pulses can more easily penetrate through vegetations.

Outlook for InSAR geodesy

Limitations of present InSAR: Although it has a potential to detect tens of km-scale or even larger-scale secular deformation signals on the order of mm/year, InSAR technique has been most successfully applied to detection of spatially localized signals on the order of centimeters or more, such as those associated with earthquakes, volcanic eruptions, and ground subsidence. This is because the artifacts due to inaccurate satellite orbit data and/or microwave propagation delays (advances) in the troposphere (ionosphere) can mask small-amplitude, long-wavelength deformation signals that are similar in both their amplitude and the spatial scale.



SAR Interferometry, Figure 6 The fringe rate (density) depends on the B_{perp}; see eq (6). The shorter the B_{perp}, the fewer the observed fringes, and thus better to detect deformation signals. In order words, there is a limit in the B_{perp} over which we cannot count the number of fringes. The InSAR image is based on JERS data over Izu-Oshima volcano island, Japan. Original SAR data is copyrighted by JAXA and MITI, Japan.



SAR Interferometry, Figure 7 Comparison of two interferograms at Izu-Osima volcano, derived from (left) L-band HH JERS data and (right) C-band VV ERS data. While clear fringes are observed to the left even with 2.5 years temporal baseline, we can recognize the fringes only around the caldera that are covered with few vegetations.

Although high-precision orbit data are indispensable to correct for the orbital fringes in the initial interferograms, their errors even on the order of 10 cm or less will generate non-negligible long-wavelength artifacts, which usually look like curved surfaces in the entire interferogram (e.g., Hanssen, 2001). Conventionally, they are fitted with low-order polynomials and simply taken out unless any sort of stacking or time-series analysis discussed below is applied. While this procedure works to eliminate the artifacts due to orbit errors, it will also take out any long-wavelength geophysically interesting signals such as the inter-seismic, post-seismic, ocean tidal loading, solid-Earth tide, and post-glacial rebound signals. Alternatively, if the ground control points (GCP) are available, where the precision ground deformation data are available, we can reestimate the baseline, based on those GCP data (e.g., Rosen et al., 1996), but such data are often unavailable in remote areas.

One approach to correct for the tropospheric delay signals is to employ the other independent estimates derived from either the GPS-based tropospheric delay estimates (e.g., Onn and Zebker, 2006) or the output results from high-resolution numerical weather model (e.g., Foster et al., 2006). These so-called calibration approaches are, however, not easily applicable. The dense ground-based GPS network is limited to a few areas in the world. Also, high-resolution numerical weather model still needs significant computational resources.

Besides the tropospheric delay problem, the effects of ionosphere on both interferograms and pixel-offset images were clearly recognized in the results of the 2008 Wenchuan earthquake (Mw7.9), China, derived from ALOS/PALSAR (Kobayashi et al., 2009; Raucoules and de Michele, 2010), although they were pointed out in polar region many years ago (e.g., Matter and Gray, 2002). It is well known that the lower the carrier frequency is, the more significant the ionospheric dispersion impacts on the propagation delay. Thus, in many of the previous applications of C-band SAR data, the effects of ionosphere could have been neglected. While GPS also employs L-band, the high-precision GPS geodetic survey corrects for the ionospheric effect with the use of dual frequency, L1 and L2, observation data. In contrast, PALSAR is a single frequency SAR sensor and incapable of the standard ionosphere-correction approach. Empirically, however, we will encounter the ionospheric signals more frequently in the ascending data acquired in the local nighttime than in the descending data acquired in the local daytime. We also recall that the JERS, the other L-band SAR operated during 1992–1998, did not reveal any significant ionospheric signals at least in mid-latitude regions, and that most of the JERS data were acquired in the descending track. Besides the latitude, the effects of ionosphere on SAR image might, therefore, significantly depend on the data acquisition time. Like the tropospheric effects, detailed studies of ionospheric impacts on the SAR data are also currently underway.

A simple approach to eliminate those noises is *stacking*, in which several interferograms are stacked to isolate small-amplitude signals, because those noises can be regarded as temporally random, whereas the deformation signals are spatially persistent. Two important prerequisites for successful stacking are: (1) the data acquisition dates of those interferograms should not be overlapped, in order not to enhance the noises of any particular acquisition date(s), and (2) each temporal baseline should be as long as possible so that each interferogram can include as much deformation signals as possible. In reality, it is not easy to gather many independent interferograms that have desirably long temporal baselines because the available data often encounter the spatial and temporal decorrelation. Also, the simple stacking approach inherently assumes temporally linear evolution in the ground deformation, preventing us from deriving time-series data.

Time-Series Analysis: Ferretti et al. (2000, 2001) proposed a new analysis technique called *Permanent Scatterer InSAR* (*PS-InSAR*), in which they take advantage of even such data pairs whose spatial baselines are longer than the critical values. Thereby, they could expand the temporal coverage, and thus could estimate the long-term deformation signals on the order of mm/year. Key idea of PS-InSAR is to pick up only such pixels that will exhibit long-term coherence due to the existence of corner-reflector-like targets, which Ferretti et al. called "permanent scatterers." Based on those pixels alone, they generate a stack of differential interferograms, using available DEM and orbit data. The phase values include not only deformation signals, but also such topographic signals that were not initially taken into account, because the longer spatial baseline pairs are so sensitive to the topography that the available DEM could not account for. In PS-InSAR and its variants (Werner et al., 2003; Hooper et al., 2004), they fit the differential interferogram stack to a phase model that describes not only temporal evolution of deformation but also corrections to the available DEM. Deviations from the phase model can be filtered into either non-linear deformation or atmospheric signals because the former signals are correlated and thus low-pass filtered along temporal axis, while the latter signals are temporally random; the orbit data must be assumed to be correct. A known limitation of PS-InSAR is its rather lower sampling density over non-urban areas. However, despite a lack of man-made objects, Furuya et al. (2007) succeeded in detecting active salt tectonic motion, applying a similar technique to Canyonlands National Park, Utah, presumably because the area was non-vegetated and the exposed surface rocks behaved like corner-reflector-like targets.

Another time-series analysis approach was devised and known as small baseline subset (*SBAS*) algorithm (Berardino et al., 2002). Key idea of the SBAS algorithm is *least-squares inversion* of unknown deformation at each SAR data acquisition epoch, based on the available unwrapped differential interferograms (e.g., Lundgren

et al., 2001; Schmidt and Burgmann, 2003). Using small baseline interferometric pairs, the SBAS approach is free from spatial decorrelation and allows us to take advantage of the fine spatial resolution of InSAR data. If the number of interferograms is greater than or equal to the number of SAR acquisitions, the inversion problem becomes an over-determined or well-determined problem, and can be easily solved in a least-squares approach. It is uncommon, however, that all the available interferometric pairs have short baselines, and accordingly the temporal sampling rate will decrease. Berardino et al. (2002) proposed to employ several groups of "small baseline subset" to overcome the lower temporal resolution issue, and solved the rank-deficient problem with the use of singular value decomposition (SVD) technique. The SVD gives the minimum-norm least-squares solution, which is equivalent to minimizing the estimated velocities at any time intervals.

Time-series analysis of SAR data is a promising technique, but almost all previous analyses are based on the C-band ERS1/2 and Envisat data, because not only more-than-decade-long data but also high-precision, well-controlled satellite orbits are available for these satellites. As noted before, not all geophysically interesting phenomena could be detected by C-band and shorter-wavelength SAR data. If the L-band ALOS/PALSAR data are archived for a much longer time, and if the follow-on ALOS-2 and the DESDynI are launched as scheduled, the time-series analysis of SAR data will become feasible even in areas that have never been monitored before. The time-series analysis with ScanSAR data should also be possible. Long-term continuous monitoring with L-band SAR will provide us with more opportunities for new discoveries.

Definition

FTLRS. Acronym for French transportable laser ranging system (Nicolas et al., 2001).

ILRS. Acronym for International laser ranging service. International service established in 1998 (Pearlman et al., 2002). See entry *Geodesy, Networks and Reference Systems*.

Laser. Acronym for light amplification by stimulated emission of radiation.

Least-squares method. Optimization method. See (Tarantola, 2004).

LLR. Acronym for lunar laser ranging. See (Bender et al., 1973).

Introduction

The Satellite Laser Ranging (SLR) technique was born in 1964, with the first returns obtained from the satellite Beacon Explorer B. Since the launch of the first dedicated laser satellite Starlette in 1975 (Schutz et al., 1993; Barlier and Lefebvre, 2001), SLR has provided range measurements which have been the foundations of, not only precise orbit computations, but also major geodetic products, fundamental for many Geosciences applications. One of the advantages is that the onboard equipment is light, cheap, has an infinite lifetime, and does not consume any energy.

Technique

Principle and instrumentation

SLR is based on the measurement of the round-trip time of flight of laser pulses, between a ground station and a satellite orbiting round the Earth. As the measurements are carried out in the visible (or near visible) spectrum, the technique is dependent on weather conditions; it does not work under a cloudy sky. The satellite is equipped (if not entirely covered) with reflectors specially designed to reflect the laser in the incident direction. The ground station is composed of several instruments: a laser, a telescope for the emission and/or the reception of light, a detection system (for the start and the return of the laser), an event timer, a timing system for the chronometry, a frequency standard, a measurement calibration system (required because of the instrumental instabilities), a weather station (for the atmospheric correction, see Sect. Data analysis and orbitography), and a completely computerized system to pilot the telescope during the satellite tracking, to process the measurements, and to send the data obtained.

This complex ground instrumentation requires a permanent staff to (1) maintain the instruments and, consequently, to guarantee a stable quality of the measurements and to (2) track the satellites. This constant manpower requirement and the need for a cloudless sky to track satellites are drawbacks of the technique, even if some stations are now on the way toward automation. Moreover, these requirements make the SLR technique different (but not less effective, far from it) from the other satellite techniques: Doppler Orbitography and Radiopositioning Integrated by Satellite (DORIS), Global

Positioning System (GPS) – see entry *GPS, Data Acquisition and Analysis*, GLObal NAvigation Satellite System (GLONASS), and the future Galileo (Europe) and Compass (China) systems. Indeed, these systems (will) operate whatever the weather conditions and their complexity lies more in the spatial segment.

Data

The raw observations produced during a satellite pass over a station are not directly put at the disposal of the scientific community. Indeed, with nearly 10 laser pulses per second, a significant number of returns can be obtained. Roughly speaking, these latter are thus compressed to deduce the so-called "normal points," gathering all the information contained in full-rate points, over specific spans of time, depending on the satellite altitude. The ILRS recommended algorithm is available at http://ilrs.gsfc.nasa.gov/products_formats_procedures/normal_point/np_algo.html. Normal point files per satellite can be retrieved through the ILRS data centers at ftp://cddis.gsfc.nasa.gov/slr/ and http://www.dgfi.badw-muenchen.de/edc/edc.html.

Technological evolution

Since the early seventies, the SLR technology and, consequently, the measurement quality have constantly improved, starting at a 1.5 m precision level, with a significant step toward the millimeter accuracy reached in the nineties (Degnan, 1993). Presently, a typical laser configuration is (1) a wavelength of 532 nm (green), (2) a pulse width ranging from 35 to 200 ps, and (3) a fire rate of 5, 10, or 20 Hz. The overall accuracy of the measurements is assessed at the 5 mm level for a few stations – see (Exertier et al., 2006) who also provide a complete error budget of the technique.

The principal technological improvements under study are the following (Noll and Pearlman, 2007, 6-1): reduction of the pulse length to 10 ps to improve the single shot precision; kHz laser ranging to improve the normal point precision (by providing a larger number of averaged raw data per normal point) and the speed of target acquisition during satellite tracking, together with more precise event timers (precision of 3 ps or less); multi-wavelength ranging to test possible improvements of the atmospheric correction.

Satellite constellation

Passive laser satellites have been developed for geodesy purposes. Their low area to mass ratios minimize the amplitude of the surface forces (atmospheric drag, for instance). The SLR network first tracks dedicated satellites, which have a practically infinite lifetime. The two first SLR satellites were Starlette, developed by CNES (France) in 1975, with a 812 km perigee height, and LAGEOS, launched by NASA (United States) in 1976, with a 5,860 km perigee height. They were followed by similar satellites in the eighties and in the nineties: Ajisai (1986, Japan, 1,490 km), Etalon-1 and -2 satellites (1989, USSR, 19,120 km), LAGEOS-2 (1992, United States and Italy, 5,620 km), and Stella (1993, France, 800 km). The constellation of SLR geodetic satellites is now composed of orbits with a wide range of altitudes and inclinations to the equator, providing various dynamical configurations. Some new SLR-only missions are under investigation, such as the LAGEOS III mission, for purposes concerning fundamental physics (Ciufolini, 1994).

The network also tracks (or has tracked) non-specific SLR satellites equipped with laser retroreflectors: altimetric (TOPEX/Poséidon, Jason-1, Jason-2), remote sensing (ERS-1 and -2, ENVISAT), gravimetric (CHAMP, GRACE-A and -B, GOCE), and GNSS satellites (some GPS, GLONASS, and Galileo – GIOVE-A and -B – satellites).

Currently, 34 artificial satellites are being tracked by the network. Moreover, few stations, equipped with large telescopes have the capability to measure the range to the Moon (LLR technique). One station is located in Europe (Grasse, France, telescope with a 1.6 m aperture), and two others are located in North America: at Apache point, in southern New Mexico, where the Apollo project utilizes a 3.5 m telescope, and at the McDonald Observatory, University of Texas (75 cm). See http://ilrs.gsfc.nasa.gov/satellite_missions/list_of_satellites/.

Ground network

Starting with five stations in the early seventies, the network configuration evolved over the last 35 years and the number of stations has been stable for several years. The current network is composed of about 30 stations (see http://ilrs.gsfc.nasa.gov/stations), distributed among 20 countries or so. Most of these stations observe only during night, a few having as well the capability of observing in daylight (useful for Global Navigation Satellite System – GNSS – satellite tracking, see Sect. Data analysis and orbitography). The distribution of this network, as is the case for the Very Long Baseline Interferometry (VLBI) network (see entry *Very Long Baseline Interferometry*), is generally admitted as a weakness of the technique. Indeed, in the northern hemisphere, most stations are located at mid-latitudes; in the southern hemisphere, there are only few stations (5, typically). Moreover, the densification and the maintenance of an ideal network are dependent on political decisions and the economic context (because of the financial commitments required to both build and maintain a SLR station).

This situation should improve in the near future, thanks to projects such as the NASA SLR2000 project (completely automated, eye-safe, highly reliable, and low-cost SLR stations), recently relaunched (McGarry and Zagwodski, 2008) and now called NGSLR, or thanks to mobile systems (FTLRS, for instance).

Data analysis and orbitography

General principle

A typical data analysis follows this two-step sketch, which is more or less the same for GPS and DORIS data analyses:

1. *Orbit computation, per satellite*. The physical forces acting on the satellite motion account for gravitational (Earth's gravity field, including the time-varying part, luni-solar attraction) and non-gravitational perturbations (mainly atmospheric drag and radiation pressure). The equations of motion are numerically propagated to provide time series of a state vector of orbital elements. The theoretical range rate is then computed, on the basis of these time series, and on geodetic products such as the Terrestrial Reference Frame (TRF), Earth Orientation Parameters – EOP, and some station displacement models. These "theoretical observations" are finally compared, in a least-squares sense, with the real data to estimate some dynamical parameters (initial satellite state vector, drag coefficients, etc.). Moreover, empirical accelerations can be estimated to compensate for some part of the modeling deficiencies (Crétaux et al., 1994) and, consequently, to improve the post-fit residual level. The computations are iterated until a given stop condition is fulfilled.
2. *Geodetic parameter estimation*. The orbital arcs are simultaneously used to derive predicted range measurements, together with a priori values of the parameters to be estimated and required models. Updates of the geodetic parameters (station positions, EOP, etc.), and generally of some of the dynamical parameters estimated during step 1, are then estimated in a least-square sense. If necessary, during this step, the measurements can be gathered for several different satellites and over a long period of time.

Most of the models applied (station displacements, Earth's gravity field, atmospheric density, etc.) are not specific to the SLR data processing. Their list is provided in the International Earth Rotation and Reference Systems Service (IERS) conventions (McCarthy and Petit, 2004).

Specific corrections

As they are carried out in the visible spectrum, SLR laser beams are not affected by the ionosphere crossing, in comparison to the radio-electric signals. But the tropospheric propagation still limits their accuracy. Recently, an improved model of zenith delay has been developed (Mendes and Pavlis, 2004). This model, together with an improved mapping function (Mendes et al., 2001), is currently the standard for SLR data analyses. This correction takes typical values of several meters and its inaccuracy is still assessed at a few-mm level (Exertier et al., 2006). In order to reach the 1-mm accuracy in the near future, improvements are under study; for example, ray tracing (Hulley and Pavlis, 2007) and multi-wavelength systems (Hamal et al., 2008).

The temporal spread of returned laser pulses due to the reflection from multiple reflectors on the satellite is another significant error at the 1-mm level. To better handle these effects, (Otsubo and Appleby, 2003) have recently proposed system-dependent center-of-mass corrections for spherical satellites (LAGEOS, Ajisai, and Etalon), with variations up to 10 mm. Efforts are still in progress in order to better understand and take these effects into account in SLR analyses (Luck et al., 2008, Sect. 8).

Despite the systematic in situ calibrations, ranges can be affected by systematic errors, dependent on the instrumentation: time and range biases. Due to their strong correlation with station heights, much attention is paid to range biases and their temporal variations. They are indeed constantly monitored in the framework of the ILRS activities – cf. (Otsubo et al., 2009) for instance. Moreover, analysis efforts towards better estimations of these biases are in progress, see (Appleby et al., 2009) as an example. Typical bias values range from a few millimeter to centimetric values. These biases can be handled in different ways (applied and/or estimated) during any data processing.

Finally, in a relativistic context, the propagation of light between a ground station and a near-Earth satellite induces a supplementary time delay with respect to the purely geometric path (Ries et al., 1988). This correction takes few-mm values.

LAGEOS satellites

Due to their relatively high altitudes (about 6, 000 km), both LAGEOS satellites are essential targets and their orbits are permanently tracked and computed with great care. Since their launch, the quality of the computed orbits has evolved with the technique: from a 50 cm precision in 1976 (Exertier et al., 2006) to a few centimeters in the mid nineties (Marshall et al., 1995) to nearly 1 cm nowadays. Additionally, various non-gravitational effects have been evidenced in the LAGEOS-1 orbit: solar radiation pressure, Yarkovsky–Shah thermal effect, asymmetric reflectivity of the satellite surface, and asymmetric thermal emissivity of the Earth (Métris et al., 1999).

GNSS satellites

Since the first study (Degnan and Pavlis, 1994), and sometimes through dedicated campaigns such as IGEX-98 (Barlier et al., 2001), SLR has always contributed to the validation of GNSS orbits. This validation generally consists in the comparison between SLR range measurements to GNSS satellites and the predicted ranges computed with the GNSS-only orbits. According to (Urschl et al., 2007), the consistency (assessed over nearly four years) between SLR and GPS (resp. GLONASS) is at an accuracy level of −3 cm (resp. −3 mm) with a precision at the level of 2.5 cm (resp. 5 cm). Further studies are in progress to get an exhaustive understanding of the inter-technique differences. Furthermore, all satellites of the future GNSS

Galileo system with be equipped with Laser Ranging Arrays (LRA) for such orbit validations.

Applications to geodesy and geodynamics

Earth's gravity field

Before the launch of dedicated space missions (CHAMP, GRACE, and GOCE), the gravity field models were mainly built on the basis of SLR data acquired on the whole constellation, providing various dynamical configurations (semi-major axes, inclinations to the equator), and, consequently, various sensitivities to the mass distribution within the Earth's system. The GRIM5-S1 model (Biancale et al., 2000), one of the latest SLR-only based, was prepared in a joint German–French effort. The solution was obtained by solving simultaneously for the gravitational and ocean tide potentials and tracking station positions. Nowadays, long wavelengths of the gravity field are still deduced from SLR data, accurate enough to provide a value of the Earth's gravitational constant with 10 significant digits (corresponding to an orbital post-fit residual error of the order of a few centimeters), see (Tapley et al., 1993). Since the CHAMP mission was launched in 2000, followed by the GRACE mission in 2002, and GOCE in 2009, a new generation of nearly monthly Earth's gravity field models was initiated, benefiting both from the high sensitivity of the orbit (a few hundred km high) to regional variations and from accelerometric data, measuring the non-gravitational forces (mainly atmospheric drag). The GRACE-only models expanded in spherical harmonics provide coefficients up to degree and order 360. See (Reigber et al., 2003; Lemoine et al., 2007; Tapley et al., 2005) and entries *Gravity Field of the Earth* and *Gravity Field, Temporal Variations from Space Techniques*.

Mass variations within the Earth's dynamic system have a temporal spectrum ranging from hours to decades, and even longer, that can be evidenced by SLR data, because they are available over a very long period of time. Many of them are related to both long-term and short-term climate forcing, and are linked to mass redistribution in the atmosphere, ocean, and continental water (Chen et al., 2000; Cheng and Tapley, 2004). By the next years, SLR data, moreover, are likely to provide an unique opportunity to continue to monitor the Earth's gravity field, after the end-of-life of the CHAMP, GRACE, and GOCE missions.

Terrestrial reference frame and Earth's rotation

Since the first computation of a combined TRF in 1984 (called BTS84), SLR has always been a keystone of the BTS (BIH – Bureau International de l'Heure – Terrestrial System) and, after 1988, of the International Terrestrial Reference System (ITRS, see entry *Geodesy, Networks and Reference Systems*) realizations (McCarthy and Petit, 2004, Chap. 4). Indeed, their origin and scale definitions have always strongly involved this technique. Parallel to the SLR-positioning precision, starting with a decimetric precision (BTS84), the successive ITRF versions have turned 1 cm-precision level with the ITRF96. For the more recently published version (ITRF2005), the whole precision of positions (resp. velocities) is under 2 mm (resp. 1 mm/y). And, for the first time of the ITRF history, the ITRF2005 was computed with times series of (weekly for SLR) station positions and (daily for SLR) EOP. Regarding positioning, the weekly WRMS for the well performing SLR stations is 5 mm for both planimetry and height (Altamimi et al., 2007). For comparison, the weekly WRMS for GPS are 2 mm (resp. 5 mm) for planimetry (resp. for height). It must be noted that the most recent ITRS realization (ITRF2008) is now available (http://itrf.ign.fr/ITRF_solutions/2008).

Regarding Earth's rotation, SLR provides (with the LAGEOS data) the longest space-geodetic time series of EOP (Gross, 2009). Starting with a 10 milliarcsecond (mas) precision in the seventies, the discrepancy between the SLR and the IERS polar motion series was assessed at the level of 0.3 mas in the mid 2000 years (Gambis, 2004). (Coulot et al., 2010) have recently showed that significant precision improvements are still possible with the help of a rigorous referencing.

Global Earth's deformations

For many years, SLR has provided unique and inestimable information about the geocenter motion (Pavlis and Kuźmicz-Cieślak, 2009a). The geocenter motion is the 3-dimensional motion of the instantaneous Earth's center-of-mass with respect to any conventional reference (the ITRF secular origin, for instance). It is related to the responses of the Earth to the displacements of its fluid masses (atmosphere, ocean, etc.) and its temporal variations are dominated by annual signals of few mm amplitudes. (Collilieux et al., 2009) provide an exhaustive review about this geodynamical signal and, moreover, assess the effect of the SLR network on its determination.

The ITR2005 computation has been a good opportunity to study the residual position time series which contain the non-linear part of the station motions. Regarding SLR station positions, most of the time series evidence annual signals. As surface loading effects (see van Dam et al. (2002) and http://www.sbl.statkart.no/) are not currently modeled in the routine data processing, they are supposed to be evidenced by the position series. (Collilieux et al., 2010) show that an a posteriori correction for these effects with a geodynamical model leads to a reduction of the amplitudes of the annual signals for a majority of stations. Furthermore, (Pavlis et al., 2009) strongly recommend the modeling of such effects in the future SLR data processing to achieve a better accuracy.

Altimetry and sea level monitoring

Stable and accurate TRF, satellites orbits, and altimeter measurements are prerequisites for robust altimetric Mean Sea Level (MSL) computations over large time periods

(Leuliette et al., 2004; Beckley et al., 2007; Ablain et al., 2009). Indeed, these conditions are crucial to connect the data provided by successive missions. Since the advent of altimetry (launch of TOPEX/Poséidon in 1992), SLR has contributed to all these efforts, first regarding the TRF (see Sect. Terrestrial reference frame and Earth's rotation). SLR has also played a major role in the Precision Orbit Determination (POD) framework, additionally to DORIS and GPS data. For instance, the technique has recently contributed to the achievement of a 1-cm radial accuracy for the orbit of Jason-1 (Luthcke et al., 2003). In this context, the laser-based short-arc technique (Bonnefond et al., 1999) is also a major method to assess the radial accuracy of the altimetric satellites on an operational basis. Finally, thanks to thoroughly instrumented sites, it is possible to monitor both bias and drift of the radar altimeters, by taking advantage of direct overflight passes (see http://www.gavdos.tuc.gr/intro.jsp for an illustration of the calibration principle). The French campaigns led in Corsica with the FTLRS show that the quality of such a calibration mainly depends on the accurate positioning (mainly deduced from Starlette and Stella data) of the mobile system and on the stability of its range bias (Gourine et al., 2008).

Summary

Observing and understanding the system Earth require numerous and accurate geodetic measurements over both spatial and temporal wide spectra. Since the early seventies, the SLR technique has provided such measurements, inestimable for the progress of Space Geodesy and, consequently, of Earth's sciences. Nowadays, in the Global Geodetic Observing System (GGOS) context, and, more particularly, with the stringent requirements on the ITRF accuracy (1 mm and 0.1 mm/y) and the crucial need of taking advantage of the features of each space-geodetic technique, SLR still has a major role to play.

Moreover, to reach the ambitious goals fixed for the near future, this technique is currently renewed. From a technological point of view, the kHz ranging has recently showed the wide spectrum of its abilities, see the dedicated sections in (Luck et al., 2008; Schillak, 2009). Regarding the ground and spatial segments, the design of the ideal SLR network of the future is in progress (Pavlis and Kuźmicz-Cieślak, 2009b), as is the design of the next generation of SLR stations, and new satellite missions are already planned. Concerning the data analysis, new modelings should help to improve the accuracy of the products (Pavlis et al., 2009). More particularly, the unprecedented quality of the Earth's gravity field models reached with the GRACE (Tapley et al., 2004) and GOCE missions should allow the use of low-orbiting satellite (Starlette, Stella, and Ajisai) data for station position computations (Lejba and Schillak, 2009).

Finally, new fundamental objectives have recently been fixed for the SLR technique in the time (frequency) domain, though time transfer projects (Samain et al., 2009) and interplanetary navigation (Ni et al., 2002).

SEAFLOOR SPREADING

Richard N. Hey
Hawaii Institute of Geophysics and Planetology, School of Ocean and Earth Science and Technology, University of Hawaii, Honolulu, HI, USA

Definition

Seafloor spreading is the mechanism by which new oceanic lithosphere is created at and moves away from divergent plate boundaries. The seafloor spreading hypothesis led to one of the most important paradigm shifts in the history of the Earth sciences.

Introduction

The revolutionary seafloor spreading hypothesis improved and subsumed the continental drift hypothesis, and rapidly culminated in what is now known as the plate tectonics scientific revolution. It was first hypothesized by Hess in 1960, in a widely circulated preprint and paper (Hess, 1962) he considered so speculative that he called it "an essay in geopoetry". This hypothesis was named "seafloor spreading" in another influential early paper (Dietz, 1961). It offered a simple explanation for many problems with the prevailing paradigm that the Earth was a mostly static, slowly contracting planet, with fixed continents and old ocean basins, and no large-scale horizontal displacements. This paradigm had previously been challenged, most notably by Wegener's continental drift hypothesis (Wegener, 1912), and by paleomagnetic measurements in the 1950s that were consistent with continental drift, but before the 1960s these ideas were not generally accepted.

The revolution

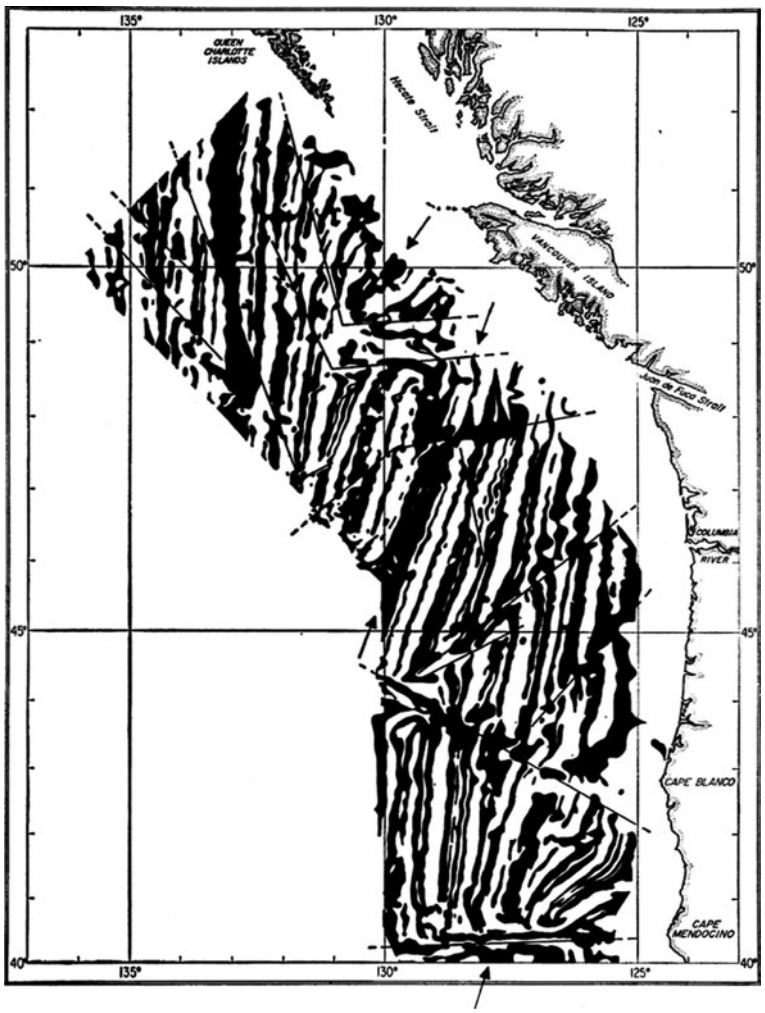
Hess realized that if mantle convection carried seafloor and continents away from seafloor spreading centers (mid-ocean ridges) toward trenches (subduction zones), with new seafloor formed at ridge axes and destroyed at trenches, this would explain the shallow bathymetry, earthquakes, high heat flow, lack of sediments, and extensional structures characterizing ridge axes, as well as the deep trenches, earthquakes, compressional structures, mountain ranges, and volcanoes characterizing subduction zones.

A key step in the confirmation of seafloor spreading was the recognition by Vine and Matthews (1963) (and independently by Morley, in a paper unfortunately turned down as too speculative by both *Nature* and the *Journal of Geophysical Research*, eventually published in Morley and Larochelle, 1964), which offered a simple explanation for the existence of puzzling magnetic "stripes" on the seafloor. The Vine–Matthews (or Vine–Matthews–Morley) hypothesis proposed that a combination of seafloor spreading and episodic reversals of the Earth's magnetic field (at the time another very speculative idea) would create alternating zones of normally and reversely magnetized crust, and thus linear positive and negative magnetic anomalies in a pattern symmetric about the spreading axis.

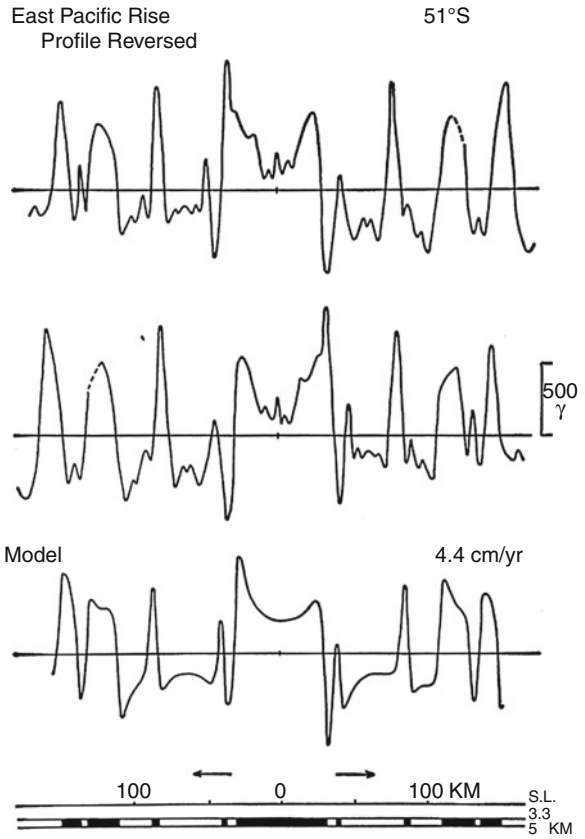
The next key step in the revolution occurred in 1965, when Wilson noted that deformation of the Earth's crust is concentrated in narrow mobile belts, and postulated that these features are all interconnected in a global network, the first qualitative model of plate tectonics (Wilson, 1965). The zones of extension and compression are connected by a new class of faults defined by Wilson as transform faults, which required relative plate motion and turned out to be the most important type of fault on Earth. He showed that seafloor spreading occurring on offset mid-ocean ridge axes would produce relative motion exactly opposite to the motion the sense of offset would predict without seafloor spreading, and that earthquakes should only occur between the offset seafloor spreading axes. These radical predictions, completely opposite to prevailing wisdom, were soon confirmed seismically. Furthermore, by correctly interpreting the San Andreas fault

as a transform fault between the Pacific and North American plates, he predicted the existence of previously unrecognized seafloor spreading offshore western North America. Vine and Wilson (1965) showed that the predicted magnetic symmetry existed in this area, where magnetic stripes had been discovered in the mid-1950s (Mason, 1958; Mason and Raff, 1961; Raff and Mason, 1961), over what they recognized as the Juan de Fuca Ridge (Figure 1), and furthermore, that the pattern of stripes corresponded perfectly with the pattern of magnetic field reversals (Cox et al., 1963; McDougall and Tarling, 1963), once the Jaramillo anomaly was discovered. Vine (1966) also demonstrated similar symmetry and correlation with the reversal timescale in another important data set, the Project Magnet aeromagnetic data collected over the Reykjanes Ridge south of Iceland. His color figures of these classic data sets and correlations (Vine, 1968) became iconic.

The smoking gun for many scientists was the discovery by Pitman and Heirtzler (1966) of near perfect symmetry in the Eltanin-19 profile collected over the Pacific–Antarctic Ridge. Essentially every tiny wiggle seen in the magnetic anomaly profile on the Pacific plate was mirrored on the Antarctic plate, and correlated perfectly with the magnetic reversal time scale (Figure 2). The symmetry in these data required a symmetric axial process, with new seafloor carried away on both plates, and thus provided compelling evidence for both the Vine–Matthews and seafloor spreading hypotheses. Vine convincingly summarized this evidence in influential symposia and publications (Vine, 1966, 1968), and, by the end of 1966, seafloor spreading was generally accepted by marine geophysicists, who quickly extrapolated the magnetic reversal time scale from ~10 Ma to ~80 Ma and worked out at least the basic recent evolutionary history of every ocean basin.



Seafloor Spreading, Figure 1 Raff and Mason (1961) magnetic stripes recognized as symmetric about seafloor spreading axes (*arrows*) by Vine and Wilson (1965). (From Vine, 1966. Reprinted with permission from AAAS.)



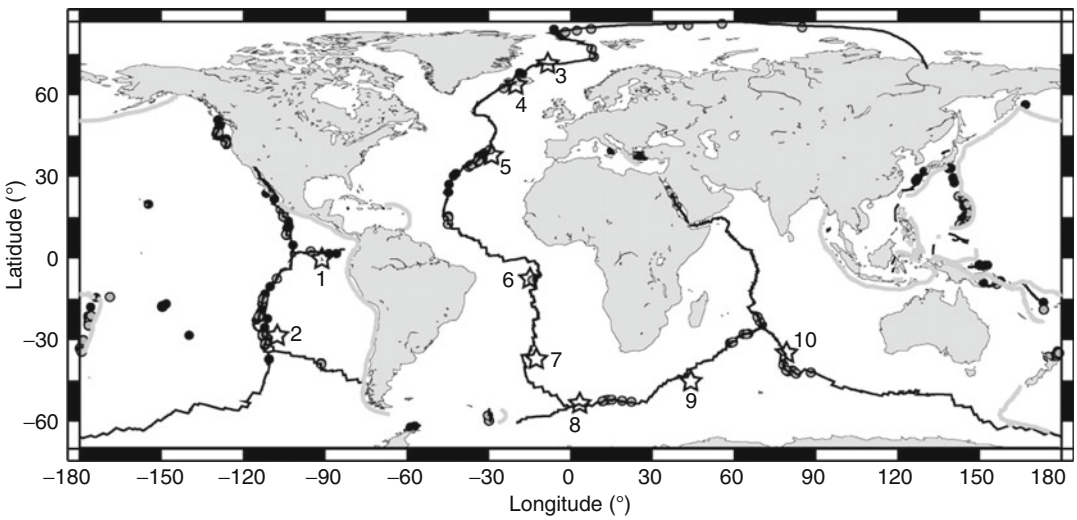
Seafloor Spreading, Figure 2 Eltanin-19 magnetic anomaly profile (*top*) from Pitman and Heirtzler (1966), shown compared with its mirror image (*middle*) and magnetic anomaly model calculated from the magnetic reversal timescale (*bottom*), assuming seafloor spreading at a constant 44 km/Myr. (From Vine, 1966. Reprinted with permission from AAAS.)

This scientific revolution culminated in plate tectonics the following year when Morgan (1968) and McKenzie and Parker (1967) made the key assumption that plates behave rigidly, and extended Wilson's transform fault geometry to the sphere. They showed that transforms are small circles about rotation poles describing relative plate motion, that seafloor spreading rates increase as the sine of the angular distance away from these poles, and that it was possible to use known patterns of seafloor spreading to quantitatively predict other plate motions and plate boundary evolution.

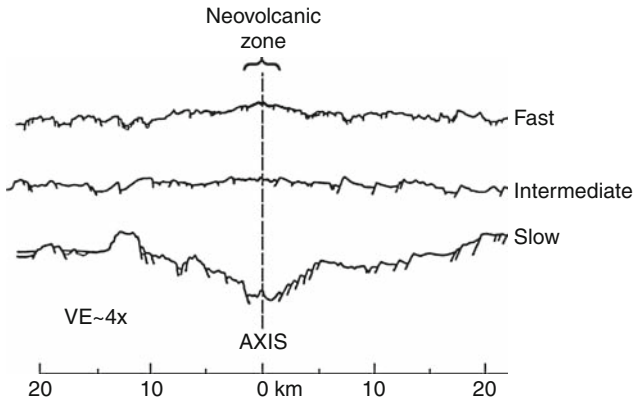
Ridge axis geometry, morphology, and crustal formation

Volcanism along the mid-ocean ridge system has formed the longest mountain chain on Earth (Figure 3). As the plates slowly (~0–150 mm/yr, or km/Myr, at present, DeMets et al., 2010, with rates remarkably similar whether using magnetic anomalies or geodetic measurements such as GPS) move apart by seafloor spreading, magma from the hot asthenosphere rises to fill the crack at mid-ocean ridge axes, elevated because of the higher temperatures. Both axial depth and morphology correlate with spreading rate (Macdonald, 1982). Fast-spreading ridge axes such as the East Pacific Rise generally have shallow depths and relatively smooth morphologies, with very small extensional axial summit troughs (except where these are completely buried by the latest eruption in the neovolcanic rift zone). Slow spreading ridges such as the Mid-Atlantic Ridge generally have much deeper, rougher, and higher-amplitude axial valleys (Figure 4), except near hotspots such as Iceland where magma supply is unusually large and even slow-spreading ridges have shallow axes with fast-spreading morphology.

The asthenosphere typically melts to become mid-ocean ridge basalt in a magma chamber under the ridge



Seafloor Spreading, Figure 3 Global distribution of seafloor spreading axes (*heavy black lines*) with known (*black dots*) or inferred (*gray dots*) hydrothermal fields. Stars are near-ridge hotspots. From NOAA/PMEL Vents Program website: http://www.pmel.noaa.gov/pubs/outstand/bake2544/images/fig01a.gif (Baker and German, 2004).



Seafloor Spreading, Figure 4 Ridge axis fault patterns and morphology as a function of spreading rate. (Modified from Macdonald, 1982.)

axis. Some basalt is erupted onto the seafloor to form pillow basalts and lava flows, which are progressively covered by sediments as the lithosphere ages and moves away from the axis. Below the basalts are the sheeted dikes, the paths through which the lava moved from magma chambers to the surface, and below the dikes are the layered gabbros which cooled and crystallized in place (intrusives) rather than erupting at axial volcanoes (extrusives). This typical sequence of mantle ultramafics – gabbro – sheeted dikes – extrusive basalts – sediments is observed on the seafloor in tectonic windows where existing lithosphere is rifted apart, and also where slices of old ocean lithosphere are thrust into ophiolite mountain belts as in Oman and Cyprus (Karson, 2002).

Hydrothermal vents

As the new seafloor cools it contracts and cracks. Water goes down these cracks, is heated, reacts with the surrounding rocks, and comes back up as buoyant hydrothermal vents (Baker and German, 2004). These occur at a range of chemistries and temperatures, up to ~400°C in black smokers, so-called because of the sulfide-rich plumes that precipitate suddenly when the superheated water is injected into the surrounding ~2°C seawater, forming sulfide chimneys (Figure 5). White and clear smokers occur at lower temperatures. The chemical reactions provide energy for an unusual kind of life that does not depend on photosynthesis but flourishes as chemosynthetic communities at many of these vents, rare deep-ocean oases in an otherwise extremely barren environment (Kelley et al., 2002).

Summary

Seafloor spreading was a critical step in the contentious scientific revolution from the previous static Earth paradigm to the now universally accepted plate tectonic paradigm. Today it refers to the processes creating new oceanic lithosphere where plates move apart. Seafloor spreading replaces the lithosphere destroyed by subduction, and exerts important influences on Earth's chemical and biological evolution.

SEDIMENTARY BASINS

Magdalena Scheck-Wenderoth
Helmholtz Centre Potsdam, GFZ German Research Centre for Geosciences
Sect. 4.4: Basin Analysis, Potsdam, Germany

Definition

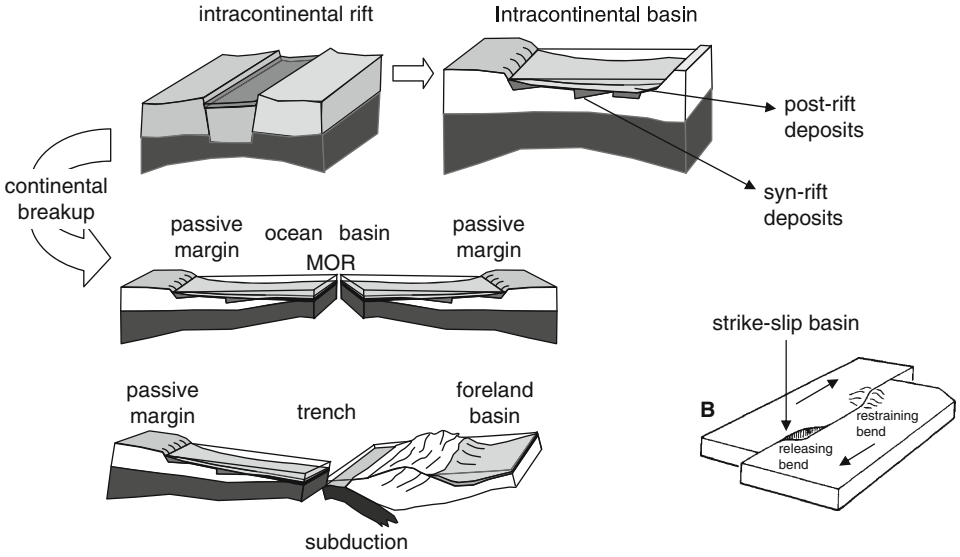
Sedimentary basins are regions of prolonged subsidence of the Earth's surface that provide the accommodation space for mineral and organic material (Allen and Allen, 2005). These deposits – the sedimentary rocks – are the record of the past geological history including tectonic events, climatic conditions, changes in sea level, and other environmental modifications. In addition, sedimentary basins are long-lived, low-temperature geo-reactors in which the accumulated material experiences a variety of transformations (Bjorlykke, 2010; Littke et al., 2008; Roure et al., 2009; Welte et al., 1997). As a result of these processes, basins contain our resources of fossil fuels, ground water, and inorganic commodities. Moreover, they are important reservoirs of heat and repositories for different socioeconomically relevant fluids such as CO_2.

Basin types

Basins can be classified in terms of their plate-tectonic setting. The plate-tectonic Wilson cycle (Figure 1) describes that the relative movements of plates on the sphere of the earth result in a closed loop of *continental rifting* and breakup, ocean basin development, closure of oceans at subduction zones and, in consequence of plate convergence, continental growth.

Basins thus can form as continental rifts that may evolve either into intracontinental basins or lead to continental breakup and ocean basin formation. New *oceanic lithosphere* (see entry *Lithosphere, Oceanic*) is produced along the Mid Ocean Ridges due to oceanic spreading. If oceanic lithosphere cools, it becomes denser and subsides in the oceanic basins that are bordered by passive continental margins. Of the latter "hot" or volcanic passive margins are distinguished from "cold" or nonvolcanic passive margins (White et al., 2003). If oceanic lithosphere cools beyond a specific threshold, it becomes too heavy to be sustained by the less dense asthenosphere and will finally descend back to the mantle at subduction zones. In these convergent settings, the descending plate is flexed downward and deep oceanic trenches develop above the down-going plate. Subduction may culminate in continent–continent collision if the oceanic lithosphere is entirely subducted and collisional fold and thrust belts form. Loading by collision-related fold and thrust belts also causes a downward flexure of the lithosphere and foreland basins to form. The Wilson Cycle may stop at any evolutionary step, because the causative forces cease to be effective. Accordingly, a continental rift not necessarily develops into an ocean basin, but may survive for hundreds of millions of years as an intracontinental basin (Heine et al., 2008; Littke et al., 2008). Finally, horizontal movements along strike-slip faults may also cause local extension and related pull-apart basins (Allen and Allen, 2005; Petrunin and Sobolev, 2008; Smit et al., 2010; Weber and group, 2009).

These different types of basins have a characteristic structure of the sediment fill as well as of the underlying crust and mantle lithosphere. This concerns the geometric configuration, the distribution of physical properties, and the resulting *isostatic* (see entry *Isostasy*) and thermal configuration. To assess the configuration of a basin, a wide spectrum of methods has to be integrated. Observations



Sedimentary Basins, Figure 1 Basins in their plate-tectonic setting.

obtained from field measurements, from *deep seismic imaging* (see entry *Deep Seismic Reflection and Refraction Profiling*), and from wells drilled into the basin fill, potential field data, and *heat flow* (see entry *Heat Flow Measurements, Continental*) data as well as new data sets from remote sensing need to be integrated with numerical models that simulate processes in basins at different scales.

Figure 2 shows exemplary crustal sections across the Norwegian passive margin and across the intracontinental Central European Basin System.

Basin-forming mechanisms

There are three main mechanisms leading to the formation of sedimentary basins (Allen and Allen, 2005)

1. Extensional stresses causing the lithosphere to thin
2. Flexure of the lithosphere in response to surface loading or compressive stresses
3. Viscous flow of the mantle causing positive or negative topography

All these mechanisms may act separately or in concert, and may affect the lithosphere over a range of spatial and temporal scales.

Conceptual models of basin formation

Conceptual models of basin formation (Figure 3) attempt to integrate geophysical and geological observations describing the geometry and the physical state of a basin into evolutionary schemes that explain basin evolution. These conceptual models also need to be consistent with data on the rheological behavior of rocks known from lab experiments as well as with data on the thermal and deformation history. All these conceptual models represent end-member scenarios and explain a large fraction of observed phenomena in specific basins.

In the concept of *passive rifting* (Figure 3) the lithosphere is stretched in response to extensional tectonic stress. This may result in pure shear thinning (McKenzie, 1978), in simple shear thinning (Wernicke, 1981), or in a mixture of the two (Lister et al., 1986).

The *uniform stretching model* (McKenzie, 1978) predicts a crustal and lithosphere thickness proportional to the stretching factor ß where ß is the ratio between initial lithosphere thickness and the stretched lithosphere thickness. Lithosphere thinning results in a passive rise of the isotherm at the thermal lithosphere–asthenosphere boundary (Turcotte and Schubert, 2002). This, in turn, causes additional thermal subsidence after the stress ceases to be effective and cooling of the previously heated lithosphere causes a density increase. In this model, uniform and symmetric lithospheric thinning by ß takes place and is accommodated by brittle faulting in the upper crust as well as by ductile flow in the lower crust and upper mantle. The uniform stretching model predicts a 2-stage subsidence: (1) as a result of tectonic stretching – on a short timescale, (10–20 my), and (2) as a result of thermal subsidence – on a longer time scale (50–100 my). Structurally, the uniform stretching model predicts syn-rift extensional faults in the upper crust with syn-rift sediments overlain by onlapping post-rift sediments of the thermal subsidence phase. The thermal history predicted by the uniform stretching model includes an initial heat peak due to the rise of the isotherm at the LAB to a shallower position (and thus an increase of the thermal gradient within the lithosphere) followed by continuous cooling during thermal re-equilibration.

Depth-dependent stretching (Sclater and Christie, 1980) is a modification of the uniform stretching model

Sedimentary Basins, Figure 3 Conceptual models of basin formation.

and accounts for different stretching magnitudes in the upper brittle part of the crust by a factor ß and the deeper lithosphere by a factor γ. In the *asymmetric stretching models* (Lister et al., 1986; Wernicke, 1981) crust- to lithosphere-scale listric faults accommodate large offsets in response to extensional stress and finally may lead to continental breakup with an "upper plate" margin developing from the hanging wall of the master detachment fault and a "lower plate" margin in the foot wall (Osmundsen and Ebbing, 2008; Sibuet et al., 2007; Zuber et al., 1986). In particular, nonvolcanic margins like the Galicia-Newfoundland (Sibuet et al., 2007) are commonly explained by this mechanism. Geodynamic modelling studies (Braun and van der Beek, 2004; Buck, 1991; Cloetingh et al., 1998; Huismans et al., 2005; Huismans and Beaumont, 2008; Kusznir and Ziegler, 1992; Lavier et al., 1999; Pascal and Cloetingh, 2002; Pérez-Gussinyé et al., 2006; Royden and Keen, 1980; Sclater and Christie, 1980; Simon et al., 2009; van Wijk, 2005; Wijns et al., 2005; Zuber et al., 1986) indicate that the nature of rheological coupling between the crust and the lithospheric mantle, local strain weakening and strengthening, and the rate of extension are the dominant factors controlling not only the subsidence evolution of basins but also if they develop in a symmetric or asymmetric style and in a narrow or wide rift mode.

In the concept of *active rifting*, basin initiation is caused by the impingement of a rising hot asthenospheric *mantle plume* (Allen and Allen, 2005; Burov and Cloetingh, 2009; Haxby et al., 1976; Turcotte and Schubert, 2002). The concept of active rifting is in fact a special case of basins initiated by *dynamic topography*. The emplacement of the *mantle plume* (see entry *Mantle Plumes*) causes uplift and induces extensional stresses at the flanks of the uplifted area due to gravitational potential. The active rise of the isotherm may lead to surface uplift above the

erosional level and the eroded material may be removed from the system. Density increase in the lithosphere due to subsequent cooling causes surface subsidence and the formation of a sedimentary basin in the previously uplifted area. As the process is transient, the system would re-equilibrate after the thermal anomaly and the related dynamic topography stop to exist. For *isostatic* reasons, net subsidence will only occur if either igneous underplating of the crust has taken place (light crust replaced by dense underplate) or if material is removed from the system by erosion during uplift. Systematic work assessing the contribution of the three processes to subsidence (extension due to gravity potential, crustal underplating, and erosion-related mass loss) is still missing. The active rift model predicts weak to missing syn-rift faulting, a syn-rift erosional unconformity, and a subsidence history corresponding predominantly to thermal subsidence. Actually, the active rift model predicts a subsidence history identical to a specific end-member case of (passive) depth-dependent stretching in which the mantle lithosphere is severely thinned whereas the crust is not. However, the active rift model predicts a colder heat flow scenario than the passive rift model, as the thermal gradient is not disturbed by an initial thinning of the lithosphere.

According to the concept of dynamic topography basins can also be initiated in response to downward flow of high density material in the convective mantle, a process causing *negative dynamic topography*. This mechanism could be related to detached subduction slabs sinking into the asthenospheric mantle and is discussed as an explanation for the subsidence of intracontinental basins that subside over several hundreds of millions of years at a very slow rate (Allen and Allen, 2005; Heine et al., 2008; Ritzmann and Faleide, 2009).

Two main conceptual models exist for *flexural basins* that form as response of the flexural rigidity of the lithosphere (Watts, 2001) to external loads: (1) downward flexure of the lithosphere due to vertical loading (Zhang and Bott, 2000) and (2) formation of crustal- to lithosphere-scale folds in response to horizontal compressive stress, a process also called *lithosphere buckling* (Burov and Cloetingh, 2009; Burov and Diament, 1992; Cloetingh and Burov, 2010). Both concepts predict a lack of syn-rift extensional faulting, a cold thermal scenario, and subsidence lasting only as long as the stress is effective (either vertical as load or horizontal as tectonic stress). Due to structural similarity, lithosphere buckling in response to far-field compressive tectonic stress (Burov and Cloetingh, 2009; Burov and Diament, 1992) can be mistaken as an expression of active rifting if the analyzed region is too small to capture the full wavelength of the buckling. Again, the different predicted subsidence and thermal histories can help to distinguish the two.

Vertical loading by sediments enhances subsidence in basins of all geodynamic settings (Watts, 2001). It has recently been proposed that mineral phase transitions may also play a role for subsidence history in different tectonic settings (Kaus et al., 2005).

The configuration of the sediment fill

The sediment fill can vary in thickness between a few to up to 20 km and is analyzed using stratigraphic methods (Allen and Allen, 2005; Catuneanu, 2006; Einsele et al., 1991; Vail et al., 1991) to assess the nature of sediments (sand, silt, shale, carbonates, evaporites), the depositional environment (continental or marine), and the climatic conditions prevailing during the time of deposition. Subsidence and deposition may alternate with nondeposition due to sea level fall or tectonic surface uplift, and lead to stratigraphic gaps separating different sequences (Figure 2). In addition, the rate of subsidence and sedimentation as well as of uplift and erosion may change with time. Stratigraphic gaps and changes in depositional conditions are expressed as unconformities separating sedimentary sequences the analysis of which is required to understand the history of a basin.

Progressive sedimentation and subsidence goes along with changes in physical properties of the deposited sediments. The two most prominent changes are (1) an increase in temperature and (2) a decrease in porosity with increasing burial depth. The initially high porosity of each layer decreases as the load of the covering deposits increases and fluids filling the initial pores are expelled. Also, chemical compaction may lead to a loss in porosity. With decreasing porosity, physical properties like density, seismic velocity, or thermal conductivity increase.

Stratigraphic analysis is performed in field studies if the fill of a basin is accessible in outcrops due to postdepositional uplift. Most of the sedimentary basins, however, extend by their very nature (areas of enduring subsidence) into the subsurface and to large depths. Accordingly, subsurface analytical methods are required to assess their configuration. The most important of these methods is *seismic imaging*. *Seismic reflections* (see entry *Deep Seismic Reflection and Refraction Profiling*) originate from the contrast in impedance at discontinuities in the subsurface that can represent stratigraphic boundaries, and unconformities or changes in attributes of a specific layer. The reflection seismic technique provides a picture of these interfaces in a two-way-travel time that is constrained by wells. Wells provide information on the absolute depth position of stratigraphic horizons and enable the conversion of seismic travel times to depth. Furthermore, wells yield data on the thermal gradient with depth as well as on changes in lithology and petrophysical properties. Properties such as composition, compaction, porosity, permeability, density, thermal and hydraulic conductivity, *radiogenic heat production* (see entry *Radiogenic Heat Production of Rocks*), and content and maturation of organic matter are measured using *Geophysical Well Logging* methods.

Apart from recording changes in relative sea level or climatic conditions, the configuration of the sediment fill may be influenced by deformation (Kley et al., 2008). Accordingly, sediments can be faulted, folded in response to tectonic forces, or deformed due to halokinetic movements (Hudec and Jackson, 2007; Scheck-Wenderoth

et al., 2008). This deformation can take place pre-, syn-, or postdepositionally, each of which is expressed by characteristic structural styles.

In particular, basin initiation in extensional plate-tectonic conditions is typically associated with normal faulting in the upper crust leading to a thinning of the lithosphere and to the accumulation of syn-rift deposits. After the tectonic stresses have declined, basins experience a phase of post-rift thermal subsidence and may even experience late basin inversion in response to compressive stress (Cooper and Williams, 1989; Mazur et al., 2005; Sandiford, 1999) (Figure 2).

Finally, there is a feedback between surface processes and deep mechanisms in the sense that *isostatic* loading by sediments will increase total subsidence and erosion of basin flanks will cause flexural rebound (Braun, 2005; Braun et al., 2008; Braun and van der Beek, 2004; Garcia-Castellanos, 2002; Kounov et al., 2007; Simoes et al., 2010; Van der Beek, 2007; Willenbring and von Blanckenburg, 2010).

The configuration of the crust beneath sedimentary basins

The different mechanisms responsible for the thinning of the lithosphere leave characteristic traces that can be detected with geophysical observations, which, however, are not always leading to unique interpretations. The most prominent attribute of the crust beneath sedimentary basins is that it is thinned compared to neighboring regions. Deep seismic data imaging of the preserved thickness of the crust helps to determine the amount of the stretching factor ß as the ratio between the initial crustal thickness as often preserved outside the basin margins and the crustal thickness beneath the basin. Crustal thinning can vary considerably across a basin with values of ß largest in the area of strongest thinning. The average initial thickness of the crust may reach up to 50 km in cratonic areas, around 30 km in Phanerozoic continental domains and less than 10 km below oceans.

As the crystalline crust is characterized by a higher density and higher velocities of seismic waves than the sediments, the interface between the two can be detected. Accordingly, the *interpretation of gravity anomalies* (see entry *Gravity Anomalies, Interpretation*) and the analysis of the observed variation of seismic velocities are key to evaluate the crustal structure. Refraction seismic techniques are used to detect variations in seismic p-wave velocities at depth whereas reflection seismic methods are useful to evaluate the changes in reflectivity of the deeper crust.

Seismic p-wave velocities (Vp) increase to values >6 km/s in the upper crystalline crust and can range up to 7.4 km/s (Christensen and Mooney, 1995) depending on the composition of the crust. There is a negative correlation between the Quartz content of crystalline rocks and seismic p-wave velocity as well as density. Silicic (Quartz-rich) rocks are characterized by smaller velocities and lower densities than mafic rocks (Table 1). Seismic shear wave velocities are also higher for crystalline than for sedimentary rocks, but are also dependent of additional parameters (Christensen and Mooney, 1995). Accordingly, the Vp/Vs-ratio is an additional parameter helping to interpret crustal structure (Afonso et al., 2010; Mjelde et al., 2003). As also the magnetic properties are different for mafic (Fe-rich) and silicic (Fe-poor) rocks, *the interpretation of magnetic anomalies* is an additional technique for the evaluation of the crustal structure beneath basins.

At the crust–mantle boundary (Moho), often a characteristic reflection and a sudden increase of seismic p-wave

Sedimentary Basins, Table 1 Overview on physical properties of rocks relevant to sedimentary basins: *seismic properties* (After Christensen and Mooney, 1995), *thermal properties* (After Artemieva, 2006; Cermak and Rybach, 1982; Fernandez et al., 2005; Förster and Förster, 2000; Ritter et al., 2004; Scheck-Wenderoth and Maystrenko, 2008)

velocity to values >8 km/s is observed in deep seismic data marking the transition to the lithospheric mantle (Bauer et al., 2000; DEKORPBASIN and Group, 1999; Fowler, 1996; Hirsch et al., 2009a; Levander et al., 2006; Meissner and Group, 1991; Thybo and Nielsen, 2009; Turcotte and Schubert, 2002; Weber and group, 2009). This is related to the change in composition from various crustal rocks to the mantle consisting mainly of peridotite.

As less dense sediments replace a denser crystalline crust, sedimentary basins should be characterized by a negative Bouguer anomaly with highest amplitude in the basin center after re-equilibration of the isotherm. Many basins, however, are characterized by a long-wavelength negative Bouger anomaly with positive anomalies superimposed. This observation, together with strong variations in the crustal velocity structure beneath sedimentary basins challenge the classical concepts of crustal thinning and related Moho uplift in that they commonly occur in concert with a flat Moho (Thybo and Nielsen, 2009).

Crustal bodies with seismic velocities >7 km, generally referred to as "high-velocity bodies," are observed in the lower crust beneath many intracontinental rift structures as, for example, the Baikal and the Kenya Rifts (Thybo and Nielsen, 2009), beneath intracontinental basins as, for example, in the Danish Basin (Nielsen and Thybo, 2006), and beneath extended passive margins as, for example, at the conjugate margins of the North and South Atlantic (Bauer et al., 2000; Contrucci et al., 2004; Faleide et al., 2008; Franke et al., 2007; Hirsch et al., 2009a; Mjelde et al., 2002; Mjelde et al., 2005; Sibuet et al., 2007). Gravity analysis indicates that these bodies are also characterized by higher densities than the average crust (Fernàndez et al., 2010, 2005; Franke et al., 2007; Hirsch et al., 2009a; Maystrenko and Scheck-Wenderoth, 2009; Osmundsen and Ebbing, 2008).

Differential thinning with depth (Huismans et al., 2005; Huismans and Beaumont, 2008; Kusznir and Ziegler, 1992; Lavier et al., 1999; Lavier and Steckler, 1997; Pascal and Cloetingh, 2002; Sclater and Christie, 1980; Steckler and Watts, 1978), emplacement of magmatic material in the crust during the thinning process or magmatic underplating (Thybo and Nielsen, 2009; Burg and Gerya, 2008) are some possible processes during basin formation and evolution that can be responsible for the actual configuration of the crust beneath a specific basin. The relative contributions of the processes vary strongly for different basins, and, accordingly, their relative importance in general terms is still under debate.

Moreover, structural inheritance may have a fundamental role in defining the crustal and lithosphere structure. Successive suturing of different plates in Earth history may result in a mosaic of crustal domains with contrasting physical properties, possibly also including lower crustal bodies predating the rifting process (Ebbing et al., 2009; Faleide et al., 2008; Plomerová and Babuska, 2010; Scheck-Wenderoth and Lamarche, 2005; van Wijk, 2005; Vauchez et al., 1998). In basins developing on such a substrate such older rheological discontinuities may be reactivated to localize deformation in areas of reduced strength, thus also facilitating discontinuous stretching with depth.

The configuration of the mantle lithosphere

Much less is known on the configuration of the mantle lithosphere below sedimentary basins due to the limited amount of direct observations. Though reflections and lateral variations in p-wave velocities in the lithospheric mantle have been observed in deep seismic data, the energy used in active seismic experiments is generally not sufficient to reach depth intervals below the Moho. Also, the gravity signal from the lithospheric mantle is difficult to isolate from the cumulative signal of the entire lithosphere. Recent development in the acquisition and evaluation of passive *seismological* data (Dalton and Faul, 2010; Fishwick, 2010; Geissler et al., 2010; Heintz and Kennett, 2005; Hieronymus and Goes, 2010; Plomerová and Babuska, 2010; Priestley et al., 2006; Ritzmann and Faleide, 2009; Zhang and Lay, 1996), electromagnetic and *magnetotelluric* methods (see entries *Magnetotelluric Interpretation*; *Magnetotelluric Data Processing*) (Jones et al., 2010), together with remote sensing gravity observation (Kaban et al., 2003; Schotman et al., 2009), as well as geochemical data (O'Reilly and Griffin, 2010; Trumbull et al., 2002; Wang, 2010) and thermal studies (Artemieva, 2006, 2009; Hasterok and Chapman, 2007; Hieronymus and Goes, 2010) indicates that the lithospheric mantle is less homogenous than previously thought. Apart from strong differences in thickness, also considerable lateral variations in surface *heat flow* (see entry *Heat Flow Measurements, Continental*) are observed, with a positive correlation between the two. The lithosphere-asthenosphere boundary (LAB) may be located deeper than 250 km in cratonic areas, lies at around 100 km beneath Phanerozoic continental domains and old oceans, and is close to the seafloor at Mid Ocean Ridges.

Agreement is established that the LAB is a fundamental boundary in plate-tectonic theory that separates the rigid plates from ductile convecting material below the plates (Artemieva, 2009; Eaton et al., 2009; Jones et al., 2010). Three broad definitions in terms of a mechanical boundary layer, a thermal boundary layer, and a chemical boundary layer are based on different types of data and partly in geometrical conflict. For the evolution of sedimentary basins, the depth of the thermal LAB is especially relevant as it determines the thermal and mechanical state of the lithosphere subjected to any of the basin-forming mechanisms. Systematic mapping of lithosphere thickness beneath sedimentary basins is, however, still lacking. The thermal LAB is interpreted as an isotherm of about 1,300°C and its depth corresponds to the depth where a continental conductive geotherm intersects the mantle adiabat. This is corroborated by heat flow inversion studies in *continental lithosphere* (see entry *Lithosphere, Continental*) (Artemieva, 2009), by combined thermal and gravity

modelling (Fernàndez et al., 2010, 2005; Hasterok and Chapman, 2007; Hyndman et al., 2009; Scheck-Wenderoth and Maystrenko, 2008) and by cooling models in *oceanic lithosphere* (see entry *Lithosphere, Oceanic*) (Crosby et al., 2006; McKenzie, 1978; Sclater, 2003; Stein and Stein, 1992).

Isostatically, thinning of the lithospheric mantle results in net surface uplift as heavier lithospheric mantle is replaced by less dense asthenospheric material (active rift model). Only if the interaction with surface processes takes place (erosion), net subsidence takes place due to subsequent cooling of the asthenospheric material.

Heat flow in sedimentary basins

The thermal field in sedimentary basins has been of primary interest in the exploration of fossil fuels (Welte et al., 1997) and gains increasing importance for the use of geothermal energy (Huenges, 2010). Moreover, together with composition, temperature is a main controlling factor for the rheological behavior of the lithosphere and accordingly its deformation. The hotter the lithosphere, the weaker is its rheology and the easier it is thinned to form a sedimentary basin. Accordingly, the main controlling factors for the thermal state of a basin are its plate-tectonic setting and its evolutionary stage.

In terms of observables, surface *heat flow* measurements and temperatures measured in wells characterize the present-day thermal state of a basin, whereas the maturity of organic matter (Welte et al., 1997) and thermochronological data (Andriessen, 1995; Braun, 2005; Braun and van der Beek, 2004; Kounov et al., 2007; Simoes et al., 2010; Van der Beek, 2007; Willenbring and von Blanckenburg, 2010) provide a record of the thermal history.

Different families of integrated process-oriented models attempt to reproduce these observables and indicate that several processes contribute to the heat flow in sedimentary basins. There is a first-order contrast in thermal properties between sedimentary and crystalline rocks, in that sediments are thermally less conductive and produce less radiogenic heat than crystalline crustal rocks (Table 1). The amount of heat entering the basin at the base of the sediment fill depends on the thickness and composition of the crystalline crust as well as on the depth of the thermal LAB. The mafic components of the crust and the lithospheric mantle are characterized by a high thermal conductivity but low *radiogenic heat production*. Accordingly, the shallower the LAB and the thicker and radiogenic the crystalline crust, the more heat arrives at the base of the sediments. Due to their higher porosities, the thermally low-conductive sediments act as a thermal blanket, causing heat storage in the basin (Cacace et al., 2010; Theissen and Rüpke, 2009; Van Wees et al., 2009). In addition, the sediments contribute a modest but, in the sum, considerable amount of radiogenic heat to the system. Also within the sediment fill, the thermal properties may vary (Table 1) with the thermal conductivity of salt being two times larger than that of clastic sediments. The upper part of sedimentary basins may store paleoclimatic signals of previous glaciations as present-day permafrost down to more than 700 m depth attest.

In response to the distribution of thermal parameters long-wavelength variations in temperatures in sedimentary basins (scale of hundreds of kilometers) are determined by the crustal structure and composition as well as by the thickness of the lithosphere (Cacace et al., 2010; Hasterok and Chapman, 2007; Hyndman et al., 2009; Scheck-Wenderoth and Maystrenko, 2008; Sclater, 2003). In contrast, the short-wavelength pattern of temperature distribution (scale of kilometers) is controlled by the internal configuration of the sediment fill.

Heat transfer by conduction is assumed to dominate the transport of heat in the lithosphere in contrast to the *convecting mantle* (see entry *Mantle Convection*). While geological and geochemical data proved that additional hydrothermal heat transport takes place along faults in the lithosphere, there is an ongoing debate on how far the thermal field in sedimentary basins is additionally influenced by convective heat transport due to moving pore fluids. The inherent vertical anisotropy due to the layered nature of sediments counteracts the development of free convection on a basin-wide scale (Bjorlykke, 2010) but local convection is indicated by geochemical data from hydrogeological studies and models of coupled fluid and heat transport (Magri et al., 2009).

Summarizing, the heat flow regime in a specific basin may vary spatially though some ranges can be given for different types of basins (Allen and Allen, 2005): Typically, the surface *heat flow* in intracontinental basins varies between 40 and 70 mW/m^2, can be up to 150 mW/m^2 in active rifts or close to volcanic arcs, and can reach values higher than 180 mW/m^2 at mid ocean ridges and oceanic rifts. In oceanic basins, surface *heat flow* decreases with increasing distance from the mid ocean ridges according to the cooling of the lithosphere with age (Parsons and Sclater, 1977; Stein and Stein, 1992). The surface *heat flow* at passive margins depends on the age of the adjacent oceanic lithosphere. At young margins as in the 55-my-old North Atlantic, the surface heat flow is still controlled by the cooling of the oceanic lithosphere that is considerably thinner than the lithosphere of the continental margin. This step in the thermal LAB is consistent with observed heat flow values increasing from 45 mW/m^2 at the continental side to 80 mW/m^2 at the oceanic side of the margin (Ritter et al., 2004; Scheck-Wenderoth and Maystrenko, 2008). At older passive margins as in the 130-my-old South Atlantic, an opposite trend is observed (Goutorbe and Bonneville, 2008; Hirsch et al., 2009b) with about 45 mW/m^2 at the oceanic side of the margin to up 65 mW/m^2 at the continental side. As the oceanic lithosphere had sufficient time to cool and thicken, the depth of the thermal LAB is continuous and similar between the continental and the oceanic part of the system. Instead, the radiogenic heat contribution of the *continental crust* (see entry *Earth's*

Structure, Continental Crust) thickening toward the continent becomes the controlling factor for heat input from the lithosphere.

Flexural basins are generally colder than extensional basins with average *heat flow* values around 40 mW/m^2 in oceanic trenches and foreland basins. The thermal signature of strike-slip basins is highly variable as it depends on the attributes of the lithosphere on which they develop and if hydrothermal heat transport takes place along the fault zones.

Summary

The *geodynamics* of sedimentary basins results from the interaction of a variety of processes acting on different spatial and temporal scales. Geophysical and geological observations indicate that intra-plate stress and heat input from the asthenospheric mantle are first-order controlling factors. On the *continental lithosphere* (see entry *Lithosphere, Continental*), structural inheritance and its impact on rheology is a third major player controlling the development of sedimentary basins. Intra-plate stress determines if an extensional or a compressional basin is formed. Temperature dominantly controls the rheological behavior of the lithosphere in addition to composition. These two parameters determine if the lithosphere is thinned uniformly, depth dependently, and in a symmetric or asymmetric mode. The more layered the lithosphere rheology is, the more discontinuous and asymmetric the stretching process will be. In contrast, a lithosphere deforms in a uniform stretching mode if the crust is strongly coupled to the mantle and no significant vertical or horizontal rheology contrasts are present. In both cases, the magnitude and rates of effective stress as well as the magnitude of the heat anomaly determine if stretching takes place slow enough to allow for cooling related strain hardening or fast enough to result in continental breakup.

These deep factors interact continuously with surface processes such as deposition or erosion of sediments influenced by climatic conditions. Deposition leads to *isostatic* loading and enhanced subsidence whereas erosion results in isostatic unloading and enhanced uplift.

SEISMIC ANISOTROPY

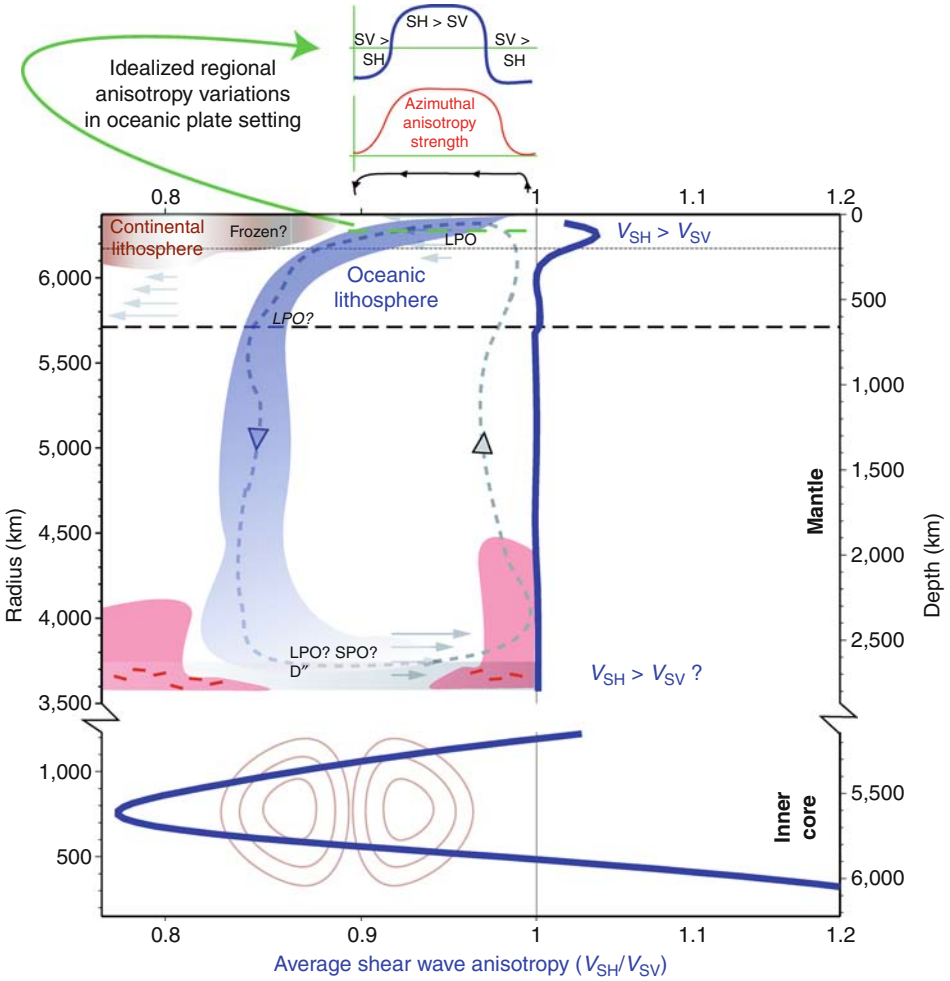
Thorsten W. Becker
Department of Earth Sciences, University of Southern California, Los Angeles, CA, USA

Definition

Seismic anisotropy refers to the directional dependence of seismic wave speeds and particle motion polarizations, as well as the splitting of normal modes, as caused by the elastic properties of rocks.

Introduction

Many of the minerals that make up Earth are intrinsically anisotropic. When rocks are progressively deformed over geologic timescales, the alignment of mineral grains (lattice-preferred orientation, LPO) can lead to bulk anisotropy of the rock. Bulk anisotropy can additionally be generated by an ordered assembly of individually isotropic materials of different wave speeds (shape-preferred orientation, SPO). Both types of anisotropy are found within the Earth; SPO anisotropy also highlights a fundamental ambiguity between isotropic heterogeneity and anisotropy. Seismic wave propagation through an anisotropic medium depends on the wavelengths over which a particular wave type averages, complicating the analysis of seismological data. Both LPO and SPO imply significantly different (up to ~10%) speeds for waves of different polarization or propagation directions, and velocity variations can be larger than those expected from compositional or thermal heterogeneity. Seismic anisotropy is therefore of fundamental importance for structural imaging studies. To get robust estimates of the quantities of interest for geodynamic interpretation, the trade-off between isotropic and anisotropic structure has to be considered. Seismic anisotropy provides a powerful link between seismic observations and the dynamic processes that shape the solid Earth, for example, convective flow in the case of LPO in the mantle (Figure 1, see *Mantle Convection*). However, anisotropic tomographic inversions are inherently more nonunique than isotropic imaging because a general anisotropic, linearly elastic medium has 21 independent components of the elasticity tensor, as opposed to 2 in the isotropic case. As a consequence of the increased number of parameters and the differences in how data sampling constrains isotropic and anisotropic structure, more data are needed for the same level of resolution in an anisotropic inversion. Typically, additional a priori constraints, such as from



Seismic Anisotropy, Figure 1 Cartoon of the possible distribution of whole Earth anisotropy (note scale break at CMB) with geodynamic interpretation (cf. Montagner, 2007); *dotted* and *dashed horizontal lines* indicate 200 and 660 km depths, respectively. The *heavy blue lines* in center show average radial anisotropy from Kustowski et al. (2008) for the mantle and from Beghein and Trampert (2003) for the inner core. Underneath oceanic plates, mantle flow is primarily horizontal, leading to LPO anisotropy alignment with $v_{SH} > v_{SV}$, while the radial mass transport associated with upwellings and downwellings may lead locally $v_{SV} > v_{SH}$. Beneath continental regions, both frozen in anisotropy from past tectonic deformation and asthenospheric anisotropy from present-day convection may contribute. The *gray, dashed, circular line* in the mantle indicates an idealized flow trajectory for a downwelling slab (*blue*) displacing a thermochemical "pile" (*red*) at the core mantle boundary (cf. Garnero and McNamara, 2008). This deep flow may affect CMB dynamics and lead to LPO and/or SPO anisotropy (Modified from Long and Becker, 2010).

petrology, are needed to narrow the parameter space. These complexities make the study of anisotropy in a geodynamic context inherently multidisciplinary, involving seismology, mineral physics, rock mechanics, and geodynamic modeling.

Basic mathematical description

Seismic anisotropy arises when the linear elasticity tensor C that connects stress, σ, and strain, ε, tensors as

$$\sigma_{ij} = \sum_{k=1}^{3} \sum_{l=1}^{3} C_{ijkl} \varepsilon_{kl} \tag{1}$$

does not simplify to the isotropic form

$$C_{ijkl} = \lambda \delta_{ij} \delta_{kl} + \mu \left(\delta_{ik} \delta_{jl} + \delta_{il} \delta_{jk} \right), \tag{2}$$

where λ and μ are the first and second (shear modulus) Lamé parameters, δ the Kronecker delta ($\delta_{ij} = 1$ for $i = j$, and 0 else), and the indices run over the three axes of the coordinate system, x_1, x_2, and x_3. In general, C has 81 components, out of which 21 are independent, and the most complex (triclinic) form of anisotropy requires the specification of all those components (e.g., Hearmon, 1961; Nye, 1985; Anderson, 1989). A typical simplification is to assume hexagonal anisotropy, which should capture most aspects of olivine LPO-related anisotropy in the upper

mantle (Montagner and Anderson, 1989; Browaeys and Chevrot, 2004; Becker et al., 2006).

If C is expressed in the 6 × 6 Voigt matrix, c, notation where c_{mn} relates to C_{ijkl} as $m = \delta_{ij}i + (1 - \delta_{ij})(9 - i - j)$, and $n = \delta_{kl}k + (1 - \delta_{kl})(9 - k - 1)$, then the five Love (1927) parameters for the transversely isotropic medium that results from hexagonal symmetry correspond to

$$\begin{aligned} A &= c_{11} = \rho v_{\mathrm{PH}}^2, \quad C = c_{33} = \rho v_{\mathrm{PV}}^2, \\ L &= c_{44} = \rho v_{\mathrm{SV}}^2, \quad N = c_{66} = \rho v_{\mathrm{SH}}^2, \quad \text{and} \\ F &= c_{11}. \end{aligned} \tag{3}$$

Here, ρ is density, and $v_{\mathrm{PH,\,PV}}$ the velocities for P waves propagating horizontally (H, in x_1–x_2 plane) and vertically (V, x_3-axis), respectively. For shear waves, $v_{\mathrm{SH,SV}}$ in Eq. 3 are the velocities for horizontally propagating waves that are horizontally or vertically polarized, respectively (see *Propagation of Elastic Waves: Fundamentals*). Transverse isotropy as a simplified description of material anisotropy is widely used and developed in exploration seismics (e.g., Thomsen, 1986). The top 220 km in the PREM 1D Earth model (Dziewoński and Anderson, 1981) are also transversely isotropic with vertical symmetry axis as in Eq. 3; such a medium is said to have bulk radial anisotropy. (Note that vertically propagating S waves in this case have the same velocity, v_{SV}, regardless of polarization direction.)

Different combinations of the Love parameters or c_{nm} are used in the literature (e.g., Babuška and Cara, 1991); for example, anisotropy in PREM is described by two measures of shear- and compressional-wave anisotropy strength

$$\xi = \left(\frac{v_{\mathrm{SH}}}{v_{\mathrm{SV}}}\right)^2 = \frac{N}{L} \quad \text{and} \quad \varphi = \left(\frac{v_{\mathrm{PV}}}{v_{\mathrm{PH}}}\right)^2 = \frac{C}{A}, \tag{4}$$

respectively, and the parameter $\eta = F/(A - 2L)$, which controls how velocities change between the vertical and horizontal directions. Another way to characterize the anisotropy of a transversely isotropic medium is due to Thomsen (1986), who defined

$$\begin{aligned} \varepsilon &= \frac{c_{11} - c_{33}}{2c_{33}} = \frac{A - C}{C} \quad \text{and} \\ \gamma &= \frac{c_{66} - c_{44}}{2c_{44}} = \frac{N - L}{L} \end{aligned} \tag{5}$$

as two different measures of the P and S wave anisotropy strength, respectively, and a combined parameter

$$\delta^* = \frac{1}{2c_{33}^2}\left[2\left(c_{13} + c_{44}\right)^2 - (c_{33} - c_{44})(c_{11} + c_{33} - 2c_{44})\right], \tag{6}$$

which, for weak anisotropy, simplifies to

$$\delta = \frac{(c_{13} + c_{44})^2 - (c_{33} - c_{44})^2}{2c_{33}(c_{33} - c_{44})}. \tag{7}$$

The δ parameter is important for near-vertical P wave propagation and identical to ε for "elliptical" anisotropy (Thomsen, 1986). Mainprice (2007) provides an account of other combinations of c_{mn} in use to characterize a transversely isotropic medium. Those differ, regrettably, quite substantially in different fields of study.

If the symmetry axis of the hexagonal anisotropy is in the horizontal plane, the anisotropy is termed azimuthal. This means that perpendicular fast and slow axes can be defined for horizontally propagating SV waves, where waves will propagate with $v_{\mathrm{SV1}} > v_{\mathrm{SV2}}$ along the fast and slow orientations, respectively. Any perturbations to phase velocity p, δp, due to general, but small anisotropy can be expressed as a series of isotropic, π-periodic, and π/2 periodic terms (e.g., Backus, 1965; Forsyth, 1975):

$$\frac{\delta p}{p} \approx A_0 + A_1 cos(2\Psi) + A_2 sin(2\Psi) + A_3 cos(4\Psi) + A_4 sin(4\Psi). \tag{8}$$

Here, Ψ is the azimuth of wave propagation, and Eq. 8 follows from the wave equation and the rank of the elasticity tensor (Smith and Dahlen, 1973). For mantle rocks, the 2Ψ terms are expected to be larger than the 4Ψ contributions for Rayleigh waves, which are predominantly sensitive to SV (Anderson, 1966; Montagner and Nataf, 1986). The 4Ψ terms are expected to be bigger than 2Ψ for Love waves, motivating the focus on Rayleigh waves for azimuthal anisotropy studies (see *Surface Waves*).

In general, the wave propagation effects of any elasticity tensor C can be analyzed by considering a plane wave $\mathbf{u} = \mathbf{a}\exp(-i\omega(t - \mathbf{s}\cdot\mathbf{x}))$ with ω angular frequency, and $\mathbf{u}$, $\mathbf{a}$, $\mathbf{s}$, and $\mathbf{x}$ the displacement, polarization, slowness, and location vectors, respectively (see *Propagation of Elastic Waves: Fundamentals*). $\mathbf{s}$ shall have the normalized direction $\check{\mathbf{s}}$ and length of $1/p$. Using the momentum equation $\ddot{u}_i = \partial_j \sigma_{ij}$, Eq. 1, the definition of the strain tensor, $\varepsilon_{ij} = \frac{1}{2}\left(\partial_i u_j + \partial_j u_i\right)$, C's symmetries, and defining $M_{ij} = \frac{1}{\rho} C_{ijkl}\,\hat{s}_j\,\hat{s}_l$, we can write

$$M\mathbf{a} = p^2\mathbf{a}, \tag{9}$$

which is an eigen problem for the symmetric matrix M. Equation 9 is called the Christoffel equation (e.g., Babuška and Cara, 1991). The eigen vector solutions correspond to one quasi-P and two quasi-S wave directions, and the associated eigen values are the density–velocity products ρv_{P}^2, ρv_{S2}^2, and ρv_{S1}^2. These quantities can be contoured for any elasticity tensor, for example as measured from single crystals, as a function of incidence angle and azimuth, to visualize the anisotropic properties of minerals or rocks in isolation (e.g., Mainprice, 2007). To generate more realistic synthetic body waves from three-dimensional (3D) variations in anisotropy,

semi-analytical reflectivity methods can be used if anisotropy is assumed to vary only with depth. However, for the general case of 3D variations of anisotropy on scales smaller than a Fresnel zone full, numerical wave propagation solutions are needed.

Seismological methods

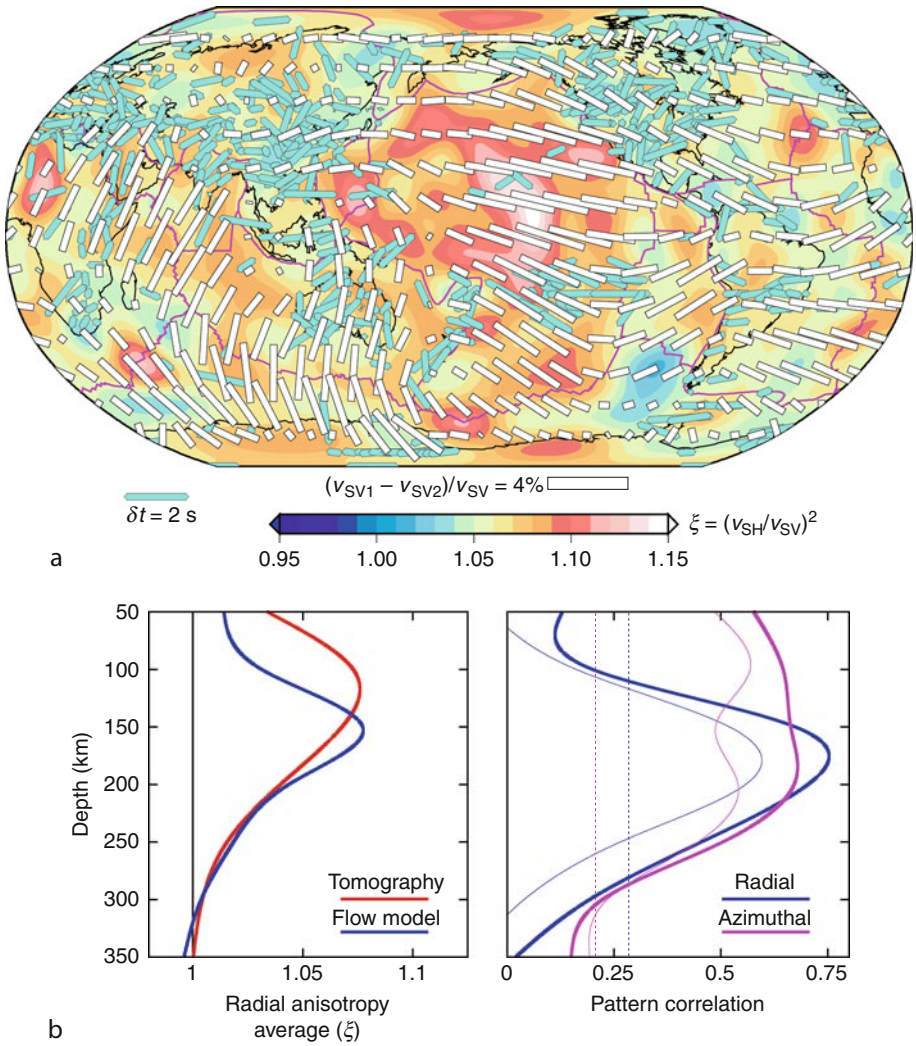
Seismic anisotropy can be detected in a number of ways that can be broadly classified into body- and surface-wave methods. The split of a shear wave into a fast and slow polarization direction as discussed for the solutions of Eq. 9 is akin to optical birefringence; it is exploited by the most popular method of measuring anisotropy, that utilizing *shear wave splitting* (Ando et al., 1983; Vinnik et al., 1984; Silver and Chan, 1991). For lithospheric and mantle applications, one typically considers near-vertical incidence SKS or SKKS core phases (see *Body Waves*), because the effects of any source-side anisotropy are removed by the S-to-P-to-S conversion upon traversal of the core. The most common splitting measurement consists of detecting the horizontal orientation of the fast (azimuth Ψ) pseudo-S wave from recorded particle motions, as well as determining the delay time δt between the arrival of the fast and slow *S* pulses (e.g., Savage, 1999; Long and Silver, 2009).

Shear wave splitting can be detected using a single earthquake measured at a single station, if wave propagation is out of a symmetry axis, and is a unique indicator for the presence of anisotropy along the ray path. However, only the highly idealized case of a single, transversely isotropic layer with horizontal symmetry axis can be directly interpreted in terms of Ψ and δt. Dipping symmetry axes, non-hexagonal anisotropy, or variations of anisotropy with depth will all cause a dependence of apparent splitting on back-azimuth (e.g., Schulte-Pelkum and Blackman, 2003). The nonlinear nature of the splitting measurement and layer splitting itself can lead to a bias of sensitivity toward the surface (∼one wavelength under the station), and not simple superposition (e.g., Saltzer et al., 2000). Such complexities make it imperative to strive for good back-azimuthal coverage, requiring the recording of several, suitable earthquakes, which is often a challenge given station-event geometry, or the duration of temporary deployments. If back-azimuth variations are detected, those can be used to make inferences about the variation of anisotropy with depth, which is undefined based on isolated measurements where anisotropy could, in principle, arise anywhere between the core mantle boundary (CMB) and the surface in the case of SKS splitting. If regional S arrivals are used, crossing ray paths can be used to infer 3D variations of anisotropy (e.g., Abt and Fischer, 2008). For teleseismic arrivals, the use of sensitivity kernels (e.g., Chevrot, 2006; Long et al., 2008) for the multichannel type of measurement of splitting holds great promise for resolving 3D anisotropy in regions for which close (closer than Fresnel zone width) station spacing is available. Broadly speaking, shear wave splitting is, however, a measurement with good lateral (∼50 km), but fairly poor depth resolution (Savage, 1999).

Another single, body-wave arrival method that follows from Eq. 9 is to use the orientation of the pseudo-*P* polarization, which may differ by more than 10° from along-ray, for *P* polarization anisotropy (Schulte-Pelkum et al., 2001), P_{pol}. A measurement of P_{pol} is sensitive to ∼half a wavelength underneath the station. If several, near-horizontal *P* paths with different azimuths are available, as in the case of the refracted P_n phase, which senses underneath the Moho, velocities can be plotted against azimuth to infer azimuthal anisotropy. This method was used for one of the earliest demonstrations of seismic anisotropy by Hess (1964), and a global comparison of P_n and SKS splitting can be found in Smith and Ekström (1999). The variations in delay times of teleseismic waves can also be used directly to infer anisotropy in the mantle lithosphere (e.g., Babuška et al., 1984; Bokelmann, 2002) by means of a tomographic inversion (see *Seismic Tomography*), but this method requires knowledge of the isotropic variations in wave speeds. This is a challenge for all tomographic approaches to anisotropy because there will always be a trade-off between isotropic and anisotropic heterogeneity in the absence of perfect data coverage (e.g., Tanimoto and Anderson, 1985). In terms of their depth-sensitivity, the body-wave methods can be ranked, from shallow to deep, as P_n, P_{pol}, SKS, and *P* delay times (Schulte-Pelkum and Blackman, 2003).

At crustal depths, anisotropy can additionally be detected by wide-angle refraction methods (e.g., Meissner et al., 2002, 2006). Orthogonal profiling, for example, may show a mismatch of derived seismic velocities, or a mismatch of refraction and reflection depths that can be interpreted in terms of anisotropic wave propagation. Receiver function methods (e.g., Park and Levin, 2002) (see *Seismic, Receiver Function Technique*) yield further evidence of crustal anisotropy from the existence of split *pS* conversions. Azimuthal variations in radial-transverse receiver function amplitudes are diagnostic of anisotropy versus tilted structure, and of the amount of anisotropy (e.g., Savage, 1998).

A wealth of information about anisotropy arises from the study of *surface waves*. The observation that Love waves, which mainly sense SH, travel faster than Rayleigh waves, which mainly sense SV due to their intrinsic polarities, implies the existence of a mean radial anisotropy in the upper mantle (Anderson, 1966; Dziewoński and Anderson, 1981). The existence of azimuthal anisotropy was documented for the Pacific by the study of Rayleigh waves (Forsyth, 1975), and Nataf et al. (1984) presented radially anisotropic, upper-mantle tomography. The current state of tomographic models for global azimuthal and radial anisotropy patterns is discussed by Montagner (2007). Surface wave propagation is dispersive, which allows the construction of 3D models of anisotropy (see *Earth's Structure, Global*; *Seismology, Global Earthquake Model*). The most easily measured phase-velocity period range for fundamental modes



Seismic Anisotropy, Figure 2 Global, uppermost mantle seismic anisotropy. (**a**) Seismological constraints: Radial (background, from Kustowski et al., 2008) and azimuthal anisotropy (white sticks indicating fast orientation, from Lebedev and van der Hilst, 2008) at 150 km, as well as SKS splitting (cyan sticks). SKS data are shown as a simple 5° average of the compilations by Fouch (2006) and Wüstefeld et al. (2009), but note that such averaging only provides a simplified view of azimuthal anisotropy (see text, and Schulte-Pelkum and Blackman, 2003, for example). (**b**) Radial anisotropy layer averages, on left, for the seismological model of Kustowski et al. (2008) and as predicted from the best-fitting geodynamic model of Becker et al. (2008). On right, pattern correlations up to spherical harmonic degree 8 between the same geodynamic model and radial (from Kustowski et al., 2008) and azimuthal (from Lebedev and van der Hilst, 2008) seismic tomography. *Heavy* and *thin lines* denote oceanic lithosphere only and global correlations, respectively. *Vertical, dashed lines* show 95% significance level (Modified from Long and Becker, 2010).

between ~50 and 150 s samples from the lithosphere down to ~300 km depth, and Figure 2a shows azimuthal and radial anisotropy at an asthenospheric depth of 150 km as well as a global compilation of SKS splitting results. At the shallow end, array methods (e.g., Deschamps et al., 2008) and in particular noise tomography (e.g., Lin et al., 2008) (see *Seismic, Ambient Noise Correlation*) facilitate extending the period range to shorter, crustal periods. Overtones can be used to constrain the deeper mantle, down to the 660-km phase transition (e.g., Trampert and van Heijst, 2002; Lebedev and van der Hilst, 2008). Lastly, the long-period surface wave equivalent of *free oscillations of the Earth* can provide constraints on the deep Earth, including inner core anisotropy (e.g., Woodhouse et al., 1986; Tromp, 2001).

Surface wave studies of anisotropy have fairly good depth sensitivity in that they are able to locate the origin of anisotropic signals in the upper mantle to within ~100 km depth. However, particularly compared to body wave measurements such as SKS splitting, the lateral resolution of surface waves is limited, for isotropic structure to perhaps ~500 and ~50 km for global and regional models, respectively, at present. Reasons for discrepancies between published tomographic models include the

different treatment of crustal corrections and phase-velocity measurements, as well as theoretical assumptions about wave propagation. Perhaps more important factors are the globally uneven ray path coverage or regularization choices.

A complete, 3D model of general seismic anisotropy would allow for more powerful petrological and geodynamic inferences than limited studies that focus only on a few aspects of anisotropy or wave propagation. Given the wide array of seismological observations, a desirable procedure to constrain the full 3D dependence of anisotropy is to compare different measures of anisotropy (e.g., Montagner et al., 2000; Wüstefeld et al., 2009) or to perform a joint inversion (e.g., Montagner and Nataf, 1988; Šíleny and Plomerová, 1996; Marone and Romanowicz, 2007). Sensitivity kernels that account for finite-frequency wave-propagation effects and the resulting complex 3D structure of a measurement's sensitivity to Earth structure (e.g., Chevrot, 2006; Long et al., 2008; Sieminski et al., 2009) can facilitate the relative weighting of different observations. Likewise, the incorporation of petrological constraints (e.g., Montagner and Anderson, 1989; Becker et al., 2006) can be used to simplify inversions further (Panning and Nolet, 2008; Chevrot and Monteiller, 2009).

Origin of anisotropy

The SPO type of anisotropy may be caused by any consistent alignment of entities with different isotropic wave speeds. Examples include lower crustal lamellae structures, cracks, or melt inclusions (e.g., Mainprice and Nicholas, 1989; Weiss et al., 1999; Meissner et al., 2006). Crack alignment will be only important for the shallowest crust where it may be indicative of crustal stress (e.g., Crampin and Chastin, 2003). Alignment of partial melt pockets may play a role both for shallow, extensional lithospheric domains, such as underneath mid-oceanic spreading centers or intracontinental rifts (e.g., Holtzman et al., 2003), and at the base of the mantle in the *Mantle D″ Layer* (e.g., Moore et al., 2004).

In between, the LPO type of anisotropy caused by the alignment of intrinsically anisotropic crystals is the most likely cause of anisotropy. The fundamental symmetry classes of material anisotropy of the constituent minerals (e.g., Nye, 1985; Anderson, 1989) determine the overall type of anisotropy in the Earth, and wave propagation depends critically on the type of anisotropy (e.g., Levin and Park, 1998; Schulte-Pelkum and Blackman, 2003). Several crustal rocks show LPO anisotropy; of particular interest are those rich in phyllosilicates (micas) in the upper-middle crust, and amphibole minerals in lower crust (e.g., Christensen and Mooney, 1995). In the upper mantle, the highly anisotropic olivine makes up ~60% of rocks (e.g., Mainprice, 2007). Laboratory experiments show that if multi-crystal olivine assemblages are deformed in the dislocation creep regime, crystals typically align such that the resulting fast propagation orientation rotates into the direction of shear, and many mantle xenoliths show corresponding LPO patterns (Mainprice, 2007; Karato et al., 2008).

This connection between rock deformation and seismic anisotropy allows an association of the patterns of azimuthal mantle anisotropy (e.g., Figure 2a) with *mantle convection* (e.g., McKenzie, 1979; Tanimoto and Anderson, 1984). A coarse approximation uses tectonic plate motion to imply deep flow direction, or, more realistically, flow can be calculated from global circulation models (Hager and O'Connell, 1981). The general association between mantle flow and anisotropy in terms of radial anisotropy is that flow in the upper boundary layer aligns olivine such that $v_{SH} > v_{SV}$ underneath oceanic plates due to a simple shear type of deformation (Figure 1). In regions of dominantly radial mass transport such as subduction zones and underneath spreading centers, $v_{SV} > v_{SH}$ (Chastel et al., 1993; Montagner, 2007). The radial and azimuthal anisotropy patterns shown in Figure 2a are broadly consistent with this expectation (Figure 2b), though there are also clear differences which are easier to constrain in regional studies (e.g., Gaherty et al., 1996). Complexities include variations azimuthal anisotropy orientations and amplitudes (e.g., Ekström and Dziewonski, 1998; Smith et al., 2004), and many of those patterns are accessible to geodynamic modeling, discussed below.

Given the importance of the details of the connection between seismology and geodynamics, several theoretical descriptions exist that predict microstructural LPO development given general deformation histories, as constrained by laboratory experiments (e.g., Kaminski and Ribe, 2001; Blackman, 2007). However, further laboratory constraints, for example on the reorientation of existing LPO fabrics under changing deformation regimes, are required to decide on the most appropriate treatment. Complex deformation histories are expected to lead to complex anisotropy. Yet, under monotonous deformation (e.g., by simple shear), olivine LPO is expected to saturate over finite strains of ~10. Amplitude variations compared to a single crystal may therefore be mainly due to orientation of the symmetry axis of the effective elastic tensor for an aggregate of crystals (cf. Karato et al., 2008).

Laboratory work over the last 10 years has further shown that the role of water content, deviatoric stress levels, and pressure can lead to significantly different LPO development from the typical, dry A-type fabrics that show the "fast axes along flow" alignment discussed above. For example, the high stress, high water content B-type fabric aligns the fast axes of olivine orthogonal to the direction of shear. Variations in water content have been used to explain some of the variability that is apparent in asthenospheric depth anisotropy, such as the decrease in azimuthal anisotropy strength across the Pacific from young to older seafloor, or the variability of orientations of SKS splitting in subduction zones (Mainprice, 2007; Karato et al., 2008).

LPO development under deformation of mantle rocks not only affects seismic properties, but also leads to thermal and mechanical anisotropy. The feedback of these effects into mantle convection and lithospheric deformation are potentially profound (e.g., Christensen, 1987; Chastel et al., 1993; Lev and Hager, 2008; Tommasi et al., 2009) and are currently an active area of research.

Observations of anisotropy and dynamic inferences

Whole earth anisotropy

Seismic anisotropy is found throughout the Earth, with the exception of the fluid outer core, though it is concentrated in certain depth regions (Figure 1). In the mantle, the best-constrained and strongest signal is found in the uppermost ~300 km where SH velocities are faster than SV by up to ~4% on average, as indicated by the Love–Rayleigh discrepancy. The exact shape of the average radial anisotropy profile is less certain, though most recent models agree that the largest anomalies are not found at the surface, but rather at ~100 km depth (Figure 2b). This peak may be associated with asthenospheric shear flow which is expected to lead to the largest strain-rates underneath the oceanic lithosphere, which is up to ~100 km thick when defined thermally (see *Mantle Convection*). Given that mantle anisotropy is most likely caused by LPO of olivine, the peak in seismic anisotropy in the uppermost mantle has been associated with the relatively high stress and low temperature depth region where dislocation dominates over diffusion creep (Karato, 1992; Gaherty and Jordan, 1995) (see *Mantle Viscosity*). Using composite rheologies, geodynamic models can be used to estimate the transition depths for the different creep laws, so delineating the region where LPO forms explicitly (e.g., McNamara et al., 2002; Podolefsky et al., 2004; Becker et al., 2008). Once rocks transition into the diffusion-creep dominated deformation regime, LPO is typically assumed to be destroyed quickly at high temperatures, or left preserved (frozen in) at low temperatures/small velocity gradients. The decrease in radial anisotropy toward the surface (Figure 2b) may therefore be associated with tectonically older, frozen in structure. On the scales accessible by surface wave studies, for example, anisotropy in old lithospheric domains may be less well aligned into the vertical, or into a coherent horizontal orientation, than in the asthenosphere, which is shaped by current mantle convection (e.g., Fouch and Rondenay, 2006).

At larger mantle depths, radial anisotropy becomes less well constrained (e.g., Visser et al., 2008). There is some indication that radial anomalies pick up around the transition zone (Figure 1), and several studies have argued for the existence of azimuthal anisotropy around 660 km (e.g., Trampert and van Heijst, 2002; Wookey et al., 2002). Most of the lower mantle is nearly isotropic until the D″ region close to the core mantle boundary where there is good evidence for the existence of anisotropy from regional studies (e.g., Moore et al., 2004), and indications for average radial anisotropy from global studies (Boschi and Dziewoński, 2000; Panning and Romanowicz, 2006). As for the upper mantle, one may invoke an LPO reactivation of dislocation creep, for example in cold, highly deformed subduction slabs (see Figure 1; McNamara et al., 2002). The other, at present perhaps equally likely, mechanism that has been invoked for D″ anisotropy is the alignment of melt tubules (SPO). Melt alignment may also play a role in the transition zone if the latter represents a melt-rich water filter (Bercovici and Karato, 2003). The D″ region is expected to be at least as dynamically complex as the upper thermal boundary layer, and both domains are affected by compositional anomalies. Those include the continental lithosphere, with its stiff, compositionally anomalous and presumably neutrally buoyant cratonic keels, and likely piles of dense material at the base of the mantle in regions displaced along the CMB from recent subduction (e.g., Garnero, 2004; Garnero and McNamara, 2008). We therefore expect significant lateral variations in the generation of anisotropy within D″ depending on the vertical flow setting (Figure 1, e.g., Moore et al., 2004). Close to the CMB, anisotropy may also vary with depth depending on if lower mantle material has transitioned to the post-perovskite phase (e.g., Wookey et al., 2005; Merkel et al., 2007).

There is also robust evidence for anisotropy within the Earth's core. Body waves that traverse the inner core and are aligned with the rotation axis arrive earlier than those that cross in the equatorial plane (Morelli et al., 1986). Evidence for anisotropy is also seen in the splitting of normal modes (Woodhouse et al., 1986), and more recent data and models for core anisotropy are discussed in Tromp (2001) and Souriau (2007). However, there are still debates on the exact nature of the anisotropy distribution with depth (cf. Ishii and Dziewoński, 2003). Figure 1 shows radial, shear-wave anisotropy for the inner core from Beghein and Trampert (2003). This particular model invoked a hexagonal close-packed phase of iron in the upper half of the inner core, and perhaps a transition into a different iron phase at depth, and predicts large amplitudes of radial anisotropy compared to the upper mantle. The origin of inner core anisotropy is also less clear than for the upper mantle (Mainprice, 2007). One hypothesis that has recently been discussed in some detail is freezing in of convective patterns during the cooling and evolution of the inner core (Jeanloz and Wenk, 1988; Buffett, 2009; Deguen and Cardin, 2009).

Structure and dynamics of the upper boundary layer

Seismic anisotropy at every depth range throughout the Earth holds valuable information on the dynamics of the planet. The connections can be made quantitative most easily for the shallower layers where seismological constraints abound, rock deformation is accessible via laboratory experiments, and geodynamic modeling is fairly well constrained. In the case of crack anisotropy in the shallow

crust, observations yield constraints on regional stress fields. Applications include industry work (vertical seismic profiling in boreholes), earthquake studies around faults, and volcano monitoring where cracking due to magma migration can be traced.

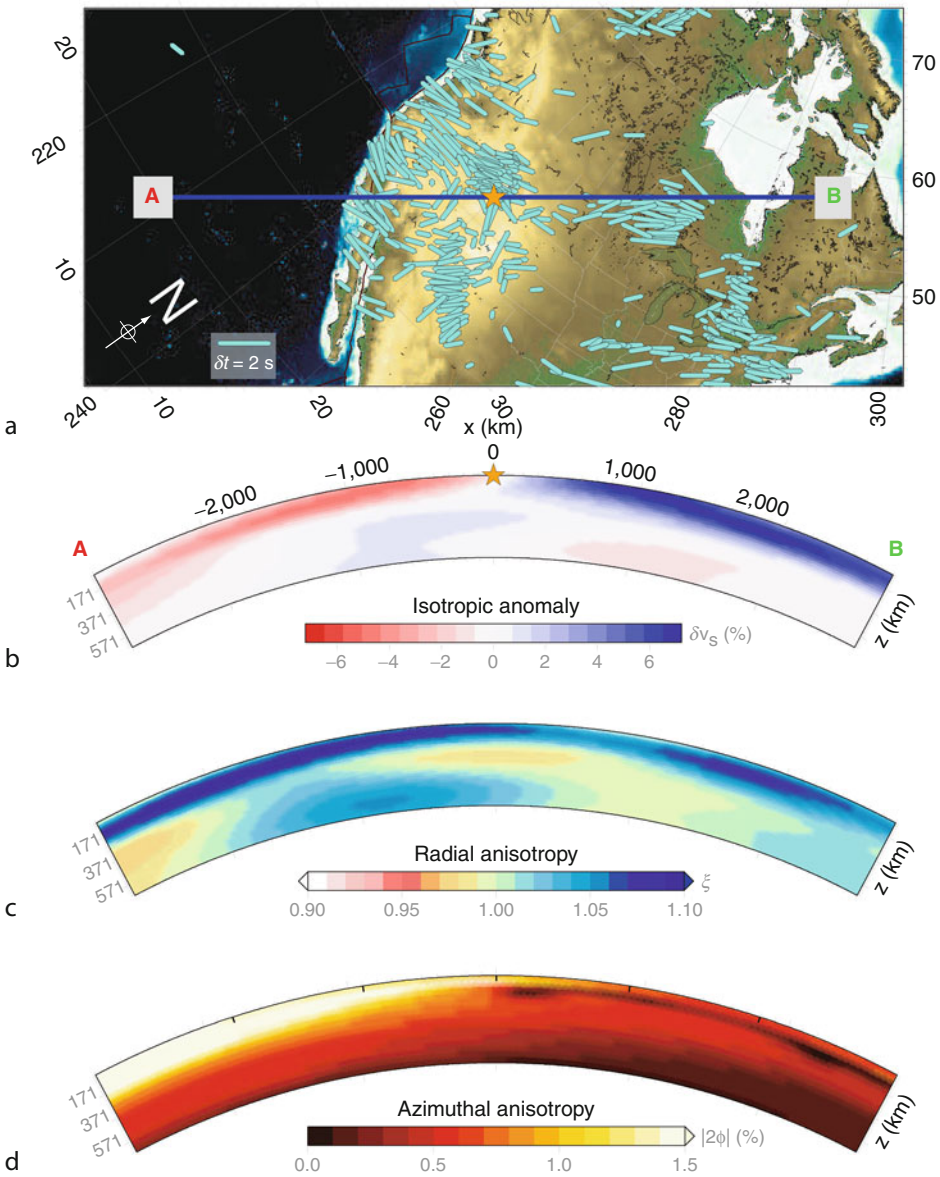
Within the upper convective boundary layer, the oceanic plate domains (see *Lithosphere, Oceanic*) should most closely resemble the simplified view of radial and azimuthal anisotropy due to LPO anisotropy formation in mantle flow as shown in Figure 1. Gaboret et al. (2003), Becker et al. (2003), and Behn et al. (2004) showed that mantle circulation from geodynamic models does indeed provide a valid explanation for azimuthal anisotropy patterns (Figure 2a), and that comparison of model predictions with anisotropy can yield constraints on mantle flow, such as the role of buoyant mantle upwellings as opposed to plate-induced shear. Becker et al. (2008) provided a quantitative model of radial anisotropy, and Figure 2b shows the fit of their preferred model to radial anisotropy averages in the upper mantle, as well as lateral patterns in azimuthal and radial anisotropy. Results are consistent with the expectation that the geodynamic models should describe recent (few 10 s of Myr) asthenospheric flow best. The correlations between geodynamics and the seismological models (Figure 2b) are comparable or better than the match between different seismological models. Such first-order agreement between global geodynamics and seismology motivates current modeling efforts, for example on constraining the amount of net rotations of the lithosphere or the degree of lateral viscosity variations (e.g., Becker, 2008; Conrad et al., 2007; Conrad and Behn, 2010; Kreemer, 2009).

Figure 2b shows that geodynamic models typically underpredict radial anisotropy in the shallower parts of the lithosphere, which is mainly due to continental domains. While anisotropy in younger continental lithosphere such as in the western USA appears to be well described by asthenospheric flow, older regions show more complex behavior such as a consistent orientation of seismic anisotropy over several hundred kilometers (e.g., Babuška and Plomerová, 2006). It has been suggested that anisotropy is concentrated in, and frozen into, the continental lithosphere, or, alternatively, that radial anisotropy is largest right underneath the mechanical boundary layer formed by stiff continents (e.g., Gaherty and Jordan, 1995; Gung et al., 2003; Fouch and Rondenay, 2006). Figure 3 shows a profile through North America; anisotropy, as inferred from these models, only partially conforms to the simplified expectations (cf. Panning and Romanowicz, 2006). The cross section of radial anisotropy shows the expected focusing of SH faster than SV in the Pacific plate, and some regionally enhanced $v_{SH} > v_{SV}$ within the eastern USA and the Canadian craton, but no enhanced anisotropy beneath what would be inferred to be the base of the continental lithosphere from the isotropic anomalies. Azimuthal anisotropy is also, expectedly, strong within the Pacific plate (compare Figure 2a), but there is an intriguing low-azimuthal anisotropy channel within the eastern North American continental lithosphere. If such features are due to complex tectonic deformation with small lateral shear-coherence, or due to the averaging properties of surface waves and incomplete ray illumination, remains to be determined. The study of continental anisotropy is an active area of research, and many questions such as to the vertical coherence of lithospheric deformation and the depth extent of fault zone localization will benefit from the information that seismic anisotropy can bring to the table. There are numerous other, regional tectonic settings where anisotropy can yield important constraints, and those cannot be comprehensively reviewed here. Important examples include continental transforms and collision zones, spreading centers, and subduction zones. Reviews of our current understanding of such settings can be found in Silver (1996); Savage (1999); Park and Levin (2002) and Long and Silver (2009).

Powerful dynamic insights notwithstanding, there are still large uncertainties in every step of the chain of modeling that has to be followed. Complexities arise from inferring mantle flow from geodynamics (e.g., role of chemical vs. thermal buoyancy, uncertainties about rheology), to predicting LPO textures (e.g., proper microphysical treatment), to inferring elasticity tensors (e.g., homogenization and temperature/pressure derivatives), to mapping those tensors in 3D to whatever seismological observable (preferred) or seismological model (more common) are used to benchmark the models (e.g., finite frequency wave propagation, sampling). The finding that overall patterns appear to be well explained (Figure 2), and that synthetic LPOs match those of xenolith samples provide some *a posterior* justification for the modeling rationale. Moreover, these agreements indicate that the bulk of the asthenospheric flow is indeed dominated by dry A-type fabrics. However, future refinements of seismological imaging, for example through array deployments such as EarthScope USArray and temporary seafloor studies, theoretical developments in seismology, and the improved geodynamic treatment of anisotropy will undoubtedly lead to adjustment of our understanding of whole Earth anisotropic structure.

Summary

Seismic anisotropy is ubiquitous throughout the Earth and provides constraints on dynamic processes, from the stress in the crust, the origin and evolution of the continental lithosphere, through convective flow in the upper mantle, to core evolution. The state of upper-mantle geodynamic modeling is such that important questions, such as about absolute plate motion reference frames, intraplate deformation, or the hydration state of the mantle can be addressed. Important issues about the resolution of different seismological datasets and degree of robustness of seismological images remain. Joint with the inherent uncertainties in geodynamic modeling and how to map flow into seismic anisotropy, this means that numerous



Seismic Anisotropy, Figure 3 Pacific and North American upper mantle anisotropy. (**a**) SKS splitting (as in Figure 2, but averaged by 0.5°) and location of cross-continental profile; (**b**) isotropic shear wave velocity relative to background (Voigt average, from Kustowski et al., 2008); (**c**) radial anisotropy ($\xi = (v_{SH}/v_{SV})^2$, from Kustowski et al., 2008); and (**d**) strength of azimuthal anisotropy ($|(v_{SV1} - v_{SV2})/v_{SV}|$, from Lebedev and van der Hilst, 2008). (Modified from Long and Becker, 2010.)

questions for the interpretation of anisotropy observable are open. This challenge mandates further theoretical and instrumentational efforts and that the study of anisotropy proceeds interdisciplinary and in a dynamics context. Answering those questions holds the promise of arriving at a new understanding of the workings of the mantle system.

Acknowledgments

Detailed comments by Donna Blackman, Mark Behn, and Sergei Lebedev and valuable suggestions from Lapo Boschi, Sebastien Chevrot, David Okaya, Mark Panning, Vera Schulte-Pelkum, and an anonymous reviewer helped improve this contribution.

SEISMIC DATA ACQUISITION AND PROCESSING

Kabir Roy Chowdhury
Department of Earth Sciences, Utrecht University, Utrecht, The Netherlands

Definition

Seismic data acquisition

Generation of (artificial) seismic signals on land (on surface, or, buried) or in water, reception of the signals after they travel through the interior of the earth, and their (digital) recording for later analysis.

Seismic data processing

Analysis of recorded seismic signals to filter (reduce/eliminate) unwanted components (noise) and create an image of the subsurface to enable geological interpretation, and eventually to obtain an estimate of the distribution of material properties in the subsurface (inversion).

Introduction

Reflection seismics is akin to the "echo-in-the-well" experiment, it involves calculating the depth of the geological boundary from the two-way travel-time (TWT) of the seismic signal and its speed.

Seismic data acquisition and processing aims mainly to obtain an image of the sedimentary basins in interior of the earth, using waves generated by "artificial" earthquakes. These images can then be used to identify locations favorable for accumulation of hydrocarbons (oil and gas), which may then be drilled to determine the ground truth – and eventually to exploit the resources. Since the first known reflection seismic experiment in 1921 near Oklahoma City, USA (Figure 1.3, Sheriff and Geldart 1995), reflection seismics has established itself as the most accurate technique to image the sedimentary basins for the exploration of hydrocarbons.

The phrase "seismic" instead of "seismological" in the following stresses the "man-made" nature of the waves used. Both seismics and seismology use the basic theory

Seismic Data Acquisition and Processing, Table 1 Imaging the earth using natural/artificial earthquakes

Keyword	Seismics	Seismology
Wave source	Explosions, vibrations	Natural earthquakes
Energy penetration	Shallow	Deep
Max imaging depth	Base of crust	Whole earth
Location of source	Precisely known	Estimated post facto
Time of occurrence	Precisely known	Estimated post facto
Energy involved	Small-medium	Can be huge
Wave-propagation	Mostly vertical	Mostly horizontal
Frequencies mostly excited/used	1–100 Hz	0.01–1 Hz
Receivers	Geophones	Seismometers
Wave-field sampling	Dense	Sparse (getting better)
Data volume	Terabytes	Gigabytes
Accuracy	Large	Small–medium
Main application	Oil and gas	Earth-structure
Other applications	Civil engg., crustal	Civil engg.
Investment	$$$$	$$

of wave-propagation through the earth, for which Aki and Richards (2002) is a good resource. Table 1 summarizes the important differences between the two approaches though; let us briefly look at two.

Frequency vs. period: Due to the spectral range of the signals involved, seismology traditionally uses period (s) to describe the waves, whereas in seismics, frequency (Hz) is used. Waves provide information about the medium through which they propagate at the scale of their wavelength, use of higher frequencies in seismics (shorter wavelengths) leads therefore to a greater resolution (of the structure) compared to seismology.

Wave-propagation: seismology – again historically – mostly uses refracted energy, whereas exploration seismics is often synonymous with reflection seismics, although refraction seismic exploration predates the latter.

This essay will be mainly concerned with acquisition and processing of reflection seismic data. Note, however, that seismics is being increasingly applied to both shallower depths (high-resolution seismics) and crustal-scale studies down to Moho and beyond (deep seismics), see *Deep Seismic Reflection and Refraction Profiling* for details of the latter. Seismic data acquisition and processing is a broad subject, the treatment here will have to make choices based upon space constraints, etc. Some subtopics, e.g., "*Seismic, Migration*" are, however, dealt with in separate essays.

The reader is assumed to be familiar with the basic theory of elasticity and wave-propagation, and the related concepts of reflection, refraction, and scattering. The concept of rays will be frequently used – especially in illustrations – for convenience; real seismic signals are of course associated with wave-fronts. Similarly, the figures will depict a 2-D (section) of the 3-D earth.

There are many good resources available even for the narrower field of Reflection Seismic Data Acquisition and (Signal) Processing, e.g., Vermeer (2002), Yilmaz (2001), Menke (1989), Liner (2004), and Sheriff and Geldart (1995); the last one also contains some historical background and material over refraction seismics. Recently, some resources have also been made available for downloading on the internet, e.g., Claerbout (1985a, b).

In this article, all-capitals will be used to denote acronyms for jargons, of which there are quite a few (e.g., TWT above); phrases within double quotes will refer to an article elsewhere in this volume.

Seismic data acquisition

Before seismic signals could be processed, an artificial wave-field has to be generated using suitable *sources* at appropriate locations, measured by *receivers* at other locations after getting reflected back from within the earth, and stored using *recorders*. Design of a seismic survey (*geometry*) needs inputs from regional geology, exploration objectives, and logistical considerations.

At first confined to land, seismic surveys are now-a-days carried out mostly in marine environments in round-the-clock operations using large vessels and a lot of instrumentation; single-channel seismics has faded away in favor of multi-channel acquisition, allowing much more information to be obtained (see *Single and Multichannel Seismics*). Table 2 gives an overview of the equipments used under different field environments.

Seismic sources

One needs a signal that is high in energy (amplitude) to ensure a good depth penetration, and short in duration to ensure accurate determination and *differentiation* of the travel-times – a Dirac-Delta spike would be ideal, which, however, is a-causal. In practice, a sharp, compact, and *repeatable* signal is preferred. This quasi-idealized wave-form, possessing finite temporal duration and frequency band-width (both with respect to the ambient noise), is called a *wavelet*. The source wavelet changes form as it travels through the earth due to several physical processes to be briefly discussed below.

Repeatability of the source wavelet – that is, that of its *amplitude* and *phase* content – is an important prerequisite for the later processing steps. Explosives were the initial choice for source on land, providing large energy (good depth of penetration) but having non-repeatable signal shape and negative environmental impact. Development of large, truck-mounted electromechanical vibrators has led since 1960s to their increasing use in land-seismics, with both above disadvantages of impulsive sources reduced significantly.

In marine environment, compressed air is used – with explosion (*air gun*) or implosion (*water gun*) – to create the acoustic waves. The sources are towed by a ship together with the receivers (*single vessel seismic*), or, by a separate ship (*two-ship seismics*).

Seismic Data Acquisition and Processing, Table 2 Sources and receivers used in seismic surveys

Environment	Sources	Receivers
Land	Explosives/ vibrators/impact	Geophones
Marine	Air/water -guns	Hydrophones
Water bottom	Explosives/guns	Geo/hydro-phones
Onshore-offshore	Explosives/guns	Geo/hydro-phones

There have also been experiments with shear-wave sources – both impact-type and vibratory. These – either alone, or together with compressive sources – can provide extra information about the subsurface medium. For investigating shallower structures in engineering, environmental and archeological applications, small impact-based sources, e.g., weight-drops, rifles, etc., and even portable vibrators are being frequently used, and provide the required higher resolution.

Seismic receivers

All land-seismic (and seismological) receivers (*geophones, seismometers*) are electromechanical devices, that transform the relative motion of the medium in which they are embedded, into electrical voltages. Fidelity of this transformation, both in *amplitude* and *phase*, is important to ensure maximum information retention for later retrieval – a flat amplitude response, with no phase distortion within the band of frequencies that are of interest, would be ideal. The output of a geophone can be made to be proportional to the displacement/velocity/acceleration associated with the causative motion. Dennison (1953) provides an overview of the physico-mathematical underpinnings of geophone design; see also *Seismic Instrumentation*.

Originally, geophones were designed to move – and hence record information – only in the vertical direction. Later, the importance of recording and analyzing the entire three-dimensional elastic wave-field came to be realized. Multi-component receivers, enabling recording/analysis of both horizontal components, or, all three spatial components of the ground movement are being increasingly used even in large-scale surveys.

For use in water, small piezoelectric elements – hydrophones – are employed to record pressure variations – modern deployments typically consist of thousands of such elements being towed near the water surface by *streamers*, several kilometers long, which are liquid-filled plastic tubes, fitted with fins (for buoyancy), gps receivers (for location information) and fiber-optic cables (to transfer the data) to the ship.

Finally, three-component receivers may be deployed together with hydrophones at the water bottom (4C), to record the wave-field across it, see *Ocean Bottom Seismics*.

Note, that both sources and receivers may be deployed in *groups*, using specific patterns, which affect the generation and sampling of the wave-field due to their direction-dependent radiation/reception characteristics.

Seismic recorder

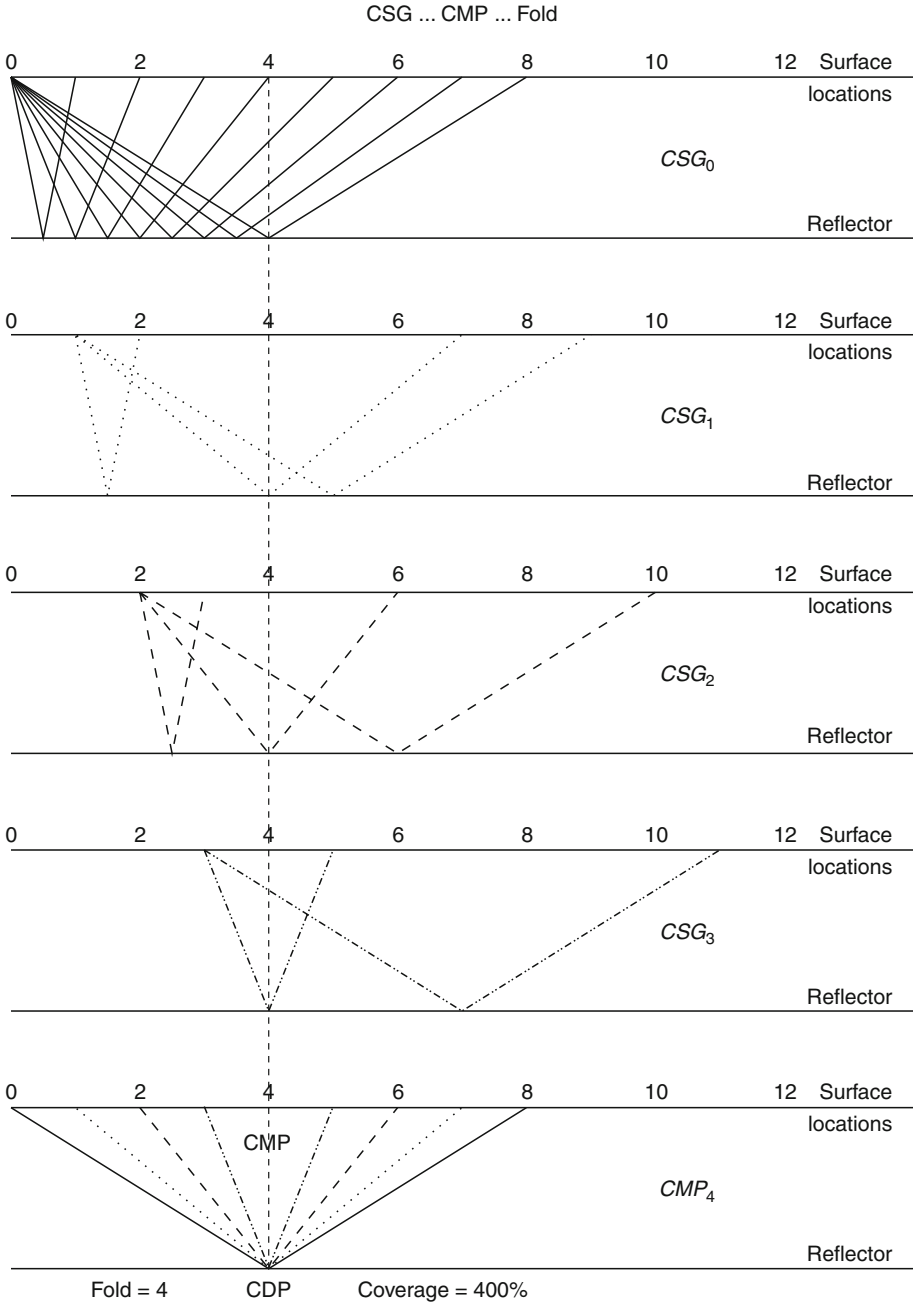
The time-varying electrical signals output by the receivers represent *arrivals* back-scattered from different depths, all juxtaposed in time and embedded within the ever present background noise, and require storage for later processing. In the beginning, photographic films and later magnetic tapes were used for this purpose. The digital revolution starting in the 1960s, itself partly driven by the needs of seismic data acquisition and processing, caused a complete shift to in-situ digitization and digital storage. Similarly, the wires connecting the receivers to the recorder have been mostly replaced by fiber-optic cables or wireless. Preserving the frequency, amplitude, and phase of the signal and the desired *dynamic range* are important considerations in designing the digitizing (*sampling*) unit. As each *receiver (group)* corresponds to a different *channel* in the recorder, digitization in such systems (typically consisting of thousands of channels) must preserve the time-base, to enable comparison of the arrival times between different *traces*. Also, the actual time of the *shot*, t_0, must be transferred from the source to the recorder and recorded; it is often used to start the recording process itself, as seismics is only interested in travel-times, i.e., arrival-times with respect to t_0. The digitized data – uniformly sampled time-series – from each individual experiment (*shot*), consisting of multiple *traces* (output of receivers), is called a *seismic record*.

Acquisition geometry

Assuming a *layer-cake* model (sedimentary beds parallel to the surface), early surveys deployed a number of sources and receivers along a straight line on the earth-surface to obtain a vertical cross-section of the geology below this line (2-D).

Figure 1 shows schematically the approach in such a survey, and is – in spite of its simplifications – useful in understanding several basic ideas. All the five panels show the earth-surface at the top, and a reflecting boundary (*target*), parallel to it, at some depth. Numerals on the surface represent surveyed equi-distant flag-positions to denote locations. The top panel shows the first measurement, with the source at "0" and eight receivers at locations "1" through "8". Assuming a homogeneous and isotropic medium, the paths predicted by Snell's law for a part of the source energy to first travel downward to the target and then reflect upward from it to reach the receivers are indicated by the oblique lines.

The signals output from the receivers are digitized in the recorder to yield a *seismic record*, i.e., a collection of *seismic traces*. Such an ordered collection of seismic traces is called a *gather*. Having a common *source*, the record resulting from our first measurement is a *common source gather* (CSG_0), the suffix denoting source position.



Seismic Data Acquisition and Processing, Figure 1 Schematics of seismic data acquisition by common-mid-point (CMP) profiling. Panels CSG_0 through CSG_3 represent common source gathers (CSG); CMP_4 is a common mid point gather for one common depth point (CDP). See text for details.

Under the twin-idealizations of no background noise, and a spike-like source signal, each channel in the recorder (*seismic trace*) will consist of one single blip corresponding to the arrival time of the signal; in reality, the arrivals will have random background oscillations due to noise, and one *wavelet* corresponding to the single reflection arrival. Assuming constant speed of propagation v and depth to the target H, it is trivial to show (e.g., Sheriff and Geldart, 1995) that the travel-times to the receivers can be written as $t_x^2 = (x^2 + 4H^2)/v^2 = t_0^2 + x^2/v^2$, t_x being the arrival time recorded by a receiver at a source-receiver *offset* of x. The travel-time curve for such a situation is thus a hyperbola – this simple relationship underlies much of seismic processing. t^2 plotted against x^2 thus yields a straight line, the slope being v^{-2}, i.e., square of the

slowness of the medium. Note that in seismics, the *velocity*, which sensu stricto is a vector, is almost always used to denote the local wave *speed* (a scalar), which is a property of the medium (rocks) . . . we shall follow this usage.

Our aim is to find H, the depth to the target ($= t_0/2v$). We have thus to estimate t_0 from the rest of the reflection hyperbola. Note that the reflection points on the target for the different receivers are different.

Hence, in what has become almost universal practice, the measurement is repeated after shifting the whole set-up laterally along the measurement line, keeping all the relative distances the same. In panel 2 of Figure 1, the source and the receivers have been shifted right by one unit; only a few ray-paths are shown for this gather (CSG_1). Similarly, gathers CSG_2 and CSG_3 are also measured and recorded. During these measurements, the same receiver locations recorded signals from different sources so that a post-measurement re-arrangement of the traces could also yield *common receiver gathers* (CRG); in our case, we would obtain $CRG_1 - CRG_{11}$. These are useful for certain processing situations.

The lowest panel of this figure shows a special kind of re-sorting, collecting the traces from the four *shots* with one *common reflection point* (CRP). Four traces corresponding to source-receiver combinations of 0/8, 1/7, 2/6 and 3/5 were selected respectively from the four gathers. For our simple geometry, the four ray-paths shown share two things – a *common mid point* (CMP_4) between their respective source and receiver locations and the *common depth point* (CDP) at the target depth, the latter being the same as CRP. Such a gather is called a CMP-gather, and indexed by the position of the CMP. The travel-time plot of the reflection arrivals in a CMP-gather is also a hyperbola.

The four ray-paths shown for the gather CMP_4 all have the same reflection point, and thus contain information about the same subsurface geology. The arrival times of the reflection signal in the four traces are of course different, as the travel paths are different. If this difference is corrected for, then adding the four traces should increase the coherent signal (information regarding the CRP) with respect to the *random* noise. The improvement of S/N by adding N traces is given by

$$\frac{\sum(\text{N traces with identical signal})}{\sum(\text{N traces with random signal})} \approx \frac{N}{\sqrt{N}} = \sqrt{N}.$$

The improvement of the signal-to-noise (S/N) ratio is thus roughly proportional to the square-root of the number of traces added. This number (4 in our case) depends upon the survey geometry, and is called the *fold* of the survey. Starting from fold 1 for $CMP_{0.5}$ (not shown), it gradually builds up to its nominal value (4 in this case), and again drops-off at the other end of the survey.

Acquisition configuration can be specified by expressions describing the position of the source relative to the receivers, viz., *end-on, split-spread, broad side*, etc. Depending upon the geology and the noise regime, these configurations, as also varying *fold*, leave subtle but important *footprints* on the data.

In reality, the geology is of course not as in Figure 1, presence of structure (*dips, faults, folds*, etc.) is what makes hydrocarbon accumulation possible in the first place. Processing of 2-D data can remedy this situation – though only partially. Availability of more equipment and data processing power led therefore to development of 3-D acquisition, with receivers laid out on the surface in a 2-D pattern, and sources also positioned in a different 2-D pattern, thus causing a better illumination of the subsurface by the seismic waves. Here too the basic concept of adding *fold* number of traces in a CMP-gather holds sway – point-shaped CMPs and CDPs being replaced by finite *bins*, their sizes depending upon the survey design and objectives (see Vermeer, 2002 for further insight into acquisition design).

In areas with structural complexity, the simplifying assumptions of CMP-processing break down, and the availability of computer power may make it possible – nay desirable – to process each trace of the recorded CSG separately, to try to obtain a better image (see also *Seismic Imaging, Overview* and *Seismic, Migration*).

Restricting the deployment to the surface of the earth implies – as we shall see later – a bias for horizontal structures; this was eventually removed by carrying out measurements inside bore-holes called VSP; see *Vertical Seismic Profiling* for details. Finally, better recording instrumentation coupled with the need to detect changes in the hydrocarbon reservoirs resulting from exploitation has given rise to *time lapse seismic* (4D), whereby repeat imaging of the same area, carried out after several years of production, is used to validate/improve production models for reservoirs.

Seismic data processing

Introduction

Reflection seismic data, acquired in the field, has to be taken through several processing steps, before it can be interpreted in terms of the subsurface structure. The source signal, on its way down, and back up to the receivers is modified by many factors; the aim of processing is to *undo* (i.e., correct for) as many/much of these effects as possible, leaving only the effects due to the causative structure of interest (geology) to be interpreted.

Seismic data is a spatio-temporal sampling of the back-scattered seismic wave-field, an ordered collection of traces, and can be considered to be a 2-D or 3-D data matrix along with some auxiliary information regarding location, etc. The traces themselves are an ordered collection of uniformly sampled amplitude values (*time-series*), with relevant information contained in their respective headers in (internationally) agreed formats. All processing steps aim to improve the spatio-temporal S/N ratio of the data by reducing the noise and/or by sharpening the wave-form (to improve the resolution).

Signal versus noise

Before proceeding further, it is useful to reflect on the terms *signal and noise*. That it is a matter of perspective is clear from this relative definition: *signal is useful noise and noise is useless signal*. In other words, someone's noise is someone else's signal, and vice-versa. For example, the *ground-roll*, hated in reflection seismics, is useful in surface-wave seismology and shallow-seismics. Amazingly, using noise for seismic imaging has now become a field of active research (see the section "*Seismic Noise*" for references).

In reflection seismics, signal is synonymous with *primary reflection. Primaries*, as these are often referred to, represent seismic energy reflected only once during its travel from source to receiver. Everything else, present in the traces, is taken to be *noise*. This includes multiply reflected energy (*multiples*), diffractions (caused by *sharp* structures in the subsurface, e.g., faults, pinch-outs), refracted arrivals, surface waves (*ground-roll*). Non-geological noise sources include nature (wind, waves, animals) and man (traffic, industry, etc.). From processing point of view, noise could be coherent (ground-roll, water-pump, multiples), or, incoherent, each needing a different strategy. See *Seismic Noise* for details.

Kinematics of the seismic signal (primaries)

Starting with some simple (but inaccurate) assumptions, e.g., horizontal layering, constant speed, etc., useful structural information can be extracted – a large data volume contributing to the robustness of the processing algorithms (also see *Seismic, Migration*). In this section, we focus on the travel-times of the waves (visualized as *rays*), see also additional information in "*Seismic, Ray Theory*."

NMO

The travel-time for a primary reflection from a horizontal reflector, shown earlier to be hyperbolic, can be rewritten as:

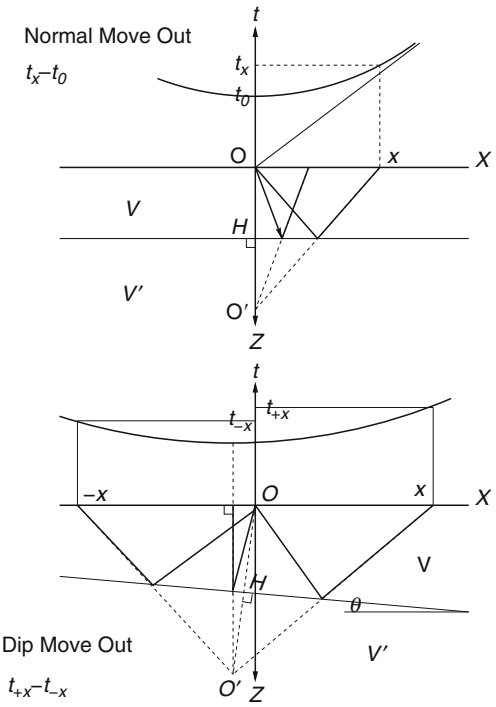
$$t_x - t_0 = \frac{\sqrt{x^2 + 4H^2} - 2H}{v}. \tag{1}$$

The quantity on the left is the difference (see Figure 2) between the oblique reflection-time at source-receiver offset (distance) x and the vertical TWT, and leads to the relation:

$$\Delta t_x = \frac{2H}{v}\left(\sqrt{1 + \frac{x^2}{4H^2}} - 1\right) = t_0\left(\sqrt{1 + \frac{x^2}{4H^2}} - 1\right). \tag{2}$$

Expanding the expression under square-root, and recognizing that in most seismic measurements offset $\ll$ target depth, we obtain the approximate relation (Equation 3), which could be improved by retaining additional higher order terms.

$$\Delta t_x \approx \frac{x^2}{4vH} = \frac{x^2}{2v^2 t_0} \tag{3}$$



Seismic Data Acquisition and Processing, Figure 2 NMO of a primary reflector; horizontal (above), dipping (below). See text for details.

Δt_x ($= t_x - t_0$) is called the *normal move-out* (NMO) associated with the reflection travel-time. NMO can be used to align the primary reflection in all traces at t_0 (TWT) by removing the effect of source-receiver distance (offset), i.e., by *flattening the reflector*. NMO, an important concept in seismics, is used both to first identify *primaries*, and later to align them for imaging the reflector. Note that to use 3, we need to know x (source-receiver offset), v (speed), and H (target depth); in practice, x is known and iteration is used to obtain optimal values for v and H.

Dipping bed

For a dipping reflector (Figure 2), travel-time for the primary reflection is still hyperbolic, given by

$$v^2 t_\theta^2 = x^2 + 4H^2 + 4Hx\,\sin\theta. \tag{4}$$

The minimum of the hyperbola is now shifted *updip*; the quantity $t_{+x} - t_{-x}$ is a measure of the asymmetry, and can be used to estimate the dip.

Many reflectors: layer-cake

Dix (1955) considered the case of many reflectors parallel to the surface – a good starting model for sedimentary sequences – and showed, that here too, the travel-time curve can be approximated at short offsets by a hyperbola:

Seismic Data Acquisition and Processing, Table 3 Jargons associated with the term velocity in seismics

Jargon	Brief description
v_{int}	Speed in a geological interval (assumed constant)
v_{av}	Average speed between two points along a ray path
v_{app}	Apparent speed measured by receivers in field (= dx/dt)
v_{nmo}	Speed used for NMO correction (strictly, only for one layer)
v_{rms}	Dix' root-mean-square NMO velocity for layer-cake situation
v_{stk}	*Best* velocity to stack CMP-gathers
v_{mig}	*Best* velocity to migrate the seismic data

$$t_x^2 \approx t_0^2 + \frac{x^2}{v_{rms}^2}, \quad \text{with} \quad v_{rms} = \sqrt{\frac{\sum v_i^2 \Delta t_i}{\sum \Delta t_i}}. \tag{5}$$

The homogeneous velocity v (= v_{nmo}) is now replaced by v_{rms} (root-mean-square velocity), which depends upon the velocities of the layers v_i and the vertical transit times t_i through them. v_{rms} plays a role similar to v_{nmo} in flattening the primaries in the multi-layer case. Individual layer-velocities may then be computed from the Dix' equation:

$$v_n = \sqrt{\frac{v_{rms,n}^2 t_n - v_{rms,n-1}^2 t_{n-1}}{t_n - t_{n-1}}}. \tag{6}$$

Velocities in seismics

In seismics, different terms are used to denote "velocity" depending upon the context. Table 3 lists a few, along with brief explanations, some of these will be elaborated later.

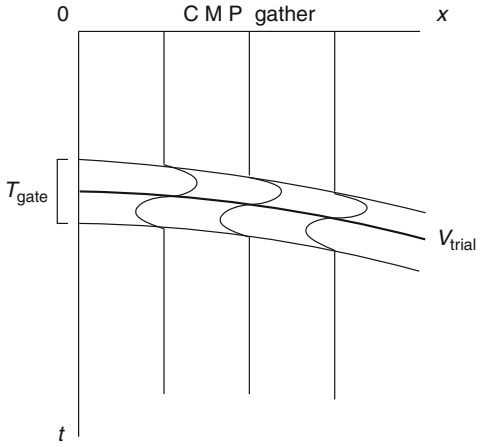
NMO stretch

After NMO correction, a time-interval Δt_x, say corresponding to a period of the wavelet recorded on a trace at an offset x, becomes Δt_0; the wavelet is thus distorted (*stretched*). The expression 100 $(\Delta t_0 - \Delta t_x)/\Delta t_x$ is a percentage measure of this stretch – 0% implying no distortion. In practice, a threshold percentage is specified to exclude parts of data – relatively largeoffsets and small arrival times – from being NMO corrected (and taking part in further processing).

Semblance: a measure of signal alignment

To apply optimal NMO correction, a quantitative measure of alignment of amplitudes, across several traces, is useful. Such a measure of similarity between n (amplitude) values, called *semblance*, is defined by

$$S = \frac{\left(\sum_n val\right)^2}{n \sum_n val^2}, \quad \text{and}$$
$$S_{gate} = \frac{\sum_{gate} \left(\sum_n val\right)^2}{\sum_{gate} \left(\sum_n val^2\right)}. \tag{7}$$



Seismic Data Acquisition and Processing, Figure 3 Schematical drawing showing calculation of multi-channel semblance. *Curved bold line* represents the move-out curve for a trial velocity, the *two surrounding lines* represent the boundaries of the time-gate; see text for details.

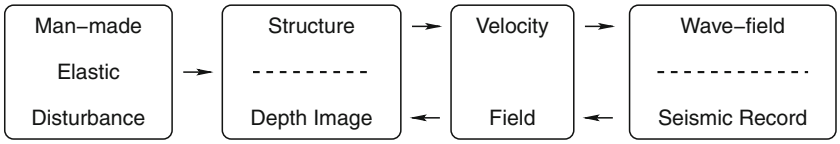
Note that semblance is a dimensionless number between 1 (perfect match), and is 0 (perfect mismatch). The second form uses a time-gate along the traces, generally having the width of the dominant period of the signal, for increased robustness. Semblance is used extensively in modern *reflection velocity analysis*, to evaluate the goodness of alignments of primary reflections along move-out curves computed for a range of trial velocities (Figure 3).

Velocity: processing point of view

Wave-speed (called velocity in seismics) in the medium is the missing link needed to convert the travel-time information to depths required for structural interpretation – and eventual drilling. Note that *velocity* is needed to find the structure (geology), but structure is needed to find the velocity. This catch-22 situation is solved iteratively – shown schematically in Figure 4.

Velocity is a macroscopic (wavelength-scale average) property of the rock depending upon the density and elastic properties of the minerals making up the lithology (see *Seismic Properties of Rocks*). In rocks of interest in seismics (*sandstone, shale, limestone*), velocity is not a good indicator of lithology, with considerable overlap in values, with some exceptions, e.g., salt, anhydrite (relatively higher velocity). Presence of *porosity and pore-fluids (water, oil, gas)* is the most important factor for this overlap, and is in turn caused by the *burial history* of the rocks. Wave-propagation in fluid-filled porous media is described by Biot-Gassman theory, see Lee (2008) for references and recent developments.

Propagation velocity (the missing link) can be estimated by direct measurements (see, e.g., Sheriff and Geldart, 1995 for details), which have shortcomings though (see Table 4). The velocity used for processing



Seismic Data Acquisition and Processing, Figure 4 Iteratively solving for both structure and velocity in seismics.

Seismic Data Acquisition and Processing, Table 4 Direct determination of seismic velocities and their shortcomings

Method	Shortcoming
Uphole-time	Useful only for the weathering layer
Check-shots, well-shoot	Limited depth-range, destructive
VSP	Available late in exploration, expensive
Sonic log	Available late, noisy (high-frequency)
Lab measurements	Limited availability

seismic reflection data is usually determined iteratively from the data itself, and will be described later.

Amplitude changes along the propagation path

Several factors cause the amplitude of the seismic waves to change as they travel from source to receiver. These can be corrected for, so as not to mask the weaker changes (signals) of interest.

Geometrical spreading

Conservation of energy requires a continuous reduction of amplitude, as a seismic wave-front spreads through a medium – hence the term *geometrical spreading*. The loss depends upon the mode of spreading and the distance traveled (r). For primaries (body-waves), amplitude ($\propto \sqrt{\text{energy}}$) decreases $\propto r^{-1}$, whereas for ground-roll (surface-wave), the decrease is $\propto r^{-1/2}$, the latter shows why ground-rolls, with their (relatively) large amplitudes, are a big problem in seismics.

Absorption

The propagating wave continuously loses energy due to absorption too, which is a physical property of the medium, and can be described by several equivalent parameters, e.g., *absorption coefficient, damping factor*, etc., the most common being the *quality factor* of the material $Q = 2\pi/$[fractional energy lost per cycle]. It is a dimensionless quantity, with a value 0 implying perfect absorption and ∞ implying perfect elasticity. Absorption, with Q considered to be frequency-independent within the band-width of interest in seismics, causes relatively greater attenuation of higher frequencies – leading to a change in the wave-form during propagation. See *Seismic, Viscoelastic Attenuation* for more details.

Energy partitioning at interfaces

Boundaries of geological heterogeneities (layering, faults, etc.) also cause changes in the amplitude of the wavelet; such changes are, indeed, of prime interest in seismics. As in optics, the interaction between the wave-fronts and the geological structure depends upon their relative dimensions, i.e., their radii of curvature-with specular reflections and point-scattering building the two end-members, both of which are encountered in seismics. Another concept from optics, *diffraction*, is useful to understand the complexity of the interaction between the wave-front and the medium. See *Seismic Diffraction*; *Seismic Waves, Scattering*, and *Energy Partitioning of Seismic Waves* for additional details.

Waveforms: convolution, deconvolution

Factors modifying the source signal along the path of the seismic wave may be divided as: near-source (*ns*), i.e., weathering layer, earth (*e*), i.e., the target geology, near-receiver (*nr*), receiver (*r*), and recorder (*rec*), with the output trace (o) as the final result. Each of these, denoted in Equation 8 below by the expression in parentheses, affects (*filters*) the source wavelet (s). In a series of papers/reports (Robinson, 2005; Treitel, 2005), the MIT geophysical analysis group (GAG) laid the foundation of the *digital revolution* in seismic data processing, by examining the nature of these filters and developing methods to undo their effects. These resulted in major advances in *time-series analysis and digital filtering* (Robinson and Treitel, 1964), and a critical evaluation of the (statistical) nature of earth's reflectivity (*target geology*).

Convolutional model of the seismic trace

As the source- and recorded-signals are both time-series (uniformly sampled, ordered collection of amplitudes), it is useful to represent all the other elements mentioned in the above-paragraph also as such. For a column of vertically layered reflectivity, such a time-series would correspond to values equal to *RC*s placed at times converted from depths using velocities. Now, making the crucial assumption that all these filter elements are linear systems, the recorded trace can be expressed as:

$$o(t) = s(t) * ns(t) * e(t) * nr(t) * r(t) * rec(t) + n(t). \quad (8)$$

In Equation 8, $*$ (*star*) is the convolution operator, well-known in the theory of linear systems; $n(t)$ represents some additive noise which does not follow this model, hopefully, it is mostly removed early in the processing.

The time-series that transform $s(t)$ into $o(t)$ can also be interpreted as the *impulse response* of the corresponding elements, e.g., $r(t)$ is the response of the receiver to a sudden spike signal. Using *Fourier Transforms* to change the time-series into their *spectra*, and remembering that convolution in time-domain corresponds to multiplication in frequency domain, one obtains:

$$O(\omega) = S(\omega) \cdot NS(\omega) \cdot E(\omega) \cdot NR(\omega) \cdot R(\omega) \cdot REC(\omega), \tag{9}$$

where the noise term has been neglected (see Sheriff and Geldart, 1995 for introduction to linear operators and Fourier theory). Equation 9 clearly shows the *filtering* effect of the different elements, each one modifying the spectrum of the incoming signal by modifying/removing a part of its frequencies. Our aim, in seismic data processing, is to extract $e(t)$, the geological structure, from the recorded signal $o(t)$.

Deconvolution as inverse filtering

Undoing the act of the filterings implied in Equations 8 and 9 is called *deconvolution* (decon), or, *inverse filtering*. Equation 9 can be rewritten as $O(\omega) = \mathrm{E}(\omega).\,\mathrm{REST}(\omega)$, where $\mathrm{REST}(\omega)$ groups together all the elements on the right besides the geology. Then, $E(\omega)$, or $e(t)$, can be *estimated* from

$$E(\omega) \cong O(\omega)/REST(\omega), \quad \text{or,} \qquad e(t) \cong o(t) * rest(t)^{-1}. \tag{10}$$

The approximation sign, for both forms of Equation 10 – in frequency domain (first), or, in time-domain (second) – is necessary, even in the *noise-free* case. Spectral division needs precautions to avoid zero-division in parts of the spectrum, where frequencies have been weakened/removed. Fortunately, addition of *noise* helps, since signals of interest in seismics exist – by definition – only above the ambient noise level. See Liner (2004), Sheriff and Geldart (1995) and Yilmaz (2001) for the stabilizing role of *spectral whitening* in decon.

Wavelet processing

Wavelets: Let's take a closer look at *seismic wavelet*, introduced in the section about seismic sources, as a signal of finite frequency band-width and temporal duration. Using standard concepts from time-series analysis (Sheriff and Geldart, 1995; Yilmaz, 2001), simple examples of wavelets are:

$$a : (3, -2, 1), \quad b : (2, 3, -1) \quad \text{and} \quad c : (-1, 2, 3),$$

the numbers representing uniformly sampled amplitudes starting from $t = 0$. Remembering that squares of the amplitudes in a wave(let) are measures of energy, we see that these three wavelets, while looking very different, have the same total energy. Depending upon the energy build-up, wavelet a is called *minimum delay* (energy is front loaded), b is *mixed delay*, and c is *maximum delay*; physical (causal) wavelets are minimum delay, although in the example, a is not strictly causal, due to the instantaneous build-up of energy at $t = 0$. In frequency domain, the expressions minimum/mixed/maximum-phase are used instead.

Wavelet estimation: *Auto-correlation* of the wavelets a-c are all symmetrical about $t = 0$, i.e., have no phase information, e.g., $\phi_{bb} = (-2, 3, 14, 3, -2)$; these are Fourier Transforms of the respective power-spectra. In seismics, an estimate of the power spectrum is often available from the data. The question then arises whether an estimate of the wavelet may be obtained from it – an outline follows. Using Z-transform notation, one can write the wavelet, say c, and its auto-correlation as polynomials:

$$C(Z) = -1 + 2Z + 3Z^2, \text{ and,}$$
$$\Phi_{cc}(Z) = -3Z^{-2} + 4Z^{-1} + 14 + 4Z - 3Z^2,$$

Z being the *unit-delay* operator, its powers denoting time-shifts with respect to $t = 0$. According to the fundamental theorem of algebra, a polynomial of degree n in Z must have n roots, i.e., it can be expressed as a product of n factors of the form: $(Z - Z_1)(Z - Z_2) \ldots (Z - Z_n)$, each factor representing a basic wavelet (*doublet*). Half the doublets of an auto-correlation polynomial are minimum delay, their product represents the Z-transform of the unique minimum delay causative wavelet. See Yilmaz (2001) and Sheriff and Geldart (1995) for details, assumptions, critical remarks, and alternate approaches (e.g., *homomorphic deconvolution*) to deconvolution of time-series.

Wavelet manipulation: Much of seismic processing is involved with manipulating the wavelet (deconvolution in a general sense). While very powerful, it contains potential for pitfalls, if applied without a proper understanding of the suitability of the particular technique, as each decon step also causes artifacts.

Spiking decon aims to sharpen the shape of the signal, to improve temporal resolution – and interpretation. Ideally, it involves convolving the wavelet with its inverse operator, to yield a spike, i.e., perfect resolution.

Zero-phasing converts the signal to one with zero-phase; the result is a symmetrical signal (a-causal), and is primarily useful for interpretation if the peak can be made to coincide with the reflecting boundary.

Any-phasing is used in merging seismic datasets of different vintages and with differing source wavelets.

General shaping groups methods to convert the signal to any desired shape optimally – using some statistical criteria.

Depending upon whether a model is available for decon, the methods could also be divided in *deterministic*, i.e., model-based and *statistical*.

Deterministic deconvolution

Vibroseis processing. Vibrators (see the section on sources) use a repeatable source signal, called *sweep*. It is a time-limited (typically, 10–20 s long) signal with the frequency continuously varying between given start- and end-values, and comes in many flavors, e.g., up-, down-, linear-, non-linear-sweeps. Neglecting other terms, one could write from Equations 8 and 9: $o(t) = s(t)^* e(t)$. The recorded signal is thus the convolution of *earth reflectivity* with the sweep signal. We could remove its effect (deconvolve) by *cross-correlating* the observed signal with the sweep (which we know precisely), a process, which is equivalent to convolving with its time-reversed version, and get

$$s(-t) * o(t) = s(-t) * s(t) * e(t) \approx \delta(t) * e(t) \qquad (11)$$

Due to the sweep signal being time-limited, its auto-correlation is not a Delta-spike (ideal), but is a symmetrical (zero-phase) signal called *Klauder wavelet*. The result is thus not quite the desired earth reflectivity (although it has the correct phase) and needs further processing for improvement (see Yilmaz, 2001; Liner, 2004; Sheriff and Geldart, 1995).

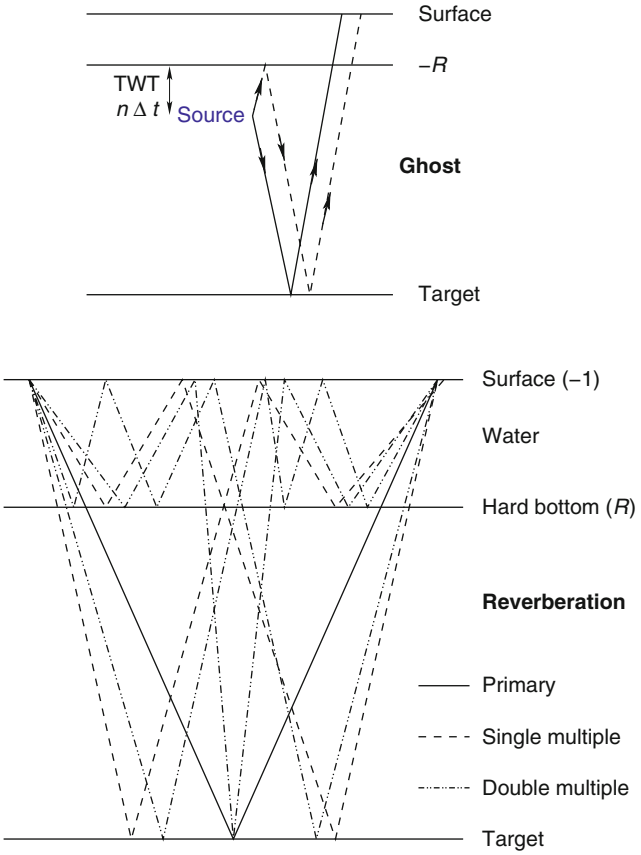
De-ghosting. The effect of large *RC*s in the shallow sub-surface has been mentioned earlier. Figure 5 shows one such situation; here the source is placed below the weathering layer, for better energy transmission toward the deeper target (ray going directly downward). A part of the wave-energy, also travels upward, and gets reflected down from the base of the weathering layer (ray going first up, and then down). In certain cases, the $RC_{\text{weathering}}$ could be quite large and negative. The energy reflected downward follows with a short delay behind the direct wave, and is called a *ghost*; the observed record is thus corrupted by that caused by a delayed ghost. Removing the latter from the recorded trace is called *deghosting,* and is an example of model-based decon. Assuming the TWT between the source and the base of the weathering to be n samples ($= n\Delta t$), one can write:

$$o(t) = s(t) - Rs(t - n\Delta t), \text{ or, using Z} - \text{transforms,}$$
$$O(Z) = S(Z) - RS(Z)Z^n = S(Z)(1 - RZ^n).$$

$(1 - RZ^n)$ is, clearly, the Z-transform of the ghost-operator. Hence, $S(Z) = R(Z)\ (1 - RZ^n)^{-1}$, or, $s(t) = o(t) + s(t - n)$. The last form above implies recursive filtering in the time-domain to achieve deghosting. Alternately, expanding $(1 - RZ^n)^{-1}$, the inverse-filter operator in time-domain can be written as

$$g(t)^{-1} = (1, 0, 0, \ldots + R, 0, 0, \ldots + R^2, 0, 0, \ldots)$$

De-reverberation. The lower part of Figure 5 shows another situation, where strong reflectivity associated with the water bottom causes long trains of high-amplitude *reverberation* of signals in the water layer. The ray-paths



Seismic Data Acquisition and Processing,
Figure 5 Deterministic deconvolution applied to ghost (above) and reverberation (below). The near vertical ray-paths are shown obliquely for better visualization, see text for details.

shown schematically are: one primary reflection from the target, two multiples reflected once in the water layer, and three multiples reflected twice; there could be many more, posing a serious problem in marine seismics. Depending upon the depth of water, certain frequencies will, as a result, experience severe distortion (enhancement or suppression). In the simplified case of a water-column with a TWT equal to the sampling interval, and remembering that the negative reflectivity causes phase-change, the total operator (signal + reverberation) can be written as:

$$w(t) = (1, -2R, +3R \ldots) \rightarrow W(Z)$$
$$= 1 - 2RZ + 3R^2Z^2 - \ldots = (1 + RZ)^{-2}.$$

It follows that the deconvolution in this case can be achieved by the operator

$$W(Z)^{-1} = (1 + RZ)^2, \quad \text{or,} \quad w(t)^{-1} = (1, 2R, R^2).$$

This elegant operator is called the Backus filter (see Backus, 1959).

Statistical deconvolution

In the absence of a deterministic model, one could attempt to change the signal wavelet to any desired shape, by designing filters that are optimal in a statistical sense. Based upon work in information theory by Norbert Wiener and others, the applications in seismics were pioneered by the MIT-GAG group, e.g., Robinson (1967). Schematically, the basic approach is:

assume filter → compute output → compute error →
minimize to get normal equations → solve for filter coefficients

If errors are assumed to be Gaussian, and l_2 norms are used, the operators obtained are called Wiener filters. Such *optimum filters* are used widely, e.g., in:

- Zero-lag spiking – to increase resolution
- Zero-phasing – to ease interpretation
- Prediction filtering – to remove multiples which are predictable, the remnant being the prediction error, corresponding to the deeper signal

Wiener optimum filter. The normal equations for the filter coefficients f are given by the matrix equation shown in Equation 12 in its compact form

$$\phi_{\text{input,input}} * f = \phi_{\text{input,output}}, \tag{12}$$

which relates the auto-correlation of the recorded (input) wavelet to its cross-correlation with the desired (output) wavelet. For the derivation of Equation 12, and a detailed treatment of statistical deconvolution, see, e.g., Yilmaz (2001) or Sheriff and Geldart (1995) – an example is shown below to illustrate the approach.

Spiking filter. If the wavelets are all n-sample long, the Matrix Equation 12 can be expanded as

$$\begin{pmatrix} \phi_{i,i}(0) & \phi_{i,i}(1) & \dots & \phi_{i,i}(n-1) \\ \phi_{i,i}(1) & \phi_{i,i}(0) & \dots & \phi_{i,i}(n-2) \\ \phi_{i,i}(n-1) & \phi_{i,i}(n-2) & \dots & \phi_{i,i}(0) \end{pmatrix} \begin{pmatrix} f_0 \\ f_1 \\ f_{n-1} \end{pmatrix} = \begin{pmatrix} \phi_{i,d}(0) \\ \phi_{i,d}(1) \\ \phi_{i,d}(n-1) \end{pmatrix} \tag{13}$$

The auto-correlation matrix $\phi_{i,i}$ in Equation 12, with the same element in each diagonal descending from left to right, is a Toeplitz matrix; f is a column vector with the filter coefficients to be determined and $\phi_{i,o}$ is a column vector with elements from the cross-correlation matrix. Equations with Toeplitz matrices can be efficiently solved by a procedure called *Levinson recursion*.

Wiener filter: a simple example. Given the input wavelet $i_t = (1, -1/2)$, let us find the optimum two-element Wiener-operator to transform it to the desired wavelet $d_t = (1, 0)$, i.e., a zero-delay unit-spike. We get $\phi_{i,i} = (5/4, -1/2)$, and, $\phi_{i,d} = (1, 0)$. Equation 13 then becomes

$$\begin{pmatrix} 5/4 & -1/2 \\ -1/2 & 5/4 \end{pmatrix} \begin{pmatrix} f_0 \\ f_1 \end{pmatrix} = \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \quad \text{yielding} \quad f_{\text{Wiener}} = \left(\frac{20}{21}, \frac{20}{21}\right). \tag{14}$$

Applying this filter to the input, we obtain the output (20/21, −2/21, −4/21), which compared to the desired output, gives a squared error of 1/21. The ideal filter for this decon is the *inverse filter* for the input wavelet. Writing $I(Z) = 1 - Z/2$ for the Z-transform of the input, the Z-transform of the inverse filter (which will convert the input to an ideal unit-spike) is $= (1 - Z/2)^{-1} = 1 + Z/2 + Z^2/4 + \ldots$, which is an infinitely long operator! For an honest comparison of its performance with that of the Wiener filter, we apply its first two terms to the input, getting the filtered version as (1, 0, −1/4); although looking better at the first glance, its squared error is 1/16, i.e., larger than that of the Wiener filter! It can be shown that the Wiener filter is the *best* two-element filter for this problem.

Suppose the input wavelet is (−1/2, 1), i.e., not minimum delay, which we want to transform to a zero-delay spike. Normal equations now give the Wiener filter as (−10/21, −4/21), with the output (5/21, −8/21, −4/21) and the squared error as 6/21. Inverse filter is now (−2, −4, −8, ...), which is extremely unstable! Its first two filter elements give the output (1, 0, −4) with 16 as error! Wiener filter performs here worse than in the first case, because, it was trying to convert a maximum delay wavelet to a minimum-delay spike, but it still does better than the (finite) inverse filter. In this case, if a maximum delay spike (0, 1) was desired, Wiener filter coefficients would be (16/21, −2/21), giving a filtered output of (−8/21, 17/21, −2/21) with a squared error 4/21, which is better than that for a zero-lag spike output. Table 5 summarizes the results.

The processing flow: putting it all together

Most of the processing *modules* (*filters*) operate on the data (time-series) sequentially, the entire process resembling a *flow*, though there are a few stand-alone modules

Seismic Data Acquisition and Processing, Table 5 Performance of Wiener and inverse filters

Input wavelet	Desired wavelet	Two-point Wiener		Two-point inverse	
		Filter	Error	Filter	Error
(1, −0.5)	(1, 0)	(20/21, 8/21)	1/21	(1, 0.5)	1/16
(−1/2, 1)	(1, 0)	(−10/21, −4/21)	6/21	(−2, −4)	16
(−1/2, 1)	(0, 1)	(16/21, −2/21)	4/21		

too. The operations could be on individual traces (*single-channel*), or on a gather of traces (*multi-channel*). Schematically, a seismic processing flow looks like:

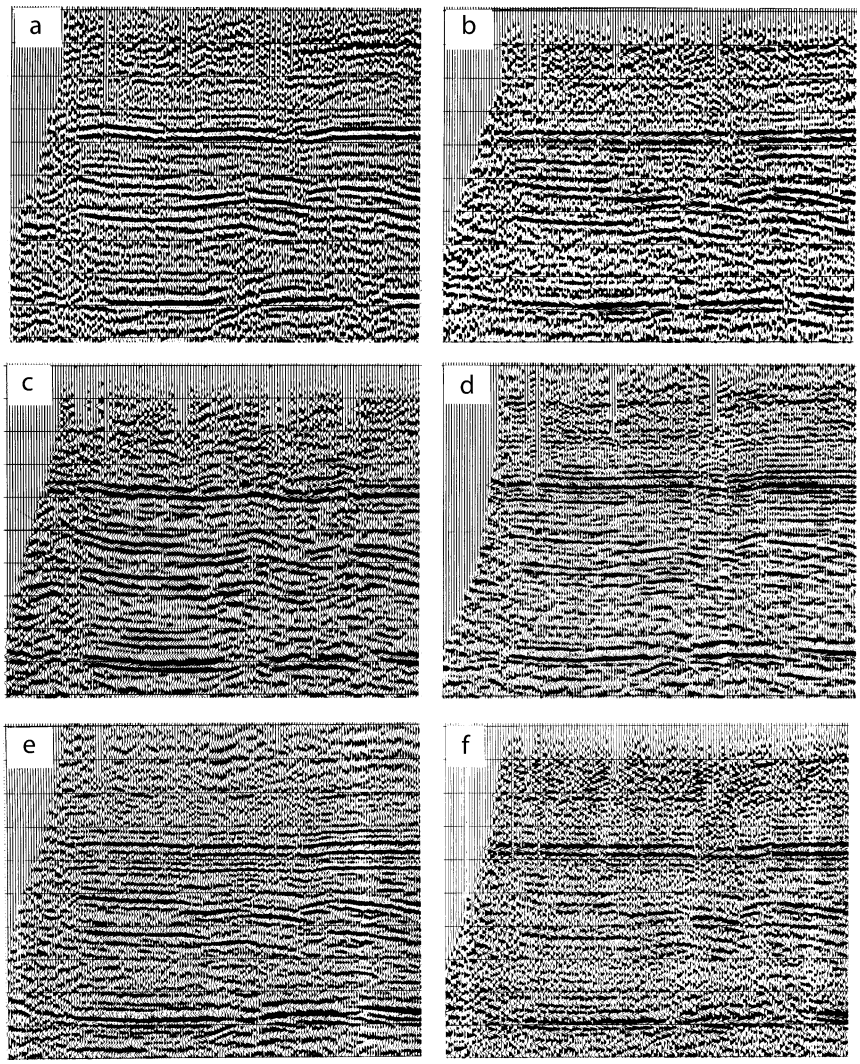
Input module → a series of processing-modules → Output module

Modules have been developed for carrying out specific tasks within the flow, e.g., static correction, band-pass filtering, stacking, migration, etc. Usually, there is a choice of modules (algorithms) available for a specific step – each with slightly different characteristics (and artifacts), and the proper selection of the modules for a flow needs both expertise and experience. This point is illustrated in the Figure 6, which shows six *different* results of processing the same data.

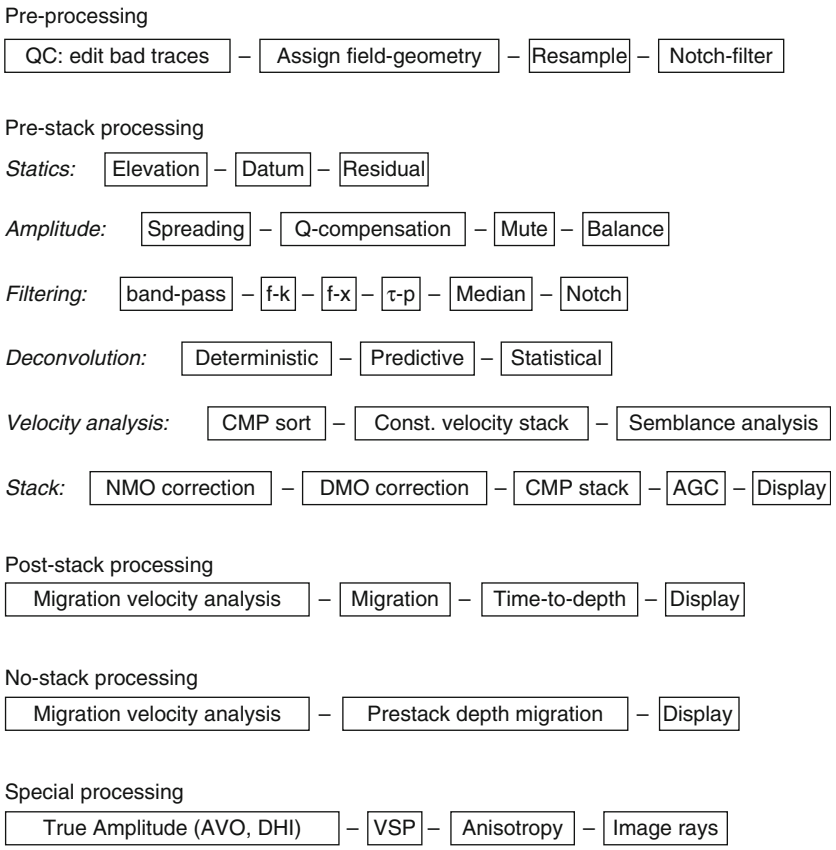
An overview of commonly applied *corrections* (processing modules) is shown in Figure 7. Space constraints will permit us to briefly describe only selected items from this list, which itself is not exhaustive; see Yilmaz (2001) for a more detailed treatment, and "*Seismic Imaging, Overview*" for additional information. Note that some modules may be applied more than once in the flow, and also, that parts of the flow may be iteratively repeated, till a reasonable result is obtained. The latter shows the importance of quality control (Q/C), by means of visual-display and other (quantitative) tools. The decision as to whether the processing of a dataset is finished depends often on the geological objectives, technical possibilities, and managerial constraints of time and money.

Pre-processing

Editing of seismic traces is an important first step, in view of the largely automated processing sequences later. *Geometry assignment* is also an essential step at this stage, and attaches acquisition information to the traces, e.g.,



Seismic Data Acquisition and Processing, Figure 6 Seismic Data Processing has no perfect answer. Seismic cross-sections produced from the same data processed by six different contractors. (Figure from Yilmaz, 2001 courtesy SEG and the author).



Seismic Data Acquisition and Processing, Figure 7 Components of seismic processing flow.

source- and receiver- coordinates. Each seismic trace is assigned a header, to store such and other information to enable efficient inter-process communication.

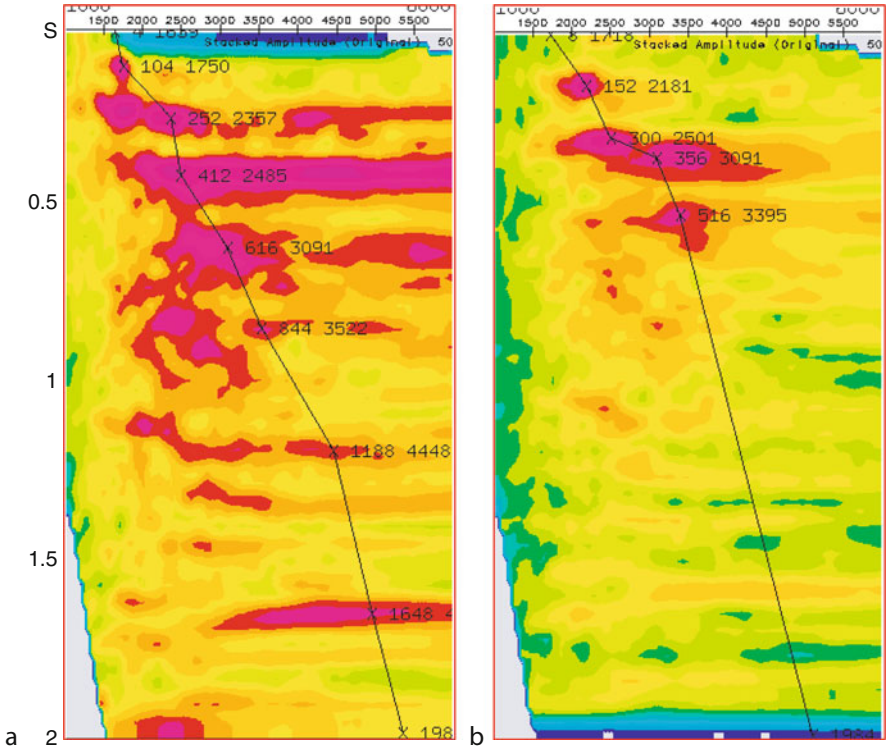
Pre-stack processing

Static corrections. These are time-invariant corrections applied to the traces, due to, e.g., elevation differences, and involve up-, or, down-shifting the entire trace in time; an example of their dramatic effect can be seen in Figure 8. The static effects due to slow lateral changes (long wavelength statics) are particularly difficult to model and can cause imaging problems. *Residual statics* involves *small* time-shifts applied late in the flow to improve the result; it uses the powerful concept of *surface-consistency* to try to correct for near-surface errors that were not modeled properly in the earlier stages. Its implementation by Rothman (1985) heralded the use of non-linear optimization (*simulated annealing, genetic algorithm*) in seismics.

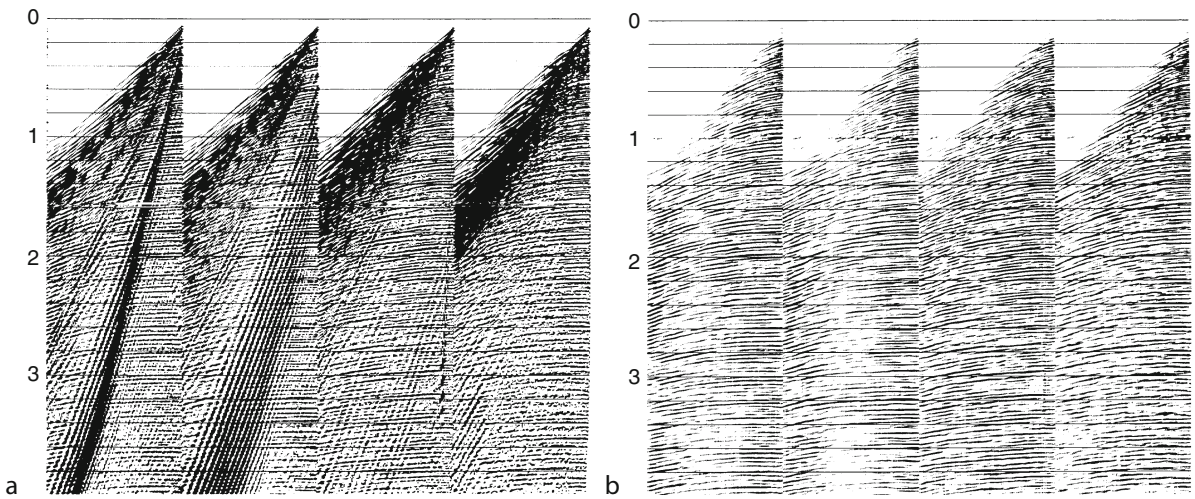
Amplitude corrections. Loss of amplitude due to *geometrical spreading* and *absorption* can be corrected for using the theory described earlier; the latter needs a Q-model, in the absence of which empirical relationships based on the total travel path/time are used. A part of the record may be removed from processing due to the presence of noise, or, suspected non-primaries; depending upon the part of the data volume removed, one then talks about *top-mute, bottom-mute, or a generalized mute*. Similarly, a *balancing* (amplitude equalization) may be applied to several adjacent traces to compensate, in an ad hoc manner, for local variations, e.g., bad receiver coupling.

Filtering, sharpness, taper. Any process that removes/reduces a part of the suspected *noise* from the data is a *filter*. Frequency-filters (high-cut, low-cut, band-pass) are the simplest examples. Data $f(t)$ is transformed using Fourier theory to its spectrum $F(\omega) = A(\omega)\ \exp^{-i\omega t}$ in the frequency domain, the amplitudes mainly corresponding to noise are zeroed-out, and the data is transformed back to the time-domain. Development of algorithms for fast and efficient Fourier transform of time-series (FFT) has caused large-scale application of digital filters.

Multi-channel data enables double-transformation of $f(x, t)$ to $F(\omega, k)$, making filtering possible based upon slopes (apparent velocities) in the $\omega - k$ plane; this is particularly effective in eliminating, e.g., slow traveling ground-roll (large amplitude surface waves), which often



Seismic Data Acquisition and Processing, Figure 8 Stacking velocity analysis using semblance (color contours). Semblance values are shown for a dataset for a range of trial velocities (*horizontal axis*), and enable interactive velocity picking as a function of TWT (*vertical axis*). The right panel shows a dramatic improvement in resolution as a result of proper static correction. (Figure from Yilmaz, 2001 courtesy SEG and the author).



Seismic Data Acquisition and Processing, Figure 9 Use of two-dimensional Fourier Transform as an apparent-velocity filter for four marine-seismic records brings out (weaker) reflections. (Figure from Yilmaz, 2001 courtesy SEG and the author).

mask the primaries. An example of such filtering is shown in Figure 9. *Notch* filters are used to remove a narrow band of frequencies, e.g., a 50-Hz noise from overhead transmission line. τ-p transforms are useful in filtering multiples, and in un-tangling far-offset data for velocity analysis, these use the Radon domain for the decomposition (Phinney et al., 1981). A few general comments apply to all filters:

- Filtering is effective only to the extent of signal-noise separation in the transformed domain.
- For any filtering, there is a trade-off between sharp cut-offs in the transform-domain and oscillatory artifacts in time-domain – and vice-versa. A compromise solution to this unavoidable problem is to apply *tapers* to smoothen the cut-off and thus minimize edge-effects.

Deconvolution. This important aspect has been dealt with in some detail in an earlier section.

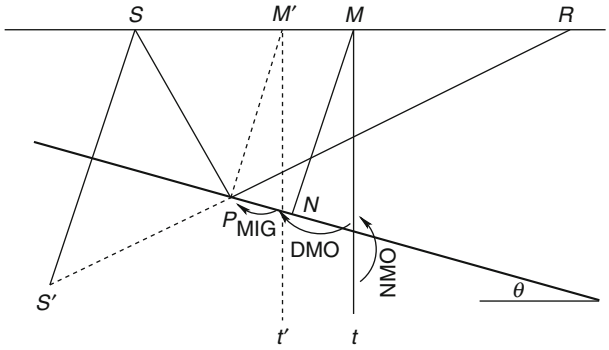
Stacking velocity analysis. This is almost always carried out in the CMP-domain, after *re-sorting* the data. The aim is to determine the velocity model, i.e., v_{rms} (TWT), to be used for computing the best move-out correction for the CMP-gathers. For a suite of velocity models, hyperbolic move-out curves are computed for the range of TWTs of interest; semblances are then computed to determine how well the arrivals in the gather line-up along these curves, and displayed in a contour plot in the v_{trial} -TWT domain, allowing interactive picking of an improved velocity model (Figure 8). The process is repeated at as many CMPs as possible – sometimes grouping neighboring CMPs together for averaging, velocity being a macroscopic property. The result is a laterally varying model of v_{rms}. Equation 6 can now be used to infer interval velocities.

CMP-stack. Once a reasonable velocity function has been determined, each trace in the CMP-gather (say, CMP_4 in Figure 1) is shifted in time by subtracting the corresponding move-out corrections. The move-out corrected traces in the CMP-gather are then added (*stacked*) together to produce one trace. This process, *CMP-stack*, reduces random noise – which does not line-up, while strengthening the reflection signal – which does, and thus improves S/N ratio of the data. Note that stacking reduces the data volume too – by a factor of *fold*! Much of the power of the seismic imaging derives from this simple step, which enhances the *primary* reflections (those only once reflected) at the expense of everything else.

Zero-offset traces/sections. The stack traces are also called *zero-offset* traces, the move-out correction having made the source and receiver coincident. A collection of stack traces is a stack- or zero-offset section, and represents the first (albeit approximate) 2-D cross-section of the subsurface. For display purposes, CMP-stack sections may be subjected to *automatic gain control* (AGC), an extremely non-linear time-variant amplitude scaling, to balance weaker/deeper signals and stronger/shallower ones.

Post-stack processing: positioning properly

The CMP-stack has one big drawback: dips were neglected throughout, which is what we are really after. This results in many artifacts in the section, e.g., crossing layering, diffraction tails, etc. Anticlinal structures are somewhat flattened, and synclinal structures could give rise to *bow-ties*.



Seismic Data Acquisition and Processing, Figure 10 Effect of dip in positioning the reflector.

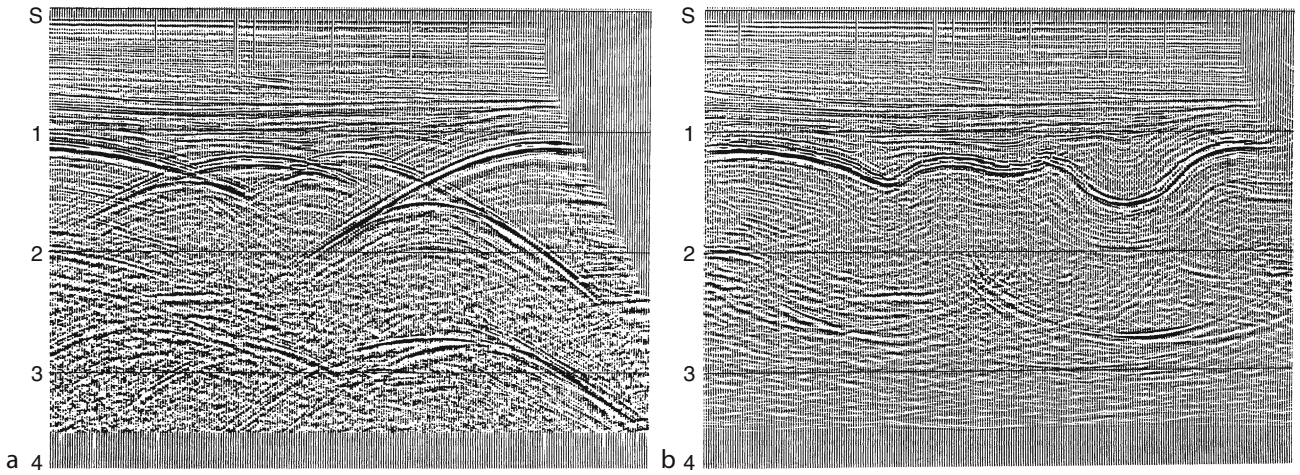
Migration. Figure 10 shows the problem schematically in the CMP-domain, for the case of a trace recorded from source S at receiver R from a reflector with a dip θ. After conventional pre-stack processing, the zero-offset trace would be plotted on the t axis below the mid-point M. This is clearly an error as the zero-offset ray for M should be incident normally on the reflector – at N; this correction is called *migration* (Yilmaz, 2001; Sheriff and Geldart, 1995).

Migration steepens and shortens energy alignments and moves these updip, clarifying the tangled image. Figure 11 shows an example of a successful migration. For further details, please see *Seismic, Migration*.

DMO. Figure 10 shows yet another error to be considered – the actual reflection point for the source-receiver combination $S-R$ is P, and not N. Even worse, for the different $S-R$ pairs making up the CMP-gather with mid-point M, the reflection points are all different, i.e., are *smeared* along the reflector, the amount of smear being dip-dependent. The process used to correct for this dip-dependent part of the move-out correction is called *DMO*. In practice, this step is applied before migration as indicated in Figure 7; Figure 10 shows the sequence:

- Reflection time is NMO corrected and plotted *below* M
- NMO corrected time is DMO corrected and plotted below M′, the *true* zero-offset point
- NMO+DMO corrected time is MIGRATED and plotted at P, the *reflection point*

Time-to-depth conversion. For final structural interpretation, the TWTs in the seismic section (stacked, or, migrated) need to be converted to depths, with velocity again playing the key role. For a homogeneous medium, this is just a rescaling of the vertical axis; with the velocity varying smoothly only in vertical direction (e.g., for flat sedimentary sequences), a nonuniform stretch of the



Seismic Data Acquisition and Processing, Figure 11 Migration positions energy from dipping structures properly. Here bow-tie like artifacts in the top part of panel (**a**) are imaged back into causative synclinal structures in panel (**b**). The artifacts persisting in the bottom of panel (**b**) probably point to lack of interest in imaging deeper structures in this case. (Figure from Yilmaz, 2001 courtesy SEG and the author).

vertical axis may suffice. Laterally varying velocities present depth-conversion problems though, increasing with the strength of the heterogeneity; ray-bending now needs to be taken into consideration.

No-stack processing: imaging complex structures
In the presence of strong lateral velocity variations (e.g., below salt structures), the conceptual model used to process CMP-gathers breaks down. Removing the simplifying assumptions makes the imaging physically more reasonable, albeit at the cost of substantially increased computational effort.

Pre-stack depth migration and migration velocity analysis. Simply put, this involves tracing the seismic energy from the source to the receiver for every recorded trace, with the philosophy that every seismic trace should be computable *if the structure and the velocity model were both known*. A detailed velocity model is essential for the success of PSDM; often a simplified model is assumed, and iteratively improved using *migration velocity analysis* (MVA). For details/issues regarding 2-D vs. 3-D, time- vs. depth- and post-stack vs. pre-stack migration, see *Seismic, Migration* and Yilmaz (2001).

Special processing
True amplitude: AVO, DHI. Observed variations of the *RC* with respect to angle of incidence may be interpreted in terms of changes in lithology across the reflecting boundary (*amplitude versus offset, or, AVO*), and may even indicate the nature of the pore-fluids. Such *direct hydrocarbon indicators* (DHI) include *bright-spots, flat-spots, polarity-reversals*, etc. (see Yilmaz, 2001; Sheriff and Geldart, 1995). A prerequisite for such analyses is *true amplitude processing*, avoiding modules that remove differential amplitude information, e.g., balancing, stacking, AGC, etc.

Converted waves. Using multi-component receivers, it is possible to identify waves that have been converted at the reflection boundary, and hence possess asymmetrical up- and down-ray-paths. Proper processing of such data, with CCP (*common conversion point*) replacing CDP, provides a better constraint for imaging.

VSP and cross-well tomography. Bore-holes can be used for placing receivers (and sources), resulting in significant noise-reduction. The first processing step now is to separate up- and down-going wave-fields, for details, see *Vertical Seismic Profiling*.

Anisotropy. Many seismic media are *anisotropic*, a common example being shales, which exhibit faster speeds parallel to the layering than across it, and require modification of procedures for proper imaging, e.g., the move-out curve would no more be hyperbolic. This field is proving important for reservoir studies too, see Helbig and Thomsen (2005) for an overview and also "Seismic Anisotropy."

Current investigations, controversies

Noise as a seismic source

This has become an exciting and active field of research (*seismic interferometry and daylight imaging*), connecting early conjectures (Claerbout, 1968) and more recent breakthroughs (Fink, 1993, 1997). See *Seismic Noise*; *Seismic, Ambient Noise Correlation* and Schuster et al. (2004) for an introduction to this evolving area.

Imaging versus inversion

Imaging tries to obtain useful (drillable) structural information using large data-redundancy and simple conceptual models, whereas inversion aims at getting values for the physical parameters of the medium, using more involved theory. *Full wave-form inversion* (see *Seismic, Waveform Modeling and Tomography*) i.e., predicting each seismic/seismological trace completely in terms of the viscoelastic properties of the medium is the ultimate goal. Note, that *perfect inversion implies perfect imaging – and vice-versa!*

Summary

The simple *echo-in-the-well* experiment mentioned at the start needs many physico-mathematical supports when applied to the earth's subsurface. Starting at data acquisition, the modules yielding the final image resemble a pipeline (flow). Several of these have been explained briefly; for others, cross-references elsewhere in this volume have been provided.

SEISMIC DIFFRACTION

Enru Liu
China University of Mining and Technology, Xuzhou, China

Definition

Diffraction – Redistribution in space of the intensity of waves resulting from the presence of an object. It is also referred as the penetration of wave energy into areas forbidden by geometrical optics, e.g., the bending of wave energy around obstacles without obeying Snell's law as explained in Huygens' principle (generation of secondary sources).

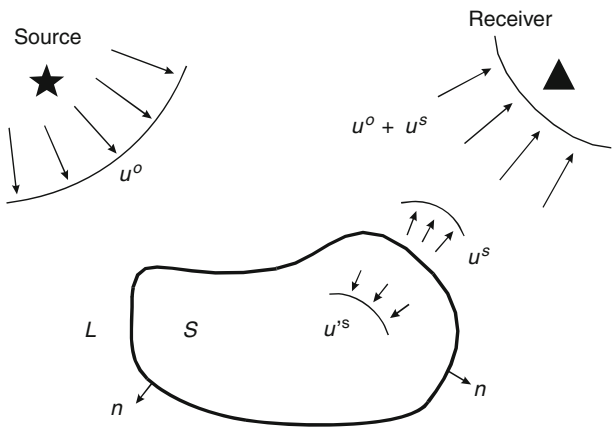
Diffraction wave-field – An event observed on seismic data produced by diffracted energy, resulting at the termination of reflectors (as at faults and other abrupt changes in seismic impedance), and it is characterized on seismic records and sections by a distinctive alignment.

Diffraction tomography – An inverse technique that is used in seismic exploration to reconstruct the physical properties under investigation using wave-equation propagation.

Introduction

When a wave (elastic wave, electromagnetic wave, or sound wave) meets an object, particle, or obstacle, it is diffracted due to scattering of energy of the propagating wave (Figure 1). However, in the literature, the terms of diffraction and scattering are often used interchangeably, and it can be sometimes confusing. Scattering and diffraction are two physical phenomena that any kind of waves can experience, but they are not the same thing. Scattering is understood in terms of particles, and behaves similarly for waves. Scattering is effectively bouncing off something. For waves, it is being absorbed and then almost immediately released in another direction. Scattering occurs because an object gets in the way of the wave. The part of the wave that strikes the object must either pass through (e.g., light through glass), be absorbed (sunburn), or be scattered (light bouncing off the wall, so we can see the wall). Diffraction is due to part of a wave being removed. It is an action taken by the part of the wave that does not strike an object. Here is an example of diffraction: Imagine a straight wave traveling forward along the surface of water. If you block the left half of the wave, the right half will not just keep moving forward, and it will expand toward the left, toward where the blocked wave would have been. A wave seems to continuously regenerate itself, always pushing forward on itself. When a section is removed, parts of the wave get pushed into the empty spot. This, in some ways, correlates to your pushing a wide row of blocks. If many people push on a few blocks each, a straight line can be maintained. If one person tries to do so, the blocks in front will tend to spread out.

In a sense, diffraction and scattering refer to a wave being redirected as a result of interacting with objects. However, a more precise definition used in optics distinguishes these two. In optics, scattering generally implies interaction of waves (or photons) with spatially uncoordinated (unordered) atoms, i.e., wave being scattered off the particles and surfaces. This means that if one looks at a picture of the scattered radiation, one would see a spatially continuous footprint. Diffraction, on the other hand, occurs when the object or part of the object is made up of ordered atoms. These atoms, being neatly arranged, "scatter" the waves or photons in a coordinated way, i.e., in specific directions, giving rise to what we can see on a film as bright spots rather. In other words, diffraction is a special type of scattering that leads to large-scale interference effects. Usually this is because the surface causing the scattering has some overall organization, such as a ruled diffraction grating or the knife-edge of a slit.



Seismic Diffraction, Figure 1 Problem configuration: a scattering object S bounded by the curve L with outward normal n. Upon an incidence of u_0 located at source, the total wave-field received at receiver is the superposition of the incident wave-field u_0 and the scattered wave-field u_s.

Although scattering and diffraction are not logically separate, the treatments tend to be separated, with diffraction being associated with departures from geometrical optics caused by the finite wavelength of the waves. Thus, diffraction traditionally involves apertures or obstacles whose dimensions are large compared to a wavelength. To lowest approximation the interaction of waves is described by ray tracing (geometrical optics). The next approximation involves the diffraction of the waves around the obstacles or through the apertures with a consequent spreading of the waves. Simple arguments show that the angle of diffraction of the waves are confined to the region $\theta \leq \lambda/a$ where λ is the wavelength and a is linear dimension of the aperture or obstacle (approximations considered work well if $\lambda/a \leq 1$). Note that diffraction may cause the localization of seismic waves – a phenomenon that is similar to the localization of lights in crystal (Larose et al., 2004). This phenomenon is caused by the focusing and defocusing of energy when seismic wave propagates through media with distributions of periodical or random distribution of scattering bodies.

In order to gain some perspective on these two extremely complex phenomena (diffraction and scattering), various theories and models have been developed in physics, and the limitations and validity of these theories are controlled by two ratios: object dimension α to wavelength (α/λ) and path-length L to wavelength λ (L/λ). In contrast to other branches of physics, in geophysics path-length is also important as we are interested both in near field as well as far field (and often near and far fields are treated differently). We also often use the dimensionless parameters $k\alpha$ and kL (where $k = \omega/\lambda$ is the wave number, ω is frequency).

Diffraction theories

Application of any diffraction model can be divided into two separate tasks. First, one must obtain the fields exiting a diffracting object (i.e., the near fields, or the boundary field values), or a reasonable approximation thereof. The second step involves propagating those fields to the

desired observation point. These are distinct and separate parts of the diffraction models. Most texts do not make this separation clear. Instead, the boundary value assumptions and subsequent propagation into the far field are lumped together into one theoretical treatment. If the resulting diffraction pattern is at all inaccurate, it is difficult to determine how much of that error is due to incorrect boundary fields and how much is the result of the propagation calculation. Because of this, it is often difficult to know which model is appropriate for a particular problem.

There are a number of different models to compute diffraction wave-field due to wave scattering, including the Huygens' Principle, the Rayleigh-Sommerfeld theory, the Kirchhoff's diffraction theory, Taylor series perturbation theory or the high-order Born approximation, Rytov phase approximation, and a model referred to as angular spectrum of plane waves. The well-known Fraunhofer and Fresnel approximations, as they appear in most introductory texts, are derived from the Kirchhoff model. Several other methods are also available for treating diffraction problems: discrete wave-number techniques; generalized ray techniques; and various numerical methods (finite difference methods; finite element method; and boundary integral or element methods). Each of these theoretical methods and models is based on some assumptions and has its strengths and weaknesses, and each can be satisfactorily employed for some ranges of problems. The choice of an appropriate model is based on what is known about a specific problem.

If there are several objects or particles, the scattering from one object will induce further scattered fields from all the other objects, which will induce further scattered fields, from all the other objects, and so on. This process is called multiple scattering. Not all theories are applicable to multiple scattering problems (in physics, this is called many-body problem). The Kirchhoff approximation ignores multiple scatterings between any two surface points. In general, it has been considered valid for the large-scale objects. Perturbation theory based on the Taylor series expansion, also sometimes called the high-order Born approximation, is valid for the small-scale objects whose dimensions are less than a wavelength (or objects whose physical properties are not too different from background solids). The Rytov phase approximation to large-scale object is not subject to the stringent restrictions that apply to the Kirchhoff approximation. Studies have shown that the Rytov approximation improves the Kirchhoff approximation in both amplitude and phase. To some degrees, the high-order Born series approximation can account for multiple scattering between closely-spaced objects. For instance, the second-order Born approximation might be sufficient to guarantee the accuracy for general rough surfaces without infinite gradients and extremely large surface heights. In contrast to other branch of field, e.g., optics, in seismology two kinds of waves exist, compressional and shear waves. These two waves can convert to each other when one meets an object. When multiple objects exist, the conversion and interaction between different wave types due to multiple scattering can be very complex. Therefore, care must be taken when one uses any diffraction theory to solve specific geophysical problems.

Geometrical theory of diffraction

The geometrical theory of diffraction (GTD) is an extension of geometrical optics that accounts for wave diffraction by edges. It was introduced in 1953 by Keller (the most commonly cited reference was published by Keller in 1962). The geometrical theory of diffraction was devised to eliminate many of the problems associated with geometrical optics. The strongest diffracted fields arise from edges, but ones of lesser strength originate from point discontinuities (tips and corners). The total field $u = (u_1, u_2, u_3)$ at an observation point $\vec{x}$ is decomposed into geometrical optic rays (the incident or reference field) u_i^0 and diffracted components u_i^d

$$u_i(\vec{x}) = u_i^0(\vec{x}) + u_i^d(\vec{x}). \tag{1}$$

The behavior of the diffracted field is based on the following postulates of GTD:

1. Wavefronts are locally plane waves.
2. Diffracted rays emerge radially from an edge.
3. Rays travel in straight lines in a homogeneous medium.
4. Polarization is constant along a ray in an isotropic medium.
5. The diffracted field strength is inversely proportional to the cross sectional area of the flux tube.
6. The diffracted field is linearly related to the incident field at the diffraction point by a diffraction coefficient (see Achenbach et al., 1982, for various analytic solutions).

GTD is a high frequency method for solving wave scattering problems from large-scale discontinuities or discontinuities in more than one dimension at the same point, and it uses ray diffraction to determine diffraction coefficients for each diffracting object-source combination. These coefficients are then used to calculate the field strength and phase for each direction away from the diffracting point. These fields are then added to the incident fields and reflected fields to obtain a total solution. Multiple scattering wave-fields cannot be easily computed using GTD.

Kirchhoff approximation

In the Kirchhoff representation of diffracted wave-fields, the ith component of diffracted wave-field u_i is computed using

$$u_i^d(\vec{x}) = -\int_{\sum} [u_k(\vec{x})] c_{kjpq}^0 \left[\frac{\partial G_i^p(\vec{x},\vec{X})}{\partial x_q}\right] n_j dS_{\vec{x}}, \tag{2}$$

where n_j is the jth component of the normal n to the surface of scattering object, $\mathbf{X}$ is a point on the face of the scattering object, $[u_k]$ is the kth displacement discontinuity across the object in the direction of n (object normal), and c_{kjpq}^0 is the elastic tensor of the background, which are often assumed to be isotropic. Equation 2 provides

a means of evaluating the diffracted field so long as the displacement discontinuity $[u]$ on the object can be estimated accurately. Since the amplitudes and phases of $[u]$ are unknown, in the Kirchhoff approximation, these are taken to be the same as if the object were infinitely long, that is, the effect of the boundary is ignored (see Douglas and Hudson, 1990; Liu et al., 1997). Therefore, the Kirchhoff approximation is a high frequency approximation, which is only applicable to diffraction from objects whose dimension is larger than the wavelength.

Perturbation theory: Born and Rytov approximation

The diffracted wave-field in Equation 1 can be written as an infinite series of the Taylor series expansion and is derived by assuming that the physical property of scattering objects is written as a perturbation of background media. The Born approximation consists of taking the incident field in place of the total field as the driving field at each point in the scatterer. It is the perturbation method applied to scattering by an extended body. It is accurate if the scattered field is small, compared to the incident field, in the scatterer. It is only valid for weak scattering or when the obstacles are small compared to both the wavelength and the spacing between the objects. Clearly, it has serious limitations when dealing with large-scale objects. The simplest approximation, called single scattering or the first-order Born approximation, is to ignore the multiply scattered field between objects. This approximation has been widely used in geophysics (Hudson and Heritage, 1981; Wu, 1982, 1989).

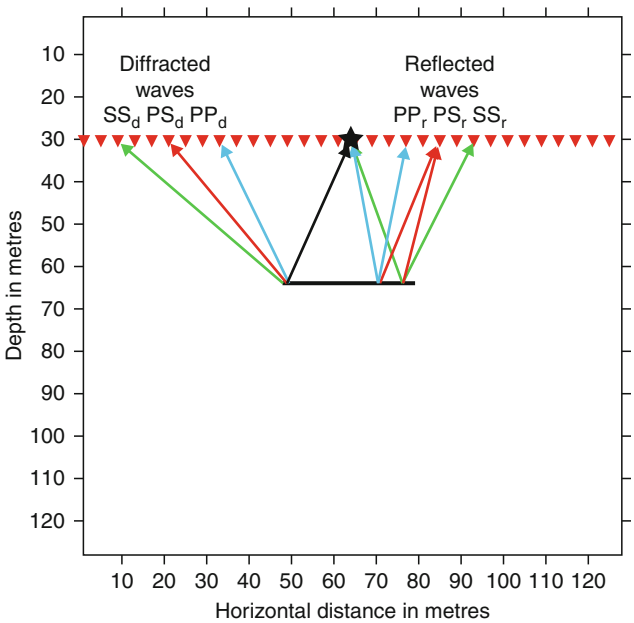
The Rytov approximation linearly perturbs the phase of a wave-field with respect to model parameters such as velocity whereas the Born approximation perturbs the amplitude. When the Green's functions for point sources are replaced by Eikonal approximations, the Rytov perturbed wave-field becomes a scaled, differentiated, time-delayed version of the reference or incident wave-field.

Numerical methods used to compute diffraction wavefield

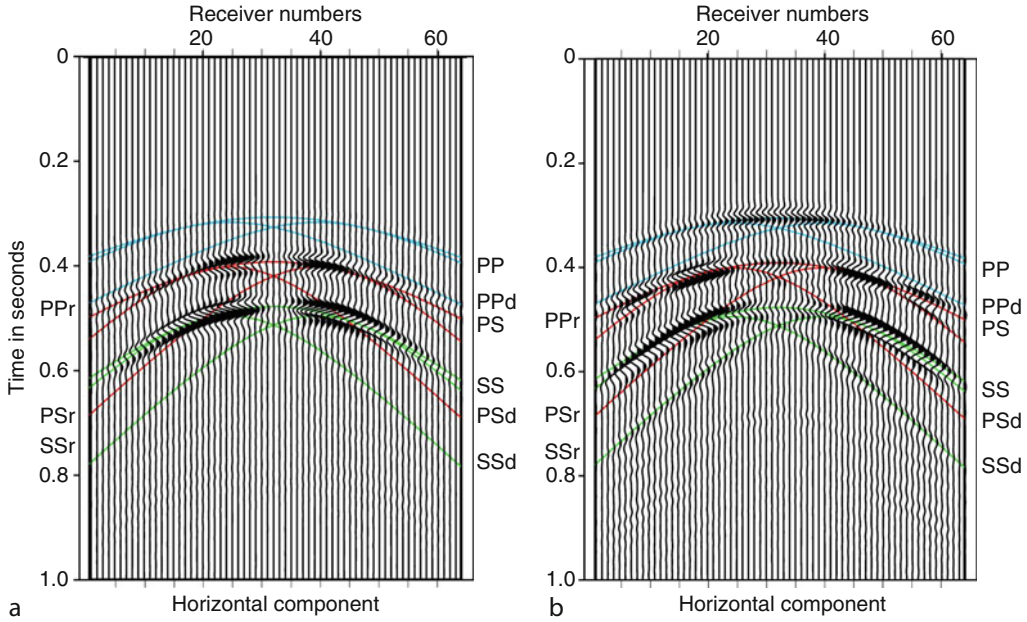
Various numerical methods can also be used to compute diffracted wave-fields, particularly now, when high-performance computers are widely available. In geophysics, finite difference methods have been used widely in the study of scattering of elastic waves by crustal heterogeneities with continuous variation of physical properties and they have also been used to model scattering by thin cracks and large fractures (see Coutant, 1989; Fehler and Aki, 1978; Coates and Schoenberg, 1995; Vlastos et al., 2003, 2007). Elastodynamic boundary integral equation or boundary element method has also been widely used to compute wave-fields from discrete inclusions with various spatial distributions as well as rough-surface topographic variations (see Bouchon, 1987; Pointer et al., 1998; Liu and Zhang, 2001; Sanchez-Sesma and Campillo, 1991, 1993).

An example of seismic diffraction from a single fracture

Some practical applications of diffraction theories in seismology include scattering from cavities; topographic variation, fractures, cracks (Figure 2). Here we give three examples to demonstrate the application of various theories in tacking diffraction problems. An example is given here for diffraction from a single fracture as computed using the finite difference method (Vlastos et al., 2003, 2007). The model geometry is shown in Figure 2. The source, receivers, and fracture are situated in an ideal elastic full space (Vp = 3,300 m/s, Vs = 1,800 m/s, density $\rho = 2.2$ g/m^3). The receiver array at which vertical and horizontal particle displacements are recorded is horizontal and 340 m above the fracture. The fracture is 300 m long. The source is located at the center of the receiver array. The source type is a vertical force. The source signal is a Ricker wavelet with a peak frequency of 25 Hz and a pulse initial time of 0.1 s. Figure 3 also shows the different kinds of waves generated by the interaction of the waves generated by the source and the fracture. The source generates both P and S waves. When they reach the fracture boundary those waves are reflected and we have PPr, PSr, SPr, and SSr waves. We calculate the theoretical ray travel-times and overlap them on the synthetic seismograms. Figures 3a and 3b show the horizontal (x) and the vertical (z) components, respectively, of the synthetic seismograms together with the theoretical ray travel-times. As we can see from both figures, we have very good agreement between the theoretical ray



Seismic Diffraction, Figure 2 Schematic representation showing diffraction from a fracture, and representation of the ray paths of the different kind of waves generated by the source that interact with the fracture.



Seismic Diffraction, Figure 3 Comparison between the theoretical ray travel-times and the synthetic seismograms generated by the modeling method: (**a**) the horizontal (*x*) and (**b**) the vertical (*z*) components.

travel-times and the synthetic seismograms. All types of waves are accurately represented in the synthetic seismograms. Owing to the type of source that we implement, we have strong arrivals at short offsets on the horizontal component and strong arrivals at long offsets on the vertical component. In addition to that, the diffracted waves from the tips of the fracture and the PPr and PPd waves are not visible in the horizontal component, but they are very clearly demonstrated in the vertical component and follow the theoretical travel-times. This is expected because the source causes vertical displacements on the medium, so very close to the source and very far away from it, the horizontal displacement is negligible. Another aspect of the comparison between the theoretical and the modeled data is that they give us further insight into the waveform patterns. For instance, we can see in both Figures 3a and 3b that in the areas of superposition between the reflected waves from the fractures and the diffracted waves from the tips we have maximum amplitude in the wave-field, as a result of constructive interference. This gives us valuable information concerning the medium we are examining.

Diffraction tomography

Seismic tomography is emerging as an imaging method for determining subsurface structure. When the view-angle coverage is limited and the scale of the medium inhomogeneities is comparable with the wavelength, as is often true in geophysical applications, the performance of ordinary ray tomography becomes poor. Other tomographic methods are needed to improve the imaging process, e.g., diffraction tomography. It has been widely used in surface reflection profiling (SRP), vertical seismic profiling (VSP), and cross-hole measurements. Theoretical formulations are derived by Wu and Toksoz (1987) for two-dimensional geometry in terms of line sources along a source line and line receivers along a receiver line. The theory for diffraction tomography is based on the Born or Rytov approximation. Multisource holography, which is similar to Kirchhoff-type migration, often gives distorted images of the object. This distortion causes long tails of the image in the case of SRP and a strong noise belt in the case of VSP and is due to incomplete and nonuniform coverage of the object spectrum. The filtering operation of diffraction tomography helps in correcting the nonuniform coverage (including duplication) of the object spectrum in the reconstruction process and therefore reduces the distortions. On the other hand, multisource holography is better suited for imaging sharp boundaries with large acoustic impedance contrasts since diffraction tomography is restricted, to weak inhomogeneities. In addition, multisource holography has the flexibility to be used with an arbitrary number of sources (including a single source). Its sampling interval is not restricted by the Nyquist frequency. Numerical examples show that combined data sets (such as surface reflection data combined with VSP data or cross-hole data combined with surface data) improve the image quality.

Summary

Diffraction refers to the spatial distribution of the intensity of seismic waves resulting from the presence of an object

(e.g., a hill- or valley-like topographic feature on the surface, or a fracture, cavity, or cave in the subsurface). It is also referred as the penetration of wave energy into areas forbidden by geometrical optics, e.g., the bending of wave energy around obstacles without obeying Snell's law as explained in Huygens' principle (as secondary sources). In the geophysical literature, the words of diffraction and scattering are often used interchangeably and it can be confusing. Diffraction and scattering are two different physical phenomena, but they are related to each other. Several analytic diffraction theories have been developed, e.g., geometrical theory of diffraction and Kirchhoff diffraction theory. More recently, numerical methods, such as finite difference and boundary element or boundary integral methods, are becoming increasingly used by geophysicists to simulate wave diffractions by complex variation of Earth's topography or subsurface cavies (cavities), fractures, irregular layers, etc. Geophysicists now often use the diffracted wave-field to reconstruct the subsurface physical properties (diffraction tomography) to solve the so-called inverse diffraction problem.

SEISMIC DISCONTINUITIES IN THE TRANSITION ZONE

Lev P. Vinnik
Institute of Physics of the Earth, Moscow, Russia

Definition

The transition zone (TZ) is the mantle layer bounded by the 410– and 660–km seismic boundaries. The high P-wave and S-wave velocity gradients within the TZ are caused by a series of polymorphic phase transitions, the depths (pressures) of which are controlled by temperature and composition. Structure of the TZ plays an important role in the heat/mass transfer between the upper and the lower mantle.

Mineral physics data on the phase transitions in the TZ

The most frequently used model of mantle composition is pyrolite which contains ~60% of olivine $(Mg,Fe)_2SiO_4$. At a depth of ~410 km olivine (α) transforms to wadsleyite (β, modified spinel). The Clapeyron slope of this transition is positive (4.0 MPa/K, Katsura et al., 2004); the increase of the S-wave velocity is ~12%. At a depth of ~520 km wadsleyite transforms to ringwoodite (γ, silicate spinel). The velocity increase at this transition is by an order of magnitude less than at the α/β transition (e.g., Ita and Stixrude, 1992; Cammarano et al., 2005). At a depth of ~660 km ringwoodite transforms to a mixture of perovskite $(Mg,Fe)SiO_3$ and

magnesiowüstite (Mg,Fe)O. The S velocity contrast of this transition is comparable to that of the α/β transition. The post-spinel transition is sharp and has a negative Clapeyron slope of −2.8 MPa/K (Hirose, 2002). This value is disputed and some recent estimates are in a range from −0.4 to −1 MPa/K (Ohtani and Sakai, 2008).

The other components of pyrolite are orthopyroxene, clinopyroxene, and garnet. These components experience in the TZ more gradual transformations: the pyroxenes dissolve into garnet (majorite) and majorite transforms to perovskite near the bottom of the TZ. The Clapeyron slope of the post-majorite transition is 1.3 MPa/K (Hirose, 2002). The post-spinel and post-majorite phase boundaries cross each other at 1,700–1,800°C, and the corresponding seismic discontinuity is a combined effect of both transitions. At the temperatures less than 1,700°C the discontinuity is formed mainly by the post-spinel transition, whilst at the higher temperatures the post-majorite transition becomes dominant (Hirose, 2002).

Seismic methods

The actual composition and temperature of the TZ can be constrained by seismic data. An increase of the seismic velocity gradient with depth is mirrored by the increase of the apparent velocity of the P and S seismic arrivals with distance. Details can be obtained from the analysis of the related loop (triplication) in the travel times and modeling the related waveforms with synthetic seismograms (e.g., Grand and Helmberger, 1984). First indications of an increase of the velocity gradient near the top of the TZ were obtained from the analysis of incidence angles of the P waves (Galitzin, 1917). The 660-km discontinuity at the bottom of the TZ with a comparable velocity contrast was discovered in the mid-1960s (Anderson, 1965). Prior to the discovery of the 660-km boundary, the TZ was defined as the region between the 400- and 1,000-km depths (Bullen's region C).

The triplications corresponding to discontinuities in the TZ are observed at epicentral distances between ∼1,700 and ∼3,200 km, whereas properties of the mantle may change significantly on a scale of a few hundred kilometers. Observations of reflected and mode-converted phases can provide better resolution. In the neighboring field of exploration seismology, accurate mapping of discontinuities is based on observations of reflected phases. These signals are small relative to noise, and the detection is performed by using receiver arrays and stacking the recordings of different sensors with move-out time corrections. These methods are very efficient, but in seismology adequate receiver arrays are few. The idea of receiver function approach in seismology is to replace receiver arrays by seismic-source arrays that can be very large and dense. The differences in the waveforms of individual earthquakes that are recorded at the same station are eliminated by appropriate frequency filtering.

P-wave receiver functions (PRFs) present the oldest and most usable variety of receiver functions (Vinnik, 1977). This technique is based mainly on observations of Ps phases, converted from P to S. The delay of the Ps phase relative to P depends on the depth of the discontinuity and velocities along the wave-propagation paths. The amplitude of the Ps phase is proportional to the S velocity contrast at the discontinuity. A gradual transition is transparent for short-period P waves, and a shift of the spectrum of the Ps phase to lower frequencies indicates the width of the discontinuity. The detection of small seismic phases in PRFs can be accompanied by measurements of their slowness. In a laterally homogeneous Earth, Ps phases from the TZ discontinuities differ by slowness from lithospheric reverberations that arrive in the same time window, and this difference may help to separate the signals from noise. The best results can be obtained by combining source and receiver arrays. Unfortunately, practical detection of the TZ converted phases in noise is often based on relaxed criteria. Some of the widely cited results are obtained from noisy receiver functions which show a continuous train of positive "swells" and negative "troughs." The "swells" are brightly painted and the resulting optical illusion may convince readers that they see separate arrivals rather than an interference pattern.

S-wave receiver functions (SRFs) (Farra and Vinnik, 2000) are complementary to PRFs and deal with the Sp phases converted from S to P. Multiple scattering at shallow discontinuities, which presents the major source of noise in PRFs, is practically absent in SRFs, because the Sp phases from large depths arrive much earlier than the scattered phases from shallow discontinuities. Another useful method is based on observations of ScS reverberations (Revenaugh and Jordan, 1991). Detection of the phases reflected from TZ discontinuities in this method is in principle similar to that employed in receiver functions and this technique can be viewed as a variety of receiver function techniques. A shortcoming of this method is its low (in comparison to PRFs and SRFs) lateral resolution. Precursors to the seismic phases SS (SH component), PP and P′P′ (SH, P and P′ waves reflected from the Earth's surface between the source and the receiver) include phases reflected from TZ discontinuities. These phases can be detected by using the receiver function approach (Shearer, 1991). Lateral resolution of the SS-precursor technique (∼1,000 km) is by an order of magnitude lower than of PRFs, but the SS precursors are useful in the studies of the TZ of remote regions, where seismograph stations are too few for high-resolution studies.

Topography and sharpness of TZ discontinuities

The amplitudes of seismic phases converted or reflected from the major TZ discontinuities at 410- and 660-km depths vary laterally but on the average are approximately two times lower than predicted for olivine. This relationship implies that the actual composition of the TZ is broadly similar to pyrolite which contains ∼60% of olivine. A comparison of synthetic and actual wave fields for the TZ indicates that the potential temperature in the mantle differs for a homogeneous pyrolite mantle and

a mechanical mixture of basaltic and olivine components: 1,720 and 1,625 K, respectively (Ritsema et al., 2009).

The amplitudes of reflected and converted phases from the 520-km discontinuity in pyrolite should be about an order of magnitude lower than from the 660-km discontinuity and, for this reason, practically unobservable. However, there are reports on observations of a discontinuity near this depth, especially in the data on SS precursors (e.g., Flanagan and Shearer, 1998; Gu et al., 1998; Deuss and Woodhouse, 2001) and P wave recordings (e.g., Ryberg et al., 1997). Revenaugh and Jordan (1991) argued that the large 520-km discontinuity in seismic data is related to garnet/post-garnet transformation. Gu et al. (1998) discussed a possibility of very deep continental roots extending into the TZ. Deuss and Woodhouse reported splitting of the 520-km discontinuity into two discontinuities. Bock (1994) denied evidence for the 520-km discontinuity in precursors to SS.

The spectra of P410s in high-quality PRFs are usually close to the spectra of P, which indicates that the 410-km discontinuity is sharp, with a width of several kilometers (Petersen et al., 1993). Benz and Vidale (1993) observed high-frequency precursors to P′P′ with implication that the widths of both 410- and 660-km transitions are ~4 km or less. There are many other observations of short-period P′ waves reflected from the 660-km discontinuity, which indicate that this discontinuity is sharp. However, the spectra of P660s are shifted to longer periods relative to P (e.g., Petersen et al., 1993) with implication that the 660–km boundary is a few tens of kilometers wide. This controversy can be reconciled with the data of mineral physics on the two phase transitions in the same depth range.

Analysis of high-quality PRFs demonstrates that the large, in a range of a few seconds, variations of travel times of the TZ phases are caused mainly by lateral heterogeneity of the upper mantle outside the TZ (Chevrot et al., 1999). If the most heterogeneous structures are excluded from consideration, these variations are similar for P660s and P410s and can be removed by taking the difference between the P660s and P410s arrival times at the same station. Lateral variations of this difference are sensitive to changes in the TZ thickness. The best data on the P660s-P410s time difference suggest that the depths of the 410- and 660-km discontinuities are stable within several kilometers everywhere, except the anomalously hot and cold regions: hotspots and subduction zones, respectively (Chevrot et al., 1999). These normal or standard depths of the major boundaries practically coincide with those in the IASP91 model (410 and 660 km, Kennett and Engdahl, 1991), and the normal TZ thickness is 250 km. This should not be mistaken for the "average" thickness.

The results for hotspots, most of which are located in oceans, are controversial (e.g., Lawrence and Shearer, 2006; Tauzin et al., 2008; Deuss, 2007; Li et al., 2003). The related data are highly variable in quality. Therefore, instead of relying on statistics, I prefer to single out the results for Iceland, which is one of the most thoroughly investigated hotspots. The network of seismograph stations in Iceland is large, and there are several independent tomographic studies of this region. This means that the topography on the 410-km discontinuity can be separated from the effects of volumetric velocity variations. Seismic tomography reveals beneath Iceland a narrow (~200 km) columnar, low-velocity body extending into the TZ (e.g., Foulger et al., 2000), in which the 410-km discontinuity is depressed by ~15 km (Shen et al., 1998), whilst the 660-km discontinuity is at its normal depth (Du et al., 2006). No TZ anomaly could be found in the data of the station BORG in Iceland (Chevrot et al., 1999), just because the columnar body is narrow, and the station is located unfavorably with respect to it. The depressed 410-km discontinuity suggests that the TZ temperature is elevated by ~150°C. The standard depth of the 660 km discontinuity implies that either the temperature at this depth is normal, or, as indicated by high-pressure experiments (Hirose, 2002), a sensitivity of depth of the transition to temperature is low in this temperature range. Note, that the accurate estimate of depth of the 660-km discontinuity in the columnar body beneath Iceland required data on the P and S velocities in this body. For most other hotspots such data are unavailable. For the ray paths outside the columnar body, the time difference between P660s and P410s is close to the normal time with implication that the TZ of the normal oceanic mantle has the same 250-km thickness as beneath the continents.

Broadly similar results are obtained for several other hotspots. For example, similar measurements at several stations in the region of the South Pacific superswell (Suetsugu et al., 2007) show that beneath one station the thickness of the TZ is 216 ± 19 km. The anomalous region cannot be larger than a few hundred kilometers. The average for all other stations is 248 ± 5 km, very close to the standard value of 250 km. By comparison, the SS-precursor data portray in the South Pacific a large (several thousand kilometers) region, where the TZ thickness is reduced to ~230 km (Flanagan and Shearer, 1998; Gu et al., 1998; Houser et al., 2008). A similar region is found in the Atlantic. These data, if accepted at face value, imply that the TZ beneath oceans differs from that beneath continents, and the TZ beneath the hotspots is the normal oceanic TZ, contrary to the receiver function data. Substantial discrepancies between the results of the two methods exist in continental regions where numerous seismograph stations facilitate good-quality receiver function studies.

Subduction zones demonstrate another kind of anomaly. Temperature in subducted slabs is anomalously low and the equilibrium depth of the olivine-wadsleyite phase transition should be ~100 km less than in ambient mantle. However, the 410-km discontinuity in most of the presently active subduction zones apparently cannot be detected with either PRFs or other methods, most likely because the olivine-wadsleyite phase transformation is kinetically hindered and a wedge-shaped zone of olivine may persist at depths greatly exceeding 410 km (Kirby

et al., 1996). The signals from the 410-km discontinuity that are sometimes obtained in seismic studies of these regions are most likely generated outside the cold subducted lithosphere. Observations of short-period phases converted from S to P near the hypocenters of deep earthquakes show that the 660-km discontinuity in subducted slabs varies in depth but sometimes is depressed by up to ~50 km (e.g., Bock and Ha, 1984; Vidale and Benz, 1992; Wicks and Richards, 1993). This can be explained by the negative Clapeyron slope of the post-spinel transition and a low temperature of the subducted slab. The temperature anomalies can be up to ~600°C. Accurate calculations are hampered by uncertainty in the estimates of the Clapeyron slope. The studies conducted with high-resolution techniques (e.g., Niu and Kawakatsu, 1998) demonstrate that the lateral scales of the anomalies are many times smaller than imaged by SS precursors.

Robust evidence for an elevated differential time P660s-P410s and a depression of the 660-km discontinuity is provided by PRFs in the Alps where the active phase of Cenozoic subduction is over, but remnants of the oceanic lithosphere are present in the TZ (Lombardi et al., 2009). Similar anomalies are either found or can be expected in other regions of the Alpine belt.

The issue of water in the TZ

The cited results of mineral physics were obtained for the dry TZ. Many researchers examined solubility of water in minerals of the TZ (for reviews see, e.g., Bolfan-Casanova, 2005; Ohtani and Sakai, 2008; Smyth and Jacobsen, 2006). Hydration means modification of structures of the TZ minerals by incorporation of hydroxyl (OH). It appears that wadsleyite and ringwoodite may incorporate up to ~2.0 wt% of water. Pressure of the olivine-wadsleyite transition decreases by hydration by up to about 1 GPa (~30 km in depth), whereas the pressure of the post-spinel transition increases. The width of the two-phase loop between olivine and wadsleyite increases with increasing water content, and may reach a few tens of kilometers in depth relative to several kilometers for dry conditions. Hydration of 1 wt% lowers S velocity by 1–2%, whereas P velocities remain practically the same.

The expected anomalies in the depth (30 km) and thickness (a few tens of kilometers) of the 410-km discontinuity are sufficiently large to be easily detected by PRFs. However seismic observations of such effects in good-quality PRFs are practically unknown. In some regions, the seismic data for the TZ are very complicated, and hydration can be one of the reasons for the complexity, but this is hard to prove. Nolet and Zielhuis (1994) reported observations of anomalously low S velocity at depths of 300–500 km beneath the Tornquist-Teisseyre zone near the western boundary of the Russian platform. They attributed this effect to hydration at the time of closure of the Paleozoic Tornquist Ocean. This observation has been made by using surface waves. The anomalous area clearly presents a good target for application of other methods, but no such study is known yet. The lack of seismic evidence for the hydrated TZ is consistent with measurements of conductivity in the TZ (Yoshino et al., 2007), which suggest that the TZ is practically dry.

A low S velocity layer atop the 410-km discontinuity may present another possible effect of hydration of the TZ. Owing to the large water solubility, the TZ may have higher water concentration than water storage capacity of the upper mantle. Then upwelling mantle material entering the upper mantle from the TZ may undergo dehydration melting (e.g., Bercovici and Karato, 2003). Huang et al. (2005) argued that even ~0.1–0.2 wt% of water in the TZ of the Pacific is sufficient for partial melting at ~410-km depth.

The layer a few tens of kilometers thick with the S velocity reduction of a few percent atop the 410-km discontinuity was detected by Revenauh and Sipkin (1994) beneath eastern China and by Vinnik et al. (1996) beneath the Kaapvaal craton in southern Africa, from multiple ScS reverberations and PRFs, respectively. Both observations were confirmed by S receiver functions for the same locations and reproduced at a number of other locations that include Antarctica, Siberia, northern Africa, and Arabian Peninsula (Vinnik and Farra, 2007). This layer is also found in the west of North America (e.g., Song et al., 2004; Jasbinsek and Dueker, 2007). Most locations of this layer seem to be associated with Cenozoic and Mesozoic mantle upwellings (Vinnik and Farra, 2007), but hydrous melting as the reason for the low S velocity still is not proved. It might be proved by observations of anomalously high anelastic attenuation, but indications of it so far were reported only for southern Africa (Vinnik et al., 2009).

Beyond the layer atop the TZ, there are indications of a low S-wave velocity layer in a depth range between 450 and 520 km at several locations (e.g., Vinnik et al., 2009). This phenomenon might also be related to hydration and it requires further analysis.

Summary

Seismic observations of the major TZ discontinuities near 410- and 660-km depths on a global scale are broadly consistent with the pyrolite mantle model. The 410-km discontinuity is related to the olivine-wadsleyite phase transition with a positive Clapeyron slope. The 660-km discontinuity is related to the post-spinel transition in the olivine component and post-majorite transition in the other components, with a negative and positive Clapeyron slope, respectively. In the normal mantle, the depths of the discontinuities are stable and in good agreement with the IASP91 model, where the thickness of the TZ is 250 km. Anomalous topography of the TZ discontinuities is related to hot and cold regions (hotspots and subduction zones, respectively). The anomalies beneath oceans are related mainly to hotspots, where the 410-km discontinuity is depressed by ~20 km. The corresponding temperature anomalies are up to ~200°C. The lack of comparable topography on the 660-km discontinuity beneath hotspots

can be explained, among other reasons, by peculiarities of phase transitions near 660-km depth. Beneath continents, except Africa and Antarctica, the anomalies are related mainly to Cenozoic subduction zones, where the 660-km discontinuity can be depressed by up to ~50 km. The related temperature anomalies are in a range of several hundred degrees Celsius. In spite of high water solubility in wadsleyite and ringwoodite, credible observations of seismic effects of hydration in the TZ are practically unknown. The thin low-S-velocity layer atop the 410-km discontinuity, found at a number of locations, is probably the only exception. The low velocity can be an effect of a hydrous melt. On a regional scale the TZ may contain less well-understood complexities such as the 520-km discontinuity or a low S velocity layer between 450- and 520-km depths.

SEISMIC HAZARD

Andrzej Kijko
Aon-Benfield Natural Hazard Centre, University of Pretoria, Pretoria, Republic of South Africa

Definition

Seismic hazard. Any physical phenomena associated with an earthquake (e.g., ground motion, ground failure, liquefaction, and tsunami) and their effects on land, man-made structure, and socioeconomic systems that have the potential to produce a loss. It is also used without regard to a loss to indicate the probable level of ground shaking occurring at a given point within a certain period of time.
Seismic hazard analysis. Quantification of the ground motion expected at a particular site.
Deterministic seismic hazard analysis. Quantification of a single or relatively small number of individual earthquake scenarios.
Probabilistic seismic hazard analysis. Quantification of the probability that a specified level of ground motion will be exceeded at least once at a site or in a region during a specified exposure time.
Ground motion prediction equation. A mathematical equation which indicates the relative decline of the ground motion parameter as the distance from the earthquake increases.

Introduction

The estimation of the expected ground motion which can occur at a particular site is vital to the design of important structures such as nuclear power plants, bridges, and dams. The process of evaluating the design parameters of earthquake ground motion is called seismic hazard assessment or seismic hazard analysis. Seismologists and earthquake engineers distinguish between seismic hazard and seismic risk assessments in spite of the fact that in everyday usage these two phrases have the same meaning. Seismic hazard is used to characterize the severity of ground motion at a site regardless of the consequences, while the risk refers exclusively to the consequences to human life and property loss resulting from the occurred hazard. Thus, even a strong earthquake can have little risk potential if it is far from human development and infrastructure, while a small seismic event in an unfortunate location may cause extensive damage and losses.

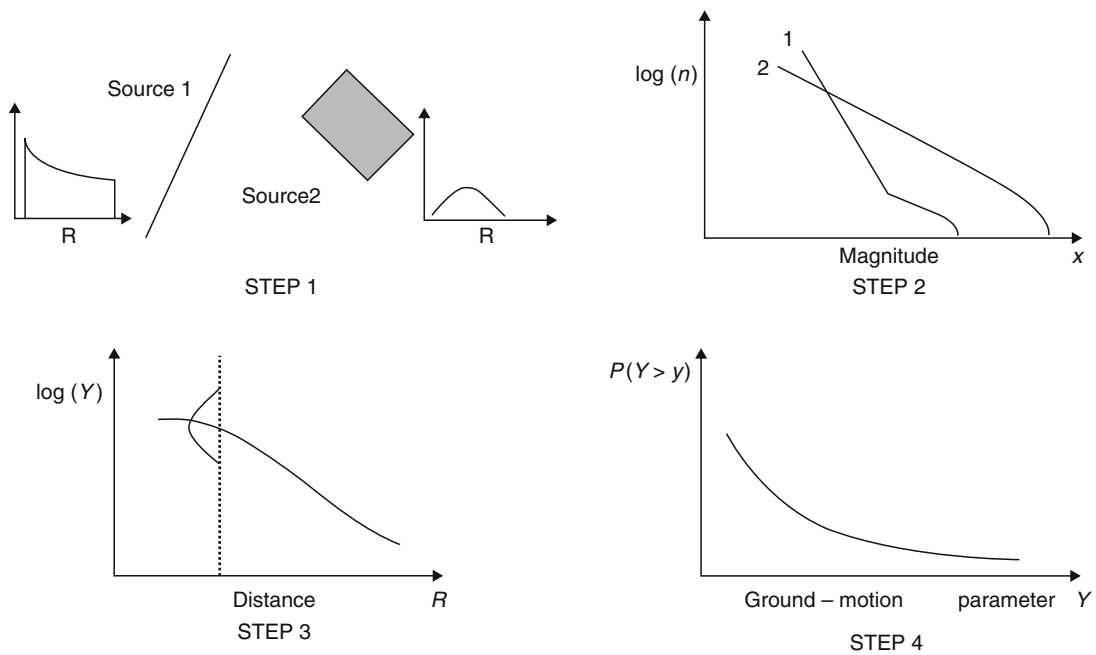
Seismic hazard analysis can be performed *deterministically*, when a particular earthquake scenario is considered, or *probabilistically*, when likelihood or frequency of specified earthquake size and location are evaluated.

The process of *deterministic* seismic hazard analysis (DSHA) involves the initial assessment of the maximum possible earthquake magnitude for each of the various seismic sources such as active faults or seismic source zones (SSHAC, 1997). An area of up to 450 km radius around the site of interest can be investigated. Assuming that each of these earthquakes will occur at the minimum possible distance from the site, the ground motion is calculated using appropriate attenuation equations. Unfortunately, this straightforward and intuitive procedure is overshadowed by the complexity and uncertainty in selecting the appropriate earthquake scenario, creating the need for an alternative, *probabilistic* methodology, which is free from discrete selection of scenario earthquakes. Probabilistic seismic hazard analysis (PSHA) quantifies as a probability whatever hazard may result from all earthquakes of all possible magnitudes and at all significant distances from the site of interest. It does this by taking into account their frequency of occurrence. Deterministic earthquake scenarios, therefore, are a special case of the probabilistic approach. Depending on the scope of the project, DSHA and PSHA can complement one another to provide additional insights to the seismic hazard (McGuire, 2004). This study will concentrate on a discussion of PSHA.

In principle, any natural hazard caused by seismic activity can be described and quantified by the formalism of the PSHA. Since the damages caused by ground shaking very often result in the largest economic losses, our presentation of the basic concepts of PSHA is illustrated by the quantification of the likelihood of ground shaking generated by earthquakes. Modification of the presented formalism to quantify any other natural hazard is straightforward.

The classic procedure for the PSHA includes four steps (Reiter, 1990), (Figure 1).

1. The first step consists of the identification and parameterization of the *seismic sources* (known also as *source zones*, *earthquake sources*, or *seismic zones*) that may affect the site of interest. These may be represented as area, fault, or point sources. Area sources are often used when one cannot identify a specific fault. In classic PSHA, a uniform distribution of seismicity is assigned to each earthquake source, implying that earthquakes are equally likely to occur at any point within the source zone. The combination of earthquake occurrence distributions with the source geometry, results in space, time, and magnitude distributions of earthquake occurrences. Seismic source models can be interpreted as a list of potential scenarios, each with an associated magnitude, location, and seismic activity rate (Field, 1995).
2. The next step consists of the specification of temporal and magnitude distributions of seismicity for each source. The classic Cornell–McGuire approach assumes that earthquake occurrence in time is random and follows the Poisson process. This implies that earthquake occurrences in time are statistically independent and that they occur at a constant rate. Statistical independence means that occurrence of future earthquakes does not depend on the occurrence of the past earthquake. The most often used model of earthquake magnitude recurrence is the



Seismic Hazard, Figure 1 Four steps of a PSHA (Modified from Reiter, 1990).

frequency-magnitude Gutenberg–Richter relationship (Gutenberg and Richter, 1944).

$$\log(n) = a - bm, \tag{1}$$

where n is the number of earthquakes with a magnitude of m and a and b are parameters. It is assumed that earthquake magnitude, m, belongs to the domain $<m_{\min}, m_{\max}>$, where $m_{\min}$ is the level of completeness of earthquake catalogue and magnitude $m_{\max}$ is the upper limit of earthquake magnitude for a given seismic source. The parameter a is the measure of the level of seismicity, while b describes the ratio between the number of small and large events. The Gutenberg–Richter relationship may be interpreted either as being a cumulative relationship, if n is the number of events with magnitude equal or larger than m, or as being a density law, stating that n is the number of earthquakes in a specific, small magnitude interval around m. Under the above assumptions, the seismicity of each seismic source is described by four parameters: the (annual) rate of seismicity λ, which is equal to the parameter of the Poisson distribution, the lower and upper limits of earthquake magnitude, $m_{\min}$ and $m_{\max}$, and the b-value of the Gutenberg–Richter relationship.

3. Calculation of ground motion prediction equations and their uncertainty. Ground motion prediction equations are used to predict ground motion at the site itself. The parameters of interest include peak ground acceleration, peak ground velocity, peak ground displacement, spectral acceleration, intensity, strong ground motion duration, etc. Most ground motion prediction equations available today are empirical and depend on the earthquake magnitude, source-to-site distance, type of faulting, and local site conditions. The choice of an appropriate ground motion prediction equation is crucial since, very often, it is a major contributor to uncertainty in the estimated PSHA.
4. Integration of uncertainties in earthquake location, earthquake magnitude and ground motion prediction equation into probability that the ground motion parameter of interest will be exceeded at the specified site during the specified time interval. The ultimate result of a PSHA is a *seismic hazard curve*: the annual probability of exceeding a specified ground motion parameter at least once. An alternative definition of the hazard curve is the frequency of exceedance versus ground motion amplitude (McGuire, 2004).

The following section provides the mathematical framework of the classic PSHA procedure, including its deaggregation. The most common modifications of the procedure will be discussed in the section (Some modifications of Cornell–McGuire PSHA procedure and alternative models).

The Cornell–McGuire PSHA methodology

Conceptually, the computation of a seismic hazard curve is fairly simple. Let us assume that seismic hazard is characterized by ground motion parameter Y. The probability of exceeding a specified value y, $P[Y \geq y]$, is calculated for an earthquake of particular magnitude located at a possible source, and then multiplied by the probability that that particular earthquake will occur. The computations are repeated and summed for the whole range of possible magnitudes and earthquake locations. The resulting probability $P[Y \geq y]$ is calculated by utilizing the Total Probability Theorem which is:

$$P[Y \geq y] = \sum P[Y \geq y|E_i] \cdot P[E_i], \tag{2}$$

where

$$P[Y \geq y|E_i] = \int \cdots \int P[Y \geq y|x_1, x_2, x_3 \ldots] \cdot f_i(x_1) \cdot f_i(x_2|x_1) \cdot f_i(x_3|x_1, x_2) \ \ldots \ dx_3\, dx_2\, dx_1. \tag{3}$$

$P[Y \geq y|E_i]$ denotes the probability of ground motion parameter $Y \geq y$, at the site of interest, when an earthquake occurs within the seismic source i. Variables x_i $(i = 1, 2, \ldots)$ are uncertainty parameters that influence Y. In the classic approach, as developed by Cornell (1968), and later extended to accommodate ground motion uncertainty (Cornell, 1971), the parameters of ground motion are earthquake magnitude, M, and earthquake distance, R. Functions $f(\cdot)$ are probability density functions (PDF) of parameters x_i. Assuming that indeed $x_1 \equiv M$ and $x_2 \equiv R$, the probability of exceedance (Equation 3) takes the form:

$$P[Y \geq y|E] = \int_{m_{\min}}^{m_{\max}} \int_{R|M} P[Y \geq y|m, r] \, f_M(m) f_{R|M}(r|m) \, dr \, dm, \tag{4}$$

where $P[Y \geq y|m, r]$ denotes the conditional probability that the chosen ground motion level y is exceeded for a given magnitude and distance; $f_M(m)$ is the PDF of earthquake magnitude, and $f_{R|M}(r|m)$ is the conditional PDF of the distance from the earthquake for a given magnitude. The $f_{R|M}(r|m)$ arises in specific instances, such as those where a seismic source is represented by a fault rupture. Since the earthquake magnitude depends on the length of fault rupture, the distance to the rupture and resulting magnitude are correlated.

If, in the vicinity of the site of interest, one can distinguish n_S seismic sources, each with average annual rate of earthquake occurrence λ_i, then the total average annual rate of events with a site ground motion level y or more, takes the form:

$$\lambda(y) = \sum_{i=1}^{n_S} \lambda \int_{m_{\min}}^{m_{\max}} \int_{R|M} P[Y \geq y|M, R] \, f_M(m) f_{R|M}(r|m) \, dr \, dm, \tag{5}$$

In Equation 5, the subscripts denoting seismic source number are deleted for simplicity, $P[Y \geq y|m,r]$ denotes the conditional probability that the chosen ground motion level y, is exceeded for a given magnitude m and distance r. The standard choice for the probability $P[Y \geq y|m,r]$ is a normal, complementary cumulative distribution function (CDF), which is based on the assumption that the ground motion parameter y is a log-normal random variable, $\ln(y) = g(m,r) + \varepsilon$, where ε is random error. The mean value of $\ln(y)$ and its standard deviation are known and are defined as $\overline{\ln(y)}$ and $\sigma_{\ln(y)}$, respectively. The function $f_M(m)$ denotes the PDF of earthquake magnitude. In most engineering applications of PSHA, it is assumed that earthquake magnitudes follow the Gutenberg–Richter relation (1), which implies that $f_M(m)$ is a negative, exponential distribution, shifted from zero to $m_{\min}$ and truncated from the top by $m_{\max}$

$$f_M(m) = \frac{\beta \exp[(-(m - m_{\min})]}{1 - \exp[(-\beta(m_{\max} - m_{\min})]}, \quad (6)$$

In Equation 6, $\beta = b \ln 10$, where b is the parameter of the frequency-magnitude Gutenberg–Richter relation (1).

After assuming that in every seismic source, earthquake occurrences in time follow a Poissonian distribution, the probability that y, a specified level of ground motion at a given site, will be exceeded at least once within any time interval t is

$$P[Y > y;\ t] = 1 - \exp[-\lambda(y) \cdot t]. \quad (7)$$

The Equation 7 is fundamental to PSHA. For $t = 1$ year, its plot versus ground motion parameter y, is the *hazard curve* – the ultimate product of the PSHA (Figure 2). For small probabilities,

$$P[Y > y; t = 1] = 1 - \exp(-\lambda)$$
$$\cong 1 - (1 - \lambda + \frac{1}{2}\lambda^2 - ...) \cong \lambda, \quad (8)$$

which means that the probability (Equation 7) is approximately equal to $\lambda(y)$. This proves that PSHA can be characterized interchangeably by the annual probability (Equation 7) or by the rate of seismicity (Equation 5).

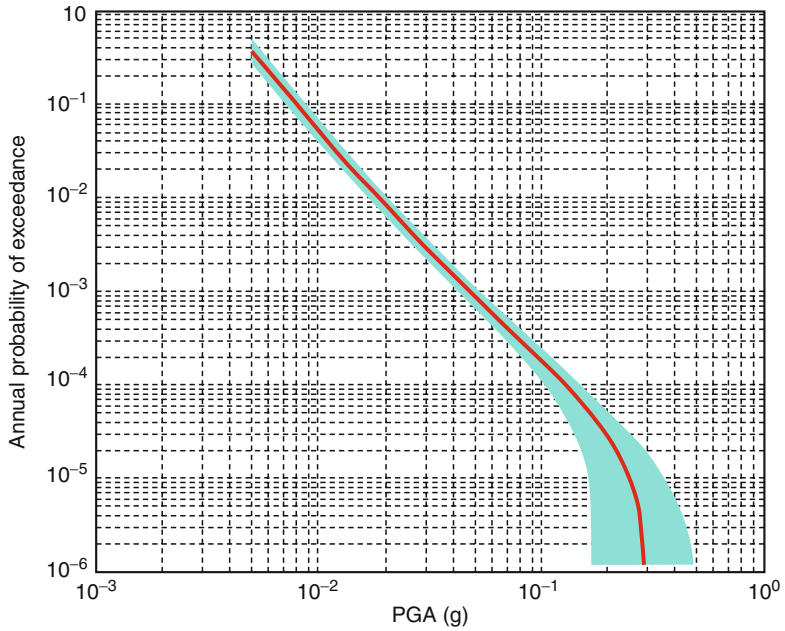
In the classic Cornell–McGuire procedure for PSHA, it is assumed that the earthquakes in the catalogue are independent events. The presence of clusters of seismicity, multiple events occurring in a short period of time or presence of foreshocks and aftershocks violates this assumption. Therefore, before computation of PSHA, these dependent events must be removed from the catalogue.

Estimation of seismic source parameters

Following the classic Cornell–McGuire PSHA procedure, each seismic source is characterized by four parameters:

- Level of completeness of the seismic data, $m_{\min}$
- Annual rate of seismic activity λ, corresponding to magnitude $m_{\min}$
- b-value of the frequency-magnitude Gutenberg–Richter relation (1)
- Upper limit of earthquake magnitude $m_{\max}$

Estimation of m_{min}. The level of completeness of the seismic event catalogue, $m_{\min}$, can be estimated in at least two different ways.



Seismic Hazard, Figure 2 Example of a Peak Ground Acceleration (PGA) seismic hazard curve and its confidence intervals.

The first approach is based on information provided by the seismic event catalogue itself, where $m_{\min}$ is defined as the deviation point from an empirical or assumed earthquake magnitude distribution model. Despite the fact that the evaluation of $m_{\min}$ based on information provided entirely by seismic event catalogue is widely used, it has several weak points. By definition, the estimated levels of $m_{\min}$ represent only the average values over space and time. However, most procedures in this category require assumptions on a model of earthquake occurrence, such as a Poissonian distribution in time and frequency-magnitude Gutenberg–Richter relation.

The second approach used for the estimation of $m_{\min}$ utilizes information on the detection capabilities of seismic stations. The approach release users from the assumptions of stationarity and statistical independence of event occurrence. The choice of the most appropriate procedure for $m_{\min}$ estimation depends on several factors, such as the knowledge of the history of the development of the seismic network, data collection, and processing.

Estimation of rate of seismic activity λ and b-value of Gutenberg-Richter. The accepted approach to estimating seismic source recurrence parameters λ and b is the maximum likelihood procedure. If successive earthquakes are independent in time, the number of earthquakes with magnitude equal to or exceeding a level of completeness, $m_{\min}$, follows the Poisson distribution with the parameter equal to the annual rate of seismic activity λ. The maximum likelihood estimator of λ is then equal to n/t, where n is number of events that occurred within time interval t.

For given $m_{\max}$, the maximum likelihood estimator of the b-value of the Gutenberg–Richter equation can be obtained from the recursive solution of the following:

$$1/\beta = \bar{m} - m_{\min} + \frac{(m_{\max} - m_{\min}) \cdot \exp[-\beta(m_{\max} - m_{\min})]}{1 - \exp[-\beta(m_{\max} - m_{\min})]}. \quad (9)$$

where $\beta = b \ln 10$, and $\bar{m}$ is the sample mean of earthquake magnitude. If the range of earthquake magnitudes $< m_{\max}, m_{\min} >$ exceeds 2 magnitude units, the solution of Equation 9 can be approximated by the well-known Aki-Utsu estimator (Aki, 1965; Utsu, 1965)

$$\beta = 1 \,/\, (\bar{m} - m_{\min}). \quad (10)$$

In most real cases, estimation of parameters λ and the b-value by the above simple formulas cannot be performed due to the incompleteness of seismic event catalogues. The alternative procedures, capable to utilize data incompleteness has been developed by Weichert (1980) and Kijko and Sellevoll (1992).

Estimation of m_{max}. The maximum magnitude, $m_{\max}$, is defined as the upper limit of magnitude for a given seismic source.

This terminology assumes a sharp cutoff magnitude at a maximum magnitude $m_{\max}$. Cognizance should be taken of the fact that an alternative, "soft" cutoff maximum earthquake magnitude is also being used (Main and Burton, 1984). The later formalism is based on the assumption that seismic moments of seismic events follow the Gamma distribution. One of the distribution parameters is called the maximum seismic moment, and the corresponding value of earthquake magnitude is called the "soft" maximum magnitude. Beyond the value of this maximum magnitude, the distribution decays much faster than the classical Gutenberg–Richter relation. Although this model has been occasionally used, the classic PSHA only considers models having a sharp cutoff of earthquake magnitude.

As a rule, $m_{\max}$ plays an important role in PSHA, especially in assessment of long return periods. At present, there is no generally accepted method for estimating $m_{\max}$. It is estimated by the combination of several factors, which are based on two kinds of information: seismicity of the area, and geological, geophysical, and structural information of the seismic source. The utilization of the seismological information focuses on the maximum observed earthquake magnitude within a seismic source and statistical analysis of the available seismic event catalogue. The geological information is used to identify distinctive tectonic features, which control the value of $m_{\max}$.

The current evaluations of $m_{\max}$ are divided between deterministic and probabilistic procedures, based on the nature of the tools applied.

Deterministic procedures. The deterministic procedure most often applied is based on the empirical relationships between magnitude and various tectonic and fault parameters, such as fault length or rupture dimension. The relationships are different for different seismic areas and different types of faults (Wells and Coppersmith, 1994 and references therein). Despite the fact that such empirical relationships are extensively used in PSHA (especially for the assessment of maximum possible magnitude generated by the fault-type seismic sources), the weak point of the approach is its requirement to specify the highly uncertain length of the future rupture. An alternative approach to the determination of earthquake recurrence on singular faults with a segment specific slip rate is provided by the so-called cascade model, where segment rupture is defined by the individual cascade-characteristic rupture dimension (Cramer et al., 2000).

Another deterministic procedure which has a strong, intuitive appeal is based on records of the largest historic or paleo-earthquakes (McCalpin, 1996). This approach is especially applicable in the areas of low seismicity, where large events have long return periods. In the absence of any additional tectono-geological indications, it is assumed that the maximum possible earthquake magnitude is equal to the largest magnitude observed, $m_{\max}^{obs}$, or the largest observed plus an increment. Typically, the increment varies from ¼ to 1 magnitude unit. The procedure is often used for the areas with several, small seismic sources, each having its own $m_{\max}^{obs}$ (Wheeler, 2009).

Another commonly used deterministic procedure for $m_{\max}$ evaluation, especially for area-type seismic sources, is based on the extrapolation of the frequency-magnitude

Gutenberg–Richter relation. The best known extrapolation procedures are probably those by Frohlich (1998) and the "probabilistic" extrapolation procedure applied by Nuttli (1981), in which the frequency-magnitude curve is truncated at the specified value of annual probability of exceedance (e.g., 0.001).

An alternative procedure for the estimation of $m_{\max}$ was developed by Jin and Aki (1988), where a remarkably linear relationship was established between the logarithm of coda Q_0 and the largest observed magnitude for earthquakes in China. The authors postulate that if the largest magnitude observed during the last 400 years is the maximum possible magnitude $m_{\max}$, the established relation will give a spatial mapping of $m_{\max}$.

Ward (1997) developed a procedure for the estimation of $m_{\max}$ by simulation of the earthquake rupture process. Ward's computer simulations are impressive; nevertheless, one must realize that all the quantitative assessments are based on the particular rupture model, postulated parameters of the strength and assumed configuration of the faults.

The value of $m_{\max}$ can also be estimated from the tectono-geological features like strain rate or the rate of seismic-moment release (WGCEP, 1995). Similar approaches have also been applied in evaluating the maximum possible magnitude of seismic events induced by mining (e.g., McGarr, 1984). However, in most cases, the uncertainty of $m_{\max}$ as determined by any deterministic procedure is large, often reaching a value of the order of one unit on the Richter scale.

Probabilistic procedures. The first probabilistic procedure for maximum regional earthquake magnitude was developed in the late 1960s, and is based on the formalism of the extreme values of random variables. A major breakthrough in the seismological applications of extreme-value statistics was made by Epstein and Lomnitz (1966), who proved that the Gumbel I distribution of extremes can be derived directly from the assumptions that seismic events are generated by a Poisson process and that they follow the frequency-magnitude Gutenberg–Richter relation. Statistical tools required for the estimation of the end-point of distribution functions (as, e.g., Cooke, 1979) have only recently been used in the estimation of maximum earthquake magnitude (Pisarenko et al., 1996; Kijko, 2004 and references therein).

The statistical tools available for the estimation of $m_{\max}$ vary significantly. The selection of the most suitable procedure depends on the assumptions of the statistical distribution model and/or the information available on past seismicity. Some of the procedures can be applied in the extreme cases when no information about the nature of the earthquake magnitude distribution is available. Some of the procedures can also be used when the earthquake catalogue is incomplete, i.e., when only a limited number of the largest magnitudes are known. Two estimators are presented here. Broadly speaking, the first estimator is straightforward and simple in application, while the second one requires more computational effort but provides more accurate results. It is assumed that both the analytical form and the parameters of the distribution functions of earthquake magnitude are known. This knowledge can be very approximate, but must be available.

Based on the distribution of the largest among n observations and on the condition that the largest observed magnitude $m_{\max}^{obs}$ is equal to the largest magnitude to be expected, the "simple" estimate of $m_{\max}$ is of the form

$$\hat{m}_{\max} = m_{\max}^{obs} + \frac{1}{n f_M(m_{\max}^{obs})}, \tag{11}$$

where $f_M(m_{\max}^{obs})$ is PDF of the earthquake magnitude distribution. If applied to the Gutenberg–Richter recurrence relation with PDF (Equation 6), it takes the simple form

$$\hat{m}_{\max} = m_{\max}^{obs} + \frac{1 - \exp[-\beta(m_{\max}^{obs} - m_{\min})]}{n\beta \exp[-\beta(m_{\max}^{obs} - m_{\min})]}. \tag{12}$$

The approximate variance of the estimator (Equation 12) is of the form

$$VAR(\hat{m}_{\max}) = \sigma_M^2 + \frac{1}{n^2} \left[\frac{1 - \exp[-\beta(m_{\max}^{obs} - m_{\min})]}{\beta \exp[-\beta(m_{\max}^{obs} - m_{\min})]}\right]^2, \tag{13}$$

where σ_M stands for epistemic uncertainty and denotes the standard error in the determination of the largest observed magnitude $m_{\max}^{obs}$. The second part of the variance represents the aleatory uncertainty of $m_{\max}$.

The second ("advanced") procedure often used for assessment of $m_{\max}$ is based on the formalism derived by Cooke (1979)

$$\hat{m}_{\max} = m_{\max}^{obs} + \int_{m_{\min}}^{m_{\max}^{obs}} [F_M(m)]^n \mathrm{d}m, \tag{14}$$

where $F_M(m)$ denotes the CDF of random variable m. If applied to the frequency-magnitude Gutenberg–Richter relation (1), the respective CDF is

$$F_M(m) = \begin{cases} 0, & \text{for } m < m_{\min}, \\ \frac{1-\exp[-\beta(m-m_{\min})]}{1-\exp[-\beta(m_{\max}-m_{\min})]}, & \text{for } m_{min} \le m \le m_{\max}, \\ 1, & \text{for } m > m_{\max}, \end{cases} \tag{15}$$

and the $m_{\max}$ estimator (Equation 14) takes the form

$$\hat{m}_{\max} = m_{\max}^{obs} + \frac{E_1(n_2) - E_1(n_1)}{\beta \exp(-n_2)} + m_{\min} \exp(-n), \tag{16}$$

where $n_1 = n/\{1 - \exp[-\beta(m_{\max}^{obs} - m_{\min})]\}$, $n_2 = n_1 \exp[-\beta(m_{\max}^{obs} - m_{\min})]$, and $E_1(\cdot)$ denotes an exponential integral function. The variance of estimator (Equation 16)

has two components, epistemic and aleatory, and is of the form

$$VAR(\hat{m}_{\max}) = \sigma_M^2 + \left[\frac{E_1(n_2) - E_1(n_1)}{\beta \exp(-n_2)} + m_{\min} \exp(-n)\right]^2, \quad (17)$$

where σ_M denotes standard error in the determination of the largest observed magnitude $m_{\max}^{obs}$.

Both above estimators of $m_{\max}$, by their nature, are very general and have several attractive properties. They are applicable for a very broad range of magnitude distributions. They may also be used when the exact number of earthquakes, n, is not known. In this case, the number of earthquakes can be replaced by λt. Such a replacement is equivalent to the assumption that the number of earthquakes occurring in unit time conforms to a Poisson distribution with parameter λ, where t is the span of the seismic event catalogue. It is also important to note that both estimators provide a value of $\hat{m}_{\max}$, which is never less than the largest magnitude already observed.

Alternative procedures are discussed by Kijko (2004), which are appropriate for the case when the empirical magnitude distribution deviates from the Gutenberg-Richter relation. These procedures assume no specific form of the magnitude distribution or that only a few of the largest magnitudes are known.

Despite the fact that statistical procedures based on the mathematical formalism of extreme values provide powerful tools for the evaluation of $m_{\max}$, they have one weak point: often available seismic event catalogues are too short and insufficient to provide reliable estimations of $m_{\max}$. Therefore the Bayesian extension of statistical procedures (Cornell, 1994), allowing the inclusion of alternative and independent information such as local geological conditions, tectonic environment, geophysical data, paleoseismicity, similarity with another seismic area, etc., are able to provide more reliable assessments of $m_{\max}$.

Numerical computation of PSHA

With the exception of a few special cases (Bender, 1984), the hazard curve (Equation 7) cannot be computed analytically. For the most realistic distributions, the integrations can only be evaluated numerically. The common practice is to divide the possible ranges of magnitude and distance into n_M and n_R intervals, respectively. The average annual rate (Equation 4) is then estimated as

$$\lambda(Y > y) \cong \sum_{i=1}^{n_S} \sum_{j=1}^{n_M} \sum_{k=1}^{n_R} \lambda_i P[Y > y | m_j, r_k] f_{M_j}(m_j) f_{R_k}(r_k) \Delta m \Delta r, \quad (18)$$

where $m_j = m_{\min} + (j - 0.5) \cdot (m_{\max} - m_{\min})/n_M$, $r_k = r_{\min} + (k - 0.5) \cdot (r_{\max} - r_{\min})/n_R$, $\Delta m = (m_{\max} - m_{\min})/n_M$, and $\Delta r = (r_{\max} - r_{\min})/n_R$.

If the procedure is applied to a grid of points, it will result in a map of PSHA, in which the contours of the expected ground motion parameter during the specified time interval can be drawn (Figure 3).

Deaggregation of seismic hazard

By definition, the PSHA aggregates ground motion contributions from earthquake magnitudes and distances of significance to a site of engineering interest. One has to note that the PSHA results are not representative of a single earthquake. However, an integral part of the design procedure of any critical structure is the analysis of the most relevant earthquake acceleration time series, which are generated by earthquakes, at specific magnitudes and distances. Such earthquakes are called "controlling earthquakes," and they are used to determine the shapes of the response spectral acceleration or PGA at the site.

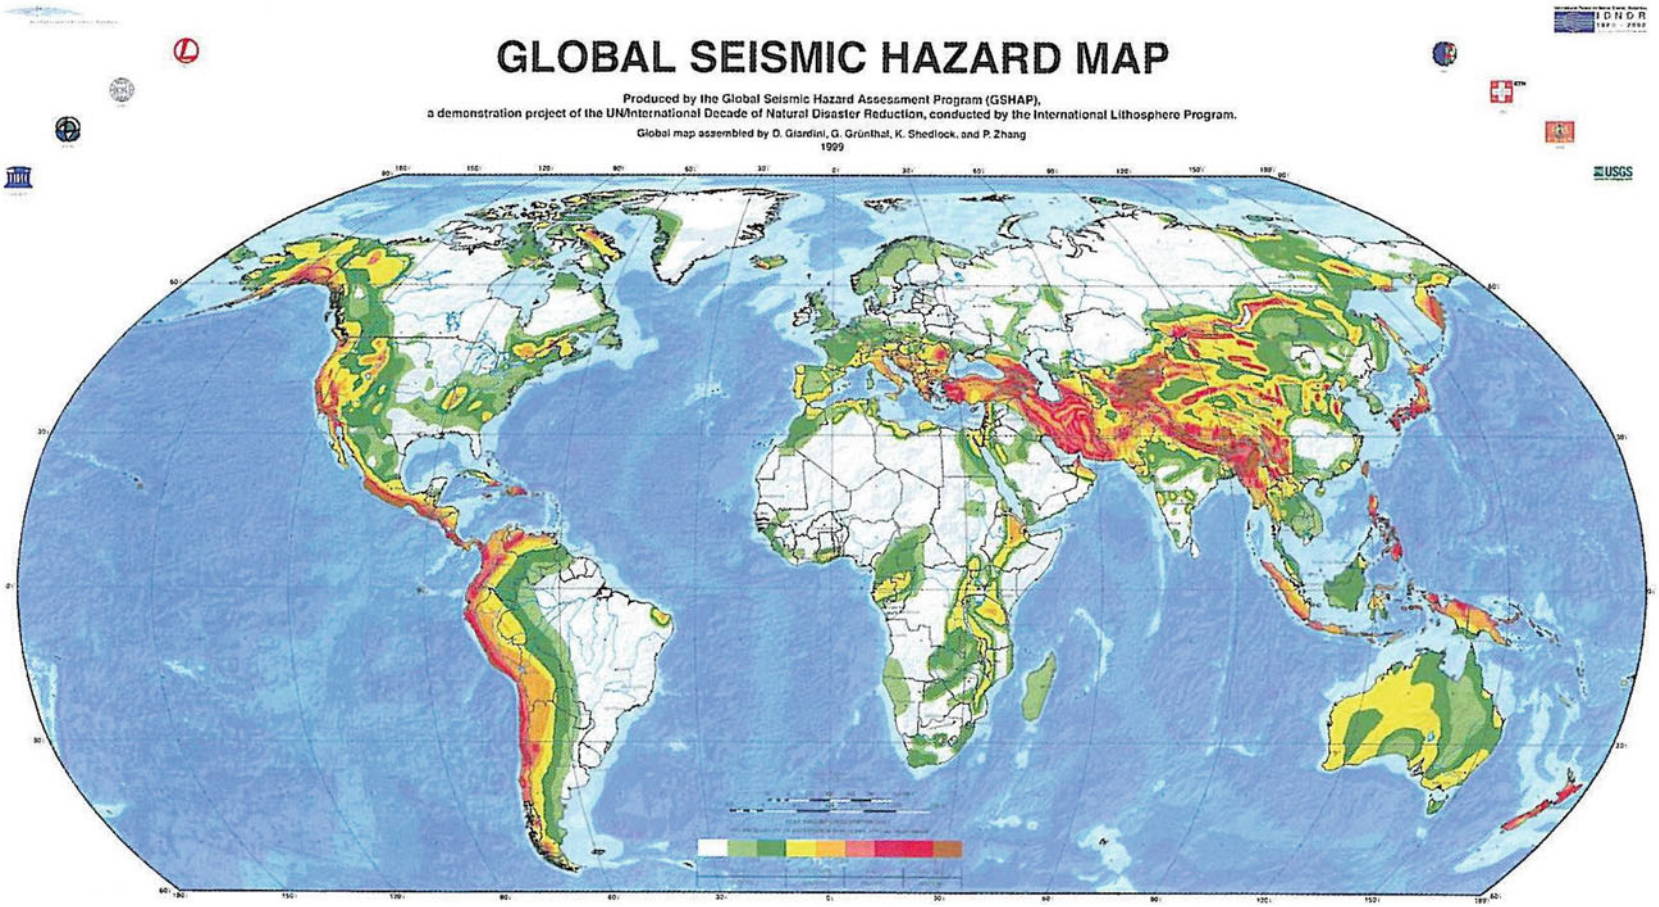
Controlling earthquakes are characterized by mean magnitudes and distances derived from so-called deaggregation analysis. During the deaggregation procedure, the results of PSHA are separated to determine the dominant magnitudes and the distances that contribute to the hazard curve at a specified (reference) probability. Controlling earthquakes are calculated for different structural frequency vibrations, typically for the fundamental frequency of a structure. In the process of deaggregation, the hazard for a reference probability of exceedance of specified ground motion is portioned into magnitude and distance bins. The relative contribution to the hazard for each bin is calculated. The bins with the largest relative contribution identify those earthquakes that contribute the most to the total seismic hazard.

Some modifications of Cornell–McGuire PSHA procedure and alternative models

Source-free PSHA procedures

The concept of seismic sources is the core element of the Cornell–McGuire PSHA procedure. Unfortunately, seismic sources or specific faults can often not be identified and mapped and the causes of seismicity are not understood. In these cases, the delineation of seismic sources is highly subjective and is a matter of expert opinion. In addition, often, seismicity within the seismic sources is not distributed uniformly, as it is required by the classic Cornell–McGuire procedure. The difficulties experienced in dealing with seismic sources have stimulated the development of an alternative technique to PSHA, which is free from delineation of seismic sources.

One of the first attempts to develop an alternative to the Cornell–McGuire procedure was made by Veneziano et al. (1984). Indeed, the procedure does not require the specification of seismic sources, is non-parametric, and, as input, requires only information about past seismicity. The empirical distribution of the specified seismic hazard parameter is calculated by using the observed earthquake magnitudes, epicentral distances, and assumed ground motion prediction equation. By normalizing this



Seismic Hazard, Figure 3 Example of product of PSHA. Map of seismic hazard of the world. Peak ground acceleration expected at 10% probability of exceedance at least once in 50 years. (From Giardini, 1999, http://www.gfz-potsdam.de/pb5/pb53/projects/gshap).

distribution for the duration of the seismic event catalogue, one obtains an annual rate of the exceedance for the required hazard parameter.

Another non-parametric PSHA procedure has been developed by Woo (1996). The procedure is also source-free, where seismicity distributions are approximated by data-based kernel functions. Comparison of the classic Cornell–McGuire-based and kernel-based procedures shows that the former yields a lower hazard.

By their nature, the non-parametric procedures work well in areas with a frequent occurrence of strong seismic events and where the record of past seismicity is considerably complete. At the same time, the non-parametric approach has significant weak points. Its primary disadvantage is a poor reliability in estimating small probabilities for areas of low seismicity. The procedure is not recommended for an area where the seismic event catalogues are highly incomplete. In addition, in its present form, the procedure is not capable of making use of any additional geophysical or geological information to supplement the pure seismological data. Therefore, a technique that accommodates the incompleteness of the seismic event catalogues and, at the same time, does not require the specification of seismic sources, would be an ideal tool for analyzing and assessing seismic hazard.

Such a technique, which can be classified as a *parametric-historic* procedure for PSHA has been successfully used in several parts of the world. Kijko (2008) used it for mapping seismic hazard of South Africa and sub-Saharan Africa. The procedure has been applied in selected parts of the world by the Global Seismic Hazard Assessment Program (GSHAP, Giardini, 1999), while Petersen et al. (2008) applied it for mapping the seismic hazard in the USA. In a series of papers, Frankel and his colleagues modified and substantially extended the original procedure. Their final approach is parametric and based on the assumption that earthquakes within a specified grid size are Poissonian in time, and that the earthquake magnitudes follow the Gutenberg–Richter relation truncated from the top by maximum possible earthquake magnitude $m_{\max}$.

In some cases, the frequency-magnitude Gutenberg–Richter relation is extended by characteristic events. The procedure accepts the contribution of seismicity from active faults and compensates for incompleteness of seismic event catalogues. Frankel's conceptually simple and intuitive parametric-historic approach combines the best of the deductive and non-parametric-historic procedures and, in many cases, is free from the disadvantages characteristic of each of the procedures. The rigorous mathematical foundations of the parametric-historic PSHA procedure have been given by Kijko and Graham (1999).

Alternative earthquake recurrence models

Time-dependent models. In addition to the classic assumption, that earthquake occurrence in time follows a Poisson process, alternative approaches are occasionally used. These procedures attempt to assess temporal, or temporal and spatial dependence of seismicity. Time-dependent earthquake occurrence models specify a distribution of the time to the next earthquake, where this distribution depends on the magnitude of the most recent earthquake. In order to incorporate the memory of past events, the non-Poissonian distributions or Markov chains are applied. In this approach, the seismogenic zones that recently produced strong earthquakes become less hazardous than those that did not rupture in recent history.

Clearly such models may result in a more realistic PSHA, but most of them are still only research tools and have not yet reached the level of development required by routine engineering applications.

Time-dependent occurrence of large earthquakes on segments of active faults is extensively discussed by Rhoades et al. (1994) and Ogata (1999) Also, a comprehensive review of all aspects of non-Poissonian models is provided by Kramer (1996). There are several time-dependent models which play an important role in PSHA. The best known models, which have both firm physical and empirical bases, are probably the models by Shimazaki and Nakata (1980). Based on the correlation of seismic activity with earthquake-related coastal uplift in Japan, Shimazaki and Nakata (1980) proposed two models of earthquake occurrence: a *time-predictable* and a *slip-predictable*.

The time-predictable model states that earthquakes occur when accumulated stress on a fault reaches a critical level; however, the stress drop and magnitudes of the subsequent earthquakes vary among seismic cycles. Thus, assuming a constant fault-slip rate, the time to the next earthquake can be estimated from the slip of the previous earthquake. The second, the slip-predictable model, is based on the assumption that, irrespective of the initial stress on the fault, an earthquake occurrence always causes a reduction in stress to the same level. Thus, the fault-slip in the next earthquake can be estimated from the time since the previous earthquake.

The second group of time-dependent models are less tightly based on the physical considerations of earthquake occurrence and attempt to describe intervals between the consecutive events by specified statistical distributions. Ogata (1999) considers five models: log-normal, gamma, Weibull, doubly exponential and exponential, which results in the stationary Poisson process. After application of these models to several paleo-earthquake data sets, he concluded that no one of the distributions is consistently the best fit; the quality of the fit strongly depends on the data. From several attempts to describe earthquake time intervals between consecutive events using statistical distributions, at least two play a significant role in the current practice of PSHA: the log-normal and the Brownian passage time (BPT) renewal model.

The use of a log-normal model is justified by the discovery that normalized intervals between the consecutive large earthquakes in the circum-Pacific region follow a log-normal distribution with an almost constant standard

deviation (Nishenko and Buland, 1987). The finite value for the intrinsic standard deviation is important because it controls the degree of aperiodicity in the occurrence of *characteristic earthquakes,* making accurate earthquake prediction impossible. Since this discovery, the log-normal model has become a key component of most time-dependent PSHA procedures and is routinely used by the Working Group on California Earthquake Probabilities (WGCEP, 1995).

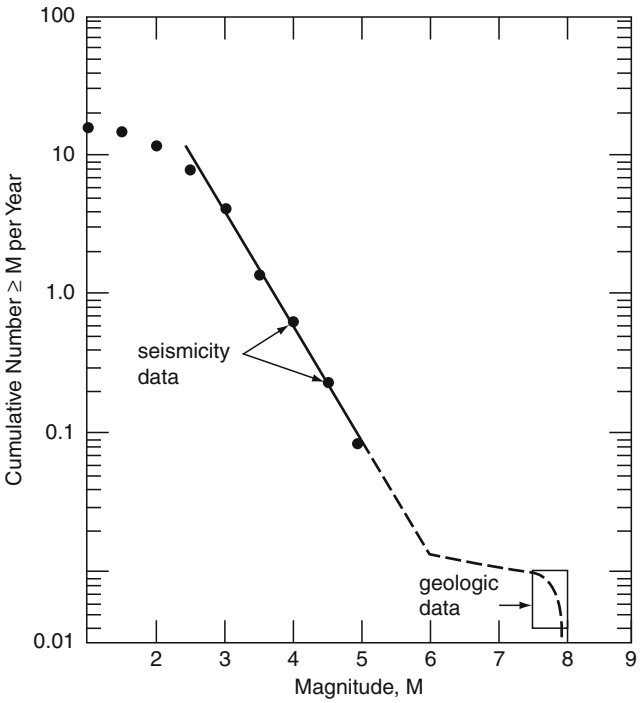
A time-dependent earthquake occurrence model which is applied more often is the Brownian passage time (BPT) distribution, also known as the inverse Gaussian distribution (Matthews et al., 2002). The model is described by two parameters: μ and σ, which, respectively, represent the mean time interval between the consecutive earthquakes and the standard deviation. The aperiodicity of earthquake occurrence is controlled by the variation coefficient $\alpha = \sigma/\mu$. For a small α, the aperiodicity of earthquake occurrence is small and the shape of distribution is almost symmetrical. For a large α, the shape of distribution is similar to log-normal model, i.e., skewed to the right and peaked at a smaller value than the mean. The straightforward control of aperiodicity of earthquake occurrence, by parameter α, makes the BPT model very attractive. It has been used to model earthquake occurrence in many parts of the world and has been applied by the Working Group on California Earthquake Probabilities (WGCEP, 1995).

Comparison of time-dependent with time-independent earthquake occurrence models have shown that the time-independent (Poissonian) model can be used for most engineering computations of PSHA. The exception to this rule is when the seismic hazard is dominated by a single seismic source, with a significant component of characteristic occurrence when the time interval from the last earthquake exceeds the mean time interval between consecutive events. Note that, in most cases, the information on strong seismic events provided by current databases is insufficient to distinguish between different models. The use of non-Poissonian models will therefore only be justified if more data will be available.

Alternative frequency-magnitude models. In the classic Cornell–McGuire procedure for PSHA assessment, it is assumed that earthquake magnitudes follows the Gutenberg–Richter relation truncated from the top by a seismic source characteristic, the maximum possible earthquake magnitude m_{max}. The PDF of this distribution is given by Equation 5.

Despite the fact that in many cases the Gutenberg–Richter relation describes magnitude distributions within seismic source zones sufficiently well, there are some instances where it does not apply. In many places, especially for areas of seismic belts and large faults, the Gutenberg–Richter relation underestimates the occurrence of large magnitudes. The continuity of the distribution (Equation 5) breaks down. The distribution is adequate only for small events up to magnitude 6.0–7.0. Larger events tend to occur within a relatively narrow range of magnitudes (7.5–8.0), but with a frequency higher than that predicted by the Gutenberg–Richter relation. These events are known as *characteristic earthquakes* (Youngs and Coppersmith, 1985, Figure 4). Often it is assumed that characteristic events follow a truncated Gaussian magnitude distribution (WGCEP, 1995).

There are several alternative frequency-magnitude relations that are used in PSHA. The best known is probably the relation by Merz and Cornell (1973), which accounts for a possible curvature in the log-frequency-magnitude relation (1) by the inclusion of a quadratic term of magnitude. Departure from linearity of the distribution (Equation 1) is built into the model by Lomnitz-Adler and Lomnitz (1979). The model is based on simple physical considerations of strain accumulation and release at plate boundaries. Despite the fact that m_{max} is not present in the model, it provides estimates of the occurrence of large events which are more realistic than those predicted by the Gutenberg–Richter relation (1). When seismic hazard is caused by induced seismicity, an alternative distribution to the Gutenberg–Richter model (1) is always required. For example, the magnitude distributions of tremors generated by mining activity are multimodal and change their shape in time (Gibowicz and Kijko, 1994).



Seismic Hazard, Figure 4 Gutenberg–Richter characteristic earthquake magnitude distribution. The model combines frequency-magnitude Gutenberg–Richter relation with a uniform distribution of characteristic earthquakes. The model predicts higher rates of exceedance at magnitudes near the characteristic earthquake magnitude. (After Youngs and Coppersmith, 1985).

Often, the only possible method that can lead to a successful PSHA for mining areas is the replacement of the analytical, parametric frequency-magnitude distribution by its model-free, non-parametric counterpart (Kijko et al., 2001).

Two more modifications of the recurrence models are regularly introduced: one when earthquake magnitudes are uncertain and the other when the seismic occurrence process is composed of temporal trends, cycles, short-term oscillations, and pure random fluctuations. The effect of error in earthquake magnitude determination (especially significant for historic events) can be minimized by the simple procedure of correction of the earthquake magnitudes in a catalogue (e.g., Rhoades, 1996). The modelling of random fluctuations in earthquake occurrence is often done by introducing compound distributions in which parameters of earthquake recurrence models are treated as random variables (Campbell, 1982).

Ground motion prediction equations

The assessment of seismic hazard at a site requires knowledge of the prediction equation of the particular strong motion parameter, as a function of distance, earthquake magnitude, faulting mechanism, and often the local site condition below the site. The most simple and most commonly used form of a prediction equation is

$$\ln(y) = c_1 - c_2 m - c_3 \ln(r) - c_4 r + c_5 F + c_6 S + \varepsilon, \tag{19}$$

where y is the amplitude of the ground motion parameter (PGA, MM intensity, seismic record duration, spectral acceleration, etc.); m is the earthquake magnitude; r is the shortest earthquake distance from the site to the earthquake source; F is responsible for the faulting mechanism; S is a term describing the site effect; and $\epsilon$is the random error with zero mean and standard deviation $\sigma_{\ln(y)}$, which has two components: epistemic and aleatory.

The coefficients $c_1, \ldots, c_6$ are estimated by the least squares or maximum likelihood procedure, using strong motion data. It has been found that the coefficients depend on the tectonic settings of the site. They are different for sites within stable continental regions, active tectonic regions, or subduction zone environments. Assuming that $\ln(y)$ has a normal distribution, regression of (Equation 19) provides the mean value of $\ln(y)$, the exponent of which corresponds to the median value of y, $\breve{y}$. Since the log-normal distribution is positively skewed, the mean value of y, $\bar{y}$, exceeds the median value $\breve{y}$ by a factor of $\exp(-0.5\sigma^2_{\ln(y)})$. This indicates that the seismic hazard for a particular site is higher when expressed in terms of $\bar{y}$, than the hazard for the same site expressed in terms of $\breve{y}$. It has been shown that the ground motion prediction equation remains a particularly important component of PSHA since its uncertainty is a major contributor to uncertainty of the PSHA results (SSHAC, 1997).

Uncertainties in PSHA

Contemporary PSHA distinguishes between two types of uncertainties: aleatory and epistemic.

The *aleatory uncertainty* is due to randomness in nature; it is the probabilistic uncertainty inherent in any random phenomenon. It represents unique details of any earthquake as its source, path, and site and cannot be quantified before the earthquake occurrence and cannot be reduced by current theories, acquiring addition data or information. It is sometimes referred as "randomness," "stochastic uncertainty," or "inherent variability" (SSHAC, 1997) and is denoted as U_R (McGuire, 2004). The typical examples of aleatory uncertainties are: the number of future earthquakes in a specified area; parameters of future earthquakes such as origin times, epicenter coordinates, depths and their magnitudes; size of the fault rupture; associated stress drop and ground motion parameters like PGA, displacement or seismic record duration at the given site. The aleatory uncertainties are characteristic to the current model and cannot be reduced by the incorporation of addition data. It can only be reduced by the conceptualization of a better model.

The *epistemic uncertainty*, denoted as U_K is the uncertainty due to insufficient knowledge about the model or its parameters. The model (in the broad sense of its meaning; as, e.g., a particular statistical distribution) may be approximate and inexact, and therefore predicts values that differ from the observed values by a fixed, but unknown, amount. If uncertainties are associated with numerical values of the parameters, they are also epistemic by nature. Epistemic uncertainty can be reduced by incorporating additional information or data. Epistemic distributions of a model's parameters can be updated using the Bayes' theorem. When new information about parameters is significant and accurate, these epistemic distributions of parameters become delta functions about the exact numerical values of the parameters. In such a case, no epistemic uncertainty about the numerical values of the parameters exists and the only remaining uncertainty in the problem is aleatory uncertainty.

In the past, epistemic uncertainty has been known as statistical or professional uncertainty. The examples of the epistemic uncertainties are: boundaries of seismic sources, distributions of seismic sources parameters (e.g., annual rate of seismic activity λ, b-value and m_{max}), or median value of the ground motion parameter given the source properties.

Aleatory uncertainties are included in the PSHA by means of integration (Equation 5) and they are represented by the hazard curve. In contrast, epistemic uncertainties are included through the use of an alternative hypothesis – different sets of parameters with different numerical values, different models, or through a *logic tree*. Therefore, by default, if in the process of PSHA, the logic tree formalism is applied, the resulting uncertainties of the hazard curve are of epistemic nature.

The major benefit of the separation of uncertainties into aleatory and epistemic is potential guidance in the preparation of input for PSHA and the interpretation of the results. Unfortunately, the division of uncertainties into aleatory and epistemic is model dependent and to a large extent arbitrary, indefinite, and confusing (Panel of Seismic Hazard Evaluation, 1997).

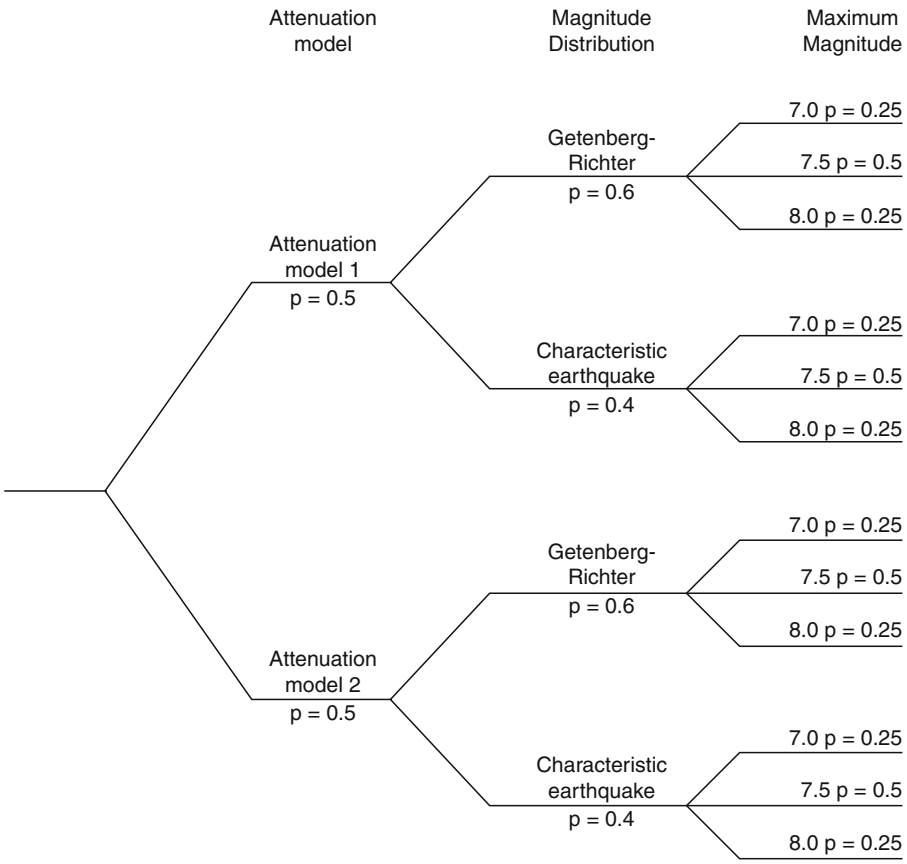
Logic tree

The mathematical formalism of PSHA computation, (Equations 7 and 9), integrates over all random (aleatory) uncertainties of a particular seismic hazard model. In many cases, however, because of our lack of understanding of the mechanism that controls earthquake generation and wave propagation processes, the best choices for elements of the seismic hazard model is not clear. The uncertainty may originate from the choice of alternative seismic sources, competitive earthquake recurrence models and their parameters, as well as from the choice of the most appropriate ground motion. The standard approach for the explicit treatment of alternative hypotheses, models, and parameters is the use of a *logic tree*. The logic tree formalism provides a convenient tool for quantitative treatment of any alternatives. Each node of the logic tree (Figure 5) represents uncertain assumptions, models, or parameters, and the branches extending from each node are the discrete uncertainty alternatives.

In the logic tree analysis, each branch is weighted according to its probability of being correct. As a result, each end branch represents a hazard curve with an assigned weight, where the sum of weights of all the hazard curves is equal to 1. The derived hazard curves are thus used to compute the final (e.g., mean) hazard curve and their confidence intervals. An example of a logic tree is shown in Figure 5. The alternative hypotheses account for uncertainty in the ground motion attenuation model, the magnitude distribution model and the assigned maximum magnitude m_{max}.

Controversy

Despite the fact that the PSHA procedure, as we know it in its current form, was formulated almost half of century ago, it is not without controversy. The controversy surrounds questions such as: (1) the absence of the upper limit of ground motion parameters, (2) division of uncertainties between aleatory and epistemic, and (3) methodology itself, especially the application of the logic tree formalism.



Seismic Hazard, Figure 5 An example of a simple logic tree. The alternative hypothesis accounts for uncertainty in ground motion attenuation relation, magnitude distribution model, and the assigned maximum magnitude m_{max}.

In most currently used Cornell–McGuire-based PSHA procedures, the ground motion parameter used to describe the seismic hazard is distributed log-normally. Since the log-normal distribution is unlimited from the top, it results in a nonzero probability of unrealistically high values for the ground motion parameter, e.g., PGA ≈ 20g, obtained originally from a PSHA for a nuclear-waste repository at Yucca Mountain in the USA (Corradini, 2003). The lack of the upper bound of earthquake-generated ground motion in current hazard assessment procedures has been identified as the "missing piece" of the PSHA procedure (Bommer et al., 2004).

Another criticism of the current PSHA procedure concerns portioning of uncertainties into aleatory and epistemic. As noted in the section (Uncertainties in PSHA) above, the division between aleatory and epistemic uncertainty remains an open issue.

A different criticism comes from the ergodic assumptions which underlie the formalism of the PSHA procedure. The ergodic process is a random process in which the distribution of a random variable in space is the same as distribution of that variable at a single point when sampled as a function of time (Anderson and Brune, 1999). It has been shown that the major contribution to PSHA uncertainty comes from uncertainty of the ground motion prediction equation. The uncertainty of the ground motion parameter y, is characterized by its standard deviation, $\sigma_{\ln(y)}$, which is calculated as the misfit between the observed and predicted ground motions at several seismic stations for a small number of recorded earthquakes.

Thus, $\sigma_{\ln(y)}$ mainly characterizes the spatial and not the temporal uncertainty of ground motion at a single point. This violates the ergodic assumption of the PSHA procedure. According to Anderson and Brune (1999), such violation leads to overestimation of seismic hazard, especially when exposure times are longer than earthquake return times. In addition, Anderson et al. (2000) shows that high-frequency PGAs observed at short distances do not increase as fast as predicted by most ground motion relations. Therefore, the use of the current ground motion prediction equations, especially relating to seismicity recorded at short distances, results in overestimation of the seismic hazard.

A similar view has been expressed by Wang and Zhou (2007) and Wang (2009). Inter alia, they argue that in the Cornell–McGuire-based PSHA procedure, the ground motion variability is not treated correctly. By definition, the ground motion variability is implicitly or explicitly dependent on earthquake magnitude and distance; however, the current PSHA procedure treats it as an independent random variable. The incorrect treatment of ground motion variability results in variability in earthquake magnitudes and distance being counted twice. They conclude that the current PSHA is not consistent with modern earthquake science, is mathematically invalid, can lead to unrealistic hazard estimates, and causes confusion. Similar reservations have been expressed in a series of papers by Klügel (Klügel, 2007 and references therein).

Equally strong criticism of the currently PSHA procedure has been expressed by Castanos and Lomnitz (2002). The main target of their criticism is the logic tree, the key component of the PSHA. They describe the application of the logic tree formalism as a misunderstanding in probability and statistics, since it is fundamentally wrong to admit "expert opinion as evidence on the same level as hard earthquake data."

The science of seismic hazard assessment is thus subject to much debate, especially in the realms where instrumental records of strong earthquakes are missing. At this time, PSHA represents a best-effort approach by our species to quantify an issue where not enough is known to provide definitive results, and by many estimations a great deal more time and measurement will be needed before these issues can be resolved.

Further reading: There are several excellent studies that describe all aspects of the modern PSHA. McGuire (2008) traces the intriguing historical development of PSHA. Hanks and Cornell (1999), and Field (1995) present an entertaining and unconventional summary of the issues related to PSHA, including its misinterpretation. Reiter (1990) comprehensively describes both the deterministic as well as probabilistic seismic hazard procedures from several points of view, including a regulatory perspective. Seismic hazard from the geologist's perspective is described in the book by Yeats et al. (1997). Kramer (1996) provides an elegant, coherent, and understandable description of the mathematical aspects of both DSHA and PSHA. Anderson et al. (2000), Gupta (2002), and Thenhaus and Campbell (2003) present excellent overviews covering theoretical, methodological, as well as procedural issues of modern PSHA. Finally, the most comprehensive treatment to date of all aspects of PSHA, including treatment of *aleatory* and *epistemic* uncertainties, is provided by the SSHAC – Senior Seismic Hazard Committee (1997) – report and in book form by McGuire (2004). The presentations here benefited from all quoted above sources, especially the excellent book by Kramer (1996).

Summary

Seismic hazard is a term referring to any physical phenomena associated with an earthquake (e.g., ground motion, ground failure, liquefaction, and tsunami) and their effects on land, man-made structures, and socioeconomic systems that have the potential to produce a loss. The term is also used, without regard to a loss, to indicate the probable level of ground shaking occurring at a given point within a certain period of time. Seismic hazard analysis is an expression referring to quantification of the expected ground motion at the particular site. Seismic hazard analysis can be performed deterministically, when a particular earthquake scenario is considered, or probabilistically, when the likelihood or frequency of a specified level of ground motion at a site during a specified exposure time is evaluated. In principle, any natural hazard caused by

seismic activity can be described and quantified in terms of the probabilistic methodology. Classic probabilistic seismic hazard analysis (PSHA) includes four steps: (1) identification and parameterization of the seismic sources, (2) specification of temporal and magnitude distributions of earthquake occurrence, (3) calculation of ground motion prediction equations and their uncertainty, and (4) integration of uncertainties in earthquake location, earthquake magnitude, and ground motion prediction equations into the hazard curve.

An integral part of PSHA is the assessment of uncertainties. Contemporary PSHA distinguishes between two types of uncertainties: aleatory and epistemic. The aleatory uncertainty is due to randomness in nature; it is the probabilistic uncertainty inherent in any random phenomenon. The aleatory uncertainties are characteristic to the current model and cannot be reduced by the incorporation of addition data. The epistemic uncertainty is the uncertainty due to insufficient knowledge about the model or its parameters. Epistemic uncertainty can be reduced by incorporating additional information or data. Aleatory uncertainties are included in the probabilistic seismic hazard analysis due to the integration over these uncertainties, and they are represented by the hazard curve. In contrast, epistemic uncertainties are included through the use of alternative models, different sets of parameters with different numerical values or through a logic tree.

Unfortunately, the PSHA procedure, as we know it in its current form, is not without controversy. The controversy arises from questions such as: (1) the absence of the upper limit of ground motion parameter, (2) division of uncertainties between aleatory and epistemic, and (3) methodology itself, especially the application of the logic tree formalism.

SEISMIC IMAGING, OVERVIEW

Gerard T. Schuster
Division of Environmental and Earth Sciences, King Abdullah University of Science and Technology, Thule, Saudi Arabia

Definition

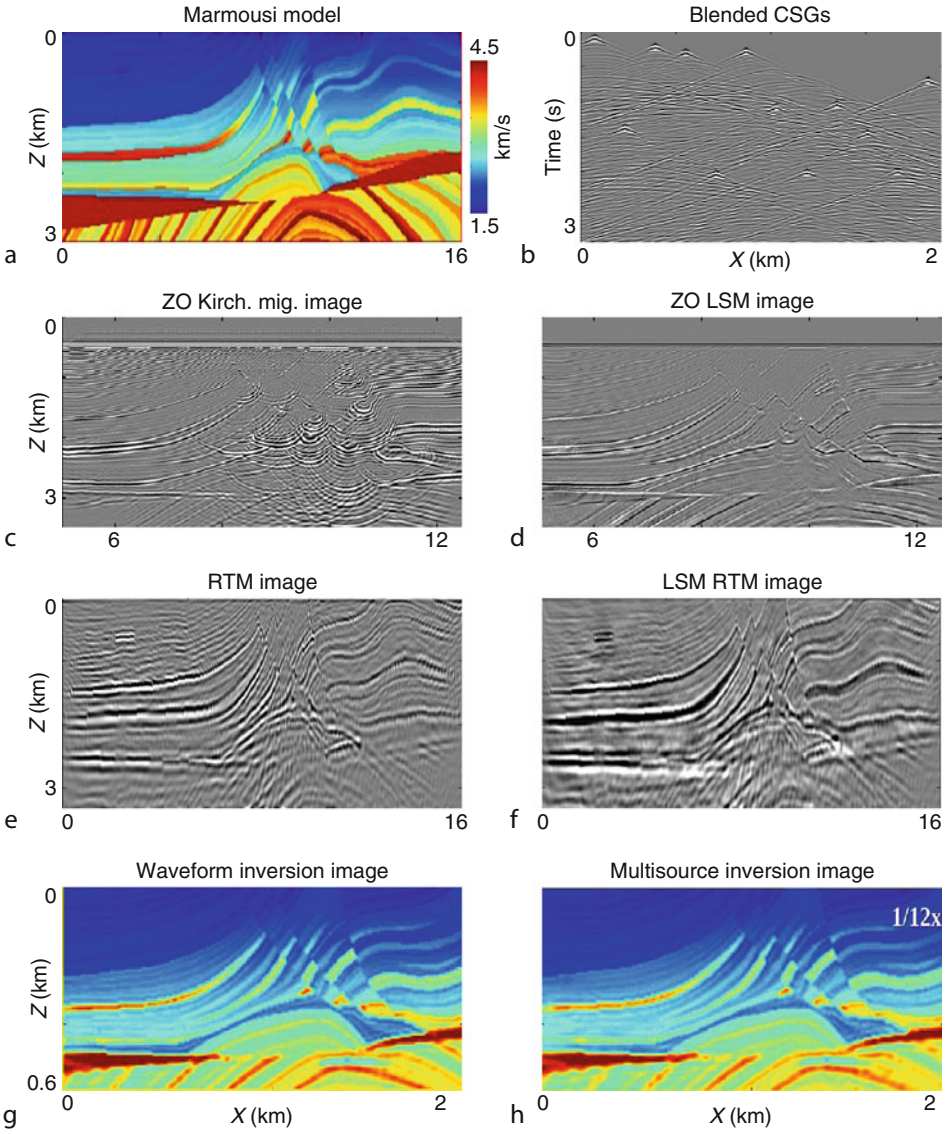
Seismic imaging or tomography (tomo = slice and graph = picture) is a procedure for estimating the earth's rock parameters from seismic data. These rock parameters can be represented by the spatial distribution of, e.g., P-wave velocity, S-wave velocity, porosity, density, or anisotropic parameters. The result of inversion is graphically presented as a 2-D or 3-D grid of pixels, where each pixel

contains the value of the model parameter of interest, which is P velocity in Figure 1g–h. Such tomograms are used to estimate the geometry and lithology of geologic layers, and can help exploration geophysicists and earthquake seismologists understand the evolution of the earth's interior.

There are five main types of seismic imaging: seismic migration, least squares migration, full waveform inversion (FWI), phase-like inversion, and migration velocity analysis. Four of these methods can be derived as special cases of finding the optimal model that minimizes a waveform or a phase-related misfit function. This entry will present these methods as they are applied to body wave events in seismic data, and overview the current best practices in waveform tomography.

Inversion theory

There are four steps to inverting for the model **m** from seismic data **d**. We will assume that the input data are either seismic traces, generated by man-made or earthquake sources, or some skeletonized part of the traces, such as first arrival traveltimes or the phase of an event at some frequency.



Seismic Imaging, Overview, Figure 1 (**a**) Marmousi velocity model, (**b**) time-shifted and blended shot gathers, (**c**) zero-offset Kirchhoff migration image, (**d**) zero-offset least squares migration image after 30 iterations (courtesy of Naoshi Aoki), (**e**) reverse time migration (RTM) image, (**f**) least squares RTM image (Dai and Schuster, 2009), (**g**) waveform tomogram after 50 iterations using the prestack gathers, and (**h**) waveform tomogram where the inputs are eight supergathers, each with 12 phase-encoded shot gathers (Zhan and Schuster, in press); images are at different scales from one another.

Step 1: $\mathbf{L}(\mathbf{m}) = \mathbf{d}$. Establish the mathematical relationship $\mathbf{L}(\mathbf{m}) = \mathbf{d}$ between the seismic data $\mathbf{d}$ and model $\mathbf{m}$.

$$\mathbf{d} = \mathbf{L}(\mathbf{m}), \tag{1}$$

where $\mathbf{L}$ represents the forward modeling operator for the actual model. Equations A1–A3 in Table 1 show the three steps in establishing a linearized version of Equation 1 for the acoustic wave equation, where the extensions to the elastic (Mora, 1987) and anisotropic (Barnes et al., 2008; Operto et al., 2009) wave equations are tedious but straightforward.

Step 2: Discretize $\mathbf{m}$, $\mathbf{d}$, and $\mathbf{L}$. Discretize the 3D earth model into a 3D grid of N physical parameters (e.g., unknown slowness in each cell) and assemble the unknowns into the $N \times 1$ vector $\mathbf{m}$. Discretize the seismic traces in both space and time (or frequency) into an $M \times 1$ vector $\mathbf{d}$ of data measurements. In this case, $\mathbf{L}$ reduces to a $M \times N$ matrix. The forward modeling for FWI requires knowledge of the source wavelet, which can be estimated in a variety of ways: stacking of the direct arrival at different near-offset hydrophones in marine data, iterative inversion of the source wavelet (Mora, 1987; Zhou et al., 1997; Pratt, 1999), or deconvolution of the shot gather with a time-windowed near-offset trace (Sheng, personal communication). The time window can be a few periods long centered about the direct arrival.

Step 3. Linearize $\mathbf{L}\delta\mathbf{m} \approx \delta\mathbf{d}$. Linearize the nonlinear relationship between the data and model. Expanding the ith data measurement $d_i(\mathbf{m})$ to first order in $\delta\mathbf{m}$ by a Taylor series about a first-guess model $\mathbf{m}_o$ (close to the true model) gives the linearized estimate:

$$\begin{aligned} d_i(\mathbf{m}) &\approx d_i(\mathbf{m}_o) + \sum_j \frac{\delta d_i(\mathbf{m}_o)}{\delta m_j}\,\delta m_j \rightarrow \delta d_i(\mathbf{m}) \\ &= \sum_j \overbrace{\left[\partial d_i(\mathbf{m}_o)/\partial m_j\right]}^{\text{wavepath function}}\,\delta m_j, \end{aligned} \tag{2}$$

or in matrix-vector notation

$$\delta\mathbf{d} = \mathbf{L}\delta\mathbf{m}. \tag{3}$$

Here, $\partial d_i(\mathbf{m}_o)/\partial m_j = \lim_{\Delta m_j \rightarrow 0}[d_i(\mathbf{m}_o + \hat{\mathbf{j}}\Delta m_j) - d_i(\mathbf{m}_o)]/\Delta m_j$ is the Fréchet derivative with respect to the jth parameter; the data residual $\delta d_i = [d_i(\mathbf{m}) - d_i(\mathbf{m}_o)]$ is the difference between the ith components of the predicted data vector $\mathbf{d}(\mathbf{m}_o)$ and the observed data vector $\mathbf{d}(\mathbf{m})$; and $\hat{\mathbf{j}}$ is the jth unit vector in the finite-dimensional model space. The model perturbation $\delta\mathbf{m} = \mathbf{m} - \mathbf{m}_o$ is the difference between the actual model $\mathbf{m}$ and the guessed model $\mathbf{m}_o$, and $\mathbf{L}$ is now interpreted as the Jacobian matrix. Its elements $[\mathbf{L}]_{ij} = \partial d_i(\mathbf{m}_o)/\partial m_j$ determine the sensitivity of the data to the perturbations in the model. For a windowed arrival, the Jacobian plots out in model space as a wavepath for a single source-receiver pair (Woodward, 1992; Luo, 1992; Dahlen et al., 2002; Marquering et al., 2002; Montelli et al., 2004; van der Hilst and de Hoop, 2006; Xu and Xie, 2009); and the velocity variations within its first Fresnel zone mostly influence the event of interest. Equation A3 shows that the linearized equations take the form of the Born approximation (Stolt and Benson, 1986) to the

Seismic Imaging, Overview, Table 1 Symbols and specific formulas for inverting the Helmholtz equation for the perturbed slowness distribution $\delta s(\mathbf{x})$, where $\delta s(\mathbf{x})$ is assumed to be small compared to the background slowness model $s(\mathbf{x})$. The harmonic pressure field is denoted by $p(\mathbf{x}|\mathbf{s})$ for a source localized about $\mathbf{s}$, and the Green's function for the Helmholtz equation is given by $G(\mathbf{x}|\mathbf{s})$ for a point source at $\mathbf{s}$ and observer at $\mathbf{x}$. The source wavelet spectrum is $W(\omega)$ at the angular frequency ω and the body force term localized about the point $\mathbf{s}$ is denoted by $f(\mathbf{x}|\mathbf{s})$. The predicted (observed) traveltime of an event received at $\mathbf{g}$ for a source at $\mathbf{s}$ is denoted as $\tau(\mathbf{g}|\mathbf{s})$ ($\tau(\mathbf{g}|\mathbf{s})^{\text{obs.}}$); and $\varepsilon = ||\mathbf{d} - \mathbf{d}^{\text{obs.}}||^2$ is the misfit function for waveform inversion

Symbol	Mathematical formula
(A1) Helmholtz equation: $\mathbf{A}(\mathbf{d},\mathbf{m}) = \mathbf{f}$	$(\nabla^2 + \omega^2 s(\mathbf{x})^2)p(\mathbf{x}\|\mathbf{s}) = f(\mathbf{x}\|\mathbf{s})$ $\mathbf{m} \rightarrow s(\mathbf{x}); \mathbf{d} \rightarrow p(\mathbf{x}\|\mathbf{s})$
(A2) Linearized Helmholtz equation: $\delta\mathbf{A}(\mathbf{d},\mathbf{m}) = 0$	$\left(\nabla^2 + \omega^2 s(\mathbf{x})^2\right)\delta p(\mathbf{x}\|\mathbf{s}) = -2\omega^2 s(\mathbf{x})\delta s(\mathbf{x}) p(\mathbf{x}\|\mathbf{s})$ $\delta\mathbf{m} \rightarrow \delta s(\mathbf{x}); \delta\mathbf{d} \rightarrow \delta p(\mathbf{x}\|\mathbf{s})$
(A3) Lippmann–Schwinger equation with Born approx.: $\delta\mathbf{d} = \mathbf{L}\delta\mathbf{m}$	$\delta p(\mathbf{g}\|\mathbf{s}) = -2\omega^2 \int G(\mathbf{g}\|\mathbf{x}) s(\mathbf{x}) \delta s(\mathbf{x}) W(\omega) G(\mathbf{x}\|\mathbf{s}) \mathrm{d}x^3$ where $p(\mathbf{x}\|\mathbf{s}) = W(\omega)G(\mathbf{x}\|\mathbf{s})$
(A4) Jacobian or wavepath function: $\delta\mathbf{d}/\delta\mathbf{m}$	$\delta p(\mathbf{g}\|\mathbf{s})/\delta s(\mathbf{x}) = -2s(\mathbf{x})\omega^2 W(\omega) G(\mathbf{g}\|\mathbf{x}) G(\mathbf{x}\|\mathbf{s})$
(A5) Misfit gradient or reverse time migration or $\mathbf{L}^\dagger[\mathbf{L}\delta\mathbf{m} - \delta\mathbf{d}]$: $\delta\varepsilon/\delta\mathbf{m}$	$\delta\varepsilon/\delta s(\mathbf{x}) = \gamma \int G(\mathbf{g}\|\mathbf{x})^* \Delta d(\mathbf{g}\|\mathbf{s}) G(\mathbf{x}\|\mathbf{s})^* \mathrm{d}g\mathrm{d}s$ where $\gamma = -2\omega^2 s(\mathbf{x}) W(\omega)$ and $\Delta d(\mathbf{g}\|\mathbf{s}) = p(\mathbf{g}\|\mathbf{s}) - p(\mathbf{g}\|\mathbf{s})^{\text{obs.}}$
(A6) Least squares migration or linearized inversion: $\mathbf{m}^{(k)} - \delta\varepsilon/\delta\mathbf{m}$	$m(\mathbf{x})^{(k)} - \gamma \int G(\mathbf{g}\|\mathbf{x})^* \Delta d(\mathbf{g}\|\mathbf{s})^{(k)} G(\mathbf{x}\|\mathbf{s})^* \mathrm{d}g\mathrm{d}s$
(A7) Waveform inversion: $\mathbf{m}^{(k)} - \delta\varepsilon/\delta\mathbf{m}$	$m(\mathbf{x})^{(k)} - \gamma \int G^{(k)}(\mathbf{g}\|\mathbf{x})^* \Delta d(\mathbf{g}\|\mathbf{s})^{(k)} G^{(k)}(\mathbf{x}\|\mathbf{s})^* \mathrm{d}g\mathrm{d}s$
(A8) Wave equation traveltime inversion: $\mathbf{m}^{(k)} - \delta\varepsilon/\delta\mathbf{m}$	$m(\mathbf{x})^{(k)} - \gamma \int G^{(k)}(\mathbf{g}\|\mathbf{x})^* \Delta d(\mathbf{g}\|\mathbf{s})^{(k)} G^{(k)}(\mathbf{x}\|\mathbf{s})^* \mathrm{d}g\mathrm{d}s$ where $\Delta d(\mathbf{g}\|\mathbf{s}) \approx p(\mathbf{g}\|\mathbf{s})^{\text{obs.}} \left(\tau(\mathbf{g}\|\mathbf{s}) - \tau(\mathbf{g}\|\mathbf{s})^{\text{obs.}}\right)$

Lippmann–Schwinger equation, and its kernel is the Jacobian given by Equation A4.

For a single source and a single receiver in a smoothly increasing velocity medium, Equation A4 plots out as a curved "fat" ray (trace a ray that connects the source and receiver and honors Snell's law. Surround this ray with a "fat finite-frequency ray" such that the propagation of events from the source to receiver within the "fat" ray differs in traveltime by no more than 1/2 the period of the source wavelet. This fat ray region is that portion of the earth which mostly influences the traveltime of the event of interest) that connects the source and receiver points. This fat ray is denoted as a wavepath by Woodward (1992) and forms the basis of finite-frequency traveltime tomography. There seems to be a general (Montelli et al., 2004), but not a universal (van der Hilst and de Hoop, 2006), agreement that finite-frequency tomography can be superior to that of ray-based tomography. As an example, earthquake seismologists use these wavepaths (renamed as banana-doughnuts) with finite-frequency tomography to invert earthquake traveltimes and surface wave data for deep mantle velocity variations attributed to, for example, ascending plumes of rocks (Dahlen et al., 2002; Marquering et al., 2002; Montelli et al., 2006).

Step 4: Solve $\mathbf{L}\delta\mathbf{m} = \delta\mathbf{d}$ by an iterative gradient method. Equation 3 is typically an overdetermined, inconsistent, and poorly conditioned system of equations. Therefore, the solution we seek is the one that minimizes the sum of the data misfit $||\mathbf{Lm} - \mathbf{d}||_K^2$ and model penalty $\lambda^2||\mathbf{Cm}||_W^2$ functions in the K and W norms (Clinthorne et al., 1993):

$$\varepsilon = \frac{1}{2}||\mathbf{L}\delta\mathbf{m} - \delta\mathbf{d}||_K^2 + \frac{\lambda^2}{2}||\mathbf{C}\delta\mathbf{m}||_W^2. \tag{4}$$

where $||\mathbf{L}\delta\mathbf{m} - \delta\mathbf{d}||_K^2 = (\mathbf{L}\delta\mathbf{m} - \delta\mathbf{d})^\dagger\mathbf{K}(\mathbf{L}\delta\mathbf{m} - \delta\mathbf{d})$ and $\mathbf{K}$ is sometimes taken as the inverse of the data covariance matrix (Tarantola, 1987) that is real and symmetric. The penalty function (also known as the regularization term) is defined as $||\delta\mathbf{Cm}||_W^2 = (\mathbf{Cm})^\dagger\mathbf{W}(\mathbf{Cm})$, where the real symmetric matrix $\mathbf{W}$ might strongly weight certain regions in the model because they mostly influence the data. The matrix $\mathbf{C}$ might be a spatial second-derivative operator in one or several directions so as to encourage solutions with smoothly varying model parameters along selected directions.

A simplified steepest descent solution for the ith model parameter m_i is given by

$$\begin{aligned} m_i^{(k+1)} &= m_i^{(k)} - \alpha \overbrace{\frac{\delta\varepsilon}{\delta m_i}}^{\text{gradient Equation A5}} \rightarrow \mathbf{m}^{(k+1)} \\ &= \mathbf{m}^{(k)} - \overbrace{\alpha\mathbf{L}^\dagger\delta\mathbf{d}^{(k)}}^{\text{migration of data residual}}, \end{aligned} \tag{5}$$

where $\lambda = 0$; $\mathbf{K} = \mathbf{I}$; α is the step length; and preconditioning is used (Beydoun and Mendes, 1989; Clinthorne et al., 1993; Causse et al., 1995) to accelerate convergence. A sequence of models is generated until the data residual falls below some acceptable level. In practice, a preconditioned conjugate gradient method (Mora, 1987; Luo and Schuster, 1991; Epanomeritakis et al., 2008), a Gauss-Newton Krylov solver (Erlangga and Hermann, 2009), or a limited memory quasi-Newton method (Pratt et al., 1998; Plessix, 2006) for different implementations of the adjoint method (Plessix, 2009) is implemented; and sometimes a direct matrix solver is used to find the Hessian inverse if the problem size is small enough (Pratt and Goulty, 1991). Approximations to the Hessian by a systematic procedure can be found in Thierry et al. (1999). There is strong evidence (Crase et al., 1990; Brossier et al., 2010) that using the L_1 norm misfit function is noticeably more resistant to data noise than the L_2 norm misfit function, and the combination of the two is sometimes the best choice.

Five types of seismic imaging methods

Five types of seismic imaging methods and their resolution properties will be discussed (there are many seismic inversion methods, but the five types discussed here are often used in the geophysical community): migration (modest resolution of reflectivity), least squares migration (high resolution of reflectivity), full waveform inversion (high resolution of velocity), phase-like inversion (modest resolution of velocity), and migration velocity analysis (modest resolution of velocity). The high-resolution methods typically pay the price of increased computational cost and decreased robustness, compared to the moderate-resolution methods with relatively low cost and desirable robustness. For reflection migration and inversion, the spatial resolution limits are approximately defined by a generalized Radon transform analysis (Beylkin et al., 1985); and the resolution limits for ray-based transmission tomography (Williamson, 1991) can be estimated by considering the width of the transmission Fresnel zone.

Migration is the first iterate solution of Equation 5, and least squares migration, sometimes known as linearized inversion, is the final iterative solution where the operator $\mathbf{L}$ is not updated after each iteration; also, $\mathbf{m}(\mathbf{x})$ represents the reflectivity model at the position $\mathbf{x}$. In contrast to migration, the waveform inversion tomogram is the final iterative solution, where the velocity model $\mathbf{m}$ and $\mathbf{L}$ are updated after every iteration; waveform inversion falls under the class of nonlinear optimization methods. It can be shown under certain assumptions that waveform inversion reduces to either wave equation traveltime tomography (Luo and Schuster, 1991) or ray-based tomography. These last two methods are classified as phase-like inversion methods. Unlike minimizing the data misfit function in Equation 4, migration velocity analysis updates the velocity model to minimize a *model misfit function*, which is the normed difference between the predicted migration image and the actual migration image

in the, e.g., common image gather. Convergence problems associated with local minima in the misfit function are reduced by emphasizing *flatness* in the CIG misfit function (Symes and Carazone, 1991; Shen et al., 1993).

Migration

If the starting model is a smoothly varying velocity distribution that only generates the accurate first arrival, then the input data $\mathbf{d} - \mathbf{d}^{(0)}$ residual becomes the scattered data. In this case the desired model is the reflectivity distribution, which is similar to the slowness perturbation function $\delta s(\mathbf{x})$, and the background velocity model is the inverse of slowness $s(\mathbf{x})$. If a finite-difference solution to the wave equation, for example, is used to calculate $G(\mathbf{x}|\mathbf{s})$ and $G(\mathbf{g}|\mathbf{x})$ in Equation A5, then the first model update $\delta\mathbf{m}^{(1)}$ in Equation 5 is known as the reverse time migration image (Whitmore, 1983; McMechan, 1983). If a one-way wave equation method is used to generate the Green's function, then the migration method is a phase-shift or FX-type algorithm (Stolt and Benson, 1986; Claerbout, 1992; Etgen et al., 2009). A diffraction-stack migration method results if the Green's function is replaced by its asymptotic approximation $G(\mathbf{x}|\mathbf{s}) = A(\mathbf{x},\mathbf{s})e^{i\omega\tau_{xs}}$ (here, $A(\mathbf{x}, \mathbf{s})$ accounts for geometric spreading losses, and τ_{xs} is the first arrival time for a ray that connects the source at $\mathbf{s}$ with the observer at $\mathbf{x}$. A ray-tracing method can be used to compute these traveltimes for a sufficiently high frequency and smoothly varying medium [Bleistein et al., 2001]). An example of standard poststack migration is depicted in Figure 1c, where the velocity model is shown in Figure 1a. The migration image depicts the reflectivity distribution computed by a Kirchhoff migration method with an eikonal traveltime solver.

Seismic migration is also used to migrate teleseismic body waves processed to form so-called receiver functions. Examples include Ryberg and Weber (2000), Sheehan et al. (2000), and also Bostock et al. (2001) who used a ray-Born inversion approach. More recently, Nowack et al. (2007) applied the Gaussian beam migration approach of Hill (2001) to the migration of teleseismic body waves. Despite its widespread use and its robustness, migration is considered to be a moderate-resolution method because it approximates the inverse Hessian matrix $[\mathbf{L}^{\dagger}\mathbf{L}]^{-1}$ by a diagonal matrix.

Least squares migration

If the background model $1/s(\mathbf{x})$ is not updated after each iteration (i.e., $\mathbf{L}$ in Equation 5 is independent of the k index), then $\mathbf{m}^{(k+1)}$ for large k is known as the least squares migration image (Nemeth et al., 1999; Duquet et al., 2000). As in standard migration, the model to be iteratively updated is the reflectivity distribution and not the velocity model. The iterative least squares migration Equation A6 is interpreted as a sequence of standard migrations, where the data residual is backprojected into the earth model by the migration operator $\mathbf{L}^{\dagger}$. Least squares migration (LSM) is also known as linearized waveform inversion (Lailly, 1984; Tarantola, 1986, 1987; Jin et al., 1992; Lambaré et al., 1992) and is superior to standard migration by reducing migration artifacts caused by a poor acquisition geometry; it also can provide a spatial resolution that is more than twice (Nemeth et al., 1999; Yu et al., 2006) that of standard migration if the migration velocity is sufficiently accurate. Its main drawbacks are that its effectiveness is very sensitive to the accuracy of the migration velocity model, and it can be more than an order of magnitude more expensive than standard migration. (Recent developments [Dai and Schuster, 2009] in phase-encoded migration suggest a great reduction in the cost of LSM.) As an example, Figure 1d depicts the LSM image obtained from zero-offset (ZO) data, which is more accurate than the ZO standard migration image in Figure 1c. Figure 1e–f depict the RTM and LSM RTM images obtained from the prestack shot gathers.

Full waveform inversion

If the background model is updated after each iteration, then Equation A7 is known as nonlinear waveform inversion (Tarantola, 1987; Mora, 1987; Mora, 1989; Song et al., 1995; and many others); a common designation for waveform inversion is FWI or full waveform inversion. Unlike LSM or standard migration, Equation A7 for FWI iteratively updates the velocity and reflectivity models so that the final velocity image can be much improved in both resolution and accuracy. Its main drawbacks are a tendency to get stuck in local minima, it is computationally expensive compared to standard migration, and there might be more than one model that can explain the same data, i.e., a nonunique solution. For example, elastic isotropic modeling codes can sometimes generate predicted traces that adequately fit the observed data, but the estimated isotropic velocity model is inconsistent with the actual anisotropic rocks in the real earth.

Successful examples of waveform tomography images are shown in Figure 1g–h and were obtained from the same shot gathers used for migration. The final tomogram shows the velocity distribution that is almost identical to that of the actual model. One of the keys to success in waveform inversion is that a good starting model is often required for an accurate result. This starting model can be obtained by migration velocity analysis (Stork, 1992; Jousselin et al., 2009), reflection traveltime tomography (Langan et al., 1985; Bishop et al., 1985; Nolet, 1987; Zelt, 2002), or refraction tomography (Pratt and Goulty, 1991; Luo and Schuster, 1991; Min and Shin, 2006; Sheng et al., 2006).

A major challenge to the success of waveform inversion is the limited offset range between sources and receivers and the lack of low-frequency information in the recorded data (Sirgue and Pratt, 2004; Barnes et al., 2008; Boonyasiriwat et al., 2009; Kelly et al., 2009). Such deficiencies can prevent waveform inversion from reconstructing the low wave-number parts of the model, and sometimes prevent convergence to any type of

reasonable model. Remedies being explored include the possibility of recording data at much lower frequencies with more capable recording devices, and obtaining very wide-offset data. Other challenges address the validity of the acoustic approximation versus the reality that the recorded data are largely of elastic (Vigh et al., 2009) or viscoelastic nature (Causse et al., 1999; Askan, 2006). Elastic inversion of elastic seismograms (Mora, 1987; Mora, 1989; Zhou et al., 1997; Brossier et al., 2009) have been presented, but the acoustic approximation can still provide useful results. One approach to viscoelastic inversion is to invert for the acoustic velocity first, then follow this with inversion for attenuation parameters (Kamei and Pratt, 2008); another approach is to use a ray-based method to invert for the attenuation factor Q and then use this Q to correct for the attenuation in the data (Pratt et al., 2005; Sheng et al., 2007; Boonyasiriwat et al., 2009).

Wave equation traveltime inversion

If the data residual $\delta d(\mathbf{g}|\mathbf{s})$ is replaced by the traveltime residual $\delta\tau(\mathbf{g}|\mathbf{s})$ weighted by the recorded trace $d(\mathbf{g}|\mathbf{s})^{\text{obs.}}$, then this is known as wave equation traveltime (Luo and Schuster, 1991) tomography (WT); it is a variant of Rytov inversion (Woodward, 1992) and updates the velocity model by smearing weighted traveltime (not waveform) residuals over the associated wavepaths (Woodward, 1992; Luo, 1992). In the high-frequency limit, it reduces to ray-based traveltime tomography (RT). The advantage of WT over RT is that it does not require a high-frequency approximation and accounts for the band-limited nature of waves as they propagate through the earth. Shin et al. (2002, 2007) use a modified logarithm norm to invert for phase data, which bears a close relationship to the Rytov inversion method; and Effelsen (2009) compares phase inversion to traveltime tomography for inverting refraction events. Figure 2 illustrates how the above seismic imaging methods are related to one another.

The main disadvantage of WT is that it is at least an order of magnitude more expensive than RT because it requires a finite-difference solution of the wave equation rather than a ray-traced approximation. Earthquake seismologists often see wave equation traveltime as a major improvement in estimating the earth's velocity parameters from earthquake records (Dahlen et al., 2002; Marquering et al., 2002; Montelli et al., 2006; van der Hilst and de Hoop, 2006).

Migration velocity analysis

The previous imaging methods can be described as estimating the earth model by predicting synthetic data that *best matches the observed data in the data domain*. In contrast, migration velocity analysis (MVA) finds the velocity model that *best flattens or focuses the migration sections in the image domain*; here, the image domain is the migration cube in the (x, y, z) indices and some other index s such as shot index, receiver index, source-receiver offset, (Yilmaz and Chambers, 1984; Faye and Jeannot, 1986; Al-Yahya, 1989; Toldi, 1989; Stork, 1992; Lafond and Levander, 1993), common angle parameter (Xu et al., 1998), or subsurface offset coordinate (Rickett and Sava, 2002; Sava and Biondi, 2004; Robein, 2010).

To understand why we seek a velocity model that flattens events in the image domain, consider the 2D migration image $m(x, z, s_0)$ in Figure 3a obtained by migrating one shot gather (the source is at the surface with shot index s_0). If the migration velocity is correct, then all of the single-shot migration images should be similar in appearance. This means that all of the migrated reflection events should be flat in the common image gather (CIG) given by $m(x_{\text{CIG}}, z, s)$ for all values of s, z, and a fixed value of x_{CIG} (see Figure 3b). Note that if the migration velocity is accurate, the reflector boundary denoted by the dotted horizontal line will be flat for a common image gather. If the migration velocity is too slow, then the imaged reflector boundary will curve upward as illustrated by the curved dashed line, and if too fast, the imaged reflector will curve downward.

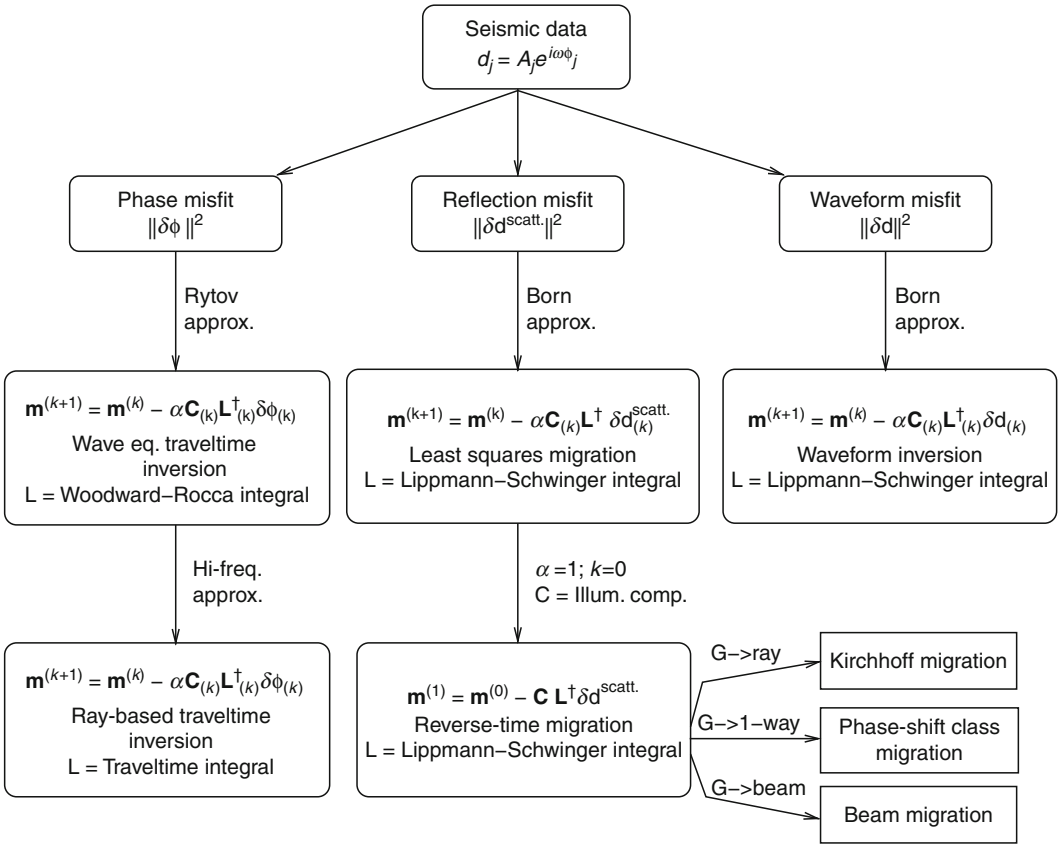
With MVA, the goal is to find the velocity model so that, ideally, the predicted migration image $\mathbf{m}_{\text{mig.}}^{\text{pred.}} = \mathbf{L}^{\dagger}\mathbf{L}\mathbf{M}$ best fits the actual migration image $\mathbf{m}_{\text{mig.}} = \mathbf{L}^{\dagger}\mathbf{d}$. The associated misfit function can be constructed so that it is similar to that of Equation 4, except that the norm of the *migration* residual

$$\varepsilon = \frac{1}{2}||\mathbf{m}_{\text{mig.}}^{\text{pred.}} - \mathbf{m}_{\text{mig.}}||_K^2 + \frac{\lambda^2}{2}||\mathbf{C}\mathbf{m}||_W^2 \tag{6}$$

is minimized rather than the *data* residual; in this case, $\mathbf{m}$ represents the velocity model. To find the velocity model, we can use the unregularized steepest descent equation:

$$\mathbf{m}^{(k+1)} = \mathbf{m}^{(k)} - \overbrace{\alpha\mathbf{L}^{\dagger}\mathbf{L}\delta\mathbf{m}_{\text{mig.}}^{(k)}}^{\text{migration}-\text{modeling of migration residual}}, \tag{7}$$

where $\delta\mathbf{m}_{\text{mig.}}^{(k)} = \mathbf{m}_{\text{mig.}}^{\text{pred.}} - \mathbf{m}_{\text{mig.}}$ is the migration residual at the kth iteration. The importance of this formula is that it shows that the gradient term is computed by modeling the migration residual to get the *filtered* data residual $\mathbf{L}\delta\mathbf{m}_{\text{mig.}}^{(k)}$, and then the velocity model is updated by smearing this filtered (the filtered data residual is constructed by migrating and modeling the actual data residual; hence, it is a filtered version of the actual data residual) data residual into the model by the migration operation $\mathbf{L}^{\dagger}[\mathbf{L}\delta\mathbf{m}_{\text{mig.}}^{(k)}]$. These filtered residuals are smeared along wavepaths for each source-receiver pair of traces, and the migration and modeling operators are updated after each iteration. This leads to a moderate resolution of the velocity model because the filtered, not unfiltered, data are kinematically fitted. Moreover, MVA



Seismic Imaging, Overview, Figure 2 Three types of seismic imaging methods: phase inversion, least squares migration (LSM), and nonlinear waveform inversion. Note that LSM is a linearized inversion so that the modeling operator **L** does not get updated after each iteration. This compares to nonlinear waveform inversion which updates **L** after each iteration. The Lippmann–Schwinger-type and Woodward–Roca-type integrals are displayed in Table 1, and details about various migration methods are in the Seismic Migration section in the *Encyclopedia of Solid Earth Geophysics*. The traces that only contain scattered arrivals are obtained by muting the direct arrivals; and the ensemble of these traces is symbolized by the vector $\mathbf{d}^{scatt.}$. Instead of computing the Green's functions in the integral equations by a finite-difference solution to the wave equation, various approximations such as ray-based Green's functions (Kirchhoff migration), one-way wave equation approximations (phase-shift type migration), and Gaussian Beam (beam-like migration) are used for migration.

is largely a curve fitting exercise that is mostly insensitive to subtle amplitude variations in the migration traces; ignoring such information will blind MVA to subtle variations in the impedance distribution.

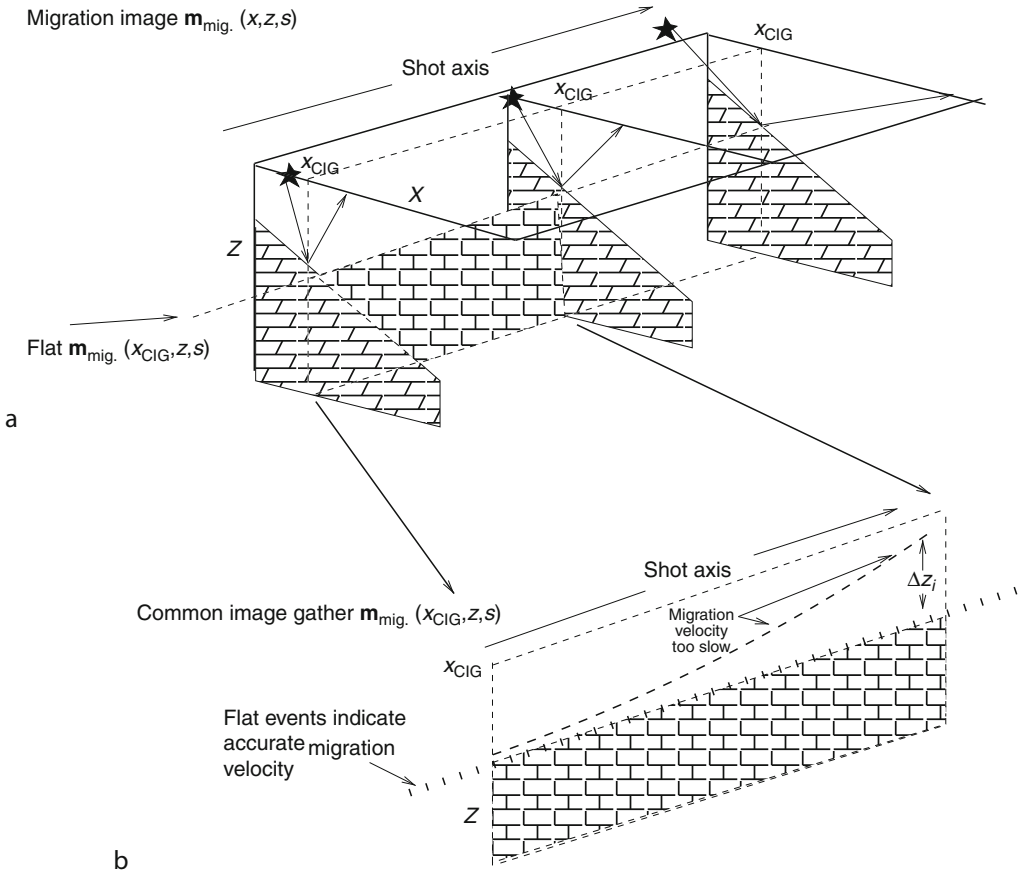
To reduce computational costs and increase robustness at the expense of reduced model resolution, MVA is sometimes implemented with the following steps:

1. Automatically pick the depth residual $\Delta z_i = z_i - z_i^{\text{ref.}}$ of a coherent CIG event in Figure 3b at the ith shot position; here, z_i is the picked depth of the targeted reflection at the x_{CIG} offset in the ith migrated shot gather. The depth $z_i^{\text{ref.}}$ of the reference event for that reflector is estimated from the near-offset trace in that CIG. A computer algorithm can window about the near-offset reflection of interest and use crosscorrelation with neighboring traces in the CIG to estimate the depth lag $z_i - z_i^{\text{ref.}}$ associated with the strongest correlation energy.
2. The misfit function is then defined as

$$\varepsilon = 1/2 \sum_i (\Delta z_i)^2 + \text{model smoothness constraints}, \tag{8}$$

for each CIG and the summation is over the shot index in Figure 3b. Sometimes the misfit function is the sum over all CIGs.
3. The velocity model is iteratively updated by a gradient optimization method until ε is minimized.

An example of the above procedure is shown in Figure 4, where the left column of images depict the (a) migration image obtained with an inaccurate velocity



Seismic Imaging, Overview, Figure 3 (**a**) Migration image $\mathbf{m}_{\text{mig.}}(x, z, s)$ cube in the model coordinates of x and z and the surface shot offset index s; the common image gather $\mathbf{m}_{\text{mig.}}(x_{CIG}, z, s)$ is computed by migrating the shot gathers and displaying the migration image at the fixed value of $x = x_{CIG}$ for all shot s and depth z values. (**b**) Common image gather $\mathbf{m}_{\text{mig.}}(x_{CIG}, z, s)$ for the common image point at x_{CIG}. The migration image should only be non-zero along the interface between the brick region and open regio shown above.

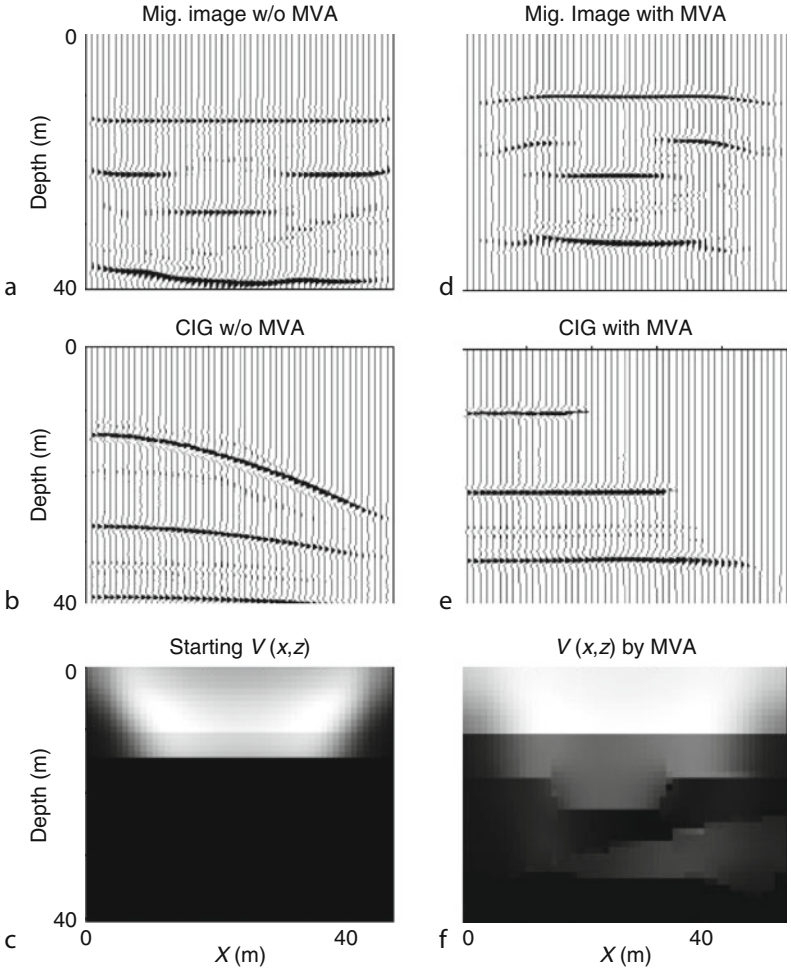
model, (b) the CIG with curved events, and (c) the migration velocity model. After seven iterations of MVA, the right column of figures is obtained. Note the flat events in the CIG, and the final velocity model is almost the same as the actual velocity model.

The Fréchet derivative $\frac{\partial z_i}{\partial c(\mathbf{X})}$ associated with the gradient of ε can be numerically computed by using a ray-tracing scheme (Stork, 1992; Chauris et al., 1998) to determine the change in depth z_i of a migrated reflection point with respect to a change in the velocity parameter at $\mathbf{x}$. Sometimes, the depth residual Δz_i for the ith ray is converted into a time residual $\Delta\tau_i$ and, similar to traveltime tomography, this *converted* time residual is smeared along the reflection ray to iteratively update the velocity model. For arbitrary reflector geometries in a homogeneous media, an analytic conversion formula was derived by Al-Yahya (1989), and a ray-tracing method was used by Stork (1992) and others (Robein, 2010).

Similar to waveform inversion, MVA seeks to predict the wiggly migration traces seen in the migration image $\mathbf{L}^{\dagger}\mathbf{d}$ and, therefore, can easily get stuck in the many local minima of ε. To avoid this problem, Symes and Carazone (1991) proposed the smoother differential semblance misfit function (Chauris et al., 1998; Shen et al., 2003):

$$\varepsilon = 1/2||\sum_{x,y}[\gamma\sum_{z}\sum_{h}\partial m(x,y,z,h)_{\text{mig.}}/\partial h^2]||^2 + \text{constraints}. \tag{9}$$

that rewards flat events (i.e., accurate velocity models) in the CIG domain. Here, γ is a normalization term that depends on (x, y). Empirical tests by Chauris et al. (1998) suggest that the semblance based ε is much smoother than that in Equation 6 and is nearly devoid of local minima in misfit function. Some links between MVA and FWI are established in Symes (2008), and MVA compared to several tomography methods is presented by Le Bégat et al. (2004). The subsurface offset domain can be exploited for MVA (Sava and Biondi, 2004) and extraction of scattering angle information



Seismic Imaging, Overview, Figure 4 (**a**) Migration image (Sun, 2001) obtained by prestack migration using the smooth homogeneous velocity model in (**c**) that is far from the true model approximated in (**f**); (**b**) common image gather in the shot offset index, where the curved events indicate an incorrect velocity model; (**c**) incorrect migration velocity model used to compute (**a**); (**d**) migration image obtained after seven iterations of MVA; (**e**) CIG after seven iterations of MVA; and (**f**) velocity model inverted by seven iterations of MVA. This result closely closely resembles the true velocity model.

(Rickett and Sava, 2002), and an excellent summary of MVA research is given in Robein (2010).

In summary, the exploration community heavily favors MVA over many other velocity estimation methods because it is robust, efficient, and the picking of depth residuals is easily automated in the migration image domain. (Traveltimes picked from traces are notoriously difficult to automate because waveforms often interfere with one another. In comparison, migration untangles these events and focuses them to their origin along the reflectors so that automatic picking is easier in the CIG. Sometimes semblance methods are used to find the best fit hyperbolic or parabolic curve to the data [Robein, 2010].) Its chief disadvantage is that an MVA image lacks the detailed resolution of waveform inversion, which suggests that MVA should be used to estimate the starting velocity models for waveform tomography.

Recent advances in seismic imaging

In the last 15 years, several breakthroughs have enabled practical waveform inversion of seismic data. One of these advances is the relentless increase in computational capabilities of cluster computers and GPU-like processors, and two others are multiscale inversion and phase-encoded waveform inversion.

Multiscale waveform inversion

One of the main difficulties with waveform inversion is that the misfit function is plagued by many local minima. If the starting velocity model is moderately far from the actual model (an erroneous velocity might be one where the modeled events arrive by more than a period after the actual arrivals), then the iterative gradient solution gets stuck there and never reaches the global minimum or actual model.

The partial cure to this local-minima problem is a multiscale approach (Bunks et al., 1995), where the initial iterations estimate a coarse-grid velocity model from low-frequency data. For a reasonable starting model, this often prevents getting stuck in local minima because the predicted low-frequency arrivals are more likely to arrive within a period of the arrivals in the low-pass filtered data. After a number of iterations, the velocity model is refined to a finer scale (the grid interval is halved) and intermediate frequency data are iteratively inverted to update the velocity model. After suitable reduction of the data misfit, the model grid is refined again and higher-frequency data are inverted until a satisfactory model is reconstructed. One of the first relevant demonstrations of multiscale FWI applied to real data in a complex environment was performed by Ravaut et al. (2004). Other results with both synthetic and field data (Sirgue and Pratt, 2004; Sirgue et al., 2007; Plessix, 2009; Vigh and Starr, 2007, 2008; Sirgue et al., 2010) convincingly demonstrate the effectiveness of this approach. As mentioned earlier, improved model reconstructions can be achieved if more accurate starting models are employed, lower frequency data are recorded, and wider offset data are acquired. The new challenges are to employ modeling and inversion codes that robustly take into account the effects of viscoelasticity and anisotropy in the data.

Phase-encoded multisource waveform inversion

A major difficulty, until recently, is the enormous computational expense of waveform inversion. Each shot gather of residuals must be migrated at each iteration, which for 3D problems can be too demanding even for the most powerful computers. To relieve this problem, Krebs et al. (2009), Virieux and Operto (2009), and Dai and Schuster (2009) proposed summing phase-encoded shot gathers into supergathers and migrating the supergathers at each iteration; a supergather is modeled with just one finite-difference simulation, where the computational cost is the same as that for one shot gather. This is similar to the phase-encoding RTM of Romero et al. (2000), except iterations are used to reduce the crosstalk noise in supergather migration. The result can be an enormous cost savings compared to conventional waveform inversion or migration.

Figure 1h shows an example of phase-encoding shot gathers, where each trace in a shot gather has the same random time shift but different shots have different time shifts. In this case, 12 shot gathers were time-shifted and blended together into one supergather; there were 192 traces per shot gather. A total of 16 nonoverlapping supergathers were input into the iterative waveform inversion code, where each supergather migration costs the same as the migration of one shot gather because 12 shots were excited at nearly the same time. Hence, the Figure 1h tomogram costs 1/12 that of the Figure 1g tomogram. For 3D inversion, the computational cost savings can be more than two orders of magnitude compared to conventional waveform inversion.

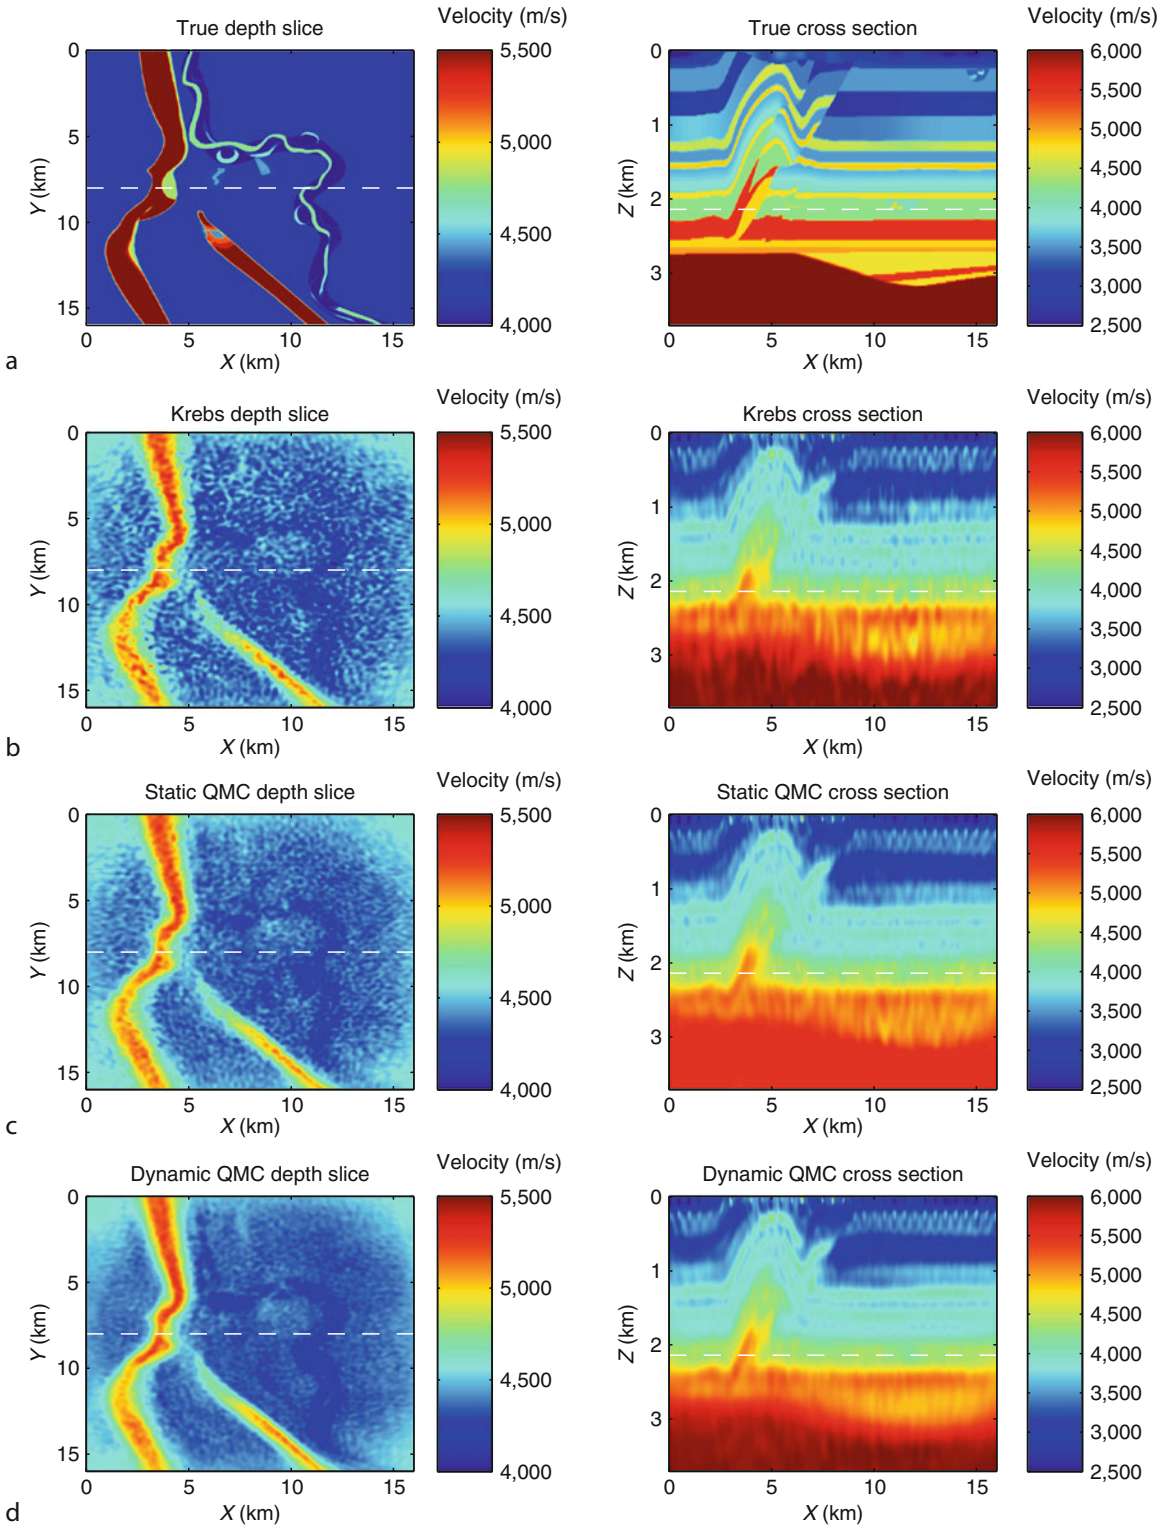
For a 3D example, Figure 5a shows results after waveform inversion of 3D synthetic data, where the model size is 800 × 800 × 186 grid points and the spatial sampling interval is 20 m. There are 1,089 sources evenly distributed along the surface with an interval of 500 m in the inline (X) and crossline (Y) directions. Multisource waveform inversion using the Krebs method (Krebs et al., 2009), static Quasi-Monte Carlo (QMC) phase encoding, and dynamic QMC phase encoding (Boonyasiriwat and Schuster, 2010) are applied to this data set.

Figure 5b–d show that dynamic QMC phase encoding provides a higher-quality tomogram than the other methods, yet the computational cost is two orders of magnitude less than that of conventional waveform inversion. The Krebs strategy is the most efficient because 1,089 shot gathers were blended into one supergather, compared to the QMC strategies that used 99 CSGs/supergather. Dynamic phase encoding changed the time shifts of each shot gather after each iteration, while the static strategy kept the phase encoding the same.

Current status and future of seismic imaging

Reverse time migration is becoming the preferred means for seismic imaging beneath complex regions such as salt bodies. Earthquake seismologists are now recognizing the benefits of migration imaging earthquake records for tectonic structures such as subduction zones (Bostock et al., 2001) or using wide-angle seismic experiments to image the crust (Brenders and Pratt, 2007) and mantle (Montelli et al., 2006). Least squares migration and waveform inversion are now being considered as viable upgrades to standard migration because of the tremendous speedup from phase-encoded multisource methodology. There is still a debate about whether waveform inversion should be computed in the frequency (there are additional advantages by formulating the problem in the Laplace transform domain [Shin and Ha, 2008]) or time domains (Vigh and Starr, 2007; Warner, 2008), but there is no debate that we eventually need to account for viscoelastic and anisotropic effects in the data.

3D waveform inversion of earthquake records for whole earth tomograms greater than 1 Hz is still too computationally demanding except at very low frequencies, and the same can be said for 3D exploration geophysics at frequencies above 50 Hz. Challenges still remain, especially in the critically important area of anisotropic RTM (Zhang and Zhang, 2009; Fowler et al., 2010) and waveform inversion; estimation of accurate anisotropic migration velocity models is an ongoing line of research. Earthquake seismologists are now testing the possibility of using earthquake records for inverting basin structures and velocity models so as to improve their simulation-based predictions of earthquake hazard. Passive seismic recordings and the use of interferometry to extract surface wave records (Shapiro and Campillo, 2004; Shapiro et al., 2005), followed by inversion for S-velocity tomograms are playing an increasingly important role in earthquake seismology.



Seismic Imaging, Overview, Figure 5 Depth slices at $z = 2.1$ km and cross-sections at $y = 8$ km of (**a**) true model, and inverted models using (**b**) the Krebs method (1089 CSGs/supergather), (**c**) static QMC method (99 CSGs/supergather), and (**d**) dynamic QMC method (99 CSGs/supergather) after 40 iterations. A greater number of CSGs/supergather require a greater number of iterations to get the same accuracy in the final tomogram; the dynamic encoding strategy is more effective than the static strategy. Seismometry

Definition

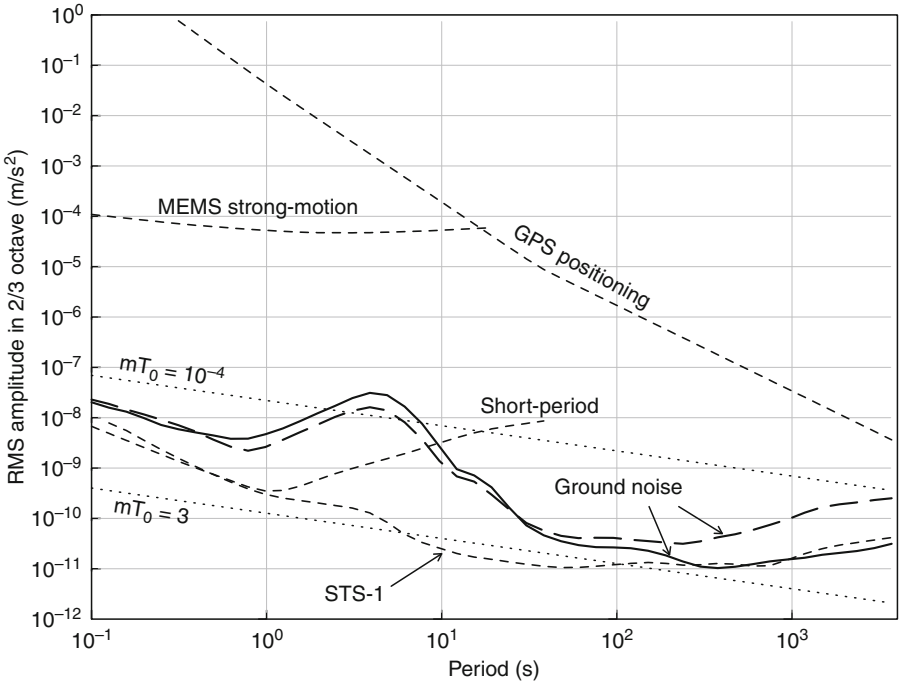
Datalogger. Device for recording electrical signal from a seismometer, usually in digital form and with accurate time information.
Geophone. Another name for seismometer, used in geophysical exploration.
Seismometer. Device for providing a record of ground motion, usually by converting it into an electrical signal.
Strainmeter. Device for continuously measuring the deformation of the Earth, either as extension along a line, or volume change.

Introduction

Seismic instruments give a time record of ground motion caused by elastic waves. The first instruments were built at the end of the nineteenth century; subsequent developments have evolved towards wider coverage of both the frequency and amplitude of the waves that could be recorded. Over most of the twentieth century much of this evolution, and of the diversity of instrument types, was related not to how ground motion was sensed but to how it was recorded; the last 3 decades have seen such rapid development in digital technology, especially in data storage, that recording techniques unique to seismology are no longer needed. Modern seismic systems all consist of a seismometer for converting some aspect of ground motion into an electrical signal, and a datalogger for recording this signal. In exploration geophysics, the name geophone is a common synonym for seismometer; now that data recording is clearly separated from sensing ground motion, the old term seismograph could probably be abandoned. Since dataloggers are not unique to seismology, this article discusses only the general requirements for them, focusing instead on the designs of seismic sensors, or seismometry. Three recent reviews cover seismometry in more detail: Wielandt (2002), Havskov and Alguacil (2004), and Bormann (2009).

Requirements for instruments

The frequencies to be measured by seismometers range from 0.31 mHz (the slowest free oscillation) up to 1 kHz (in near-surface geophysics): roughly 6 orders of magnitude. Figure 1 shows the amplitudes that can occur over most of this frequency range, from the background noise level at quiet sites (Berger et al., 2004) to the large signals that have been observed at moderate distances from very



Seismic Instrumentation, Figure 1 Seismic and instrument noise levels. The solid and long dashed lines show the lowest levels of vertical and horizontal ground motion observed by the stations of the Global Seismographic Network. The dotted lines show the seismometer Brownian noise limit for two different values of the product of the sensor mass and free period. The dashed lines show the noise levels for a high-quality short-period system using a moving-coil transducer (Rodgers, 1994), for a MEMS sensor used for measuring strong motion (Evans et al., 2005), for a sensitive broadband system (Ringler and Hutt, 2009), and for GPS used at seismic frequencies.

large earthquakes, to the even larger, and damaging, strong ground motions close to an earthquake. The large signals are infrequent, but also of considerable scientific importance – but so are very small signals, which can be seen only if the seismometer has lower noise than the ground does.

Since digital dataloggers can record over a much wider range of amplitudes and frequencies than the older analog recorders could, modern seismic systems can be characterized as broadband (covering a wide band of frequencies) and high dynamic range (a wide range of amplitudes). But the range from noise to the largest signal covers over 10 orders of magnitude, too much for any single instrument and datalogger. Since most seismometer designs require practical tradeoffs between low-frequency capability and other performance goals, seismometers are still classified by what frequencies and amplitudes they cover best. Systems for recording the largest signals without distortion are called *strong-motion* seismometers, and have usually been designed to meet the needs of earthquake engineers rather than seismologists, though digital technology is blurring this distinction.

Inertial seismometers: basic principles

Almost all seismometers measure motion of the ground using the inertia of an internal mass, and so are called *inertial* sensors. This mass, of amount m, is subject to five forces: (1) constraints that restrict the mass motion to be in a particular direction (denoted by a unit vector $\mathbf{e}$) making the system one with a single degree of freedom; (2) the gravitational force vector, $\mathbf{g}m$, along that direction, namely, $\mathbf{e} \cdot \mathbf{g}m$; (3) an elastic restoring force (from a spring), $-k(x - x_0)$, where k is the spring constant and x the displacement (in the direction $\mathbf{e}$) away from an equilibrium position x_0; (4) a viscous damping force proportional to velocity $-d\dot{x}$; (5) additional forces F_b that may be applied by a feedback system (discussed below).

The displacement of the mass relative to an inertial frame is $x + \mathbf{e} \cdot \mathbf{u}$, where x is the motion of the mass relative to the Earth, which is what we can measure, and $\mathbf{u}$ is the (vector) motion of the Earth relative to the inertial frame, which is that of the Earth in the absence of seismic waves (we can neglect non-inertial effects from the Earth's rotation). Combining forces (2), (3), and (4), and applying the momentum equation, the acceleration of the mass is given by

$$m(\ddot{x} + \mathbf{e} \cdot \ddot{\mathbf{u}}) = \mathbf{e} \cdot \mathbf{g}m - k(x - x_0) - d\dot{x}$$

where we allow the possibility of variations in both $\mathbf{e}$ and $\mathbf{g}$. With no motion, we assume that the mass position is x_0, so that $\mathbf{e}_0 \cdot \mathbf{g}_0 m = -kx_0$. Then the above equation

becomes, for small variations in **e** and **g**, and after some rearrangement of terms,

$$\frac{k}{m}x + \frac{d}{m}\dot{x} + \ddot{x} = -\mathbf{e}_0 \cdot \ddot{\mathbf{u}} - \mathbf{e}_0 \cdot (\mathbf{g} - \mathbf{g}_0) - (\mathbf{e} - \mathbf{e}_0) \cdot \mathbf{g}_0$$

more usually written as

$$\ddot{x} + 2\gamma\dot{x} + \omega_0^2 x = -\mathbf{e}_0 \cdot \ddot{\mathbf{u}} - \mathbf{e}_0 \cdot (\mathbf{g} - \mathbf{g}_0) - (\mathbf{e} - \mathbf{e}_0) \cdot \mathbf{g}_0 \quad (1)$$

where $\omega_0 = \sqrt{k/M}$ is the natural frequency of the seismometer ($T_0 = 2\pi/\omega_0$ is called the free period); $\gamma = d/2M$ is the damping constant. These names describe the behavior of the seismometer if the right-hand side of the equation is zero and $x = x_0$ at $t = 0$; the subsequent motion of the seismometer mass is then

$$x(t) = x_0 cos\left(\frac{2\pi t}{T_0}\right) e^{-\gamma t},$$

which is a decaying sinusoid with period T; the damping γ needs to be large enough to avoid ringing (a sign of resonance effects), and is usually set to about 0.8.

The right-hand side of Equation 1 shows that an inertial sensor responds to three inputs:

1. The acceleration of the ground, $\ddot{\mathbf{u}}$; this is why inertial sensors are often called accelerometers.
2. Changes in the gravitational vector **g** along the direction of sensitivity; if this is the dominant signal, the sensor is usually referred to as a gravimeter (see *Gravimeters*).
3. Changes in the direction of sensitivity relative to the direction of gravity. If $\mathbf{e}_0$ and $\mathbf{g}_0$ are parallel (the mass moves vertically), then to first order $\mathbf{e} - \mathbf{e}_0$ is perpendicular to $\mathbf{g}_0$, and this contribution is zero. However, if $\mathbf{e}_0$ and $\mathbf{g}_0$ are perpendicular (the mass moves horizontally), then to first order $\mathbf{e} - \mathbf{e}_0$ is parallel to $\mathbf{g}_0$, and this contribution can be significant; if this is the dominant signal, the sensor would be referred to as a tiltmeter, since changes in **e** reflect tilting of the sensor (or the ground it is attached to).

Much confusion has been created by the use of these different terms for what is the same kind of sensor, when the difference actually refers to the type of signal being measured.

Ignoring the tilt and gravity terms, suppose that the ground displacement is purely sinusoidal, $u(t) = Ue^{i\omega t}$ (U being complex, and the real part being taken). Then the mass motion will be $Xe^{i\omega t}$, where

$$\frac{X}{U} = \frac{\omega^2}{\omega_0^2 - \gamma i\omega + \omega^2} \quad (2)$$

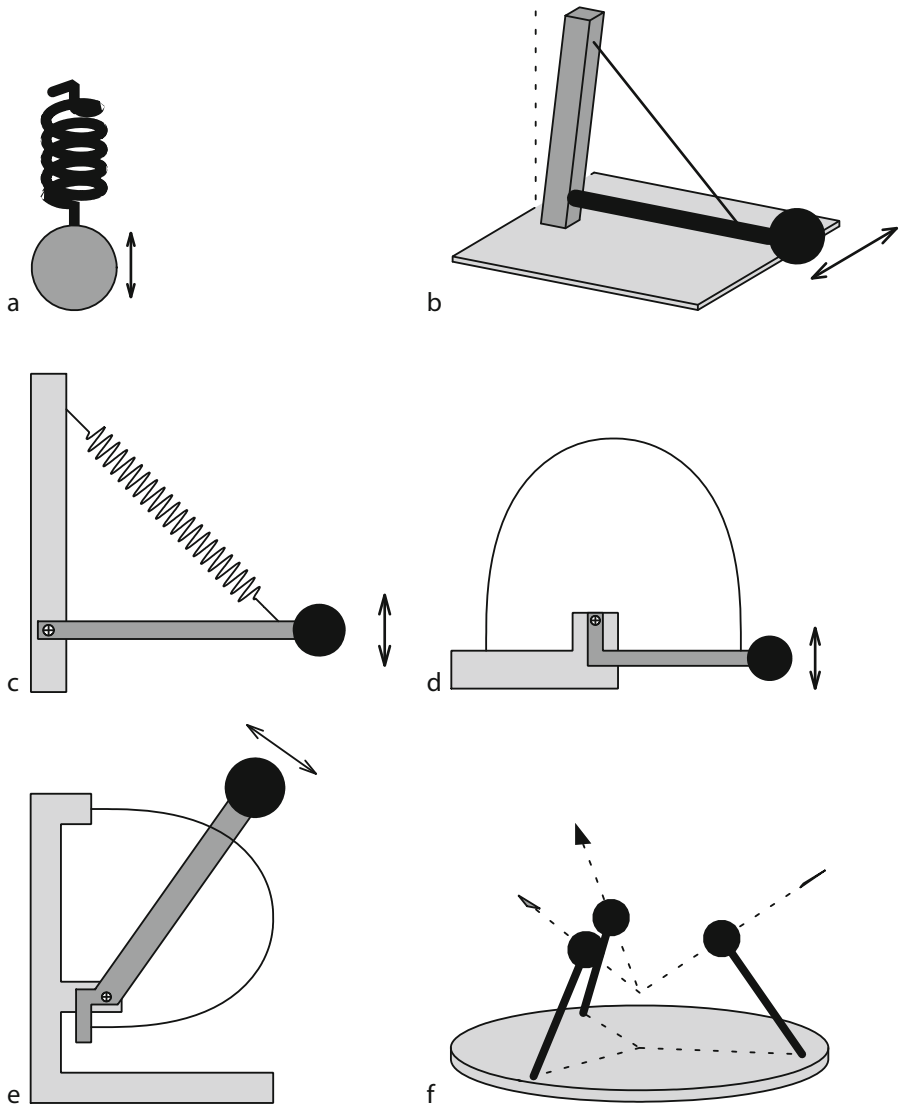
is the frequency response of the seismometer. For ground motion at frequencies much higher than the natural frequency ω_0, $X \approx U$: the mass motion looks like ground displacement. For ground motion at much lower frequencies, $X \approx U\omega^2/\omega_0^2$: the mass motion looks like ground acceleration, scaled by the inverse of the natural frequency of the seismometer.

The minimum noise level of any inertial sensor is set by the thermal (Brownian) motion of the mass in equilibrium with its surroundings. This noise level can be expressed as an equivalent ground acceleration, with a flat power spectral density of $8\omega_0\gamma k_B\theta/m$, where k_B is Boltzmann's constant and θ is the temperature (Aki and Richards, 2002). For a temperature of 310 K and $\gamma = 0.8$, this expression is $1.72 \times 10^{-19}/(mT_0)m^4s^{-3}$, with m in kilograms and T_0 in seconds. The dotted lines in Figure 1 show noise levels for two cases that cover the range of designs: $mT_0 = 10^{-4}$ (1 g mass and free period of 0.1 s), which cannot resolve ground noise at the longer periods, and $mT_0 = 3$ (300 g and 10 s), which shows that a moderately large mass and long period are necessary and sufficient for this thermal noise limit to fall below ground noise at all frequencies.

Mechanical design

In an inertial sensor, the mass needs to be constrained to move in one direction only, with a restoring force that is both exactly linear in the mass displacement and of whatever amount needed for the sensor to have the desired free period. The free period enters into the design partly because of Equation 2: the longer the period, the greater the displacement of the mass for a given acceleration at periods longer than the free period; that is to say, the higher the long-period sensitivity, and the lower the noise. Sensors designed to measure only high frequencies, such as the geophones used in geophysical exploration, can have a short free period, which means that the springs used can be relatively stiff (large k) and rugged. Seismometers for high frequencies use elastic elements both to constrain mass motion to a straight line and to provide a linear restoring force (Figure 2a). The latest innovation for short-period instruments is the MEMS (Micro-Electronic Mechanical Systems) sensor, in which the mass-spring system is machined from monolithic silicon and packaged with integral electronics; these are mass-produced for non-seismological applications and so are relatively inexpensive. While not as sensitive as traditional seismometers, they are already useful for measuring strong ground motions.

The high sensitivity needed for scientific purposes makes the mechanical design more challenging. If the mass moves vertically, it must be stably suspended against gravity while the restoring force is also kept low. In most long-period seismometers, the mass is constrained by hinges and stops to move along a small part of the circumference of a circle, which for most applications is an adequate approximation to a straight line (departures from this cause cross-coupling [Rodgers, 1968; LaCoste, 1967]). For sensing horizontal motion, the circle is slightly tilted from a horizontal plane, in which case the hinged



Seismic Instrumentation, Figure 2 Mechanical designs for seismometers, shown in cartoon form. (**a**) is a simple mass on a spring. (**b**) is the "garden-gate" design used for long-period horizontal instruments; note that the support post is not vertical. (**c**) shows the geometry of a Lacoste suspension; the restoring force of the spring must be equal to its physical length. (**d**) shows a vertical sensor that uses a leaf spring (elastica) to supply the restoring force. (**e**) and (**f**) show the design of a single sensor in a triaxial seismometer, and how three such sensors are arranged to record orthogonal motions.

mass is a horizontal pendulum (also called a garden-gate suspension, shown in Figure 2b). The restoring force then comes from gravity and is easily adjusted by tilting the instrument.

Long-period sensors that measure in other directions use a spring arranged to give a weak, but still linear, restoring force. One common design is the LaCoste suspension (Figure 2c), which uses a *zero-length spring*: a helical spring that exerts a force exactly proportional to its physical length. The geometry of the spring and hinged mass is chosen to make the restoring force nearly independent of mass position, giving a very long period. An alternative method uses a single sheet of elastic material, bent to form a leaf spring (Figure 2d), to create a long-period system with adequate linearity over the actual range of motion.

The traditional arrangement of seismometers is an orthogonal pair for horizontal motion, and a single sensor of vertical motion; if only one sensor is used, it is usually a vertical to give the best signal-to-noise ratio for P waves. Many systems now use a "triaxial" arrangement, with three identical systems measuring motion at an angle of 54.73° to the vertical, and at azimuths 120° apart; this also gives three orthogonal directions, namely those of the edges of a cube balanced on a corner (Figure 2e and f).

Any seismometer requires careful design to ensure that the only vibration that takes place is the mass motion, or at

least that other modes of vibration (called *parasitic resonances*) will not produce any signals if excited by ground motion. Long-period seismometers need special materials that do not creep much under load and whose dimensions and elastic constants are insensitive to temperature changes; even then, isolation and active environmental control may be needed to reduce the effects of changes in air temperature, air pressure (which causes varying buoyancy of the mass), and magnetic fields (which affect spring materials).

Electronic design

Sensing the mass motion in a seismometer is now almost always done electronically, in one of two ways (Agnew, 1986). In the first, electrodynamic method, permanent magnets and coils of wire are arranged so that the motion of the sensor produces an induced voltage $V = G\dot{x}$, where G is the generator constant; this voltage is then amplified and recorded. This method is simple and rugged, and provides damping if some of the induced current flows through a resistor. However, because the voltage produced depends on the velocity of the mass, and because the noise in the amplifiers rises with low frequency, electrodynamic sensing cannot resolve ground noise at periods longer than about 10 s.

The second method is active sensing of the mass motion. An oscillating voltage is input to a variable capacitor or inductor attached to the mass, which produces an output voltage with the same frequency and amplitude proportional to x; this output voltage is then demodulated to produce $V = Sx$, where S is the sensitivity. Up to the point of demodulation, the signal is at a frequency (several kHz) at which electronics noise is relatively low, so such displacement sensors can be made sensitive enough to measure motions less than an atomic diameter.

This output voltage can be recorded directly, but more often is used in a feedback system: the integral of this voltage (over some frequency band) is used to apply an additional force to the mass, usually with a coil and magnet, acting against the mass displacement. Because this force acts against the apparent force of ground acceleration, this is called a force-balance accelerometer. Feedback does not decrease noise, but does have three other merits. First, it can be used to vary the seismometer response much more than mechanical modifications can; for example, a mechanical system with a free period longer than 10 s is difficult to make, but this is easy to create electronically; and the response of the electronic system will be much more stable over time. Second, because the feedback force reduces the mass motion, the mechanical system needs to be linear over a smaller range. Finally, the calibration depends on the relation between voltage and feedback force, and this is very stable over time.

Calibration

Equation 2 is an example of the transfer function of a seismometer: the relation, as a function of frequency, between the ground motion and the output. In that example, the output was assumed to be mass motion x; a more realistic example would include a displacement sensor that generates a voltage $V = Sx$ followed by a datalogger that digitizes the voltage and produces a number $N = AV$. The total transfer function of the system, from input Earth displacement to digital output, would then be

$$\frac{AS\omega^2}{\omega_0^2 - \gamma i\omega + \omega^2}. \tag{3}$$

Seismometer calibration consists of determining all the parameters in expressions like this one. Some components, such as the datalogger, are calibrated by putting a known signal in and recording the output. For the seismic sensor, this requires producing a known ground motion, which can be done with a shake table before the seismometer is installed. After installation, a seismometer calibration can be checked by putting a signal into the seismometer electronics that will apply force to the mass without otherwise disturbing the output.

Calibration information is usually provided in a form like Equation 3: a leading constant, and the (complex) polynomials that give the response as a function of a frequency. Often the polynomials are specified by giving their roots in the complex plane, referred to as poles and zeros. The frequency response can usually be found quite accurately, though the absolute response to ground motion is usually difficult to estimate to better than 1%. Sometimes mundane aspects of the calibration, such as the actual direction of measurement, can be in error by significant amounts.

Installation

An ideal seismometer installation should maximize signals of interest whether distant earthquakes or the shaking of a building, while minimizing noise that might hide these signals. Any actual installation will be a compromise between this ideal and such practical matters as access and cost. For earthquake signals, putting an instrument deeper below the Earth's surface will give better results, but if this requires a deep drill-hole, a shallower installation may be all that can be done. An extreme example of low-quality installations being accepted for reasons of cost is ocean-bottom seismometers, for which the standard installation is the seismometer sitting on the bottom, sometimes on very soft sediments, however it happens to land after being dropped off a ship.

On land, the shallowest installations are for temporary instruments used in geophysical exploration, with seismometers planted on the surface with an attached spike to hold them in place. More permanent installations range from instruments set on surface rock exposures or in shallow holes in soil, to purpose-built deep vaults, caves (if available), and drill-holes. Deeper installations reduce the noise from wind and the range of temperature variation, and even a meter of soil will attenuate daily fluctuations. It is advisable, though not always possible, for instruments to be installed away from noise sources such as roads, machinery, rivers, and trees; in an urban setting borehole

installations at depths of a few hundred meters may be the only way to reduce the noise to reasonable levels.

Displacement seismometry using satellites

Because the mass motion is proportional to acceleration for motions with periods longer than the seismometer free period, data from inertial seismometers has to be integrated twice to find long-period displacements. This integration can introduce significant error, especially if the response is slightly nonlinear or the sensor tilts.

Direct sensing of displacement can now be done using repeated distance measurements between a ground sensor and Earth satellites, since the satellites define an inertial reference frame unaffected by ground motion. Distances between satellites of the Global Positioning System (GPS) and a receiver on the ground can be measured to within less than a millimeter precision, even over short times and in the presence of large accelerations; the actual ground displacement can be found after some processing (Bilich et al., 2008). The accuracy of GPS distance measurements is lower than their precision because of propagation effects, including interference from signals reflected from nearby objects (known as multipath), but it has proved possible to determine horizontal ground displacements to within a few millimeters over time spans up to several minutes and at rates up to 10 Hz. This sensitivity is too low to measure most earthquake signals, but can provide high-quality displacement data for ground motions near large earthquakes; a combination of inertial and GPS sensors is the optimal way to measure strong motion.

Deformation seismometers

A final class of seismometers measures, not the displacement at a point, but quantities related to the displacement gradient. For a vector displacement $\mathbf{u}$, the gradient $\nabla\mathbf{u}$ is a tensor, which can be decomposed into two parts: a symmetric part, the strain tensor, which describes local deformation; and an antisymmetric part, which is equivalent to a vector that describes local rotation, tilting about horizontal axes and rotating about the vertical axis.

Two types of instruments, both known as strainmeters, can measure components of the strain tensor (Agnew, 1986). Extensometers measure relative displacement along a line between two end points; this displacement divided by the baseline (the distance between the points) gives the extensional or compressional strain. Extensometers with baselines as short as a few centimeters are installed in boreholes, and ones with baselines up to tens of meters in tunnels. In both of these, the measurement is made relative to a solid length standard. Much longer instruments use optical methods to measure strain over hundreds of meters. The other class of strainmeter is the volumetric type, in which the change in a volume of fluid is found by sensing the displacement of fluid in and out of a container cemented in a borehole: such an instrument measures the volume strain, or dilatation.

Measuring the rotation vector requires either a stable direction of reference or some way of measuring rotation directly with respect to inertial space. Until recently, no technology existed that do could this with the low noise levels required. A few instruments measure rates of rotation around a vertical axis using Sagnac interferometers, also called laser gyroscopes (Schreiber et al., 2009). These sense the difference in frequency between two light beams propagating in opposite directions around a closed loop.

Seismic data recording

Three specialized requirements for seismological dataloggers are: (1) a high dynamic range, to capture all the signals possible; (2) large amounts of storage, since it may be necessary to record for a long time to capture unpredictable events; and (3) accurate absolute timing, to relate seismic-wave travel times to a common system. In all three areas, the progress of electronics has meant rapidly improving performance at ever-lower cost.

Many seismic dataloggers use specialized systems to provide 24 bits of range (about 5×10^7); this is accomplished by oversampling followed by digital filtering. The amount of storage depends on the sample rate; except in limited situations, a rate of about 200 Hz will capture all seismic data without aliasing. A day of 3-component data with this resolution and sample rate comes to just over 50 Mb, an amount that in the last two decades has gone from requiring specialized and bulky storage to something easily dealt with. Cross-correlation methods can find time delays to a precision of 0.1 of the sample interval, and so the time of each sample point should be known well: for 200 Hz sampling, this requirement would be 500 μs. This too is a level of accuracy that until recently was not easily attained. It can be reached without much difficulty if radio signals from the GPS satellites are available, though providing it over long times in the absence of such a signal still requires expensive equipment. Lower levels of accuracy can be obtained from other radio signals, and, over intervals of a few days, from inexpensive crystal oscillators.

Often, a single system records data telemetered from multiple sensors, forming an array (if the region covered spans only a few wavelengths of the waves being recorded) or network (if larger). The most precise timing then requires corrections for the transmission time of the data (latency) unless a separate datalogger is used for each sensor.

Summary

With over a century of development, inertial seismic sensors are a mature technology, usually capable of recording ground motion much better than it can be modeled. While no single sensor can cover the full range of amplitudes and periods of seismic waves, only a few instruments are needed to provide a faithful record of ground motion. Since other developments in electronics have largely routinized digital recording of seismic data, most users treat seismometers as a "black box" system that can be acquired

and used with little specific expertise: a usually justifiable assumption, though as always it is important to know enough to recognize poor performance when it does occur.

SEISMIC MICROZONATION

Fumio Yamazaki, Yoshihisa Maruyama
Graduate School of Engineering, Chiba University, Inage-ku, Chiba, Japan

Definition

Seismic microzonation. The mapping of an area on the basis of various factors that can affect the intensity of ground shaking, such as seismic hazard, geological conditions, and topographical features, so as to account for the effects of local conditions on earthquake-induced damage.

Introduction

Local site conditions affect the intensity of ground shaking, and as a consequence, the extent of earthquake-induced damage. The amplitude, frequency content, and duration of strong ground motion are significantly influenced by local site conditions. A well-known example is the 1985 Mexico City earthquake. Although the fault rupture of the earthquake was about 350 km away from Mexico City, the city sustained catastrophic damage due to the strong amplification of the ground motion by soft soil deposits (Seed et al., 1988). The 1989 Loma Prieta earthquake caused extensive damage in the San Francisco Bay Area. The San Francisco Bay mud significantly influenced the amplitude, frequency content, and duration of ground shaking and resulted in the collapse of the northern portion of the I-880 Cypress Viaduct (Earthquake Engineering Research Institute, 1990; Kramer, 1996). Seismic microzonation provides the basis for site-specific risk analysis, which can assist in the mitigation of earthquake-induced damage.

Methodology

Seismic microzonation typically involves the mapping of predominant periods, soil amplification factors, topographical conditions, liquefaction susceptibility, etc. To draft microzonation maps for a particular region, various data such as existing geological maps, borehole survey data, seismic observation data, and microtremor observation data are collected. Since seismic microzonation entails spatial classification of soil conditions in a small area (e.g., a city), geological data are required for not just a single location, but for many locations. In this regard, geological classification maps are most often used as one of the data sources. However, to classify the target area in a more quantitative manner, actual soil profiles obtained from borehole survey data or seismic observation data are better sources. Unfortunately, in most cases, the borehole survey data and/or seismic observation data available for a small area are insufficient. Thus, microtremor observation data have emerged as a popular source for dense spatial information on site amplification characteristics. Three examples of seismic microzonation are described hereafter.

Example 1. Seismic microzonation based on geomorphological classification maps

Several seismic microzonation studies in Japan have employed geomorphological and geological data from the Digital National Land Information (DNLI), which is a GIS database that covers the whole of Japan with a 1×1 km mesh, to estimate site amplification characteristics (Matsuoka and Midorikawa, 1995; Fukuwa et al., 1998; Yamazaki et al., 2000).

Wakamatsu et al. (2004) drafted the Japan Engineering Geomorphologic Classification Map (JEGM) on the basis of the analysis of local geomorphological features at scales of 1:50,000, and all the attributes were digitized and stored in a GIS database. They recently extended the JEGM to 250 × 250 m grid cells that were categorized into 24 classes on the basis of geomorphological characteristics.

The shear-wave velocity averaged over the upper 30 m (V_s^{30}) is often used as a simplified index of site conditions (Building Seismic Safety Council, 2003). Region-wide site condition maps for California were constructed on the basis of V_s^{30} and the classification of geological units (Wills et al., 2000). The Next Generation of Ground-Motion Attenuation Models (NGA) project was launched in an attempt to collect all publicly available site condition information at strong motion stations. V_s^{30} is used in the absence of site condition information (Chiou et al., 2008). Matsuoka et al. (2006) constructed a nationwide V_s^{30} distribution map using the nationwide shear-wave velocity datasets for Japan, which were obtained from 1,000 K-NET and 500 KiK-net seismic stations and the JEGM.

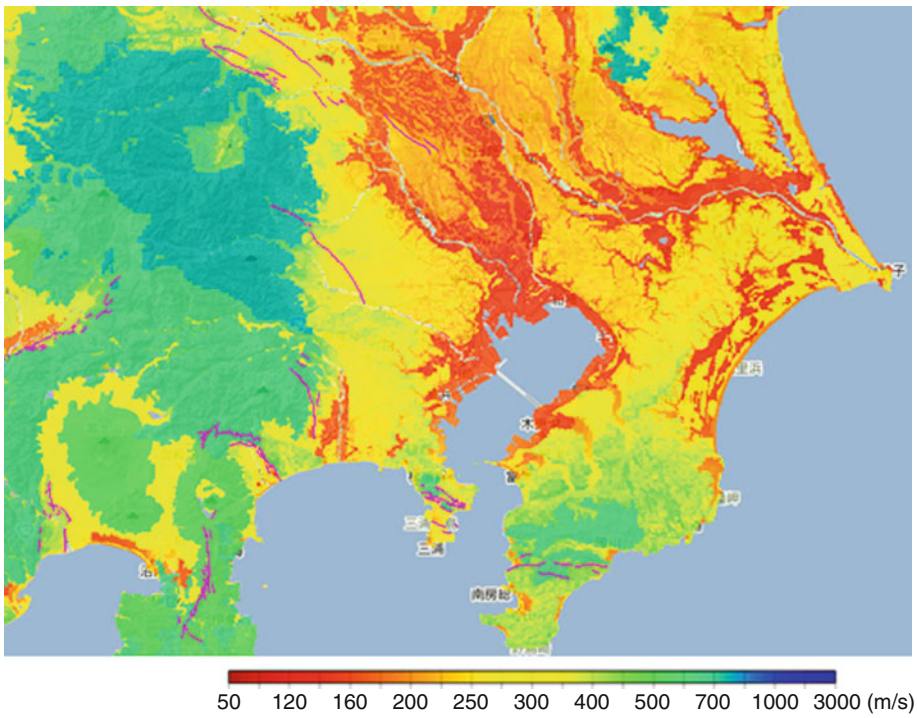
The National Research Institute for Earth Science and Disaster Prevention (NIED), Japan, has developed an open web system that interactively provides seismic hazard maps for Japan; this system is called the Japan Seismic Hazard Information Station (J-SHIS) (Fujiwara et al., 2006). J-SHIS uses the JEGM and V_s^{30} distribution map to draw probabilistic seismic hazard maps for the whole of Japan made by the Headquarters of Earthquake Research Promotion, Japan (Figure 1).

Example 2. Seismic microzonation based on dense borehole data and GIS

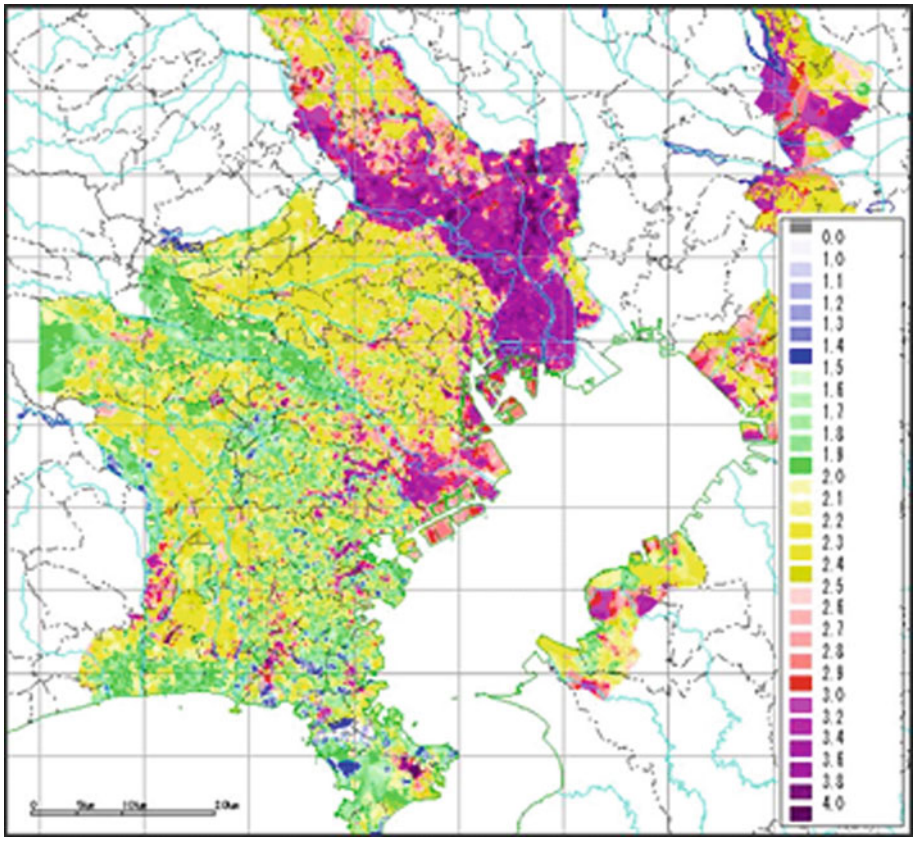
Since 2001, the Tokyo Gas Co., Ltd. has been operating the *Sup*er-Dense *Re*al-time *M*onitoring of *E*arthquakes (SUPREME) system, having about 4,000 seismometers (SI-sensors), in order to control natural-gas supply soon after the occurrence of earthquakes (Shimizu et al., 2006).

This system employs a GIS to interpolate the monitored spectral intensity (SI) values by using subsoil data from 60,000 boreholes. The digitized borehole data specify the location, depths of soil layers, classification of subsurface soil, standard penetration test (SPT) blow counts, surface elevation, and elevation of the ground water table. Thus, microzonation of the area on the basis of individual borehole data is possible. Shear-wave velocities are estimated from an empirical relationship by using the SPT-N values; then, the average shear-wave velocities in the top 20 m of soil at a borehole site are used to estimate the amplification factors of the SI values (Figure 2).

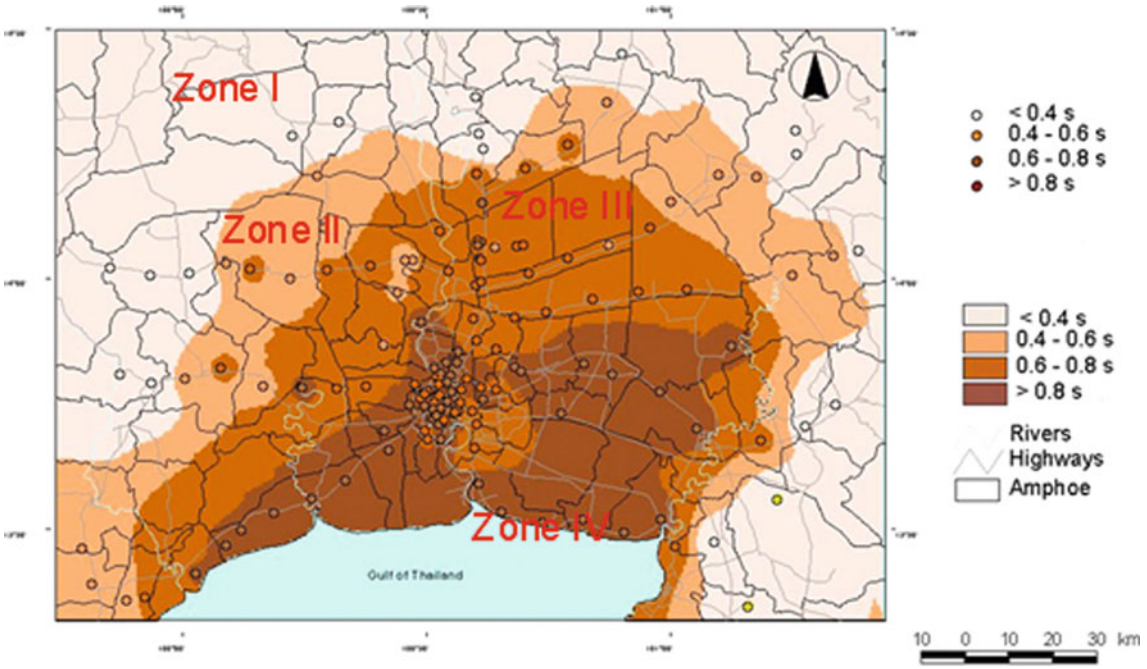
The accuracy of seismic microzonation can be confirmed after several years of operating a dense seismic network by evaluating the seismic records obtained for moderate to small earthquake events occurring in that period.



Seismic Microzonation, Figure 1 V_s^{30} distribution map of Tokyo metropolitan area (http://www.j-shis.bosai.go.jp/).



Seismic Microzonation, Figure 2 Site amplification map of Tokyo and surrounding areas, developed using dense borehole data.



Seismic Microzonation, Figure 3 Microzonation of greater Bangkok area on the basis of variation in predominant period.

Example 3. Seismic microzonation based on microtremor measurements

Microtremor measurements have emerged as a popular tool for determining the dynamic properties of soil layers, and hence, are being widely employed for seismic microzonation. In this method, ambient vibrations (of the order of microns) on the earth's surface are measured. The main sources of these vibrations are traffic and industrial and human activities (Kanai, 1983; Lermo and Chavez-Garcia, 1994). Microtremor measurements can be used to determine the predominant period of vibrations at a site. Nakamura (1989) proposed the horizontal-to-vertical (H/V) spectral ratio method, in which the predominant periods of ground vibrations are determined from the ratio of horizontal and vertical Fourier spectra of the microtremors recorded at a site. Konno and Ohmachi (1998) drafted a map of fundamental periods and amplification factors for the 23 wards of Tokyo on the basis of microtremor measurements carried out at 546 stations.

Tuladhar et al. (2004) drew a seismic microzonation map for the greater Bangkok area, Thailand, on the basis of microtremor observations carried out at 150 sites. The predominant periods of these sites were obtained by using the H/V method. The estimated predominant periods were validated by comparing them with the transfer functions obtained from one-dimensional wave-propagation analysis conducted at eight sites. According to the variation in the predominant period of the ground, the greater Bangkok area was classified into four zones as follows: Zone I (period less than 0.4 s), Zone II (0.4–0.6 s), Zone III (0.6–0.8 s), Zone IV (longer than 0.8 s). Figure 3 illustrates the microzonation of the greater Bangkok area on the basis of variation in the predominant period.

Summary

The objectives and methodologies to perform seismic microzonation are described and some examples are presented. The three major methods introduced to achieve seismic microzonation are the uses of geomorphological classification maps, dense borehole datasets, and microtremor measurements. The results of seismic microzonation are compiled for a GIS to draft microzonation maps and they can be used to predict ground motions during disastrous earthquakes and thus can assist in the mitigation of earthquake-induced damage.

Introduction

The original development of nuclear weapons, and their first use in 1945, was followed by several decades of further weapons development in which more than 2,000 nuclear test explosions were conducted. About 500 of these were carried out in the atmosphere, mostly in the 1950s and 1960s. They generated radioactive fallout that was detected worldwide with some regional concentrations, and aroused widespread public opposition to nuclear testing. A few nuclear tests were carried out underwater and in space. The great majority, about 1,500, were conducted underground in ways that greatly reduced fallout – the first of them in 1957, in Nevada, USA – generating signals that have been intensively studied by seismologists. Hundreds of these individual nuclear tests consisted of multiple nuclear devices and exploded almost simultaneously.

A ban on nuclear testing in the atmosphere, underwater, or in space, was negotiated and went into effect in 1963 between the USA, the USSR, and the UK. Known as the Limited Test Ban Treaty (LTBT), it has since been ratified or acceded to by more than a hundred countries. Though France and China did not sign, and China carried on with nuclear testing in the atmosphere up to 1980, eventually both these countries came to abide by its terms.

The concept of a Comprehensive Test Ban Treaty (CTBT) emerged in the 1950s, intended as a restraint upon nuclear weapons development. It was debated in many forums for more than 40 years, and finalized in terms of specific treaty text in September 1996. But this treaty is not in effect (as of 2010), due to continuing debate in specific countries that have not ratified this treaty, and whose ratification is needed as a condition for the CTBT to enter into force. They include India, North Korea, and Pakistan (not signed or ratified); and China, Israel, and the United States (signed but not ratified). Those countries that have signed the treaty are effectively adhering to a moratorium on nuclear testing. They include the five countries recognized as nuclear weapons states by the Non-Proliferation Treaty of 1968. Listing them in the order in which they acquired nuclear weapons capability, these are the USA, the USSR (whose CTBT obligations have been assumed by Russia), the UK, France, and China. The two countries that by far have conducted the most nuclear test explosions – the USA with 51% of the world total, and the USSR/Russia with 35% – ended nuclear testing in the early 1990s. See Yang et al. (2003) for lists of nuclear explosions conducted in the twentieth century, and Bennett et al. (2010) for a relevant database and seismic waveforms. Since 1996, the only nuclear explosions (as of 2010) have been those conducted by India and Pakistan (in May 1998), and by North Korea (in October 2006, and May 2009).

Seismic monitoring of nuclear explosions has been an important activity ever since the first nuclear test in July 1945 in New Mexico. Such monitoring is driven by two different objectives that have engaged a range of different institutions and organizations. The first objective, which dominated for the early decades of nuclear testing up to the early 1990s when nuclear explosions were being conducted on average about once a week, was to acquire basic information about military weapons being tested, especially if (from the point of view of the monitoring organization) the tests were being carried out by a potential adversary. Relevant questions were: what countries had nuclear weapons programs, developed to the level of carrying out nuclear explosive tests? And how big were these explosions? The second objective, which has become important in recent decades, has been in the context of a major initiative in nuclear arms control, namely, to achieve confidence in the capability to monitor compliance with a CTBT, recognizing that many countries considering whether or not to support such a treaty and to be bound by its terms, would need to have confidence in the monitoring system to some adequate degree. Given that monitoring cannot be done all the way down to zero yield, evaluation of progress toward this second objective entails questions such as: down to what small size can nuclear explosions be detected, and identified, and attributed with high confidence? And what are the specific capabilities of different types of monitoring program, applied to different parts of the world, to catch evidence of a nuclear test, should one occur?

Seismology is the most effective technology for monitoring nuclear tests carried out underground, which is the one environment that was not covered by the LTBT, and which is also the hardest of the environments to monitor. The importance of achieving the two objectives stated above has shaped modern seismology itself, in that much of the funding that has led to the facilities and bodies of knowledge now used widely in seismological research (including studies of seismic hazard), were stimulated by government programs intended to improve capabilities for seismic monitoring of nuclear explosions. These facilities and methods include high-quality Seismic Instrumentation, global networks that monitor for earthquakes as well as explosions, quantitative methods of characterizing seismic sources (various magnitude scales, the moment tensor), theoretical understanding of seismic wave propagation in Earth models of increasing and more realistic complexity, our knowledge of the Earth's internal structure, and methods of seismic signal detection and interpretation.

The technical capability to monitor explosions, or a perceived lack of such capability, has played a role in the development of policy options on weapons testing

and/or arms control and the content of international treaties. A key technical question arising in debates has been: down to what value of yield can monitoring be accomplished – and with what level of confidence? Seismologists claim now that there is no fundamental technical problem with monitoring explosions down to 1 kt, even if determined efforts at evasion must be considered. But there have been assertions that it is possible to muffle and thus hide (or confuse the procedures for identifying) the seismic signal, even from a substantial underground explosion at the level of ten kilotons or more. These latter assertions do not appear plausible after review of the technical difficulties; but, as assertions, one finds that they continue to survive.

Seismic monitoring for underground nuclear explosions must be done with recognition of the great variety and number of earthquakes, chemical explosions, and other nonnuclear phenomena that generate seismic signals every day. Efforts to sort out and identify signals from underground nuclear explosions in the midst of signals from these other phenomena have made great progress since they commenced in the 1950s, and improvements in monitoring capability will surely continue to be made.

Sections below describe basic properties of earthquake and explosion signals, and different steps in seismic monitoring for nuclear explosions. A review is given of methods used for decades in the era when thousands of kilometers separated nuclear weapons testing activity and monitoring stations, when nuclear weapons testing was commonplace and there was little incentive to hide testing activity. Descriptions are then given of modern methods that monitor for very small explosions and the possibility of tests conducted in ways intended to evade discovery. A description is given of so-called "problem events" that were important is developing effective and in some cases new discriminants; and finally a brief summary is given of monitoring capabilities, as of 2010, emphasizing the utility of data and data products from the International Monitoring System and its associated International Data Centre that are operated today by the CTBT Organization, headquartered in Vienna, Austria.

Basic properties of earthquake and explosion signals

Seismic monitoring for underground nuclear explosions has to face the reality of hundreds of earthquakes, chemical explosions, and other nonnuclear phenomena, generating seismic signals daily that will be recorded at multiple stations by any effective monitoring network. But after decades of effort, an extensive infrastructure of national and international agencies now sorts out and identifies the signals from earthquakes, chemical explosions, and the occasional underground nuclear explosion. Modern methods of nuclear explosion monitoring are vastly more capable than they were when this work began in the late 1950s. The improvements have mostly been steady as data quality and quantity from monitoring networks increased, but with occasional jumps in capability as new types of analysis were validated.

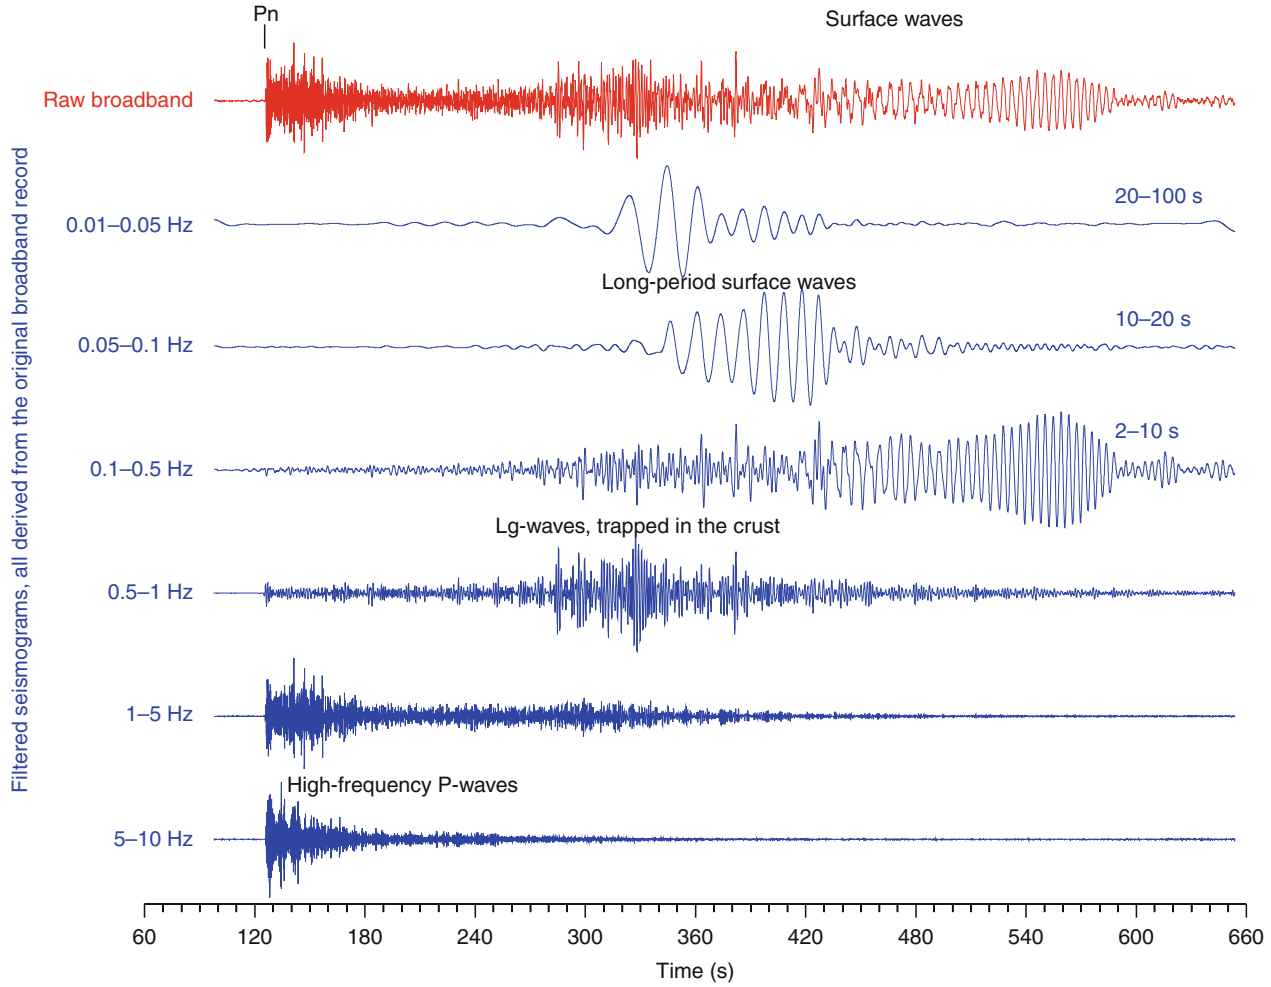
Seismic signals are traditionally grouped into teleseismic waves and regional waves, depending on the distance at which they are observed. Teleseismic waves propagate either as Body Waves through the Earth's deep interior, emerging with periods typically in the range 0.3–5 s at distances greater than about 1,500 km, or as Surface Waves, analogous to the ripples on the surface of a pond, with periods of about 15–100 s.

Teleseismic waves were the basis of most US monitoring of foreign nuclear tests prior to 1987. Teleseismic body waves are further subdivided into *P*-waves and *S*-waves. *P*-waves, which are the fastest-traveling seismic waves and are therefore the first to arrive, are excited efficiently by explosions: earthquakes tend to excite *S*-waves and surface waves more efficiently.

For subkiloton explosions, teleseismic signals can be too weak for detection at distant stations and monitoring then requires regional signals. Regional waves are of several types, including *P*-waves and *S*-waves, all propagating only at shallow depths (less than 100 km below the Earth's surface) with periods as short as 0.05 s (frequencies as high as 20 Hz, i.e., cycles per second). Regional waves reach distances up to 1,000 km and sometimes beyond, depending on source size and whether the propagation path is an attenuating one, or not. They are regional also in the sense that they have speeds and attenuation properties that vary according to details of local structures in the Earth's crust and uppermost mantle, so they can vary from place to place within continents and oceans.

Figure 1 shows a regional seismogram of a Soviet underground nuclear explosion in Kazakhstan recorded in July 1989 at a distance of slightly less than 1,000 km by a high-quality station in northwestern China. The original recording is shown in red. Different signals derived from it are shown in blue, each of them filtered to pass information in a particular band of frequencies.

Seismologists characterize the size of seismic signals by means of logarithmic magnitude scales (see *Earthquake, Magnitude*), with each scale based on a different type of seismic wave. A magnitude scale using teleseismic surface waves was first described in the 1930s based on the logarithm (to the base 10) of amplitude of maximum ground displacement due to surface waves with periods about 20 s. It is known as the M_s scale. Another widely used magnitude scale is that based on the amplitude of teleseismic *P*-waves. Known as m_b, it entails measurement of ground motion at about 1 s period. As part of the assignation of M_s and m_b values, for a particular seismic event as recorded at a particular station, a standard correction is applied to account for the distance between the source and the receiver at which the data was obtained. Magnitudes range from about -3 for the smallest observable microearthquakes, up to above 8 for the largest earthquake. A 1 kt underground explosion has an m_b roughly about 4, and each year there are about 7,500 shallow earthquakes worldwide with $m_b \geq 4$ (Ringdal, 1985). Although use of



Seismic Monitoring of Nuclear Explosions, Figure 1 The seismogram recorded at station WMQ in northwestern China, for an underground nuclear explosion on July 8, 1989 in Kazakhstan at a distance of almost 1,000 km, is shown in red (*top*). Filtered versions of the original trace in different frequency bands are shown in *blue*. Time in seconds at *bottom* is with respect to the time the explosion occurred. Different types of seismic wave propagate at different frequencies, and hence their ground motions show up in different bands. *P*-waves, in this case the regional wave called *Pn* that travels in the uppermost mantle, arrive about 120 s after the explosion at this distance, involving short-period (high frequency) motions. Long-period surface waves can be seen in the top two *blue* traces. Some surface waves arrive up to 600 s after the explosion at this distance and, thus, travel as much as five times slower than *P*-waves. *S*-waves (weak in this example) are shear waves, traveling slower than *P* waves. A high-frequency wave marked as *Lg*, which is often the largest wave at regional distances from an earthquake but is only weakly excited by explosions, is dominated by shearing motions and is largely trapped in the Earth's crust. The amplitude of ground motion in the longest period band is less than 2% the amplitude in the short period band from 1 to 5 Hz. (Adapted from work of W.-Y. Kim.)

seismic moment has superseded use of m_b and M_s in much of modern seismology and magnitude is only an empirical estimator of seismic event size, magnitude scales are still often used in discussion of seismic monitoring because this a practical way to relate that discussion directly to properties of signal strength. For example, monitoring capability is often characterized in terms of contour maps or shaded maps indicating the magnitude levels down to which detection or identification is deemed possible with given resources, such as a particular network. We conclude this article with such a map (see Figure 8). Explosion energy is measured in kilotons. A kiloton is formally defined as a trillion calories, and is roughly the energy released by exploding a thousand tons of TNT.

The different steps in explosion monitoring

Nuclear explosion monitoring entails a series of steps, beginning with *detection* of signals (did a particular station detect anything?) and *association* (can we gather all the different signals, recorded by different stations, that originate from the same "event"?). The next steps involve making a *location* estimate and an *identification* (did it have the characteristics of an earthquake, a mining blast,

a nuclear weapon test?). Then follow the steps of *yield estimation* (how big was it?) and *attribution* (if it was a nuclear test, what country carried it out?).

Detection

Concerning detection, nuclear explosion monitoring is often done with arrays of sensors, deployed as a group spread out over an area about 10 km across (or less), that facilitate methods to enhance signal-to-noise ratios. This is done typically by stacking signals from independent sensors, often with appropriate delays to increase signal strength and reduce noise. Array data can also give estimates of the direction from which signals are arriving.

In the *evaluation* of detection capability, one of the key concepts widely used in seismology is the *magnitude of completeness*, which means that *all* events above this magnitude can be recorded by the monitoring system. Transferring from magnitude to yield, one infers the capability for detecting nuclear tests (NAS, 2002). Practically, however, one of the often-cited expressions of monitoring capability is the *magnitude threshold*, above which 90% of the seismic events can be detected at more than three stations, the least number of stations for routine location.

Association

Association is the effort to identify those sets of signals, from different stations, which all originate from the same seismic event. It is one of the hardest steps in practice, particularly when multiple seismic sources around the world are active at the same time, resulting in signals from different events that are interlaced in the waveforms recorded by each station. In such cases, array data can be helpful in resolving which signals correspond to which event.

Location

To obtain a location estimate, typically the arrival times of various seismic waves are measured from the recorded waveforms such as shown in Figure 1. They are used to find four parameters: latitude, longitude, depth, and origin time. In this work, it is necessary to know the travel time from any hypothesized source location to any particular seismographic station for any type of seismic wave that the station might observe. In practice, locating seismic events accurately on a global basis (say, to within 10 km of their true location) using sparse networks (stations several hundred kilometers apart) requires extensive efforts in station calibration. Thus, it is important to include path-specific travel-time corrections to standard travel-time models to account for lateral variations of Earth structure (Murphy et al., 2005; Myers et al., 2010). Many authors have shown that greatly improved precision of location estimates can be achieved for a given region if seismic events are located in large numbers – preferably thousands of them or more, all at the same time – rather than one at a time (Richards et al., 2006; Waldhauser and Schaff, 2008).

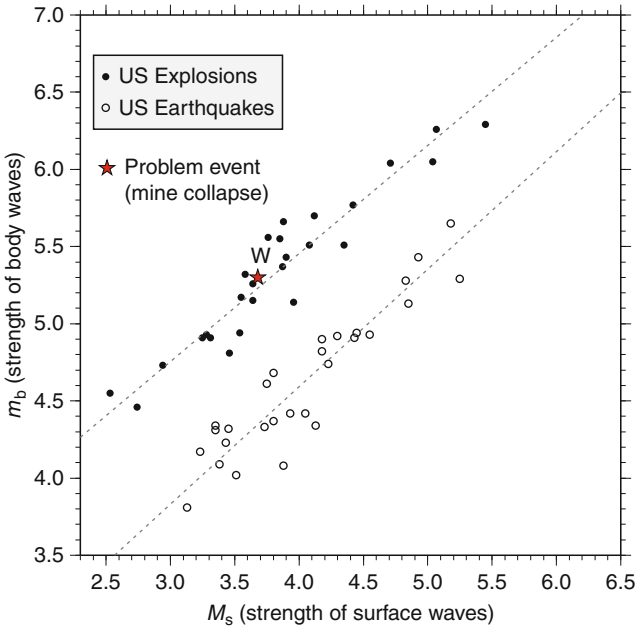
Methods of identification

Identification of the nature of a seismic source on the basis of its seismic signals – that is, making a determination from seismograms as to whether it could be a nuclear explosion, or a natural earthquake, or a mine blast, or something more exotic such as a bolide impacting our planet and exploding in the atmosphere – is a large subject in view of the many possibilities. See for example, Richards (1988), OTA (1988), Dahlman et al. (2009), and Bowers and Selby (2009). Seismic events generate many different types of seismic wave, in various different frequency bands as shown in Figure 1, and different types of seismic source generate a different mix of seismic waves. We can make an analogy here with sound waves, and the capability of the human ear and brain to analyze them. A deep bass voice, a gunshot, a whistle, and rolling thunder, constitute a set of sound sources that are easily distinguished from each other on the basis of their different frequencies, their emergent or impulsive nature, and their duration. It is the mix of information in both the time domain and the frequency domain that is effective.

Seismic methods for discriminating between earthquakes and explosions are based on interpretation of the event location (including its depth); on the relative excitation of a variety of body waves and surface waves; and on properties of the signal spectrum associated with each of these two different types of source. Within these three broad categories, many different methods have been tried, with various degrees of success. As the capabilities of each method are probed, the question of interest is often: "Down to what size of seismic event, does this method of discrimination work?" In some cases, discrimination is unambiguous even at very small event size. (For example, however small an event, it may be presumed to be an earthquake if it is located at a depth greater than 15 km below the Earth's surface. Even a small event will attract attention if it occurs in an area that is geologically stable that for decades has had no seismic activity.)

The most useful methods for discrimination can be listed as follows:

- Interpretation of the location: Is the event in a seismic or an aseismic area? Below the floor of an ocean? At depth below a continent? There is an important role here for common sense: seismic events in Canada tend to attract less attention from western monitoring agencies than such events in North Korea (though a seismic event in the middle of the Canadian Shield would still attract attention and intensive study).
- Relative amplitude of body waves and surface waves. This can be studied by plotting the event of interest on an M_s: m_b diagram, as shown in Figure 2. The surface-wave amplitude is read typically from signals with period about 20 s, and the body-wave amplitude at about 1 s period. (Though effective for large enough



Seismic Monitoring of Nuclear Explosions, Figure 2 An M_s: m_b diagram from Bowers and Walter (2002). It can be seen here that for seismic events of the same M_s value, earthquakes have a significantly smaller m_b value than do the explosions. The offset is about 0.8 m_b units, at $M_s = 5$. Because magnitudes are based on logarithmic scales, and $10^{0.8} \sim 6$, it follows that at frequencies near those at which body wave magnitude is measured (about 1 Hz), the *P*-waves from an underground nuclear explosion are about 6 times larger than such waves from an earthquake having the same strength of surface waves. Also, indicated by the red star are the body-wave and surface-wave magnitudes of an interesting but fortunately rare event, a large mine collapse with *P*-wave magnitude greater than 5. This event, which plots with the explosion population, is discussed further below – see Figures 6 and 7.

events, an explosion with m_b much below 4.5 may not have large enough surface wave signals at teleseismic distances to apply this method dependably.)

- Use of the observed "first motion" of the ground. Is the initial *P*-wave motion of the ground indicative of compression radiated to all directions from the source, leading to upward motions, as would be the case for a simple explosion? Or, are dilatations recorded at some azimuths, leading to downward motions, as would sometimes be expected from earthquakes but not from explosions?

The methods described so far in this section have concerned the use of teleseismic signals, which can be used to monitor effectively for high magnitudes, and on down to somewhere in the magnitude range from 4.0 to 4.5. Since the early 1990s, there has been growing recognition of the merits of regional waves, to monitor down to far lower magnitudes, often well below magnitude 3. The method is based upon the general observation that explosion signals, when compared to earthquakes, have much stronger *P*-waves at high frequency, whereas those from earthquakes have stronger *S*-waves (and surface waves).

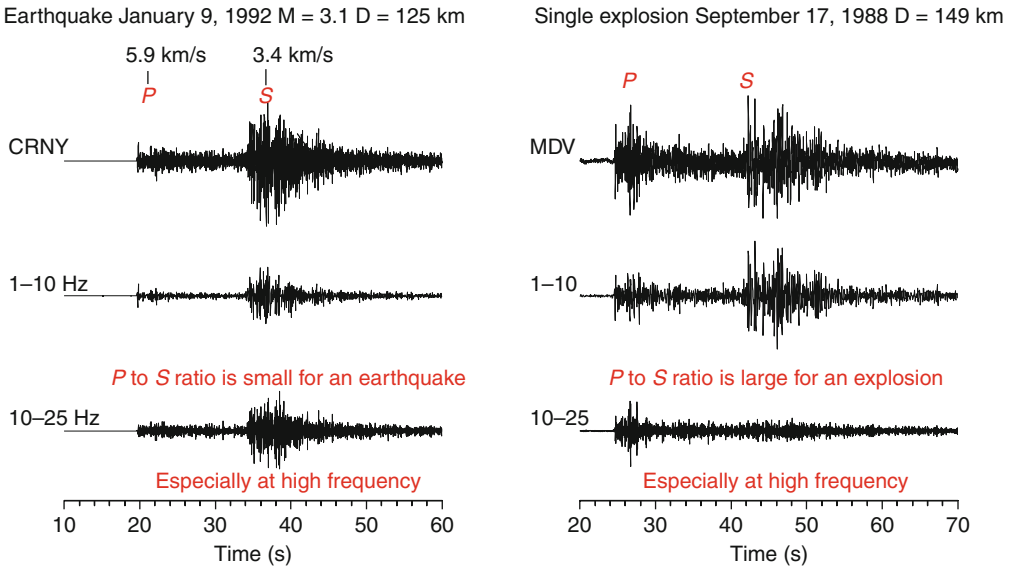
This modern method is being studied with frequencies in the range 0.5–20 Hz. and sometimes even higher. An example is shown in Figure 3 comparing regional signals of a very small earthquake and a small explosion. The method has been demonstrated even down to around m_b 2.

As an important example of this development, Figure 4 shows the results of an analysis of the *P*-wave and *S*-wave spectra, pertinent to identifying the very small underground nuclear explosion conducted by North Korea on October 9, 2006, and the larger test nearly 3 years later on May 25, 2009. The smaller explosion took place at 0135 h (GMT) and by 0706 h the US Geological Survey (USGS) had issued a report based on seismic signals from 20 stations around the world including sites in China, South Korea, Russia, Japan, Kazakhstan, Kyrgyzstan, Alaska, and Nevada. Its magnitude, about 4, indicated a sub-kiloton yield (see Koper et al., 2008, who discuss the uncertainty of estimating yield in view of the variability of seismic signal excitation for shots of different depth). But from such teleseismic signals, the nature of the event was difficult to distinguish from an earthquake. Fortunately, discrimination for events such as this is often very clear, provided high-quality regional data is available.

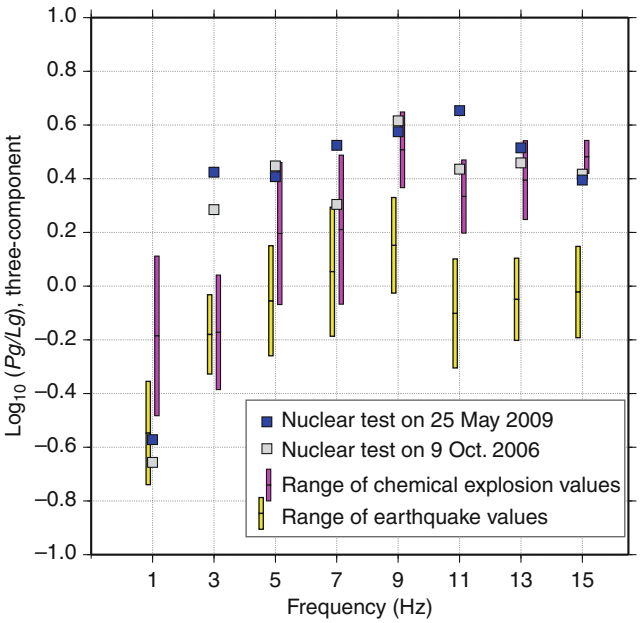
In this analysis, the original seismograms from station MDJ, located in China, are filtered in eight narrow frequency bands as illustrated in blue in Figure 1, but this time with bands centered on each of the frequencies from 1, 3, 5, 7, 9, 11, 13, to 15 Hz as indicated for the horizontal axis in Figure 4. The amplitudes of the *Pg* and *Lg* waves are measured in each narrow band, the amplitude ratio is formed (the "spectral ratio"), and the quantitative comparison can begin. Figure 4 shows how this ratio varies with frequency for the set of eight earthquakes, and for the set of four small chemical explosions. The ratio differs for these two populations as frequency rises, and the separation between them is very clear at high frequencies (from 9 to 15 Hz in this case). It is also clear that the spectral ratios of the signal recorded for the events of 2006 and 2009 are like those of the known chemical explosions.

This successful seismic discriminant based upon regional waves is important in enabling monitoring capability to be extended down to lower magnitudes. In practice, there is often very little difference between the magnitude thresholds for detection (at enough stations to enable a useful location estimate), and identification, since so many regions of the Earth are now monitored to low magnitude for earthquakes as part of investigations into seismic hazard. It may take only one regional seismogram to enable discrimination to be carried out with high confidence (provided the recording is of adequate quality, and is for a station that has an archive of signals from previous known earthquakes and explosions).

Along with the use of regional seismic waves and their spectral ratios at 5 Hz and higher, another discriminant turning out to be successful at distinguishing between



Seismic Monitoring of Nuclear Explosions, Figure 3 Typical vertical-component records from an earthquake and an explosion. Traces plotted are: unfiltered (*top*), low-frequency bandpass filtered (*middle*), and high-frequency bandpass filtered (*bottom*). (From Kim et al., 1993.)



Seismic Monitoring of Nuclear Explosions, Figure 4 Spectral ratios are shown, for the two nuclear explosions carried out by North Korea in 2006 and 2009, as measured from waveforms recorded at station MDJ in China (distance, about 370 km). They are compared with these ratios for a small group of earthquakes, and another group of chemical explosions, all in the vicinity of North Korea's nuclear test site. Colored bars represent ± 1 standard deviation in the ratios for chemical explosions (*magenta*), and small earthquakes (*yellow*). The spectral ratios for events in North Korea on October 9, 2006, and on May 25, 2009, are both explosion-like. (Courtesy of Won-Young Kim.)

earthquakes and explosions is the use of observed seismic waveforms to make estimates of the set of forces that appear to be acting at the seismic source. The set of forces here is quantified by what seismologists call the *moment tensor*. As shown by Ford et al. (2009) from study of numerous earthquakes and underground explosions, seismic events separate into specific populations as determined by the way their moment tensors behave – whether they are more representative of the all-around (isotropic) features of an explosion, or of the type of shearing motions more typical of an earthquake.

In general for underground tests, seismic data alone cannot distinguish between nuclear explosions, and chemical explosions in which all the material making up the explosive is fired within less than about a tenth of a second. But such chemical explosions, if large, are very rare. In the case of the two North Korea tests, both of which were announced as nuclear, objective evidence for the nuclear nature of the 2006 explosion came from several different detections of radionuclides that are diagnostic of a nuclear explosion. Such radionuclides were not detected from the 2009 explosion, which, however, was so large as to be implausible as a chemical explosion, since it would have to have consisted of literally thousands of tons of explosives.

Yield estimation

Yield estimation was of particular importance in the years following 1974 when a bilateral treaty between the USA and the USSR was negotiated, intended to go into effect in 1976. This was the Threshold Test Ban Treaty (TTBT), limiting the size of underground nuclear explosions

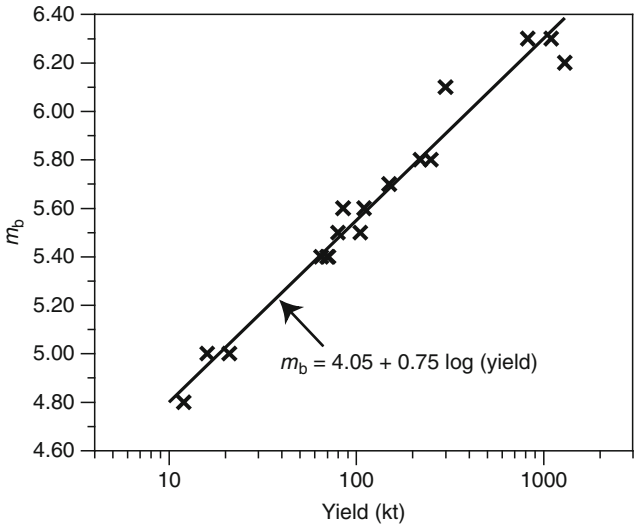
conducted by these two countries to a yield of not more that 150 kt. The TTBT proved contentious, with each side sending the other several inquiries asserting that the agreed-upon limits had possibly been exceeded (Timerbaev, undated). But this treaty was finally ratified in 1990, and has become less important since the CTBT was finalized and a nuclear testing moratorium by the signatory countries began in 1996. Yield estimation is however still important as an exercise in the interpretation of signals from the few underground explosions since that date, specifically those of India and Pakistan in 1998, and of North Korea in 2006 and 2009.

For a few tens of underground nuclear explosions, most of them at the Nevada Test Site, the yield has been announced by the agency conducting the test. It has therefore been possible to calibrate observed seismic magnitudes for these tests against the announced yields, and an example is given in Figure 3 using m_b values and yields reported for Nevada explosions in tuff and rhyolite.

The line $m_b = 4.05 + 0.75$ log (Yield) fits the data well (yield in kilotons). Such a calibration curve can be applied to obtain a seismic yield estimate for Nevada explosions with unannounced yield. But it requires correction, prior to its use in obtaining a seismic yield estimate for an explosion at a different site. This must be done, to allow for physical and geological differences between the sites. For example, in different rock types there can be different efficiencies in the coupling of nuclear yield into seismic energy; and differences in the propagation efficiencies as seismic waves travel out from the source of interest, as compared to seismic signals from a Nevada explosion. In this connection, it is of interest to note m_b and yield for the US nuclear explosion LONGSHOT (conducted in 1965 in the volcanic breccias of an Aleutian island). The m_b value is 5.9, corresponding to a yield of about 300 kt. if the Nevada curve of Figure 5 is applied directly. But the announced yield for LONGSHOT is 80 kt. One way to obtain a calibration curve for the Aleutians is therefore to add a correction of about 0.4 m_b units to the Nevada values of m_b at a given yield, before the curve of Figure 5 is used to supply a seismic yield estimate in this new location. This m_b correction, for a site differing from that where a calibration curve is directly available, is called the *bias*. If the bias correction is not applied, then a Nevada magnitude–yield curve can give too high a seismic yield estimate for a non-Nevada explosion.

Note that the Nevada Test Site is in a region of active tectonics, with significant episodes of volcanism in the last few million years, resulting in high temperatures within the upper mantle, and thus anomalous attenuation of seismic waves propagating through the hot and partially molten upper layers of the Earth, 100 or 200 km in thickness beneath the Nevada Test Site. Such propagation through an attenuating medium is presumed to be a contributing cause of bias.

The existence of m_b bias has long been known in seismology in connection with what is called "station bias." By this term is meant the systematic difference between



Seismic Monitoring of Nuclear Explosions, Figure 5 Seismic magnitude m_b vs. announced yield, for 17 Nevada Test Site nuclear explosions in tuff and rhyolite. The straight line here, which fits the data quite well, can be used to make a yield estimate of other events at this test site, in similar rock, if the seismic magnitude is known. (Data from Nuttli, 1986.)

mean m_b values (obtained for a particular seismic event by averaging reported m_b from seismometers all over the globe), and m_b reported by just one station. For example, the station BMO in Oregon (another region of active tectonism) has reported m_b values that for a given earthquake are typically about 0.3 units below the global average; and station KJN in Finland (in a stable shield region) reports values about 0.15 m_b units higher than the average. Their station bias values are thus −0.3 and +0.15, respectively. Station bias values commonly range over ±0.4 m_b units, so it may be expected that source region bias (which is what must be applied when a standard m_b – yield curve is used for different source regions) will also range over about 0.8 m_b units.

The nuclear weapons test site of the USSR that conducted the most underground nuclear explosions was near the city of Semipalatinsk, in northeastern Kazakhstan. Several multi-megaton underground explosions were conducted on Russia's Novaya Zemlya island test site, far to the north of continental Eurasia (see Khalturin et al., 2005). But these were all prior to the intended date of entry-into-force of the TTBT (March 1976). After that date, the magnitude of the largest underground tests at Semipalatinsk rose higher and higher over several years, with some magnitudes exceeding 6.1. Such magnitudes, according to the Nevada Test Site formula discussed above, $m_b = 4.05 + 0.75$ log (Yield), implied yields great than 500 kt, far in excess of the TTBT limit (150 kt). Intensive discussion in political and technical arenas ensued with stronger and stronger evidence accumulating to indicate a substantial test site bias between the Nevada and Semipalatinsk test Sites. For example, it

was of great interest that teleseismic signals from the largest underground explosions from these two tests, if recorded at the same station in a shield region, looked significantly different. The teleseismic *P*-wave from a large underground explosion at the site in Kazakhstan would routinely have frequency content at the 5 Hz level and sometimes higher (Der et al., 1985). The signal from Nevada would not contain such high frequencies. It was as if the signal from Nevada had passed through some type of filter, which of course would reduce its amplitude. Correcting for that effect would mean that the appropriate relation between magnitude and yield for an underground nuclear explosion at Semipalatinsk had the form

$$m_b = 4.05 + \text{bias} + 0.75 \log (\text{Yield}),$$

and Ringdal et al. (1992) and Murphy (1996) among many others concluded that the appropriate formula relating teleseismic *P*-wave magnitude and yield at Semipalatinsk should be this equation with a bias of 0.4. Support for this conclusion came from many arguments (see Richards, 1988 for a review). But in the political realm, the most persuasive was the very practical one associated with a Joint Verification Experiment of September 14, 1988, in which a team from the USA at the Semipalatinsk Test Site was allowed to make close-in measurements (within a few tens of meters) of a large Soviet underground nuclear explosion, in particular of the speed and extent of the shock wave it sent out into rock near the source at that test site. From such shock measurements, a reliable non-seismic method provided an accurate yield estimate (it was in the range 100–150 kt). Stations around the world provided measurements teleseismically, giving a seismic magnitude around 6.1 – comparable with the largest magnitudes of Semipalatinsk explosions since 1976, indicating that they too had been conducted in a way that respected the 150 kt limit of the TTBT. A reciprocal Joint Verification Experiment had been conducted at the Nevada Test Site, on August 17, 1988 with a Russian team making its own close-in measurements of the shock wave from a large US underground nuclear test intended to be in the range 100–150 kt. According to many news reports, the yield of this explosion slightly exceeded 150 kt. Timerbaev (undated) and news reports give it as 180 kt.

Problem events

The work of monitoring – for both earthquakes and explosions – is done in practice by hundreds of professionals who process the vast majority of seismic events routinely, and who also look out for the occasional events that, in the context of monitoring for the possibility of underground nuclear explosions, exhibit interesting characteristics, and which may then become the subject of special study.

These special events have stimulated the development of effective new discrimination techniques and a better appreciation of overall monitoring capability. Examples include a mine collapse in 1989 in Germany and two such collapses in 1995, in the Urals (Russia) and in Wyoming (USA); a small earthquake of magnitude 3.5 and its smaller aftershock in 1997 beneath the Kara Sea near Russia's former nuclear test site on Novaya Zemlya; and two underwater explosions in 2000 associated with the loss of a Russian submarine in the Barents Sea; the series of nuclear explosions carried out by India and Pakistan in 1998; and the nuclear tests conducted by North Korea in 2006 and 2009.

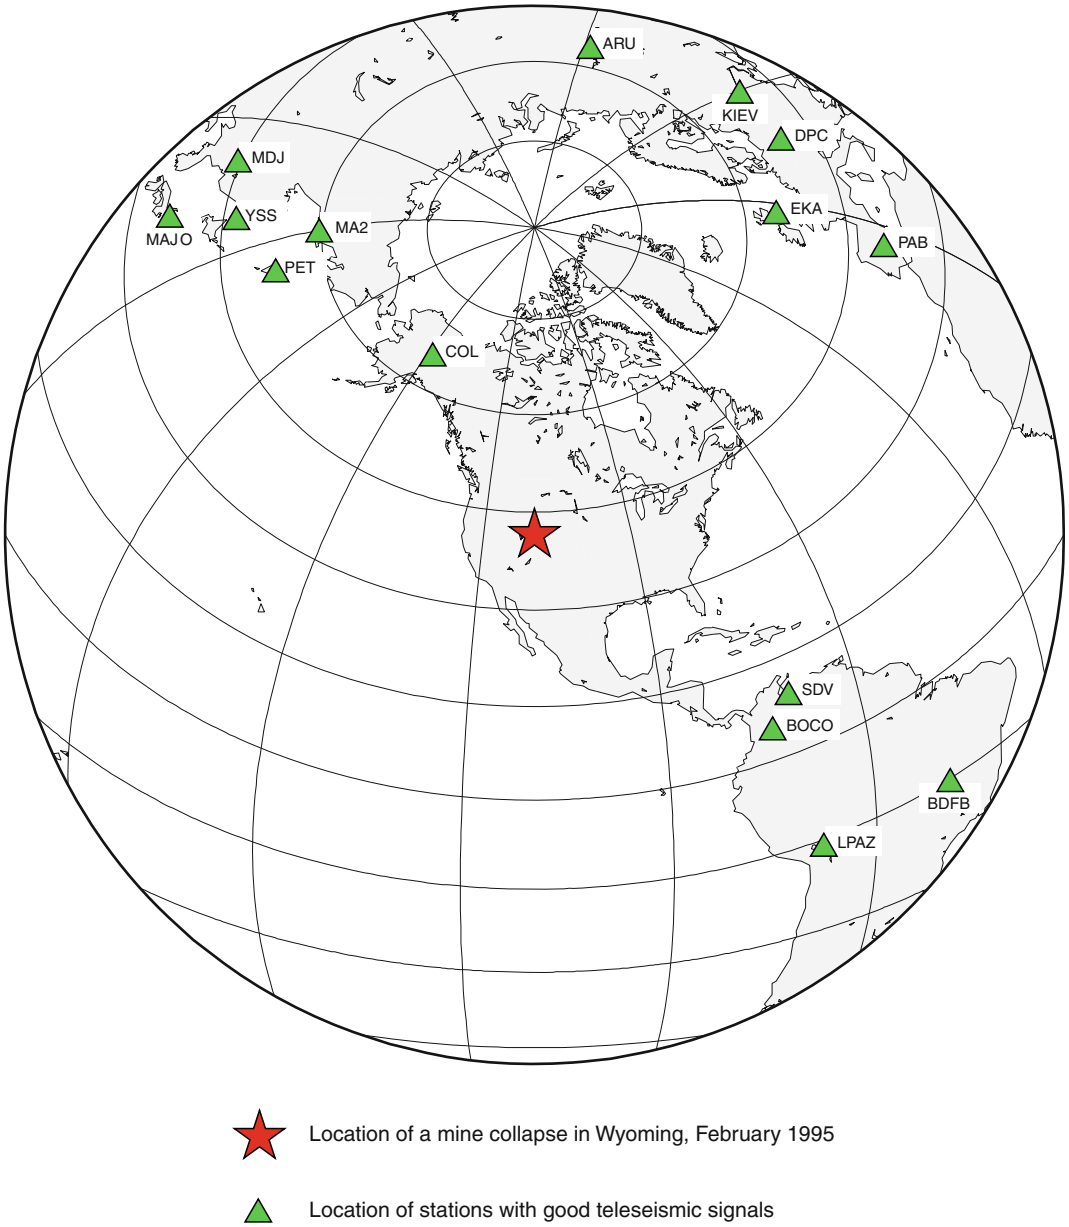
The mining collapses were seismically detected all over the world. For example, stations that detected the Wyoming event of 1995 are indicated in Figure 6. Mining collapses such as these have caused concern because their mix of surface waves and body waves as recorded teleseismically can appear explosion like using the classical M_s: m_b discriminant, as shown in Figure 2. But a careful analysis of regional and teleseismic waves from these events has showed that although the surface waves were quite weak, and in this respect seemed explosion like, they had the wrong sign. Therefore the motion at the source was *implosive* (the ground had moved inward toward the source) rather than *explosive*. Indeed, mining collapses are an implosion phenomenon, and it was important to learn that their implosive nature could be reliably determined from seismic recordings. Teleseismic waveforms from the Wyoming mine collapse are shown in Figure 7. This is an example of the use of what seismologists call the "first motion" of the *P*-wave, which is clearly downward in these data.

The Kara Sea earthquake was too small to apply the M_s: m_b discriminant (the surface waves were too small to measure reliably). This event showed the importance of accurate locations, and of using spectral ratios of regionally recorded *P*-waves and *S*-waves to discriminate small events (Richards and Kim, 1997).

As we have discussed earlier, the North Korea nuclear test of 2006 was of interest as an example of a nuclear explosion that was promptly detected globally, though its yield has been estimated at less than 1 kt. This event required regional seismic data in order to determine that indeed an explosion had been carried out and that the signals were not from an earthquake. Subsequently, xenon radionuclides were detected that decisively identified the explosion as nuclear.

Evasion

Several methods have been proposed, by which underground explosions might be concealed. One method is simply to make them small enough; but then there would be relatively little to learn, from the point of view of a weapons designer. The more important methods are those which combine as many features as possible, designed to reduce seismic signal-to-noise ratios at all relevant monitoring stations. Proposed methods include: emplacement of the nuclear device in material such as dry alluvium, to reduce the coupling of explosion energy into seismic signal (but that method is likely to result in leakage of detectable radioactivity); waiting until a sufficiently large natural earthquake occurs fairly near

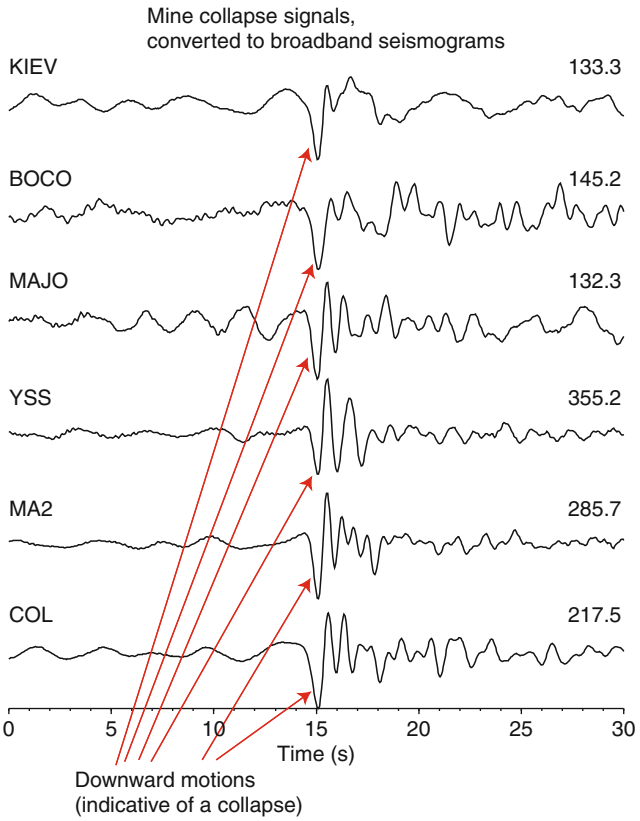


Seismic Monitoring of Nuclear Explosions, Figure 6 A global map showing stations recording teleseismic *P*-waves from a mine collapse in Wyoming. Its body wave magnitude was 5.3, and surface wave magnitude was 3.7. This combination is explosion like, as shown in Figure 2. (From Bowers and Walter, 2002.)

a test site (which presents the formidable challenge of identifying the event within a few minutes of its occurrence as large enough, and then within a couple of minutes executing the weapons test so that its seismic signals would hopefully be swamped by the large and prolonged signals from the earthquake); and setting off a sequence of several explosions that are designed to simulate a natural earthquake signal.

Careful study of each of these methods indicates that they are relatively ineffective in comparison with the methods known as cavity decoupling and mine masking, which we next discuss, and which are widely regarded as setting the practical levels down to which seismic monitoring of nuclear explosions is possible.

When an underground explosive device is tightly packed into its hole ("tamped" or "fully coupled"), and is detonated at sufficient depth to contain all radioactive products, a shock wave travels some distance from the shot-point out into the surrounding rock at speeds that exceed the normal *P*-wave speed. This nonlinear phenomenon reduces at sufficient distance from the shot-point, and thereafter the wave propagation can be regarded as



Seismic Monitoring of Nuclear Explosions, Figure 7 The *P*-wave signals of the Wyoming mine collapse are shown at six teleseismic stations, processed to bring out the fact that the first motion of the ground at these stations is downward, indicative of an implosion rather than explosion (for which the first motion would be upward). (From Bowers and Walter, 2002.)

elastic. The so-called "elastic radius" for a tamped explosion, i.e., the radius beyond which wave propagation is linear, is roughly 100 meters times the cube root of the yield (in kilotons).

If the explosion is set off inside a large underground cavity instead of being tamped, then the shock wave set up in the rock can be weakened or even eliminated, in which case only elastic waves are radiated. The explosion is said to be fully decoupled if only elastic waves result, and theoretical work reported in 1959 has addressed the question of how much weaker the seismic signal might be made. Theoretical work has indicated that signals could thereby be reduced by factors in the range 50–100, compared to a tamped explosion. The cavity radius itself is the "elastic radius" for a fully decoupled shot. For salt, the cavity radius required for full decoupling has been estimated at about 25 m times the cube root of the yield (in kilotons). For hard rock, the cavity size for full decoupling is comparable; for weak salt it is somewhat greater. See Sykes (1996) for further discussion, and Denny and Goodman (1990) for estimates of the decoupling factor derived from the practical experience in 1966 of carrying out a small nuclear explosion (about 0.38 kt) in the cavity produced by a tamped shot of 5.3 kt conducted 2 years earlier in a Mississippi salt dome. They conclude that the amplitude reduction is about 70, at low frequencies, for salt. At frequencies that have conventionally been used for seismic monitoring, the seismic signal strength is proportional (very roughly) to the volume within the elastic radius. This volume is substantially reduced by fully decoupling, which is the reason why cavity decoupling has been proposed as offering the technical possibility of a clandestine program of nuclear testing. However, the signal strength is not nearly so strongly reduced, by decoupling, at frequencies above that associated with resonances of the internal surface at the elastic radius. In practice, the frequency above which decoupling is likely to be substantially less effective is around 10–20 Hz, divided by the cube root of the yield (in kilotons). The overall effect on the seismic signals from a fully decoupled shot of yield Y, given the results of Denny and Goodman, is to make these signals look like those from a tamped shot of yield $Y/70$.

A thorough discussion of decoupling as an evasion scenario would have to include several non-seismological considerations. These include: the military significance of being able to carry out nuclear tests up to various different yield levels (e.g., 0.1, 1, or 10 kt.); and the political consequences if a clandestine test program were uncovered. Technical considerations include methods of (clandestine) cavity construction, and the capabilities of non-seismological surveillance techniques. Leakage of radioactivity from an underground cavity would be a challenge, given that much of the energy of a decoupled explosion goes into pumping up the pressure in the cavity. While some assert that clandestine use of cavity decoupling would be so difficult to execute that it belongs to the realm of fantasy, others have been persuaded that the risk might indeed be manageable, and that estimates of concealable yields, under this evasion scenario, must be made. The NAS (2002) report describes ten "layers of difficulty" with successfully hiding an underground nuclear explosion via cavity decoupling, concluding that even a nation committing significant resources to this work could not have confidence in being able to get away with tests above 1 or 2 kt.

The evasion scenario known as mine masking hypothesizes the execution of an underground nuclear weapon test explosion in a mining region, concurrently with a large mine blast. Such blasts in a big commercial operation consist of hundreds of separate charges, fired in sequence to break and/or move as much rock as possible, in a procedure known as ripple-firing (Khalturin et al., 1998). Regardless of the logistical difficulties of such a scenario, estimates of the possibilities of concealment via this approach can come from taking examples of signals from large mine blasts, and signals from small underground nuclear explosions, then adding them together before subjecting them to the methods used to discriminate between various types of seismic events. What is

typically found, is that the maximum size of the identifiable waves (e.g., the *P*-waves) from the mine blast is about that expected from individual sub-blasts (commonly called "delays"), and these amplitudes are spread out over a longer time in seismograms.

A study of mine masking possibilities by Smith (1993) used several different examples of mine-blast seismograms together with single-fired explosion records, and found a number of features that could be used to identify a simultaneous shot within a ripple-fired blast. He concluded that to conceal a single-fired deep detonation (depth is required for containment of radionuclides), the single explosive shot should not exceed 10% of the total explosive.

The conclusion here is that mine blasts are not effective for concealing large releases of energy at the level associated with kiloton-scale nuclear weapons tests, unless the nuclear explosion were subject to efforts at decoupling. Again non-seismic considerations arise, including an assessment of the plausibility of carrying out a complicated decoupled and masked nuclear explosion at the same time and location as a large mine blast that would itself attract some level of monitoring attention – particularly if the seismic signals seemed unusual in comparison with those from prior blasting in the region.

Event detection capability of the international monitoring system

In 1976, a group of international scientists was established at the Conference on Disarmament in Geneva, for the study of monitoring technologies and data analysis methods in the context of supporting a future test ban treaty. This group of scientific experts (GSE) played an essential role in laying the scientific groundwork for the final stage of CTBT negotiations conducted from 1994 to 1996. Prior to the negotiation, GSE organized a series of technical tests – GSETT-1 in 1984, GSETT-2 in 1991, and GSETT-3 in 1995. These tests contributed significantly to the development of the international system being built today to support treaty verification.

The finalized sections of the CTBT include an extensive description of networks to monitor treaty compliance using hydroacoustic, infrasound, and radionuclide technologies as well as seismological methods. The CTBT Organization (CTBTO) operates an International Monitoring System specified in treaty text, as well as an International Data Centre to analyze signals sent via satellite to headquarters in Vienna. Extensive descriptive material on these networks is available online (see http://www.ctbto.org).

To implement the CTBT seismic monitoring system, a sequential four-step process is needed to build each station (CTBTO PrepComm, 2009): (1) Site survey, (2) Installation, (3) Certification, and (4) Operation. It must be demonstrated for IMS stations that data received at the International Data Centre (IDC) are *authentic*. This is achieved through a special digital "signature" embedded in the data flow from each station. The IMS station must be certified to ensure that all of its equipment, infrastructure, and settings meet the technical specifications set by the CTBTO, and to also ensure that all data are transmitted to the IDC through the Global Communication Infrastructure (GCI) in a timely manner.

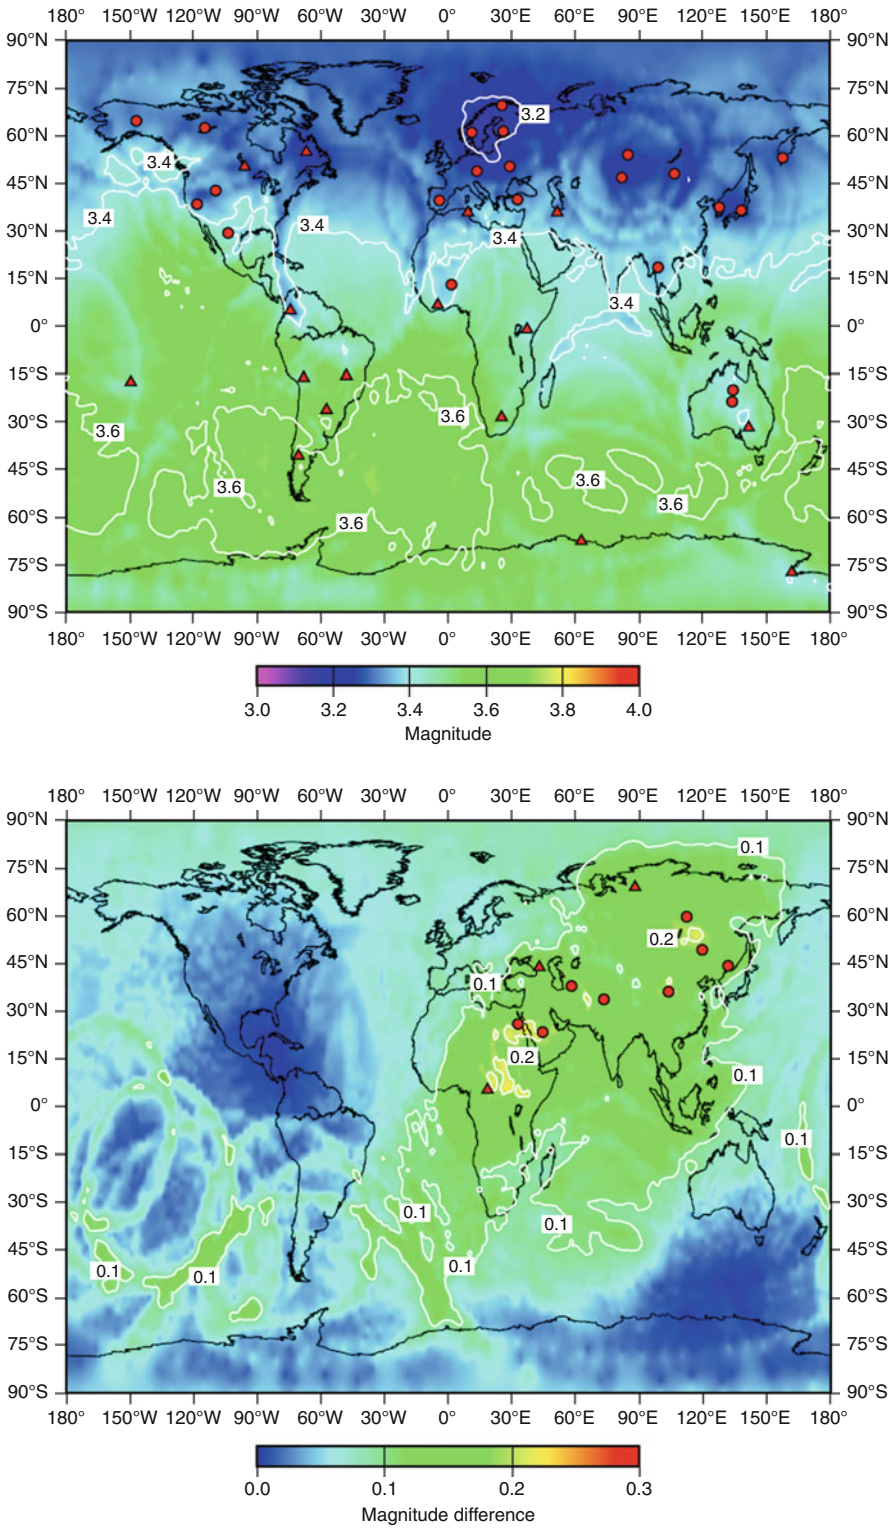
Here, we note that the primary seismographic network is to consist of 50 stations, many of them arrays; and that location estimates are based upon detection of signal at 3 stations or more. An auxiliary network of 120 continuously operating stations is to provide seismic waveform data, again via satellite, in order to help characterize the events detected by the primary network. Although these two networks are not completely built (as of 2010), there are enough stations operating to provide good indications of what the detection capability will be when all stations are installed and providing data.

Figure 8 shows maps of the detection capability of the primary seismic network of the IMS. The upper figure shows the actual capability of 38 operating stations based upon experience in the year 2007. The lower figure shows how much this capability is expected to improve when 11 additional stations are operational, most of them in Eurasia. Capability is expressed in terms of magnitude thresholds, above which 90% of the seismic events are expected to be detected at enough stations to provide a location estimate. The work of identifying events is left to member states. This work is not just a technical matter since it is a political act for one country to make an allegation that another country has committed a treaty violation. The evidence in support of such an allegation can come from the IMS and IDC, as well as from the National Technical Means of member states, and/or from a subset of the thousands of seismographic stations operated around the world for purposes not directly related to monitoring for nuclear explosions.

Summary

We have described the basic steps in monitoring nuclear explosions, and have emphasized the seismic monitoring system specified by the Comprehensive Nuclear Test Ban Treaty of 1996.

When the treaty was being negotiated, the goal for the International Monitoring System was that it be capable of detecting and identifying treaty violations – nuclear explosive tests – at the 1 kt level and higher, if they were not evasively tested. Recognizing that a 1 kt underground nuclear explosion has a magnitude in the range about 4–4.5, if it is conducted in the way that almost all the more than 1,500 prior underground nuclear explosions were carried out (i.e., well tamped and not with intent to reduce the signals picked up by monitoring networks), the evidence from Figure 8 is that this design capability has been significantly exceeded. For almost the entire northern hemisphere, including Eurasia and North America, capability is good down to about magnitude 3.3. This corresponds to a yield of less than 100 t (0.1 kt) for a well-tamped explosion in hard rock. Only time will tell whether this capability, combined with other monitoring assets, is deemed adequate to support entry into force of the CTBT.



Seismic Monitoring of Nuclear Explosions, Figure 8 Maps showing the detection capability of the IMS primary seismographic network. The upper figure shows the capability of the network in late 2007, with 38 stations sending data to the IDC. The capability is represented by the magnitude of the smallest seismic event that would be detected with a 90% probability by three stations or more. The lower figure shows the estimated improvement over this capability that could be achieved by bringing 11 of the remaining 12 primary seismic stations into operation. Definition

Seismic noise. Noise is the undesirable part of seismic data that is not signal, and signal is what fits our conceptual model.
Multiple. A seismic event that experiences more than one reflection in the subsurface.
SNR. Signal-to-noise ratio – is a measure of strength of signal compared to noise, and it is a measure of seismic data quality.
Active seismic. Seismic data recordings of artificial man-made sources such as dynamite and vibroseis in land surveys and air gun in marine surveys. Example: exploration and engineering seismology.
Passive seismic. Seismic data recordings of natural sources such as earthquake, solar waves, and ocean waves. Example: earthquake seismology.

Introduction

Seismic noise comprises all of the unwanted recorded energy that contaminates seismic data. A part of the seismic energy is considered noise if it does not fit the conceptual model of seismic signal. Seismic noise can be random or coherent. The identification of seismic noise depends on the type of data analysis and the type of data available – a part of data treated as noise in one application can be signal in another application. For example, the S-wave energy is generally considered noise in a P-wave processing project; vice versa, the P-wave energy is considered noise in an S-wave processing project.

Historically, only the traveltime information of the seismic data was used to study the subsurface. For example, the knowledge about the earth's deep interior was primarily derived from seismic traveltime information recorded during deep earthquakes. Also, only the traveltime information was used to derive the structural image of subsurface for exploration projects. As seismic technology has advanced and the appetite for understanding complicated geological features has increased, there has been a push toward technologies using the complete waveforms (amplitude and traveltime) in seismic analysis. Full waveform inversion technology (Tarantola, 1986) is one such example that uses the complete waveform to estimate properties of the subsurface from the seismic data. The success of such technologies is understandably very dependent on clean, noise-free seismic data.

It is essential that seismic data are carefully processed to derive high quality seismic images (see Yilmaz, 2001 for seismic data processing). One of the major challenges in seismic data processing is to separate noise from signal or to attenuate noise. In practice, noise cannot be completely attenuated and occasionally it is not even desired to attenuate noise but to use it as signal. The objective of the noise attenuation or noise separation process in seismic data processing is to enhance signal-to-noise ratio (SNR). There have been significant progress in data processing to improve SNR; advances have been made in random noise attenuation (Yilmaz, 2001) and coherent noise attenuation (see Weglein and Dragoset, 2005 for multiple attenuation methods).

Recently, there have been various efforts to use seismic noise as signal, for example: (1) using multiple reflected energy (multiples) in seismic migration and inversion to image subsurface; and, (2) using very low and very high frequency passive seismic signal for reservoir monitoring. In the following sections, we write brief descriptions about the types of seismic noise, the noise attenuation techniques, and how seismic noise can be useful.

Types of seismic noise

There are two types of seismic noise: random noise and coherent noise. In a multichannel seismic dataset, random noise does not correlate either with the neighboring channels (i.e., no spatial correlation) or along the same channel (i.e., no temporal correlation). Coherent noise, however, is part of the data that correlates spatially and/or temporally. Random noise is easier to attenuate during seismic data processing. Coherent noise is difficult to attenuate in processing; therefore, residual coherent noise can interfere with real signal and be misinterpreted as signal. The possible sources of these seismic noises can be placed under four categories: (1) ambient sources, (2) wave propagation related noise, (3) data acquisition related noise, and (4) data processing artifacts. The severity and types of noise can differ between marine and land acquisition environment.

Ambient noise is the noise from unwanted sources like wind, swell, power line, activities on nearby road, surface facility, marine activities like ships and marine animals, and other cultural noise. Ambient noise can be present in various forms on seismic data, such as linear features, localized very high amplitude response, and mono-frequency events. Ambient noise can be random noise and coherent noise.

Wave propagation related noise includes the surface waves, multiples, and geologic noise. Seismic response for an active source survey include primary reflection event (e.g., incident P-wave reflected back as P-wave), refraction, ground roll, mode converted event (e.g., incident P-wave reflected as S-wave), and several events reflected multiple times in the subsurface (multiples). In reflection seismology, we are interested in P-wave (and/or S-wave) primary reflections. All the other coherent energies recorded are considered noise. Multiples are considered the major source of coherent noise in the seismic experiment and are really difficult to attenuate. Wave propagation related noise also includes seismic response from unwanted geology (complicated stratigraphy,

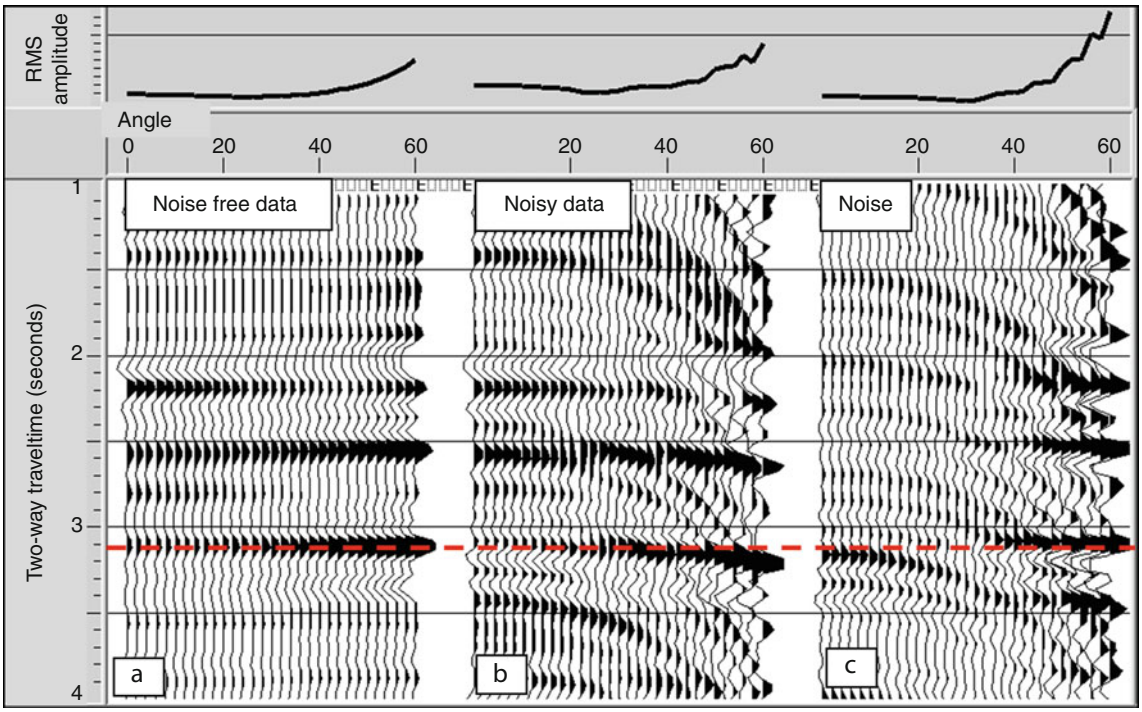
shallow gas, and faults) not considered in seismic analysis; they are known as geologic noise.

Data acquisition related noise is due to poor source and receiver coupling to the earth, source and recording instruments-generated noise, and acquisition footprint related to the acquisition design. Noise from poor coupling and noise related to instruments can be easily identified and attenuated. Acquisition footprint related to the acquisition design, observed as linear trend in seismic amplitude map view, is common in seismic data and can be suppressed in processing.

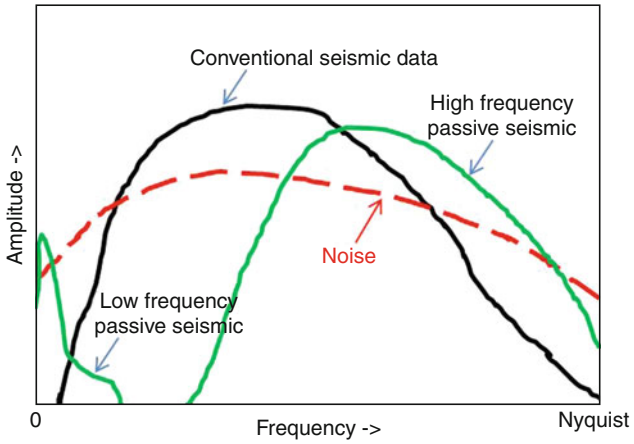
Seismic data processing is another source of noise in processed seismic data. There are various factors affecting seismic reflection amplitude that do not contain subsurface information (Sheriff, 1975), but it is impossible to correct for all the factors affecting amplitudes. Many approximations and assumptions are made in seismic data processing depending on computer resources availability, project timeline, understanding of the physics of wave propagation, and the type of seismic data available. Some of these factors may alter the data and may introduce noise in the recorded data. Some examples are: (1) noise introduced in seismic data due to poor multiple attenuation and poor normal move-out (NMO) correction (Figure 1); (2) noisy subsurface image due to imperfect velocity model used and/or approximate physics used for migration; (3) noise introduced due to inaccurate amplitude calibration of the raw amplitudes from the processed seismic data with synthetics seismic amplitude for quantitative AVO/AVA (amplitude variation with offset/angle) analysis; (4) artifacts introduced from the process of frequency enhancement to broaden frequency bandwidth for better depth resolution; and (5) artifacts introduced from the process of interpolation and regularization to compensate for the irregular acquisition geometry.

Enhancing signal over noise

There is always some noise present in the seismic data. Figure 2 schematically shows amplitude spectra of various seismic signals and noise, and noise is present in the whole signal bandwidth. Thus, the objective is to enhance SNR by noise attenuation or separation so that data can be effectively used for analysis. An important step in noise



Seismic Noise, Figure 1 Example of seismic noise. Shown in this figure is normal move-out (NMO) corrected synthetic seismic angle gather for AVA analysis with angle (in degrees) as *x*-axis and two-way traveltime (in seconds) as *y*-axis for: noise-free case (**a**), with noise (**b**), and the noise present in data (**c**). The response in the third panel (**c**) is the difference between response in the first panel (**a**) and the second panel (**b**). On the top of angle gather is the root mean square (RMS) amplitude value as a function of angle; the RMS value is computed in entire time gate shown here. In (c), the dipping coherent noises are multiples and the strong amplitudes at far angles are residual data after NMO. Thus, part of the data became residual data (un-flattened data after NMO in (b) is noise in AVA analysis) due to imperfect seismic velocity and/or seismic modeling method used in NMO (see red lines marked at 3,100 ms across three gathers for residual data).



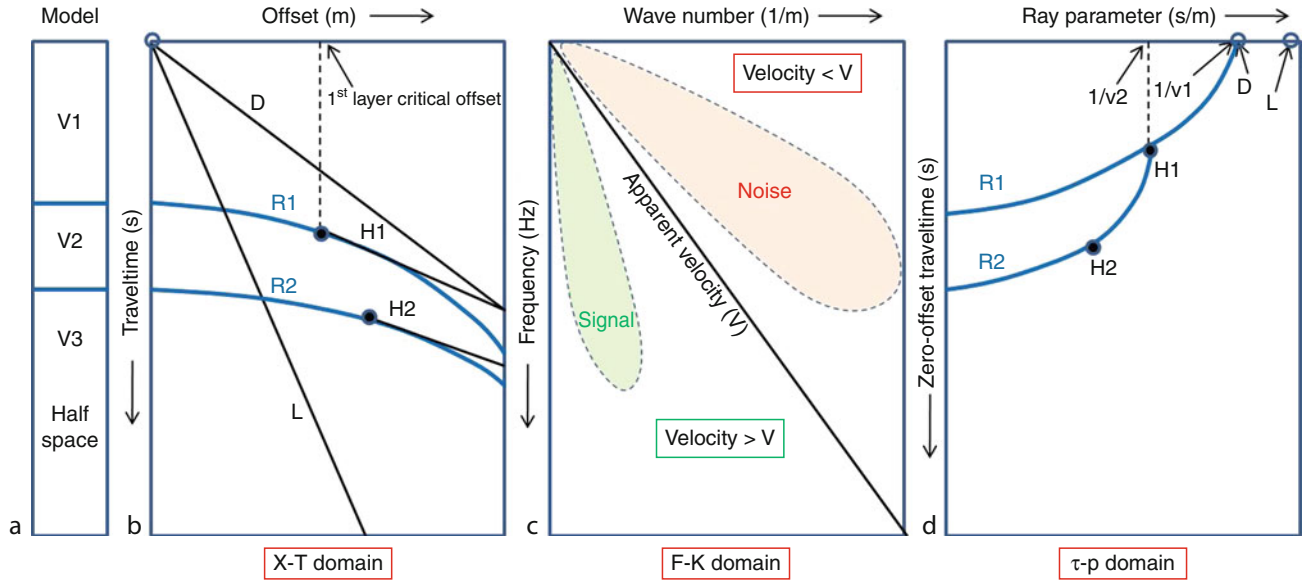
Seismic Noise, Figure 2 Schematic amplitude spectrum: for conventional broadband seismic data (active seismic for exploration range 10–60 Hz, and passive seismic for earthquake range from 10–100 Hz), low frequency passive seismic data (typically less than 10 Hz), high frequency passive seismic (microseismic) data (typically 30–300 Hz), and noise. Because noise is present at all frequencies, there is a need to do noise attenuation so that we get signal-to-noise ratio greater than 1. Spectrum is plotted for near zero frequency to Nyquist frequency. Nyquist frequency is the highest frequency without aliasing; beyond this frequency signal cannot be reliably estimated. Note that passive low and high frequency data can be treated as noise in broadband seismic data.

attenuation/separation is to identify signal from noise. White (1984) discusses spectral methods for signal and noise estimation on seismic reflection data. Kanasewich (1990) and Chapter 6 of Yilmaz (2001) have good discussion on noise and multiple attenuation methods with data examples. Noise level in data compared to signal can be estimated as the ratio of autocorrelation of data to a cross correlation of data. This is because autocorrelation of data represents both signal and noise but cross correlation of data with a representative signal trace (can be local partial stack of data) represents signal in data. Signal and noise separation process can be broadly divided into two methods: prediction based methods and separation based methods. By performing seismic simulation over a known (conceptual) model and comparing synthetics to the field seismic data, signal and noise can be identified on data, and therefore noise can be attenuated. Also, signal and noise representation differs in different data domains. Therefore, a suitable data domain can be identified for the optimum separation of the two. Figure 3 schematically shows various seismic events for a three-layer model in native acquisition (X-T) domain and transformed domains: (1) X-T domain (represents spatial-time domain), (2) F-K domain (represents frequency – wave number domain), and (3) τ-p domain (representing zero-offset traveltime – ray parameter domain). The key to successful noise attenuation is large separation between signal and noise in a specific data domain. Different types of noise may require different domains for better separation between signal and noise. For example, a linear event on a shot gather (X-T domain) maps to a radial line in the F-K domain and it maps onto a point in the τ-p domain, and thus can be rejected by F-K filtering and τ-p filtering, respectively. Caution should be observed while performing the forward and inverse transforms, as some implementations may not be completely reversible and may also introduce artifacts.

Random noise is not correlated and can be attenuated easily during data processing. One of the most robust methods to attenuate random noise on multichannel data by a factor of square root of N is by stacking (compositing) data from N channels. If prestack data is needed, however, F-X deconvolution (predictive deconvolution) is effective in random noise attenuation, where F-X corresponds to frequency – space domain. Deconvolution operation (Yilmaz, 2001) is designed in space domain to predict coherent signals, and then coherent signals can be subtracted from the seismic record.

Coherent noise is relatively more difficult to attenuate. An appropriate data domain (Figure 3) can be selected to distinguish signal from noise using the noise characteristics, like velocity and frequency. Radon filtering in τ-p domain and wavelet transform filtering in F-K domain is very effective method for coherent noise attenuation. In many field data cases, signal and noise are not well separated in any data domain and therefore it is very difficult to attenuate the noise. Recently a version of F-K filtering called Curvelet transform filtering has shown better results for both random and coherent noise attenuation (Neelamani et al., 2008). Multiples are example of coherent noise present in the data. There has been extensive research in the field of multiples suppression. The surface related multiple elimination (SRME) has been heavily relied upon to suppress multiples (Berkhout and Verschuur, 1997). This technique is based on the stationary phase theory of the seismic signal and the multiples are predicted by convolving traces with one another and then stacking these convolved traces.

Another way to have better SNR in seismic data is via improved seismic acquisition techniques. There have been various developments in seismic acquisition on land and in marine environment. For example, over/under marine seismic acquisition promises better SNR in both low and high frequency range (Moldoveanu et al., 2007). In over/under towed-streamer acquisition pairs of streamer are deployed at two different depths in the same vertical plane. Other advances in seismic acquisition promise cleaner and better seismic images, for example, Multicomponent Ocean Bottom recording, Wide Azimuth recording, and Simultaneous Sources recording. The multiples suppression is strongly dependent on the acquisition effort. For example, the suppression of multiples in the case of Wide Azimuth acquisition is the result of a natural weighting of the traces going into the stack



Seismic Noise, Figure 3 Seismic responses in various data domains for a three-layer model. The time domain earth model is shown in left (**a**) with seismic velocity for three layers as V1, V2, and V3. The second from left is the seismic response for a three-layer model in X-T domain (**b**), where D represents direct arrival, L represents linear noise, such as ground rolls, R1 and R2 are primary reflection events from 1st and 2nd layer interfaces, and H1 and H2 are refraction events. The third from left shows the seismic response in F-K domain (**c**), where noise (D, L events) is on the upper right corner with apparent velocity less than the reference apparent velocity (V) and signal (R1, R2, H1, H2 events) are on the lower left corner corresponding to lower wave numbers. The right most plot (**d**) shows the seismic response in the τ-p domain, where the linear event in X-T domain plots on a point in the τ-p domain (Diebold and Stoffa, 1981).

because of the areal nature of the acquisition (VerWest and Lin, 2007).

Some noise will always remain in the seismic data even after careful seismic processing. Also, there are some noises that are still not understandable and difficult to attenuate. Therefore, it is important to incorporate noise in the seismic data analysis – for example, in seismic inversion the data should not be over fitted as it might be fitting the noise.

Use of noise as signal

There have been significant efforts recently to use all of the recorded energy in the seismic data. Traditionally, only the primary reflection wavefield is used in reflection seismic imaging, while the multiple/ghost is discarded. However, the ghost/multiples can be used as signal, for example, as an input to mirror migration (Verm, 1987) to produce superior shallow images for the sparse receiver ocean bottom data where illumination holes deteriorate the primary images (Clarke et al., 2006; Dash et al., 2009). Note that multiples are also generated from the same source as primary, they travel longer paths and contain more information than primary, and therefore in some circumstances multiples can be more useful than primaries. Full waveform inversion is another technique that uses both the primary and the multiples to invert for the subsurface parameters more effectively.

Multiples have also been used to interpolate for missing near offsets in seismic recording using the technique of interferometry (Schuster, 2009). Seismic interferometry can also be used to extract primary signal from background noise and multiples by simply cross-correlating recorded data at two different stations (Sabra et al., 2005; Curtis et al., 2006; Draganov et al., 2007).

Some new seismic acquisition methods have been useful in using conventional multiples to improve SNR and/or extract primary. For example, over/under towed-streamer acquisition technology uses multiples to improve seismic data quality (Moldoveanu et al., 2007), and there is a possibility to estimate primaries from surface multiples from data recorded with simultaneous sources also called blended data (van Groenestijn and Verschuur, 2010). In the simultaneous source acquisition (Berkhout, 2008; Hampson et al., 2008) multiple sources are fired in a short time interval to speed up the acquisition.

Converted S-wave data, regarded as noise in reflected P-wave data imaging, has been quite successful in imaging gas reservoirs and areas where we have shallow gas anomalies (Tatham and McCormack, 1991). The property that S-wave does not get as attenuated as P-wave when the wavefield travels through these porous medium helps create better images through pure S-wave or converted S-wave imaging.

Low frequency earth's ambient passive response caused by natural phenomenon (such as wind, ocean waves, and human-made noise) and high frequency passive seismic response due to small earthquakes (microseisms) caused by induced fractures in a petroleum reservoirs are considered noise in a broadband active seismic data, but they can be effectively used to study subsurface. Low frequency earth's ambient noise can be used to extract signal (Draganov et al., 2007), and the low frequency passive seismic anomaly can be correlated with the presence of hydrocarbon (Saenger et al., 2009); however the research is still in its early stages. High frequency passive seismic data (also called microseismic data) are effectively used in hydraulic fracture monitoring (Warpinski, 2009) by locating microseisms induced by hydrocarbon production related activities.

Summary

Seismic noise is an integral part of the seismic record and is defined as all unwanted seismic energy on data. It can be divided into two categories: random and coherent noises. Random noise is not correlated among traces and is easier to attenuate compared to coherent noise that is spatially and/or temporally correlated. Multiples and geologic noise that are coherent noise are more difficult to attenuate and often interfere with seismic signal and makes seismic analysis challenging. Strategies for seismic noise attenuation are needed to preserve the seismic signal of interest and to improve signal-to-noise ratio (SNR). The success in noise attenuation lies in identification and then separation or prediction of signal and noise. Transformation of data to different data domains (X-T, F-K, τ-p, curvelet, wavelet domains) have helped in better separating noise from signal. Wave-equation extrapolations, inverse scattering methods, surface related multiple elimination, deconvolution, etc., model the noise and/or data in the process of noise attenuation. Advances in seismic data acquisition and processing have been made to improve SNR. Recently various efforts have been made to use noise as signal and are an active topic of research. This includes using multiples as well as primaries in seismic migration and inversion, and using low and high frequency passive seismic data in imaging subsurface.

SEISMIC PHASE NAMES: IASPEI STANDARD

Dmitry A. Storchak[1], Johannes Schweitzer[2], Peter Bormann[3]
[1]International Seismological Centre (ISC), Thatcham, Berkshire, UK
[2]NORSAR, Kjeller, Norway
[3]Department 2: Physics of the Earth, GFZ German Research Center for Geosciences, Potsdam, Germany

Introduction

The working group (hereinafter WG) on the Standard Seismic Phase Names was set up by the IASPEI Commission on Seismological Observation and Interpretation (CoSOI) in 2001. The WG was chaired by D. A. Storchak, and included R. D. Adams, P. Bormann, E. R. Engdahl, J. Havskov, B. L. N. Kennett, and J. Schweitzer. The WG put together a modified standard nomenclature of seismic phases that was meant to be concise, consistent, and self-explanatory on the basis of agreed rules. The list was not meant to satisfy specific requirements of seismologists to name various phases used in a particular type of research. Instead, it was hoped that the new list would ensure an expanded standardized data reporting and exchange by data analysts and other users. After numerous consultations with the seismological community, the Standard Seismic Phase List was finalized and adopted by the CoSOI/IASPEI at its meeting in Sapporo on July 04, 2003.

The original list of standard seismic phase names was first published as part of the New Manual of Seismological Observatory Practice (Storchak et al., 2002) and then the version formally approved by the IASPEI was published in the Seismological Research Letters (Storchak et al., 2003). Various updates to the list were required due to progress in observational seismology and relevant changes in other observational standards. This article accommodates the advances made in the nomenclature since its last publication.

The new nomenclature partially modified and complemented an earlier one published in the old edition of the Manual of Seismological Observatory Practice (Willmore, 1979). It is more in tune with modern Earth and travel-time models. As opposed to former practice, the WG tried to make sure that the phase name generally reflects the type of wave and the path it has traveled. Accordingly, symbols for characterizing onset quality, polarity, etc., are no longer part of the phase name. The WG was also aware that seismic phases exist that are common in some regions but are only rarely or not found in other regions, such as Pb, PnPn, PbPb, etc.

The extended list of phase names as presented below reflects significantly increased detection capabilities of modern seismic sensors and sensor arrays, even of rather weak phases, which were rarely observed on the classical analog records. It also accounts for improved possibilities of proper phase identification by means of digital multi-channel data processing such as frequency-wave number (f-k) analysis and polarization filtering, by modeling the observations with synthetic seismograms or by showing on the records the theoretically predicted onset times of phases. Finally, the newly adopted IASPEI Seismic Format (ISF) (www.isc.ac.uk/doc/code/isf/isf.pdf) is much more flexible then the older formats previously used by the ISC, the NEIC, and other data centers. It also allows reporting, computer parsing, and archiving of phases with long or previously uncommon names. ISF also accepts complementary parameters such as onset quality, measured back azimuth and slowness, amplitudes and periods of other phases in addition to P and surface waves, for components other than vertical ones, and for instruments with nonstandard response characteristics.

This increased flexibility of the parameter-reporting format requires improved standardization, which limits the uncontrolled growth of incompatible and ambiguous parameter data. Therefore, the WG agreed on certain rules. They are outlined below prior to the listing of the standardized phase names. To facilitate the understanding of the phase names, ray diagrams are presented below. They have been calculated for local seismic sources on the basis of an average one-dimensional two-layer crustal model and for regional and teleseismic sources using the global 1D Earth model AK135 (Kennett et al., 1995).

Before assigning abbreviated shortcut seismic phase names, one should agree first on the language to be used and its rules. As in any other language, we need a suitable alphabet (here plain Latin letters), numbers (here Arabic numbers and +/− signs), an orthography, which regulates, for example, the use of capital and lower case letters, and a syntax, that describes the rules of correct order and mutual relationship of the language elements. One should be aware, however, that like any historically developed language, the seismological nomenclature will inevitably develop exceptions to the rules and depend on the context in which it is used. Although not fully documented below, some exceptions will be mentioned. Note that our efforts are mainly aimed at standardized names to be used in international data exchange so as to build up unique, unambiguous global databases for research. Many of the exceptions to the rules are related to specialized, mostly local research applications. The identification of related seismic phases often requires specialized procedures of data acquisition and processing that are not part of seismological routine data analysis. Also, many of these exceptional phases are rarely or never used in seismic event location, magnitude determination, source mechanism calculations, etc., which are the main tasks of international data centers. We focus, therefore, on phases that are particularly important for seismological data centers as well as for the refinement of regional and global Earth models on the basis of widely exchanged and accumulated parameter readings. In addition, we

added references to the first definition of some wave types and phase names.

Standard letters, signs, and syntax used for describing seismic phases

Capital letters

Individual capital letters that stand for primary types of seismic body waves include:

P:	Longitudinal wave that has traveled through the Earth's crust and mantle, from *undae primae* (Latin) = first waves (Borne, 1904)
K:	Longitudinal wave that has traveled through the Earth's outer core, K, from Kern (German) = core (Sohon, 1932; Bastings, 1934)
I:	Longitudinal wave that has traveled through the Earth's inner core (Jeffreys and Bullen, 1940)
S:	Transverse wave that has traveled through the Earth's crust and mantle, from *undae secundae* (Latin) = second waves (Borne, 1904)
T:	Wave that has partly traveled as sound wave in the sea, from *undae tertiae* (Latin) = third waves (Linehan, 1940)
J:	Transverse wave that has traveled through the Earth's inner core (Bullen, 1946)

Exceptions

- A capital letter N used in the nomenclature does not stand for a phase name but rather for the number of legs traveled (or N-1 reflections made) before reaching the station. N should usually follow the phase symbol to which it applies. For examples see syntax below.
- The lowercase letters p and s may stand, in the case of seismic events below the Earth's surface, for the relatively short *upgoing leg* of P or S waves, which continue, after reflection and possible conversion at the free surface, as downgoing P or S wave. Thus seismic depth phases (e.g., pP, sP, sS, pPP, sPP, pPKP, etc.) are uniquely defined. The identification and reporting of such phases is of utmost importance for source depth determination (Scrase, 1931; Stechschulte, 1932; Gutenberg et al., 1933; Macelwane et al., 1933).
- Many researchers working on detailed investigations of crustal and upper-mantle discontinuities denote both the up- and downgoing short legs of converted or multiply reflected P and S phases as lowercase letters p and s, respectively.

Individual or double capital letters that stand for surface waves include:

L:	(Relatively) long-period surface wave, unspecified, from *undae longae* (Latin) = long waves (Borne, 1904)
R:	Rayleigh waves (short- to very long-period waves in crust and upper mantle) (Angenheister, 1921)
Q:	Love waves, from Querwellen (German) = transverse waves (Angenheister, 1921)
G:	(Very long-period) global (mantle) Love waves, firstly observed and reported by Gutenberg and Richter (1934); in honor of Gutenberg, Byerly proposed the usage of G for these waves (Richter, 1958)
LR:	Long-period Rayleigh waves, usually relating to the Airy phase maximum in the surface wave train
LQ:	Long-period love waves

Lowercase letters and signs

Single lowercase letters generally specify the part of Earth's crust or upper mantle in which a phase has its turning point or at which discontinuity it has been reflected and/or eventually converted:

g:	Following the phase name characterizes waves "bottoming" (i.e., having their turning point in case of P or S body waves) or just travel (surface waves) within the upper ("granitic") Earth's crust (e.g., Pg, Sg; Rg), (Jeffreys, 1926)
b:	Following the phase name characterizes body waves bottoming in the lower ("basaltic") Earth's crust (Jeffreys, 1926) (e.g., Pb, Sb; alternative names for these phases are P*, S*, (Conrad, 1925))
n:	Following the phase name characterizes a P or S wave that is bottoming or traveling as head wave in the Earth's uppermost mantle (e.g., Pn, Sn), introduced after Andrija Mohorovičić discovered the Earth's crust and separated the crustal travel-time curve from the normal (=n) mantle phase (Mohorovičić, 1910)
m:	(Upward) reflections from the outer side of the Mohorovičić (Moho) discontinuity (e.g., PmP, SmS)
c:	Reflections from the outer side of the core-mantle boundary (CMB), usage proposed by James B. Macelwane (see Gutenberg, 1925)
i:	Reflections from the outer side of the inner core boundary (ICB)
z:	Reflections from a discontinuity (other than free surface, CMB or ICB) at depth z (measured in km). Upward reflections from the outer side of the discontinuity may additionally be complemented by a + sign (e.g., P410 + P; this, however, is not compulsory) while downward reflections from the inner side of the discontinuity must be complemented by a − sign (e.g., P660−P)

An exception from these rules is the use of lowercase p or s to indicate arrivals of longitudinal or transverse waves that were first radiated to go up toward the free surface to be reflected/converted back into the Earth as normal P or S waves (see near source surface reflections and conversions section of the phase list below).

Double lowercase letters following a capital letter phase name indicate the travel-time branch to which this phase belongs. Due to the geometry and velocity structure of the

Earth, the same type of seismic wave may develop a triplication of its travel-time curve with different, in some cases, well-separated, branches. Thus, it is customary to differentiate between different branches of core phases and their multiple reflections at the free surface or the CMB. Examples are PKPab, PKPbc, PKPdf, SKSac, SKKSac, etc. The separation of the different PKP branches with letters ab, bc, and df was introduced by Jeffreys and Bullen (1940).

Three lower case letters may follow a capital letter phase name to specify its character, e.g., as a forerunner (pre) to the main phase, caused by scattering (e.g., PKPpre) or as a diffracted wave extending the travel-time branch of the main phase into the outer core shadow (e.g., Pdif in the outer core shadow for P).

Syntax of generating complex phase names

Due to refraction, reflection, and conversion in the Earth, most phases have a complex path history before they reach the station. Accordingly, most phases cannot be described by a single capital letter code in a self-explanatory way. By combining the capital and lower case letters as mentioned above, one can describe the character of even rather complex refracted, reflected, or converted phases. The order of symbols (syntax) regulates the sequence of phase legs due to refraction, reflection, and conversion events in time (from left to right) and in space.

Examples for creating complex standard phase names

Traditional examples of complex phase names are as follows.

Refracted and converted refracted waves

- PKP is a pure refracted longitudinal wave. It has traveled the first part of its path as P through crust and mantle, the second through the outer core, and the third again as P through mantle and crust. An alternative name for PKP is P' (Angenheister, 1921), which should be read as "P prime."
- PKIKP (alternative to PKPdf) is also a pure refracted longitudinal wave. It has traveled the first part of its path as P through crust and mantle, the second through the outer core, the third through the inner core, and the fourth and fifth parts back again through outer core and mantle/crust.
- SKS is a converted refracted wave. It has traveled as a shear wave through crust and mantle, being converted into a longitudinal P wave when refracted into the outer core and converted back again into an S wave when entering the mantle.
- SKP or PKS are converted refracted waves with only one conversion from S to P when entering the core or from P to S when leaving the core, respectively.

Pure reflected waves

- In the case of (downward only) reflections at the free surface or from the inner side of the CMB, the phase symbol is just repeated, e.g., PP, SS (Geiger, 1909), PPP, SSS, KK, KKK, etc.
- In the case of (upward) reflections from the outer side of the Moho, the CMB, or the ICB, this is indicated by inserting symbols m, c, or i, respectively, between the phase symbols, e.g., PmP, PcP, ScS, PKiKP.
- Reflections from any other discontinuity in mantle or crust at depth z may be from the inner side (−; i.e., downward back into the mantle) or from the outer side (+; i.e., back toward the surface). To differentiate between these two possibilities, the sign has to follow z (or the respective number in km); for example, P410 + P or P660 − P.
- To abbreviate names of multi-leg phases due to repeated reflections, one can also write Phasename N. This type of abbreviation is customary in case of multiple phases with long phase names such as PmP2 for PmPPmP (free-surface reflection of PmP), SKS2 for SKSSKS (the alternative name for S'2, the free-surface reflection of SKS), PKP3 for PKPPKPPKP (double free-surface reflection of PKP; alternative name to P'3) or P4KP for PKKKKP (triple reflection of P at the inner side of the CMB).

Two additional notes are to be mentioned. First, PKP2 = PKPPKP are now alternative names for P'2 or P'P', respectively. This should not be mistaken for the old usage of PKP2 for PKPab. Secondly, in the case of multiple reflections from the inner side of the CMB, the WG followed the established tradition of placing the number N not after but in front of the related phase symbol K.

Reflected waves with conversion at the reflection point

In the case that a phase changes its character from P to S, or vice versa, one writes:

- PS (first leg P, second leg S) or SP (first leg P, second leg S) in the case of reflection/conversion from the free surface downward into the mantle (Geiger and Gutenberg, 1912a, 1912b).
- PmS or SmP, respectively, for reflection/conversion from the outer side of the Moho.
- PcS or ScP for reflection/conversion from the outer side of the CMB.
- Pz + S or Sz−P for reflection/conversion from the outer (+) side or inner (−) side, respectively, of a discontinuity at depth z. Note that the − is compulsory, the + is not.
- pS or sP reflection/conversion at the free surface for body waves with a direct upgoing first leg.

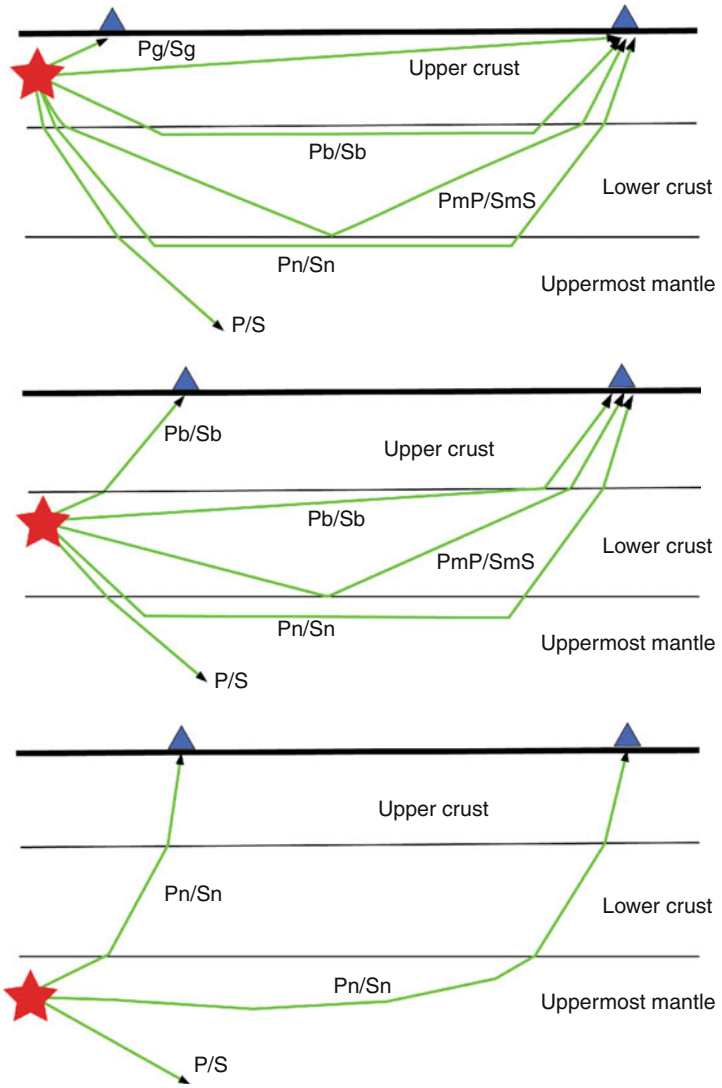
In this context, it is worth mentioning that mode conversion is impossible for reflections from the inner side of the CMB back into the outer core because the liquid outer core does not allow the propagation of S waves.

The WG determined the new IASPEI standard phase names along these lines and rules. Where these deviate from other traditionally used names, the latter are given

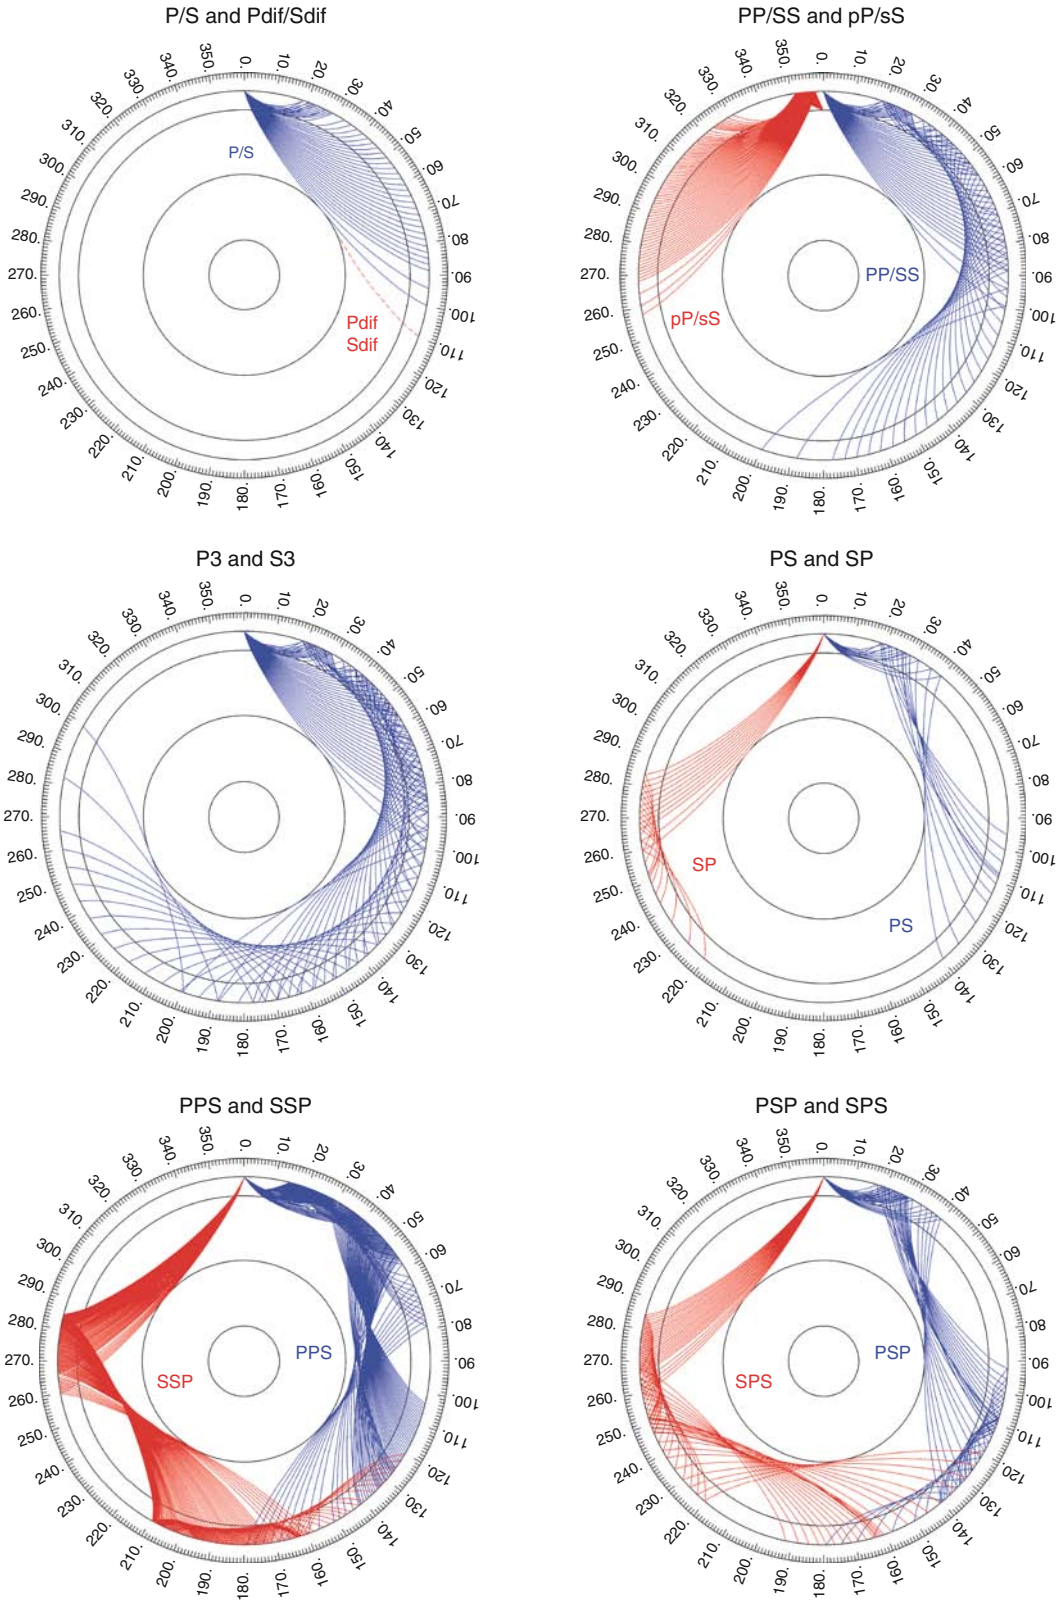
as well. Either the traditional names are still acceptable alternatives (alt) or they are old names (old), which should no longer be used.

Ray-path diagrams for some of the IASPEI standard phases

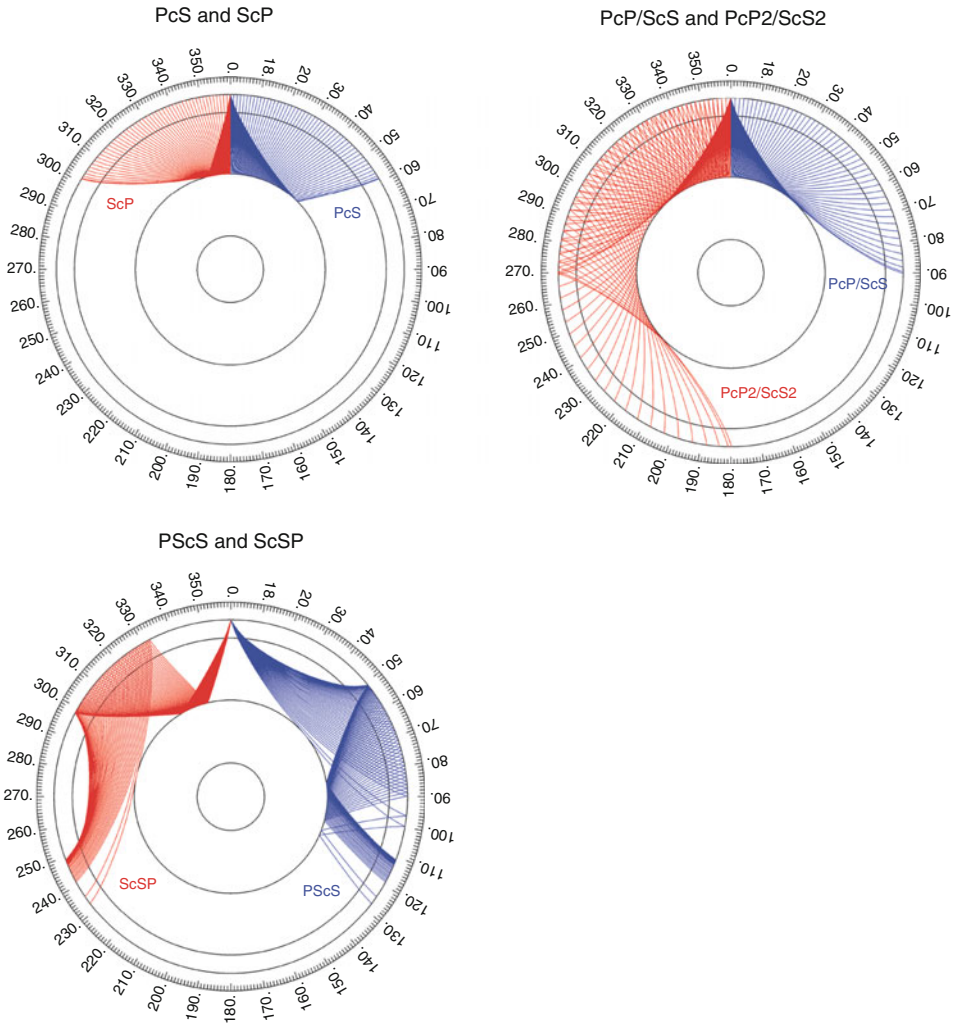
We show ray paths through the Earth for many of the mentioned phases. The three diagrams for crustal phases are sketches illustrating the principal ray paths in a two-layer crust (Figure 1). The rays in all other figures (Figures 2–6) were calculated by using the ray picture part of the WKBJ3 code (Chapman, 1978; Dey-Sarkar and Chapman, 1978); as the velocity model, we chose the standard Earth model AK135 (Kennett et al., 1995). For some types of P and S phases, the ray paths through the Earth are very similar because the velocity ratio V_P/V_S does not change enough to give very different ray pictures. In these cases, we calculated only the ray paths for the P-type ray (i.e., P, Pdif, pP, PP, P660P, P660−P, PcP, PcP2 and PcP4) and assume that the corresponding ray paths of the respective S-type phases are very similar. To show the different ray paths for phases with similar phase names, we show on many figures rays leaving the source once to the left and once to the right in different colors. The three most important discontinuities inside the Earth are indicated as black circles (i.e., the border between upper and lower mantle, the CMB, and the ICB).



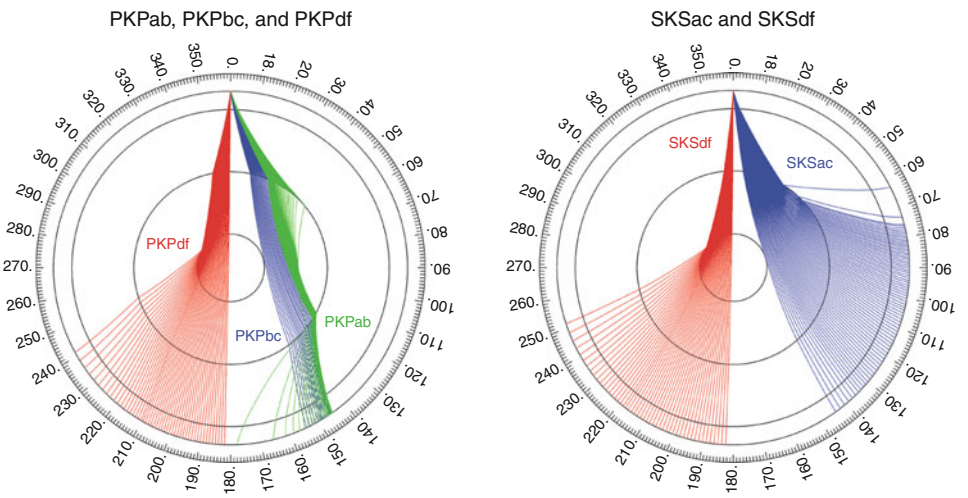
Seismic Phase Names: IASPEI Standard, Figure 1 Seismic "crustal phases" observed in the case of a two-layer crust in local and regional distance ranges ($0^\circ < D <$ approximately 20°) from the seismic source in the: (**a**) upper crust; (**b**) lower crust; and (**c**) uppermost mantle.



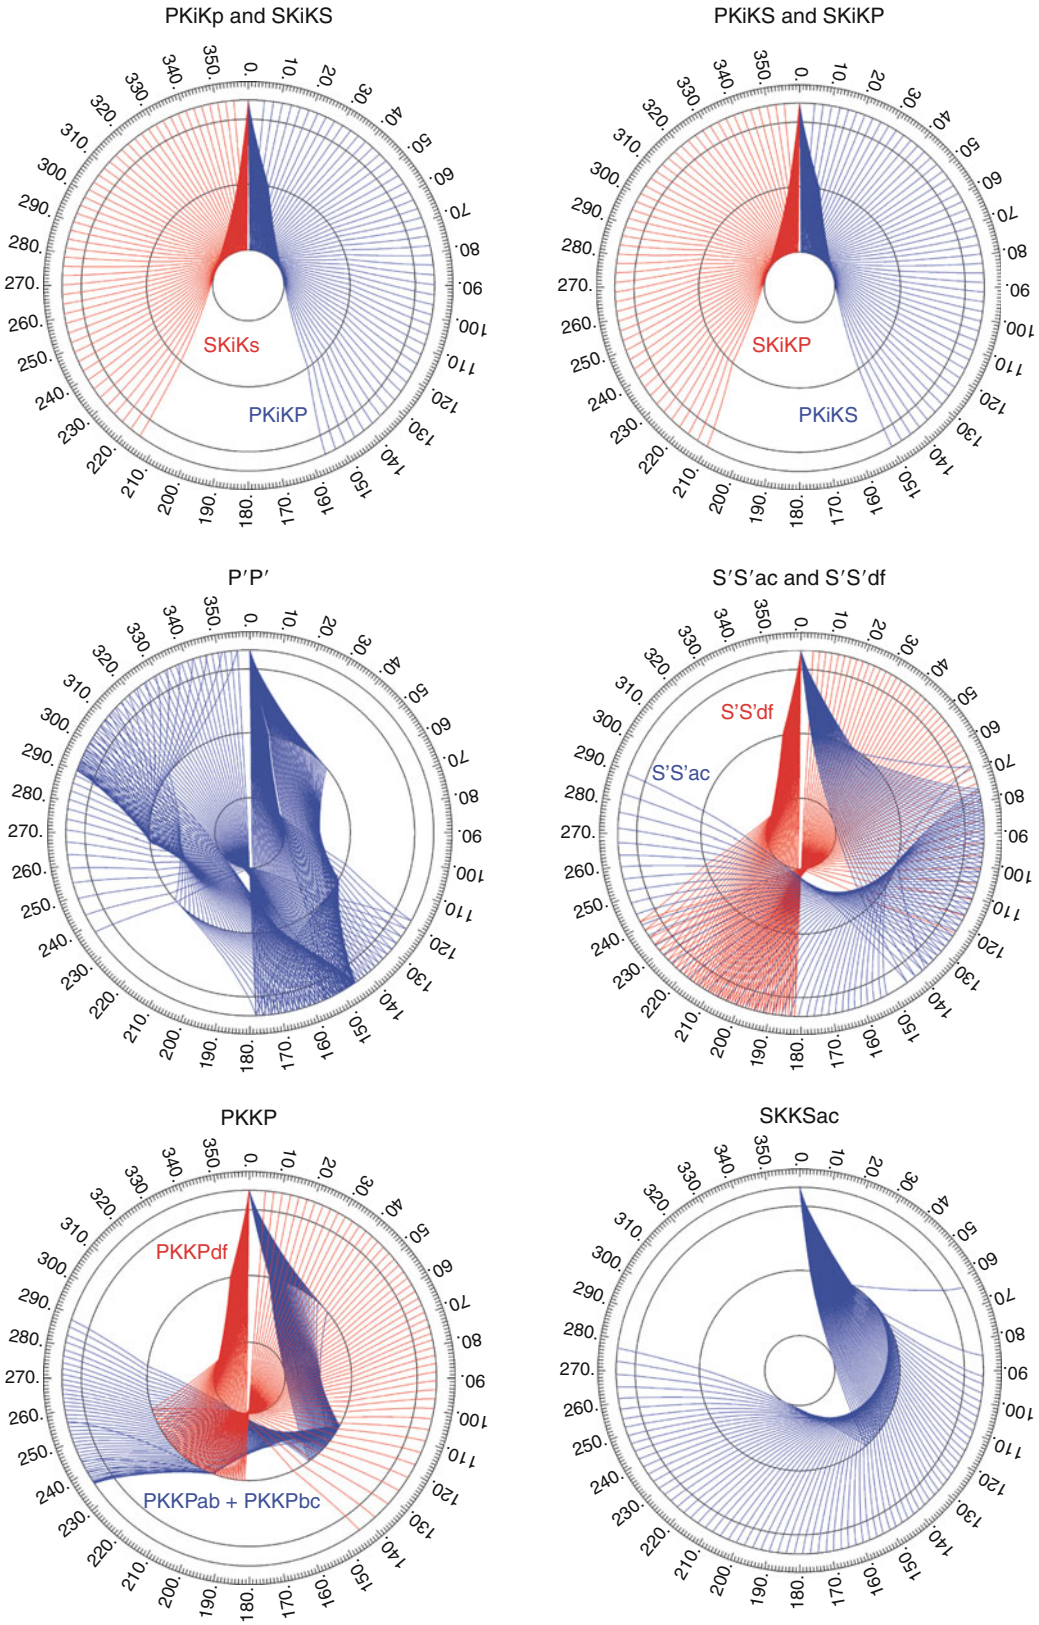
Seismic Phase Names: IASPEI Standard, Figure 2 Mantle phases observed at the teleseismic distances range (D > approximately 20°).



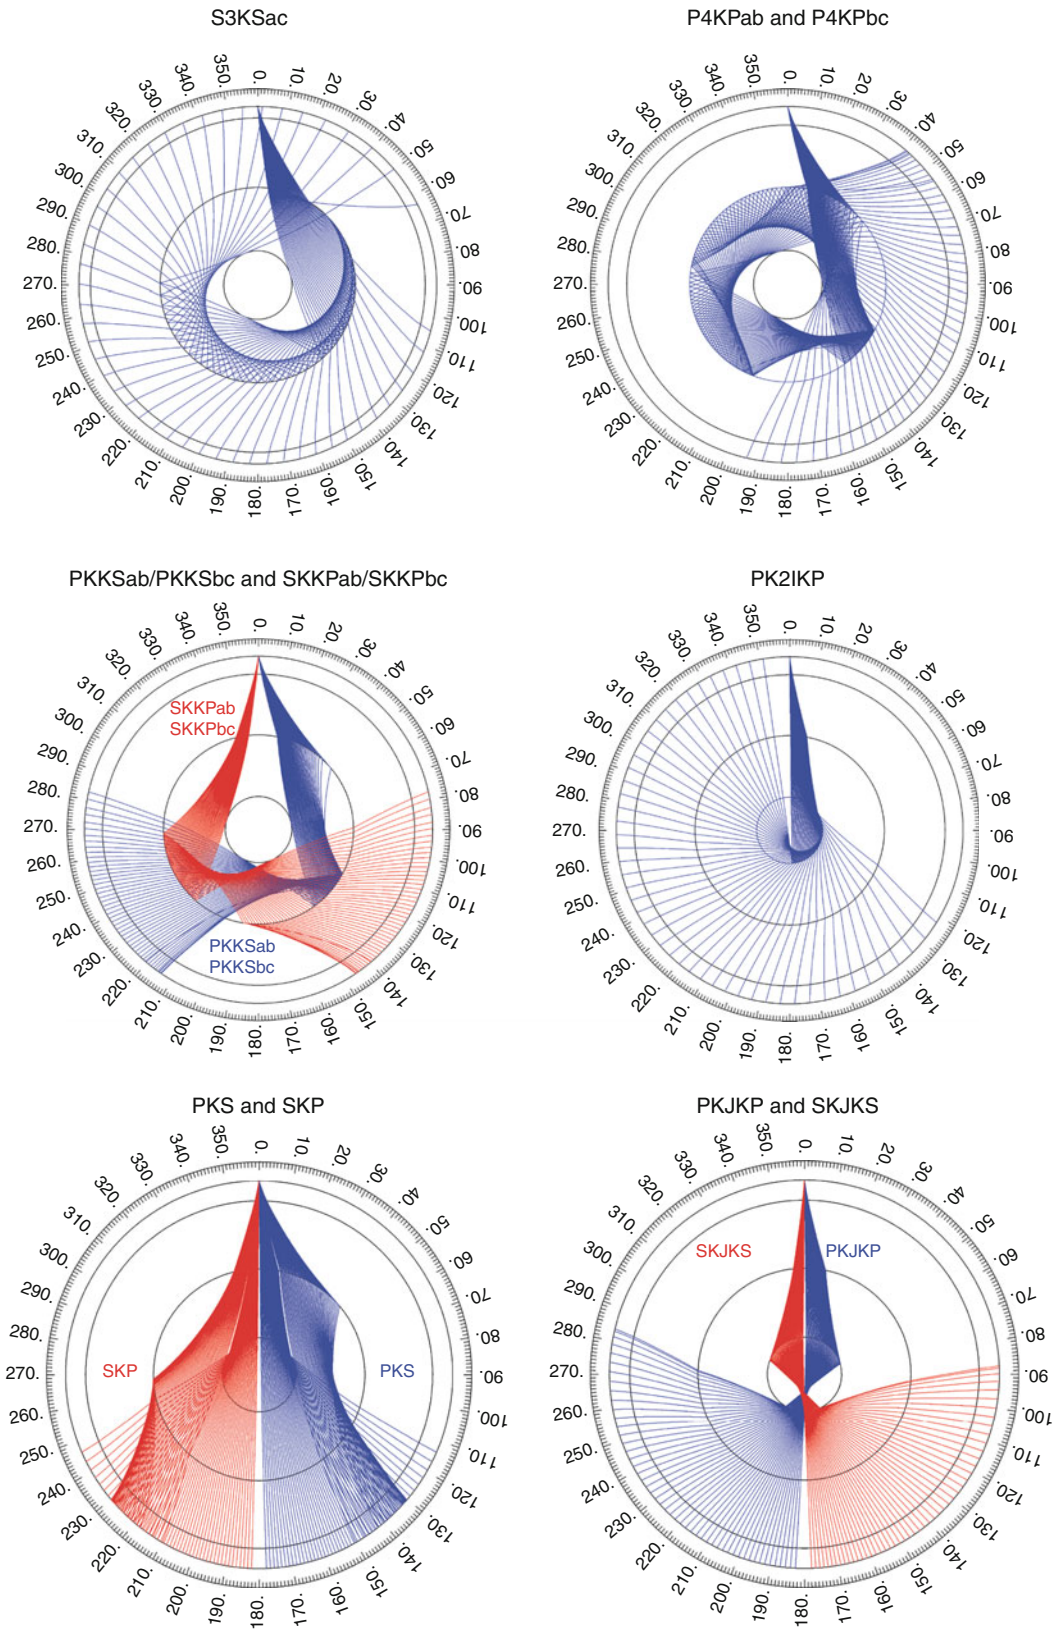
Seismic Phase Names: IASPEI Standard, Figure 3 Reflections from the Earth's core.



Seismic Phase Names: IASPEI Standard, Figure 4 Seismic rays of direct core phases.



Seismic Phase Names: IASPEI Standard, Figure 5 Seismic rays of single-reflected core phases.



Seismic Phase Names: IASPEI Standard, Figure 6 Seismic rays of multiple-reflected and converted core phases.

IASPEI standard seismic phase list

Crustal phases

Pg	At short distances, either an upgoing P wave from a source in the upper crust or a P wave bottoming in the upper crust. At larger distances also, arrivals caused by multiple P-wave reverberations inside the whole crust with a group velocity around 5.8 km/s
Pb	(alt:P*) Either an upgoing P wave from a source in the lower crust or a P wave bottoming in the lower crust
Pn	Any P wave bottoming in the uppermost mantle or an upgoing P wave from a source in the uppermost mantle
PnPn	Pn free-surface reflection
PgPg	Pg free-surface reflection
PmP	P reflection from the outer side of the Moho
PmPN	PmP multiple free-surface reflection; N is a positive integer. For example, PmP2 is PmPPmP
PmS	P to S reflection/conversion from the outer side of the Moho
Sg	At short distances, either an upgoing S wave from a source in the upper crust or an S wave bottoming in the upper crust. At larger distances also, arrivals caused by superposition of multiple S-wave reverberations and SV to P and/or P to SV conversions inside the whole crust
Sb	(alt:S*) Either an upgoing S wave from a source in the lower crust or an S wave bottoming in the lower crust
Sn	Any S wave bottoming in the uppermost mantle or an upgoing S wave from a source in the uppermost mantle
SnSn	Sn free-surface reflection
SgSg	Sg free-surface reflection
SmS	S reflection from the outer side of the Moho
SmSN	SmS multiple free-surface reflection; N is a positive integer. For example, SmS2 is SmSSmS
SmP	S to P reflection/conversion from the outer side of the Moho
Lg	A wave group observed at larger regional distances and caused by superposition of multiple S-wave reverberations and SV to P and/or P to SV conversions inside the whole crust. The maximum energy travels with a group velocity of approximately 3.5 km/s
Rg	Short-period crustal Rayleigh wave

Mantle phases

P	A longitudinal wave, bottoming below the uppermost mantle; also an upgoing longitudinal wave from a source below the uppermost mantle
PP	Free-surface reflection of a P wave leaving a source downward
PS	P, leaving a source downward, reflected as an S at the free surface. At shorter distances, the first leg is represented by a crustal P wave
PPP	analogous to PP
PPS	PP which is converted to S at the second reflection point on the free surface; travel time matches that of PSP
PSS	PS reflected at the free surface
PcP	P reflection from the core-mantle boundary (CMB)
PcS	P converted to S when reflected from the CMB
PcPN	PcP reflected from the free surface N − 1 times; N is a positive integer. For example PcP2 is PcPPcP
Pz + P	(alt:PzP) P reflection from outer side of a discontinuity at depth z; z may be a positive numerical value in km. For example, P660 + P is a P reflection from the top of the 660 km discontinuity
Pz−P	P reflection from inner side of a discontinuity at depth z. For example, P660 − P is a P reflection from below the 660 km discontinuity, which means it is precursory to PP
Pz + S	(alt:PzS) P converted to S when reflected from outer side of discontinuity at depth z
Pz−S	P converted to S when reflected from inner side of a discontinuity at depth z
PScS	P (leaving a source downward) to ScS reflection at the free surface
Pdif	(old:Pdiff) P diffracted along the CMB in the mantle
S	Shear wave, bottoming below the uppermost mantle; also an upgoing shear wave from a source below the uppermost mantle
SS	Free-surface reflection of an S wave leaving a source downward
SP	S, leaving a source downward, reflected as P at the free surface. At shorter distances, the second leg is represented by a crustal P wave
SSS	Analogous to SS
SSP	SS converted to P when reflected from the free surface; travel time matches that of SPS
SPP	SP reflected at the free surface
ScS	S reflection from the CMB
ScP	S converted to P when reflected from the CMB
ScSN	ScS multiple free-surface reflection; N is a positive integer. For example ScS2 is ScSScS
Sz + S	(alt:SzS) S reflection from outer side of a discontinuity at depth z; z may be a positive numerical value in km. For example S660 + S is an S reflection from the top of the 660 km discontinuity
Sz−S	S reflection from inner side of discontinuity at depth z. For example, S660 − S is an S reflection from below the 660 km discontinuity, which means it is precursory to SS
Sz + P	(alt:SzP) S converted to P when reflected from outer side of a discontinuity at depth z
Sz−P	S converted to P when reflected from inner side of a discontinuity at depth z
ScSP	ScS to P reflection at the free surface
Sdif	(old:Sdiff) S diffracted along the CMB in the mantle

Core phases

PKP	(alt:P') unspecified P wave bottoming in the core
PKPab	(old:PKP2) P wave bottoming in the upper outer core; ab indicates the retrograde branch of the PKP caustic
PKPbc	(old:PKP1) P wave bottoming in the lower outer core; bc indicates the prograde branch of the PKP caustic

PKPdf	(alt:PKIKP) P wave bottoming in the inner core
PKPpre	(old:PKhKP) a precursor to PKPdf due to scattering near or at the CMB
PKPdif	P wave diffracted at the inner core boundary (ICB) in the outer core
PKS	Unspecified P wave bottoming in the core and converting to S at the CMB
PKSab	PKS bottoming in the upper outer core
PKSbc	PKS bottoming in the lower outer core
PKSdf	PKS bottoming in the inner core
P'P'	(alt:PKPPKP) Free-surface reflection of PKP
P'N	(alt:PKPN) PKP reflected at the free surface N − 1 times; N is a positive integer. For example, P'3 is P'P'P'
P'z−P'	PKP reflected from inner side of a discontinuity at depth z outside the core, which means it is precursory to P'P'; z may be a positive numerical value in km
P'S'	(alt:PKPSKS) PKP converted to SKS when reflected from the free surface; other examples are P'PKS, P'SKP
PS'	(alt:PSKS) P (leaving a source downward) to SKS reflection at the free surface
PKKP	Unspecified P wave reflected once from the inner side of the CMB
PKKPab	PKKP bottoming in the upper outer core
PKKPbc	PKKP bottoming in the lower outer core
PKKPdf	PKKP bottoming in the inner core
PNKP	P wave reflected N − 1 times from inner side of the CMB; N is a positive integer
PKKPpre	A precursor to PKKPdf due to scattering near the CMB
PKiKP	P wave reflected from the inner core boundary (ICB)
PKNIKP	P wave reflected N − 1 times from the inner side of the ICB
PKJKP	P wave traversing the outer core as P and the inner core as S
PKKS	P wave reflected once from the inner side of the CMB and converted to S at the CMB
PKKSab	PKKS bottoming in the upper outer core
PKKSbc	PKKS bottoming in the lower outer core
PKKSdf	PKKS bottoming in the inner core
PcPP'	(alt:PcPPKP) PcP to PKP reflection at the free surface; other examples are PcPS', PcSP', PcSS', PcPSKP, PcSSKP
SKS	(alt:S') unspecified S wave traversing the core as P
SKSac	SKS bottoming in the outer core
SKSdf	(alt:SKIKS) SKS bottoming in the inner core
SPdifKS	(alt:SKPdifS) SKS wave with a segment of mantle-side Pdif at the source and/or the receiver side of the ray path
SKP	Unspecified S wave traversing the core and then the mantle as P
SKPab	SKP bottoming in the upper outer core
SKPbc	SKP bottoming in the lower outer core
SKPdf	SKP bottoming in the inner core
S'S'	(alt:SKSSKS) Free-surface reflection of SKS
S'N	SKS reflected at the free surface N − 1 times; N is a positive integer
S'z−S'	SKS reflected from inner side of discontinuity at depth z outside the core, which means it is precursory to S'S'; z may be a positive numerical value in km
S'P'	(alt:SKSPKP) SKS converted to PKP when reflected from the free surface; other examples are S'SKP, S'PKS
S'P	(alt:SKSP) SKS to P reflection at the free surface
SKKS	Unspecified S wave reflected once from inner side of the CMB
SKKSac	SKKS bottoming in the outer core
SKKSdf	SKKS bottoming in the inner core
SNKS	S wave reflected N − 1 times from inner side of the CMB; N is a positive integer
SKiKS	S wave traversing the outer core as P and reflected from the ICB
SKJKS	S wave traversing the outer core as P and the inner core as S
SKKP	S wave traversing the core as P with one reflection from the inner side of the CMB and then continuing as P in the mantle
SKKPab	SKKP bottoming in the upper outer core
SKKPbc	SKKP bottoming in the lower outer core
SKKPdf	SKKP bottoming in the inner core
ScSS'	(alt:ScSSKS) ScS to SKS reflection at the free surface; other examples are ScPS', ScSP', ScPP', ScSSKP, ScPSKP

Near source surface reflections and conversions (depth phases)

pPy	All P-type onsets (Py) as defined above, which resulted from reflection of an upgoing P wave at the free surface or an ocean bottom; WARNING: The character "y" is only a wild card for any seismic phase, which could be generated at the free surface. Examples are pP, pPKP, pPP, pPcP, etc.
sPy	All Py resulting from reflection of an upgoing S wave at the free surface or an ocean bottom; for example, sP, sPKP, sPP, sPcP, etc.
pSy	All S-type onsets (Sy) as defined above, which resulted from reflection of an upgoing P wave at the free surface or an ocean bottom. For example, pS, pSKS, pSS, pScP, etc.
sSy	All Sy resulting from reflection of an upgoing S wave at the free surface or an ocean bottom. For example, sSn, sSS, sScS, sSdif, etc.
pwPy	All Py resulting from reflection of an upgoing P wave at the ocean's free surface
pmPy	All Py resulting from reflection of an upgoing P wave from the inner side of the Moho

Surface waves

L	Unspecified long-period surface wave
LQ	Love wave
LR	Rayleigh wave
G	Mantle wave of Love type
GN	Mantle wave of Love type; N is integer and indicates wave packets traveling along the minor arcs (odd numbers) or major arc (even numbers) of the great circle
R	Mantle wave of Rayleigh type
RN	Mantle wave of Rayleigh type; N is integer and indicates wave packets traveling along the minor arcs (odd numbers) or major arc (even numbers) of the great circle

PL	Fundamental leaking mode following P onsets generated by coupling of P energy into the waveguide formed by the crust and upper mantle
SPL	S wave coupling into the PL waveguide; other examples are SSPL, SSSPL

Acoustic phases

H	A hydroacoustic wave from a source in the water, which couples in the ground
HPg	H phase converted to Pg at the receiver side
HSg	H phase converted to Sg at the receiver side
HRg	H phase converted to Rg at the receiver side
I	An atmospheric sound arrival, which couples in the ground
IPg	I phase converted to Pg at the receiver side
ISg	I phase converted to Sg at the receiver side
IRg	I phase converted to Rg at the receiver side
T	A tertiary wave. This is an acoustic wave from a source in the solid Earth, usually trapped in a low velocity oceanic water layer called the SOFAR channel (SOund Fixing And Ranging)
TPg	T phase converted to Pg at the receiver side
TSg	T phase converted to Sg at the receiver side
TRg	T phase converted to Rg at the receiver side

Amplitude measurements

The following set of amplitude measurement names refers to the IASPEI Magnitude Standard (see www.iaspei.org/commissions/CSOI/Summary_of_WG_recommendations.pdf), compliance to which is indicated by the presence of leading letter I. The absence of leading letter I indicates that a measurement is nonstandard. Letter A indicates a measurement in nm made on a displacement seismogram, whereas letter V indicates a measurement in nm/s made on a velocity seismogram.

IAML	Displacement amplitude measured according to the IASPEI standard for local magnitude M_L
IAMs_20	Displacement amplitude measured according to IASPEI standard for surface-wave magnitude $M_S(20)$
IVMs_BB	Velocity amplitude measured according to IASPEI standard for broadband surface-wave magnitude $M_S(BB)$
IAmb	Displacement amplitude measured according to IASPEI standard for short-period teleseismic body-wave magnitude m_b
IVmB_BB	Velocity amplitude measured according to IASPEI standard for broadband teleseismic body-wave magnitude $m_B(BB)$
AX_IN	Displacement amplitude of phase of type X (e.g., PP, S, etc.), measured on an instrument of type IN (e.g., SP, short-period; LP, long-period; BB, broadband)
VX_IN	Velocity amplitude of phase of type X and instrument of type IN (as above)
A	Unspecified displacement amplitude measurement
V	Unspecified velocity amplitude measurement
AML	Displacement amplitude measurement for nonstandard local magnitude
AMs	Displacement amplitude measurement for nonstandard surface-wave magnitude
Amb	Displacement amplitude measurement for nonstandard short-period body-wave magnitude
AmB	Displacement amplitude measurement for nonstandard medium to long-period body-wave magnitude
END	Time of visible end of record for duration magnitude

Unidentified arrivals

x	(old: i, e, NULL) unidentified arrival
rx	(old: i, e, NULL) unidentified regional arrival
tx	(old: i, e, NULL) unidentified teleseismic arrival
Px	(old: i, e, NULL, (P), P?) unidentified arrival of P-type
Sx	(old: i, e, NULL, (S), S?) unidentified arrival of S-type

Seismogram Interpretation

SEISMIC PROPERTIES OF ROCKS

Nikolas I. Christensen
Department of Earth and Ocean Sciences, University of British Columbia, Vancouver, BC, Canada

Synonyms

Rock P and S velocities

Definition

Compressional (*P*) *waves.* Seismic waves in which the rock particles vibrate parallel to the direction of wave propagation.

Shear (*S*) *waves.* Seismic waves in which the rock particles vibrate perpendicular to the direction of wave propagation.

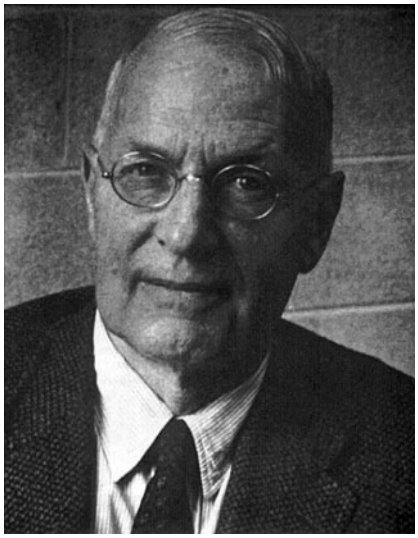
Poisson's ratio (σ). The ratio of the lateral unit strain to the longitudinal unit strain in a body that has been stressed longitudinally within its elastic limit ($2\sigma = (R^2 - 2)/(R^2 - 1)$ where $R = Vp/Vs$).

Transversely isotropic. Anisotropic solids with a single symmetry axis. Rock symmetry axes are usually normal to foliation, cleavage, or layering.

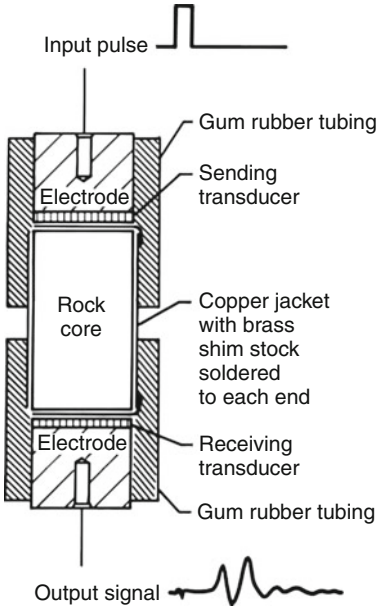
Introduction

Although many disciplines have contributed significantly to our knowledge of the Earth's interior, none has a resolution comparable to seismology. For nearly 6 decades seismic studies have provided geophysicists with worldwide information on crustal and upper mantle compressional (P) and shear (S) wave velocities. Significant data have recently become available on velocity gradients, velocity reversals, compressional and shear wave velocity ratios, and anisotropy in the form of azimuthal variations of compressional wave velocities, as well as shear wave splitting. Reflections within the crust and mantle originate from contrasts of acoustic impedances, defined as products of velocity and density. The interpretation of this seismic data requires detailed knowledge of rock velocities provided by laboratory techniques to a precision at least comparable with that of seismic measurements. In particular, to infer composition of the Earth's upper 30–50 km, the "crust," requires studies of the elasticity of rocks at conditions approaching those that exist at these depths. Of fundamental importance is the presence of mean compressive stress and temperature increasing with depth and on the average reaching about 1 GPa and 500 °C at the base of the crust. Because of this, the most relevant velocity measurements for identifying probable rock types within the crust have been measurements at elevated pressures and temperatures. These measurements often allow the seismologist to infer mineralogy, porosity, the nature of fluids occupying pore spaces, temperature at depth, and present or paleolithospheric stress based on mineral and crack orientations.

Francis Birch (Figure 1) was the pioneer in the study of rock velocities. In addition to his laboratory work on physical properties of rocks and minerals at high pressures and temperatures, he was well known for his studies of heat flow and theoretical work on the composition of the Earth's interior. Two of his benchmark papers on compressional wave velocities in rocks (Birch, 1960, 1961) set the stage for modern experimental studies of rock elasticity and have been frequently cited during the past 5 decades. These papers for the first time provided information on compressional wave velocities for many common rock types, as well as major findings on their anisotropies and relations to density. It is interesting to note that these measurements were carried out to pressures of 1 GPa, a pressure at which even today only a limited number of



Seismic Properties of Rocks, Figure 1 Francis Birch (1903–1992), a pioneer in rock physics research.



Seismic Properties of Rocks, Figure 2 Transducer and rock core assembly for velocity measurements at elevated pressures.

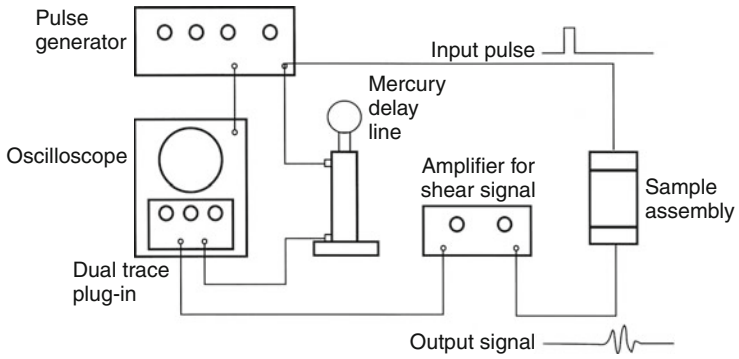
laboratories have been able to generate for modern rock seismic velocity measurements.

Measurement techniques

Rock velocities are usually measured in the laboratory using the pulse transmission technique. The transit time of either a compressional or shear wave is measured along the axis of a cylindrical rock specimen of known length. The cores are usually taken from rock samples using a 2.54 cm inner diameter diamond coring bit. The cores are trimmed and ground flat and parallel on a diamond grinding disk. The volume of each core is obtained from the length and diameter. The cores are weighed and densities are calculated from their masses and dimensions. The cores are then fitted with a copper jacket to prevent penetration of high-pressure oil into the rock samples. For measurements at high temperatures, where gas is the pressure medium, the samples are usually encased in stainless steel. Transducers are placed on the ends of the rock core (Figure 2). Compressional and shear waves are often generated by means of lead zirconate titanate (PZT) and AC cut quartz transducers with resonant frequencies of 1 MHz. The sending transducer converts the input, an electrical pulse of 50–500 V and 0.1–10 μs width, to a mechanical signal, which is transmitted through the rock. The receiving transducer changes the wave to an electrical pulse, which is amplified and displayed on an oscilloscope screen (Figure 3). Once the system is calibrated for time delays, the travel time through the specimen is determined directly by a computer or with the use of a mercury delay line. The major advantage of the delay line is that it increases the precision, especially for signals with slow rise times, because the gradual onset of the first arrival from the sample is approximated by the delay line. The velocity is the ratio of the length of the specimen to the travel time of the compressional or shear wave. The total error limits for Vp and Vs are estimated to be less than 1%. Interfacing the pressure system with a computer for data acquisition and storage permits automatic calculations of velocities as successive readings are taken. Using a least-squares routine, the computer fits a curve to the data points and calculates velocities for selected pressures. A velocity versus pressure curve is plotted along with recorded data points. Sample length, density, measured pressure velocity pairs, traces of the waveforms at selected pressures, the curve fit equations, and calculated pressure velocity pairs are recorded and stored digitally.

Hydrostatic pressure generating systems capable of producing true hydrostatic pressures as high as 3 GPa, equivalent to a depth of approximately 100 km, have been used for rock velocity measurements. Low viscosity synthetic petroleum and argon for high temperature measurements are frequently used as pressure media. An alternate technique for obtaining velocities under quasi-hydrostatic conditions has used a triaxial press with cubic samples. Transducers are placed on the six pistons and corrections are made for travel times through the pistons. Rock velocities obtained using this technique have provided valuable information on the effect of temperature on velocity, but have been limited to pressures of 0.6 GPa.

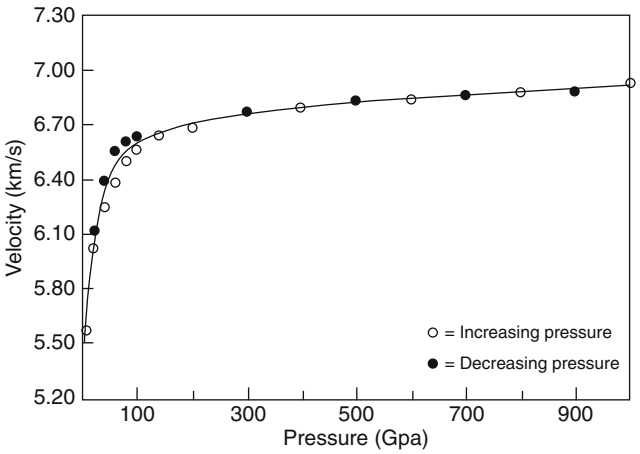
The behavior of a rocks velocity as a function of pressure is primarily dependent upon mineralogy and porosity. Many igneous and metamorphic rocks have porosities of the order of a few tenths of 1%, which are present as thin openings between grain boundaries. As pressure is applied to the rock, the cracks close and velocities increase. Once the cracks close any increase in velocity with increasing pressure is related to the intrinsic effects of pressure on



Seismic Properties of Rocks, Figure 3 Electronics for velocity measurements using a mercury delay line.

the mineral velocities. This is illustrated in Figure 4 for a garnet granulite. Velocities first increase rapidly over the first 100 MPa as cracks close and then increase slowly as pressure is increased. Also the velocity determined at a given pressure depends upon whether the pressure is approached from lower or higher pressure (Figure 4). This hysteresis is usually quite small if sufficient time is taken for measurements between pressure increments.

A considerable number of investigations have also focused on the influence of temperature on rock velocities. These studies have used either resonance techniques or more frequently the pulse transmission method. Early studies demonstrated that the application of temperature to rock at atmospheric pressure results in the creation of cracks that often permanently damage the rock and dramatically lower velocities. Thus reliable measurements of the temperature derivatives of velocities are obtained only at confining pressures high enough to prevent crack formation. At elevated confining pressures $\delta Vp/\delta T$ for common rocks often ranges from -0.3×10^{-3} to -0.6×10^{-3} km/s/°C and $\delta Vs/\delta T$ varies between -0.2×10^{-3} and -0.4×10^{-3} km/s/°C.



Seismic Properties of Rocks, Figure 4 Compressional wave velocity measurements as a function of confining pressure for a mafic granulite.

Rock velocities

Seismic velocities have been measured for practically all igneous and metamorphic rock types believed to be important constituents of the lithosphere. Because rock classification schemes allow for considerable variations in mineralogy for a given rock type, many rocks have wide ranges in elastic properties. However, some lithologies, such as the monomineralic rocks hornblendite and dunite with little or no alteration have fairly well-defined velocities. For detailed summaries of rock seismic properties the reader is referred to the compilations of Birch (1960), Christensen (1982, 1996), Gerbande (1982), Holbrook et al. (1992), Rudnick and Fountain (1995), and Mavko et al. (1998).

Table 1 contains average velocities, in the order of increasing compressional wave velocity, for several common igneous and metamorphic rocks. Volcanic rocks usually have lower velocities than their plutonic equivalents. This is due to the presence of glass, abundant alteration products and vesicles in volcanic rocks, all of which have lower velocities. In general, for a given composition, velocity increases with increasing metamorphic grade. For example, mica and quartz bearing schists have higher velocities than slates and phyllites. Low-grade metamorphosed basalts have lower velocities than higher grade amphibolite and mafic granulite. Eclogites have the highest velocity of mafic rocks. Note that shear velocities are relatively high in quartzites and low in serpentinites.

Early attempts to infer crustal composition by comparing laboratory and field derived velocities relied primarily on compressional wave velocities. However correlations between compressional wave velocity and composition are limited due to the similar velocities of many common crustal rock types. Because of this nonuniqueness of compressional wave velocity laboratory and field data comparisons, many recent studies have focused on investigations of crustal composition using both compressional and shear

wave velocities. In these studies the ratio Vp/Vs or Poisson's ratio (σ) calculated from Vp/Vs have resolved some of the ambiguities.

The values of Vp/Vs and σ, assuming isotropic elasticity, are given in Table 1 for several common igneous and metamorphic rocks at 1 GPa. This high-pressure eliminates cracks so the values only reflect mineralogy. The relatively low σ for quartzites (0.10) agrees well with isotropic aggregate calculations based on the elastic constants of single crystal quartz. Anorthosites, on the other hand, have relatively high Poisson's ratios (~0.31). As expected, values for the granites and granitic gneisses, consisting primarily of quartz and feldspar, fall in between those of quartzites and anorthosites and are relatively low. Thus, crustal regions where field measured values of $\sigma \leq 0.25$ are observed, are likely quartz-rich. Serpentinites containing lizardite, the variety of serpentine stable at crustal PT conditions, have extremely high values of Poisson's ratio (0.36), whereas unaltered dunites and peridotites have Poisson's ratios in the range of 0.25–0.26. Partially serpentinized dunites and peridotites have Poisson's ratios that fall between these limiting values. Laboratory measurements have established a well-defined relationship between Poisson's ratio, percent serpentinization and density. Changes in Poisson's ratio with progressive metamorphism of mafic igneous and pelitic rocks are considerably more complicated than the above examples (Christensen, 1996).

Seismic Properties of Rocks, Table 1 Average compressional (Vp) and shear (Vs) wave velocities, velocity ratios (Vp/Vs), and Poisson's ratios (σ) at 1 GPa for common rock types Christensen (1996)

Rock	Vp (km/s)	Vs (km/s)	Vp/Vs	σ
Serpentinite	5.607	2.606	2.152	0.36

Velocity anisotropy

Most crustal and upper mantle rocks show some degree of velocity anisotropy, which can originate from several processes. Laminar flow within magma and lava will orient elongate crystals such as feldspars along flow directions. Tabular sediments may settle preferentially and anisotropy may be enhanced by sediment compaction. Plastic flow and recrystallization during metamorphism often produce strong mineral orientations parallel to foliation and banding. In shallow crustal rocks oriented cracks producing anisotropy often originate from differential principle stresses. Anisotropy observed in laboratory measurements at pressures above approximately 100 MPa, where cracks are closed, often originate from preferred orientations of highly anisotropic minerals such as micas, amphiboles, pyroxenes, and olivine.

In general, for a given propagation direction in an anisotropic rock there are three waves, one compressional and two shear. Their vibration directions form an orthogonal set, which usually are not parallel or perpendicular to their propagation direction. Compressional and shear wave velocities vary with propagation direction, and two shear waves travel in a given direction through the rock with different velocities. This latter property of anisotropic rocks, termed shear wave splitting, was first recognized in laboratory studies and has been observed by field studies in several crustal and upper mantle regions.

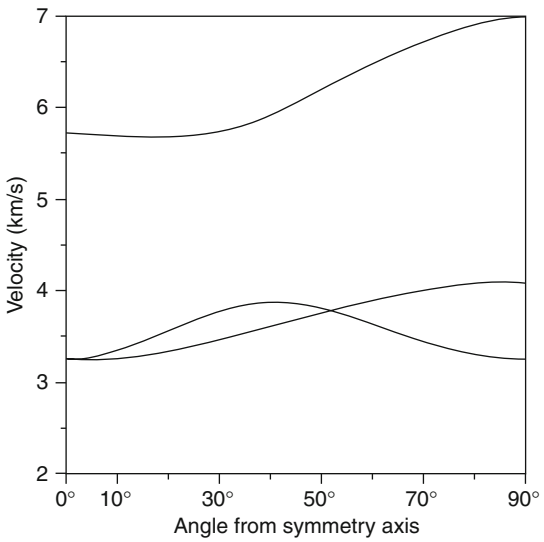
Anisotropy is usually studied in the laboratory by taking cores from a rock in different directions. Following the early investigations of Birch (1960, 1961) it is common practice to take three mutually perpendicular cores for velocity measurements. If the rock has a planar structure, such as a foliation, cleavage, or bedding, two cores are oriented with their axes within the planar structure. One of these cores is oriented parallel to a lineation, if present. In general, three velocities are measured per core: the compressional wave velocity, the velocity of the shear wave vibrating parallel to the layering, and the velocity of the shear wave vibrating in a plane perpendicular to layering. For cores taken perpendicular to layering, shear wave velocities are measured with vibration directions parallel to the axes of the cores taken in the layering.

It has been demonstrated that the above procedure provides information on maximum compressional wave anisotropy and maximum shear wave splitting. In general, the highest compressional wave velocities propagate in the plane of the foliation and parallel to lineations. Maximum shear wave splitting is observed for propagation within the planar structures. At near- normal incidence there is often minimal shear wave splitting.

Velocity measurements using multiple cores have provided detailed information on anisotropic velocities for non-axial propagation (e.g., Johnston and Christensen, 1995; Christensen and Okaya, 2007). The number of measurements necessary to completely describe wave propagation depends on the symmetry of the rock fabric. In the most general anisotropic elastic solid, 21 independent

constants are required to describe the equations of motion. Examples of materials with this type of behavior are minerals possessing triclinic symmetry such as kyanite and some feldspars. For many rocks, the existence of symmetry elements in the elastic properties leads to the vanishing of some elastic constants along with simple algebraic relations between others (e.g., Auld, 1990). Some crustal and upper mantle metamorphic rocks behave as elastic solids with orthorhombic symmetry, which require nine independent constants to describe the elastic tensors. Shales and many low to medium grade metamorphic rocks often have well-developed bedding or foliation and behave as transversely isotropic elastic solids (hexagonal symmetry with the symmetry axis normal to bedding or foliation). Transversely isotropic solids have five independent elastic constants, which can be calculated from five independent velocity measurements (two compressional wave velocities, one quasi-compressional wave velocity, and two shear wave velocities) and density. In an isotropic solid, only two independent constants are required for a complete description of elastic behavior and wave velocities are independent of propagation direction.

To describe three-dimensional wave propagation in anisotropic rocks, phase velocity surfaces can be calculated using the Kelvin-Christoffel equations (e.g., Auld, 1990) and elastic constants can be determined from velocity and density measurements. For transversely isotropic rocks, these surfaces describe variations in velocity as a function of angle to the bedding or foliation (Figure 5). Three velocity surfaces are calculated, one for the quasi-compressional wave, one for the shear wave vibrating parallel to the planar structure, and one for the quasi-shear wave vibrating in a plane perpendicular to the foliation or bedding. For propagation parallel and perpendicular to the foliation all wave modes are pure. The velocities shown in Figure 5 were calculated from velocity measurements at 600 MPa for a transversely isotropic quartz -mica schist from South Island, New Zealand. They show several important features about elastic wave propagation in this rock, which are typical of many foliated rocks. First, compressional wave velocities do not increase significantly until propagation directions greater than about 45° from foliation normal are reached. At larger angles, compressional wave velocity increases rapidly and reaches a maximum for propagation parallel to the foliation. Shear wave singularities (directions in which two shear waves have equal velocities) occur for propagation parallel to and at approximately 50° to the symmetry axis. Shear wave splitting occurs for all other propagation directions and reaches to maximum of 90° from the normal to the foliation.



Seismic Properties of Rocks, Figure 5 Compressional wave anisotropy (*upper curve*) and shear wave splitting (*lower curves*) for a transversely isotropic quartz-mica schist.

Summary

Beginning with the compressional wave velocity measurements of Birch (1960, 1961), much has been learned about elastic wave propagation in rocks. Compressional wave velocities are now available for most common rock types at pressures existing in the continental crust and uppermost mantle. Additional important contributions include laboratory measurements of shear wave velocities, velocity ratios, and the influence of temperature on velocities. Estimates of crustal composition from compressional wave velocities are nonunique, but this ambiguity is often reduced by complimentary shear wave velocity (and Poisson's ratio) observations. Recent field studies have found that seismic anisotropy is an important crustal feature. Thus systematic laboratory studies of compressional wave anisotropy and shear wave splitting will be critical in understanding crustal composition and deformation, just as they have been in investigations of the upper mantle.

SEISMIC QUIESCENCE AND ACTIVATION

Gennady Sobolev
Institute of Physics of the Earth, Russian Academy of Sciences, Moscow, Russia

Definition

Seismic quiescence. Relative decrease in number of earthquakes or energy in any area of a seismic active region within a certain time interval in comparison with long-term observations in the same region.
Seismic activation. Relative increase in number of earthquakes or energy in any area of a seismic active region within a certain time interval in comparison with long-term observations in the same region.

Introduction

Both seismic quiescence and seismic activation before large earthquakes have been repeatedly described in the scientific literature. Large earthquakes are viewed as natural hazards, which may cause destruction of buildings, loss of life, and economic damage. Comparative size of different earthquakes is measured by their magnitude M (see *Earthquake, Magnitude*). The most destructive earthquakes fall in the range of magnitudes 7–9; and seismic energy released from an earthquake's source (see *Earthquakes, Energy*) lies in the range of 10^{22}–10^{25} ergs and the intensity of seismic shaking at the Earth surface (see *Earthquakes, Intensity*) exceeds the 7 level of the 12° scale.

Just the first condition of detection of quiescence or activation follows from the stated above: a necessity of long-term history of seismic observations. However, for the purpose of rigorously proven detection of such occurrences one should be sure that any seismic event, magnitude of which exceeded some minimum threshold, was not missed within the observation period. Just in the second half of the (twentieth) century development of seismic networks of observation equipped with calibrated seismographs lead to creation of instrumental catalogs of earthquakes what enabled to judge objectively about appearance of seismic quiescence and activation.

The first sufficiently founded reports of appearance of seismic quiescence before large earthquakes were published at the beginning of 1960s in Japanese and were practically unknown outside Japan. Then, in 1969, Mogi, on the basis of a visual analysis of seismicity maps, formulated a hypothesis that a seismic quiescence may be a precursor of a large earthquake (Mogi, 1979). At the end of the 80th year, Wyss and Habermann studied instrumental seismic catalogs of a number of regions of the Earth and determined basic rules of a formal detection of a seismic quiescence (Wyss and Habermann, 1988). In brief, they may be summarized as follows: (1) Evaluation of homogeneity of a seismic catalog for the analyzed time interval, including magnitude calculations, taking into consideration changes in methods of determination of coordinates and depth of seismic events. (2) Determination of a minimum magnitude of earthquakes being recorded without any omissions. (3) Removal of groups and aftershocks in order to analyze the so-called background seismicity. (4) Quantitative evaluation of size and significance of an anomaly, whereas significance shall be considered a statistically proven difference of an anomaly from random variations of the background seismicity. (5) Quantitative determination of the beginning of an anomaly. (6) Evaluation of sizes of an anomalous region. Wyss and Habermann (1988) determined that numerous events of seismic quiescence described in the literature are explained by changes of a minimum representative magnitude that were not taken into account, owing to the expansion of a seismic network or development of information processing technique. However, there remain dozens of published events of seismic quiescence that may not be explained by any omissions of technical nature (artifacts).

Description of certain events of seismic quiescence exceeds the limits of this article. We will mention only as an example two widely discussed events. Ohtake et al. (1977) studied the seismicity along the Pacific Ocean coast of Mexico and found that after the middle of 1973, the seismicity rate in the region with the linear dimensions of 100 by 200 km around coordinates of (16.5°N, 96.5°W) declined sharply what was interpreted as a seismic quiescence. The Oaxaca earthquake of November 29, 1978 with M = 7.6 occurred in this region. Kisslinger (1988) found a seismic quiescence before an Andreanof Islands earthquake of May 7, 1986 with M = 8. Our task does not include any evaluation of authenticity and significance of these and other events, especially because it is not correctly to do it without the authors' participation. We will

note only that about 100 authors of scientific works published their investigations of seismic quiescence in regions with different geological and tectonic structure. It may be assumed that such phenomenon exists objectively in the nature and sometimes arises before a large earthquake. Since a seismic process to a great extent is self-similar in a wide range of magnitudes, a seismic quiescence most likely arises before a relative weak earthquake as well.

Main phases of seismic quiescence and activation

On the basis of thousands of observations of seismicity in various regions of the world, there exists a generally accepted opinion among the seismologists that the large earthquake arises after a long-term (dozens of years) increase in seismicity in a relative region connected with a gradual growth of tectonic stresses. The latter, in their turn, arise at the joints of the earth's crustal plates moving with a different rate. Let us name this period of increase in seismicity as a *phase of long-term seismic activation* (phase I in the Figure 1). Spatial dimensions of a region of long-term activation before the large earthquake (M = 7 to 8) may exceed 1,000 km.

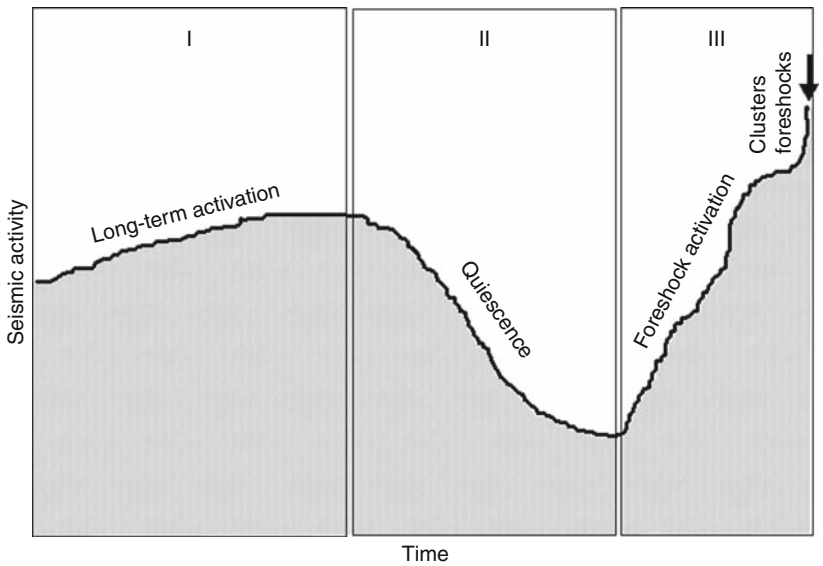
On the background of such process, in some area of the region of long-term activation a mean seismicity rate decreases what, as a rule, results in decrease in rate of release of the seismic energy. A researcher has a task to detect such decrease in the seismic activation and to prove its significance at a quantitative level, that is, to detect the seismic quiescence. All the suggested methods are based somehow or other on an analysis of statistics of earthquakes that at today's level of development of seismological networks of observations includes events contained in catalogs, the magnitude of which is from 3 to 4 units less in comparison with the magnitude of the large earthquake. This statistics includes at best the first thousands of events within a period of some years what makes the task of quiescence detection difficult and not always solvable. Below we will describe in brief two methods that were analyzed to reveal a seismic quiescence before several earthquakes both *a retrospective one* (after the large earthquake) and *a prospective one* (before the large earthquake).

In the Z-value method, there is calculated the standard deviation Z, to estimate the significance of the rate change,

$$Z = \frac{m_1 - m_2}{\left(\frac{S_1}{n_1} + \frac{S_2}{n_2}\right)^{1/2}},$$

where m is the mean rate, S the variance, and n the number of events in the first and second period to be compared (Wyss and Habermann, 1988).

For the purpose of significance evaluation there is applied the normal distribution law, but when having a rather large statistics of earthquakes the method gives plausible evaluations by other distribution law as well. The more the Z value is the more the difference between a rate of a seismic flow in the area of a supposed seismic quiescence and in comparison with a long-term rate. The calculations are carried out by the enumeration of nodes of the geographical grid and a changing number of earthquakes located near each node. It results the averaged Z values are presented in the form of maps in the researched seismic active region. The area of a seismic quiescence is determined according to high values of Z isolines above the given rate of statistic significance. The experience showed that the more reliable results appeared in the task if there were removed swarms and aftershocks of previous earthquakes from the catalog.



Seismic Quiescence and Activation, Figure 1 Main phases of seismic quiescence and activation.

The RTL method uses three functions to measure the state of seismicity at a given location as a function of time (Sobolev, 2001).

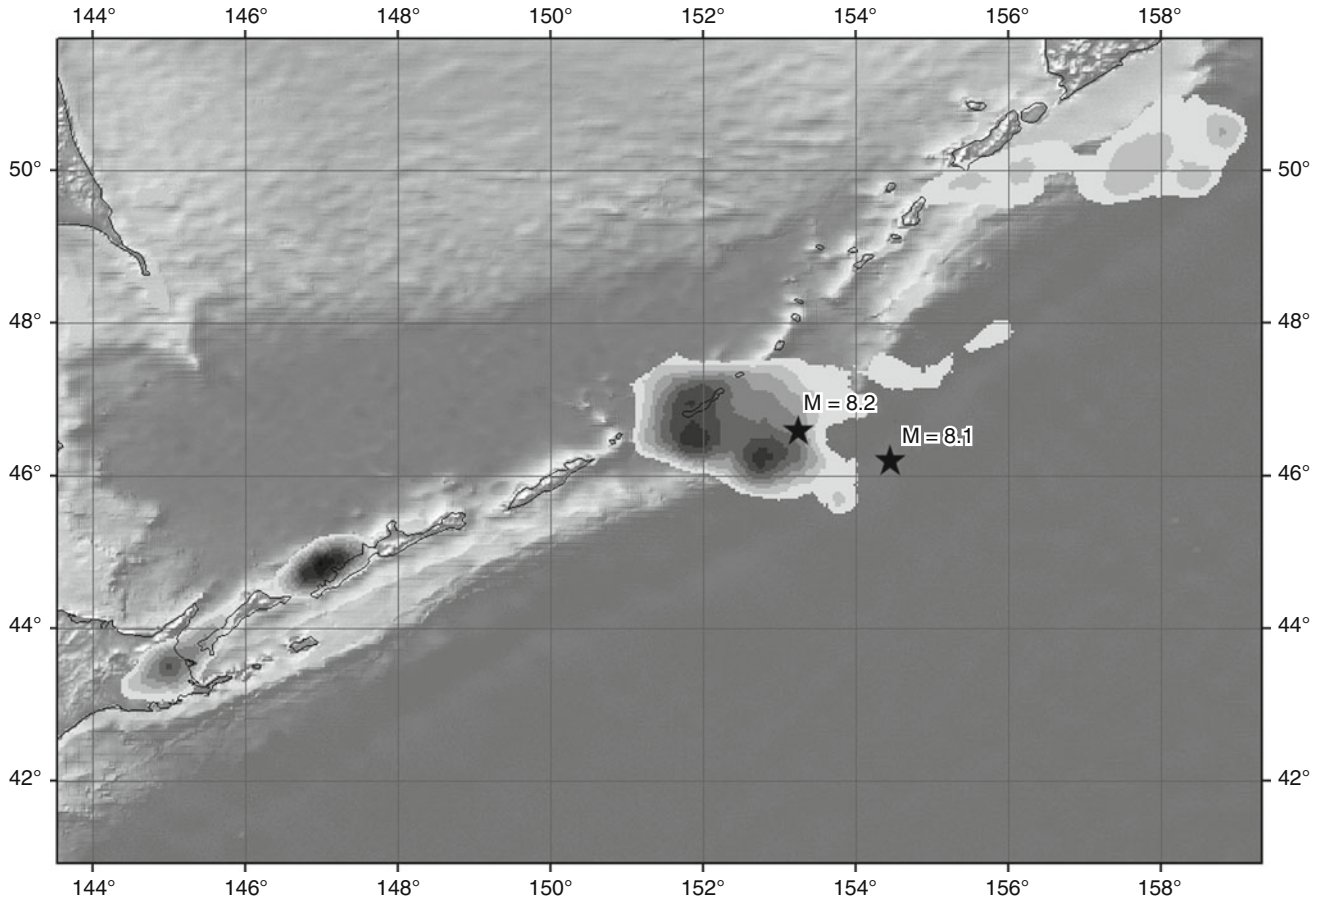
$$R(x,y,z,t) = [\Sigma \exp(-r_i/r_0)] - R_{\text{ltr}},$$
$$T(x,y,z,t) = [\Sigma \exp(-(t-t_i)/t_0)] - T_{\text{ltr}},$$
$$L(x,y,z,t) = [\Sigma \exp (l_i/r_i)^p] - L_{\text{ltr}}.$$

In these formulas, x, y, z, and t are the coordinates, the depth and the analysis time, respectively. r_i is the epicentral distance from the location selected for analyses, t_i is the occurrence time of the past seismic events, and l_i is the length of rupture estimated by empirical relation with the magnitude. The R_{ltr}, T_{ltr}, and L_{ltr} are the long-term averages of these functions. r_0 is a coefficient that characterizes the diminishing influence of more distant seismic events; t_0 is the coefficient characterizing the rate at which the preceding seismic events are "forgotten" as the time of analysis moves on; and p is the coefficient that characterizes the contribution of size of each preceding event. R, T, and L are dimensionless functions. They are normalized by their standard deviations. The product of the above three functions is calculated as the RTL-parameter, which describes the deviation from the background level of seismicity and is in units of the standard deviation, $\sigma_R\sigma_T\sigma_L$. The RTL-parameter decrease in relation to the background level means a seismic quiescence, and a structure of isolines of such parameter on the map indicates to the size of a quiescence area. In the RTL method, the outgoing catalog is cleaned of the aftershocks but the swarms are not removed.

Both methods (Z-value and RTL) require that the duration of period, which is included in calculations of the rate of background seismicity, must be by an order more than the supposed duration of the seismic quiescence. The experience of application of the described and other methods of revealing of the seismic quiescence in different tectonic conditions has shown that the duration of a quiescence period before the large earthquakes amounts to several years, that is, by an order less than the phase of the long-term activation (Figure 1). The area of significant values of the quiescence has linear dimensions about 300 km. In the most published works, the seismic quiescence was determined by the application of only one method. The exception, apparently, is a work by Wyss et al., in which a situation before the large earthquakes on the Sakhalin Island was analyzed by using of one and the same regional seismic catalog but by the application of both methods mentioned above: Z value and RTL (Wyss et al., 2004). The duration of quiescence anomalies before the Neftegorsk earthquake of May 27, 1995 with the M = 7.1, amounted according to results of both methods to 2.7 years. The size of a quiescence region was determined according to Z value in the form of a rectangle with dimensions of 200 × 600 km, and according to the RTL data – in the form of a circle with the radius up to 400 km. The epicenter of the earthquake lied at the periphery of anomalies in both determinations. Before the Uglegorsk earthquake of August 4, 2000, M = 6.8, the duration of quiescence was according to Z value 2.5 years and according to the RTL 3.0 years. The dimensions of the anomalous regions were determined in the form of a circle with the radius up to 165 and 200 km, respectively. The epicenter of the earthquake was also at the lateral part of quiescence area. The examination conducted with random catalog has shown that the probability that the anomaly occurred by chance before the Neftegorsk earthquake did not exceed 1% and before the Uglegorsk earthquake – 2% according to the results of both methods.

In spite of available facts of the seismic quiescence before some large earthquakes, the practical application of such anomaly for the forecast of earthquakes remains undecided. Authors of publications on the subject of seismic quiescence do not cite any data on a number of false alarms when no large earthquake occurred in the region of quiescence. According to our evaluations, the number of false alarms exceeds by several times the number of forecasts proven to be correct (even by a retrospective analysis). There is no statistic evaluation of a real *prospective* forecast with the use of such anomaly indeed. Let us illustrate the above stated by Figure 2, where the areas of seismic quiescence in the region of the Kurile arch are shown, which were detected before the Simushir earthquake of November 15, 2006, M = 8.2. In this case the RTL method was applied, but it is not a matter of principle. The dark spots mean the areas of seismic quiescence. The main one of them with linear dimensions of about 200 km is located in on the territory with coordinates of 46°–48°N – 151°–154°E; the epicenter of the main shock is located at its periphery, and the another major earthquake of January 13, 2007, M = 8.1 – outside the anomalous region. Several other anomalies of a lower size are shown in the figure: the territory with coordinates (45°N, 147°E), (43°N, 145°E), and (50°N, 158°E). Any large earthquakes in these regions did not occur up to now.

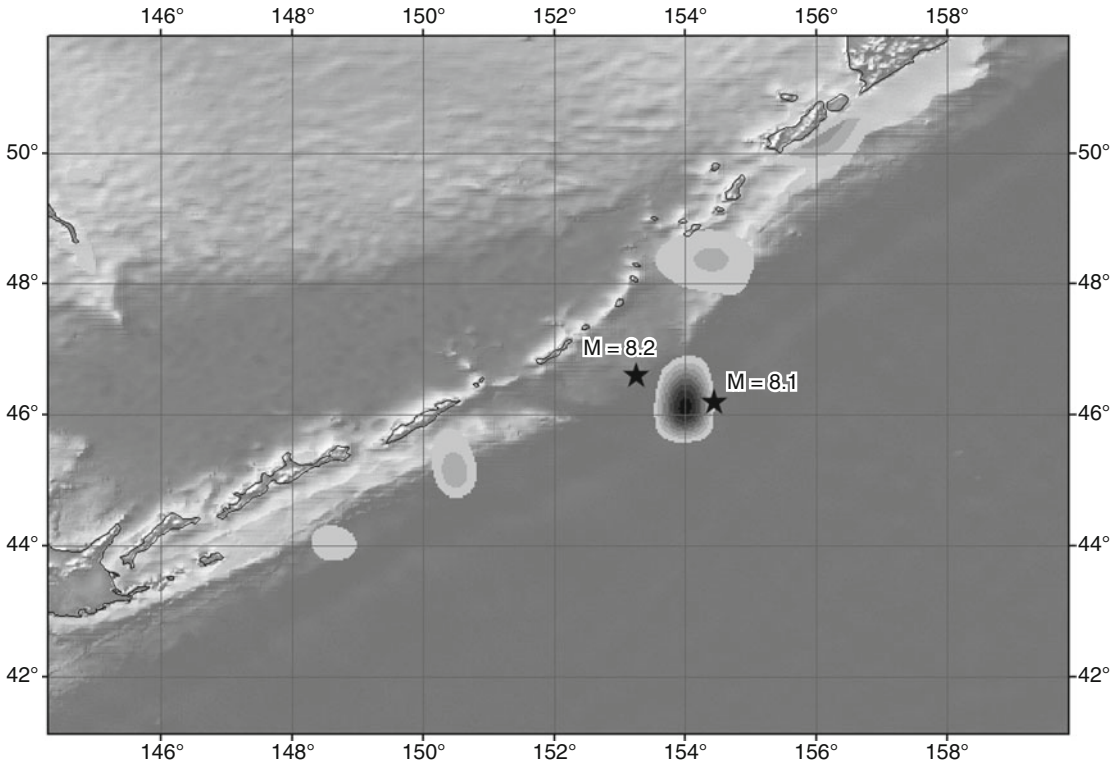
It follows from the experience of investigations of the seismic quiescence that a large earthquake seldom occurs during the most significant rate of quiescence. It arises more often after the rate of seismic activity has increased again and even exceeded that which has been observed before the beginning of the quiescence. Let us name the time interval from minimal values of activity at the stage of quiescence to the moment of the large earthquake as a phase of foreshock activation (phase III on Figure 1). Its duration has a wide range: from several days to the dozens of months. The areal of foreshock activation in general coincides with the area of aftershocks (see *Earthquake, Aftershocks*) and its size is estimated in hundreds of kilometers. These properties of the phase of foreshock activation bring to the understanding of the term "foreshock" in the broad sense. At the final step of development of such phase there may occur seismic events, the locations of which coincide practically with the source of the



Seismic Quiescence and Activation, Figure 2 Areas of seismic quiescence before the Simushir earthquake.

following large earthquake. They are traditionally called foreshocks and should be understood as foreshocks in the narrow sense (see *Earthquake, Foreshocks*). Usually they arise several hours before a large earthquake, reflecting apparently the nucleation of a rupture. This phenomenon is of a great interest for a short-term forecast, but the practical application thereof has some difficulties because no reliable criteria are found till today in order to differentiate foreshocks from usual earthquakes. In exceptional events when a number of events occurring during several hours and at one and the same place amounts to dozens, they may be interpreted presumably as foreshocks of a future large earthquake and serve as a ground for a short-term forecast. The striking example is a prediction of the Haicheng earthquake of February 4, 1975, $M = 7.3$ (Ma Zongjin et al., 1989). The foreshocks determined after the large earthquake (retrospectively) are described in a great number of publications and the description thereof is beyond the scope of this article.

Returning to the phase of foreshock activation (Figure 1), we cite the example of its detection before the Simushir earthquake mentioned above as of November 15, 2006, $M = 8.2$. The RTL method developed for the detection of a seismic quiescence allows also to identify the foreshock activation as a period of increase in the seismic activity after the quiescence. The situation showed in Figure 3 is a continuation in time of that which appeared in this area of the Kurile arch during the seismic quiescence (Figure 2). The development of the stage of seismic quiescence from the level of a long-term background to the lowest values of the seismic activity lasted in this event 1.5 years and the period of recovery of the stage of activity to the level of a long-term background (foreshock activation) lasted 1.5 years as well. The linear dimensions of foreshock activation amounted to about 100 km (Figure 3). It was located in the area of aftershocks between the main shock with the $M = 8.2$ and the strongest aftershock, $M = 8.1$. Also, like at a seismic quiescence, within the region as showed on the map (Figure 3) during the development of the main anomaly there was selected a number of anomalies with a lower intensity: on the territory of coordinates (44°N, 149°E); (45°N, 150.5°E); (48.5°N, 154.5°E.). In these places, no large seismic events occurred up to now. Thus, the foreshock activation, like the seismic quiescence, is not of high reliability in the prognostic aspect because there exist anomalies qualified as false.



Seismic Quiescence and Activation, Figure 3 Areas of foreshock activation before the Simushir earthquake.

Physical mechanisms leading to seismic quiescence and activation

Let us consider possible physical mechanisms, which bring to occurrences of the seismic quiescence and of the foreshock activation. There is no unified explanation at present and it is expedient to discuss various hypotheses. We would like to note at first that except for the three phases discussed above and the occurrence of foreshocks in the narrow sense, other anomalies may also appear sometimes. Scholz selected additional phases: doughnut pattern was observed in the period of development of the seismic quiescence around its external limits, and seismic silence was noticed just prior to the main event (Scholz, 1990).

Let us consider in a more detailed manner the hypotheses of nature of the stages of a seismic quiescence and of a foreshock activation. Ma Zongjin et al., investigated the seismic patterns before nine large earthquakes in China (Ma Zongjin et al., 1989). The authors did not select specially occurrences of a seismic quiescence or activation. They did describe mainly a migration of sources of seismic events for several years before large events in the regions adjacent to their epicenters with the dimensions of about first 100 km. Actual data cited by them are of interest as applied to a problem of physical nature of occurrences discussed in this article. A migration of sources was considered, mainly with the magnitudes 3–6, while the large earthquakes had the magnitudes of above 7. The regions round the epicenters of large events were separated in three parts: a hypocentral area A, which included a hypocenter of a large event; area of aftershocks B; and external area C.

The following main characteristics of migration were selected: During 3–10 years, till the moment of the large earthquake, two phases were varied in time. In the first one the events occurred mainly in the area C, while the areas A and B were characterized as relatively quiet. During the second phase which finished in the large earthquake, the activity was detected in the areas A and B, while the seismic activity in the area C was reduced. As the second phase developed, the activity in the areas A and B continued to last up to several months or days in relation to the moments of the large earthquake; at the end of such series the activity either accumulated inside the hypocentral area A or continued to last in the area B, while the area A was calm. We should note that the authors did not cite any quantitative evaluations of the seismicity rate, thus conclusions may be made based on a qualitative manner only. In summarization, there may be made a conclusion that the process of development of a large earthquake may occur according to various scripts, though in described events it (is) related to continental events only.

The seismic quiescence may be a consequence of increase in the strength of rocks within the seismically active area. In the dilatancy-diffusion model the increase in the strength is explained by laboratory experiments, being a consequence of appearance of open microcracks

and a relative drying of the rocks. However, it is not explained how such process can develop in the heterogeneous lithosphere in the spatial regions with the linear dimension of above 100 km.

The quiescence occurs also when the acting stresses decrease. This can be a consequence of development of an unstable deformation in the source of a future large earthquake what constitutes one of the corner stones of the model of avalanche-like fracturing. Expenditure of the accumulated potential energy brings to a decrease in stress both in the source and in the surrounding space. This explanation leads to expect an increase in seismic activity in the hypocentral area of a future large earthquake and a simultaneous occurrence of a seismic quiescence in the external area. This cannot always be observed. But the situation that the activation in the source occurs at the level of seismic events with small magnitudes, which are not registered by the available seismological network, cannot be excluded.

Decrease in the tectonic stress in some area of lithosphere can be a consequence of the motion of the neighboring blocks with a different rate. If one of the blocks stops because of a strong asperity at its tectonic boundaries with any neighboring blocks, then the stress will be accumulated at points of an asperity, while in the middle of the stopped block it will relax gradually. The activation will start at boundaries of the stopped block and then it will migrate to central parts when the asperity is destroyed.

As a modification of such assumption is the situation when the stress increases and brings to the seismicity in the stronger blocks, and the block between them is relatively discharged. The quiescence occurring in the discharged block in such situation causes an effect of "false forerunners" as no large earthquake follows after them.

Kanamori suggested an explanation of different phases of seismicity based on a model of existence of a strong inclusion at a fault being heterogeneous in its strength (Kanamori, 1981). When the stress increases gradually, the less strong inclusions disintegrate sequentially what brings to an accelerated growth of the stress at points being not disintegrated. A background seismicity is observed at the low stress. As the stress increases, there occurs the doughnut pattern – a mass destruction of rocks around the strong inclusion. The latter has a seismic quiescence. When the stress approaches to a critical level, there occurs a destruction of subunits of the strong inclusion which characterizes the phase of foreshock activation. In this hypothesis, the facts of existence of the seismic quiescence at distances that significantly exceed the rupture sizes when a large earthquake occurs are not explained.

The reason of seismic quiescence can be a change of orientation of the tensor of the current stress due to development of a creep at the fault where a future earthquake will occur. The existing fractures, which get into new conditions, require the time for unstable development (kinetics of destruction). It is not proven that this, undoubtedly, existing phenomenon can cause a quiescence at distances that significantly exceed the length of a rupture of a future earthquake.

Another reason can be a transformation of the medium surrounding the source to the quasi-plastic state, for example, when the temperature or the hydrostatic compression increases. Then the process of fracturing will occur at a lower scale level which is beyond the registration of earthquakes by the seismic network. There remains a question what are the physical reasons of increase of the temperature or the compression in the lithosphere or the earth's crust within a relatively short time period (years).

It is necessary to mention another effect, which influences on the fracturing in the geological medium. Laboratory and field observations prove that an increase or a decrease in the degree of water saturation of rocks results in a significant acceleration or retardation of occurrence of the seismic events (seismicity, triggered/induced). Further, if the rate of the seismic activity increases due to that, then it results in a relative increase in the number of events with the relatively small magnitudes and in a decrease in the number of big events. The seismic quiescence may occur: (a) if a degree of water saturation decreases, (b) if under the influence of the increased water saturation the seismicity transforms to the level of small events being not registered by the seismic network. The activation is a direct consequence of the increased water saturation and may appear also in the form of swarms.

It follows from the most available experimental facts that the foreshock activation develops in the epicentral region. Its size is less than the area of seismic quiescence, and the centers of anomalous areas of these two phenomena do not coincide as a rule. There is a ground to suppose that the physics of foreshock activation is connected with the development of unstable deformation, which is localized under the laws of mechanics in the zone of mainly two-dimensional extension. The complexity of fault systems, which display a fractal geometry, causes a successive occurrence of several zones of unstable deformation.

At the final period of foreshock activation, there often occur clusters of seismic events, that is, groups of events, the distances between the hypocenters and the times between the successive events of which are less than mean values of the background seismicity. The occurrence of clusters at the phase of foreshock activation can be explained by two reasons. First, they occur by chance because of the increase in rate of formation of events in the narrow zone of unstable deformation. Second, when the spatial density of accumulated active faults exceeds the critical level, there arise stress interactions among neighboring faults with the formation of the faults of a larger length. In the latter case, such effect must appear in the increase of middle magnitudes of seismic events, that is, in the decrease of the b value.

Summary

It follows from the above-mentioned hypotheses that there exist various physical mechanisms of occurrence both of the seismic quiescence and of the foreshock activation. For the purpose of more fundamental understanding of

such phenomena, the additional laboratory and fieldworks are required. In our opinion, special attention should be paid to the following directions.

To investigate on the same catalogs of earthquakes both the quiescence and the activation in a complex, paying attention to their distribution in space, time, and magnitudes.

To compare, where possible, the seismic patterns with the field of deformations being estimated based on the data of satellite geodesy.

To compare, where possible, the seismic patterns with the data of deep geoelectrical and hydrogeological investigations with the purpose of better understanding of the role of water.

SEISMIC SEICHES

Art McGarr
U.S. Geological Survey, Menlo Park, CA, USA

Definition

Seismic seiche is a term first used by Kvale (1955) to discuss oscillations of lake levels in Norway and England caused by the Assam earthquake of August 15, 1950. This definition has since been generalized to apply to standing waves set up in closed, or partially closed, bodies of water including rivers, shipping channels, lakes, swimming pools and tanks due to the passage of seismic waves from an earthquake.

The first published mention of seismic seiches is thought to be reports of those observed throughout much of Europe due to the great earthquake at Lisbon, Portugal in 1755 (Wilson, 1953; Richter, 1958). In addition to the Lisbon and Assam earthquakes, seismic seiches at teleseismic distances have been observed for many other large earthquakes including the 1964 Alaska (McGarr and Vorhis, 1968) and the 2002 Denali, Alaska, an earthquake that caused damaging seiches in Lake Union, Seattle, Washington at an epicentral distance of 2,400 km (Barberopoulou et al., 2004).

Kvale (1955) showed that seismic surface waves from the Assam earthquake were the most probable cause of the seiches observed in Norway and England at that time. Moreover, he concluded that the natural period of a basin must be matched by the periods of the passing seismic surface waves. Motivated by observations reported by Donn (1964) of a seiche generated in a channel near Freeport, Texas, at an epicentral distance of about 5,040 km from the 1964 Alaska earthquake, McGarr (1965) developed a relation between the ground motion of seismic waves and the resulting seiche. The passing seismic wave exerts a horizontal acceleration on a closed or partially closed body of water, which can be idealized as a long channel of uniform depth. This causes a seiche, composed of standing water waves whose periods depend on the dimensions of the channel. The amplitude of the seiche is a function of channel depth, the amplitudes of the horizontal accelerations of the passing seismic waves, and the extent to which the periods of the seismic waves match those of standing water waves. The gravest mode of the standing waves has a period given by $T = 2L/\sqrt{gH}$, where T is the period in seconds, L is the channel width in meters, H is the channel depth in meters, and g is gravity. For instance, if L = 100 m and H = 10 m, then the period of the gravest seiche mode is 20 seconds, which tends to be the period where surface waves show maximum amplitudes at teleseismic distances. Any factor that enhances the amplitudes of surface waves, such as basins containing low-velocity sediments, tends to result in greater production of observed seiches from a given earthquake (McGarr and Vorhis, 1968; Barberopoulou et al., 2004).

SEISMIC SIGNALS IN WELL OBSERVATIONS: PRE, CO, POST

R. K. Chadha
National Geophysical Research Institute, Hyderabad, Andhra Pradesh, India

Synonyms

Abnormal water level changes; Hydrological earthquake precursors

Definition

Seismic signals in wells – rise or fall in water level fluctuations in bore wells due to earthquakes. Pre, co, and post means abnormal fluctuations prior, during, and after the occurrence of earthquake.

Introduction

Water levels in wells are found to be affected by local and distant earthquakes in addition to other phenomena like, rainfall, atmospheric pressure, and earth tides. These anomalous changes that could be pre, co, and post earthquake are believed to reflect pore pressure changes related to the redistribution of stress in the near and far fields of dislocation sources, but in general are poorly understood because of inadequate data. Numerous reports of the well-documented cases of this phenomenon have appeared from China, Japan, Russia, the USA, India, Taiwan, and other countries during the last 30 years (Wakita, 1975; Roeloffs, 1988, 1996, 1998, 2003; Liu et al., 1989, 2006; King et al., 1999, 2000; Rudnicki et al., 1993; Koizumi et al., 1996, 1999; Quilty and Roeloffs, 1997; Chadha et al., 1997, 2003, 2008; Gavrinlenko et al., 2000; Wen-Chi Lai et al., 2004; Akita and Matsumoto, 2004; Kitagawa et al., 2006; Sil, 2006a, b). Since the earthquake-related groundwater level changes were scattered and rarely observed by a sufficiently dense network of observations wells, such studies have not been adequately developed. Recently, some experiments have been taken up to drill bore wells in the seismically active region to continuously monitor water-level changes related to earthquakes.

Types of observed changes

Four types of changes in well water levels have been observed, which are related to earthquakes, namely, pre, co, post, and transient. While, the pre and post earthquake observations are mostly interpretative in nature and difficult to substantiate, coseismic and transient changes are well established. The most suitable wells for observing anomalous coseismic and transient changes are the ones that are connected to confined aquifers and show the effect of earth tides. The presence of tidal signals in well level data indicates that the well is sensitive to small strain changes in the connected rock formations and hence also should be sensitive to variations in local stress fields, and thus to earthquakes. Unconfined aquifers also show seismic signals in case of large magnitude earthquake at closer distances. Few typical examples of coseismic and transient changes are described below.

Coseismic seismic signals

Coseismic signals are generally observed in wells connected to confined aquifers and are located in the near field of earthquake source location. These are generally steplike changes coinciding with the occurrence of the earthquake. In case of shallow unconfined aquifers, coseismic oscillatory changes have also been reported.

The Chi-Chi earthquake of Mw 7.6 on September 21, 1999 is one of the well-documented events for earthquake-induced water level changes in wells. Based on the hourly digital record of the water levels, all changes were reported as coseismic or postseismic. Chia et al. (2001) described the details of these changes and compared the coseismic changes with the distances between the earthquake fault and observation wells. Wang et al. (2001) discussed the distribution of the coseismic changes and attributed them to liquefaction. Wen-Chi Lai et al. (2004) compared these changes with geological setting and seismic ground motion. They showed that in the nearby Choshui River alluvial fan area, the groundwater levels coseismically rose and those amplitudes increased as the ground acceleration and hydraulic conductivity became larger. In the slope area near the earthquake fault, the water level coseismically dropped and those amplitudes increased as the ground acceleration became larger.

Akita and Matsumoto (2004) reported coseismic changes in 29 wells associated with M 8.0 Tokachi-oki earthquake in 2003 in Japan. These changes were observed as increase in groundwater in wells located in the southeast part of Hokkaido. The maximum increase was 430 cm. In other area of Hokkaido, coseismic decreases were observed, the maximum being 59 cm. These anomalous changes were explained in terms of poroelastic response to the volumetric strain after the Tokachi-oki earthquake. The strain sensitivities determined by coseismic responses in the groundwater level were found to be consistent with those estimated by M_2 tidal strain in few wells.

Matsumoto et al. (2003) studied hydrological response at Haibara well to earthquakes in central Japan. They reported 28 coseismic changes during the period from 1981 to 1997 and obtained a relationship $M \geq 2.45 \log_{10}$

Dis + 0.45 which holds good for 26 events. Most of the water level changes in Haibara well could not be explained by poroelastic response of the water level to coseismic volumetric strain steps in confined aquifers, because the sizes and directions of the coseismic water level changes correlate poorly with the sizes and directions of the volumetric strain steps. Ground motion due to seismic waves was put forward as a more probable reason for coseismic drops in water level. Few preseismic or inter-earthquake changes were also observed by them in the residual water level data at Haibara well, which was interpreted to be related to local aseismic crustal deformation.

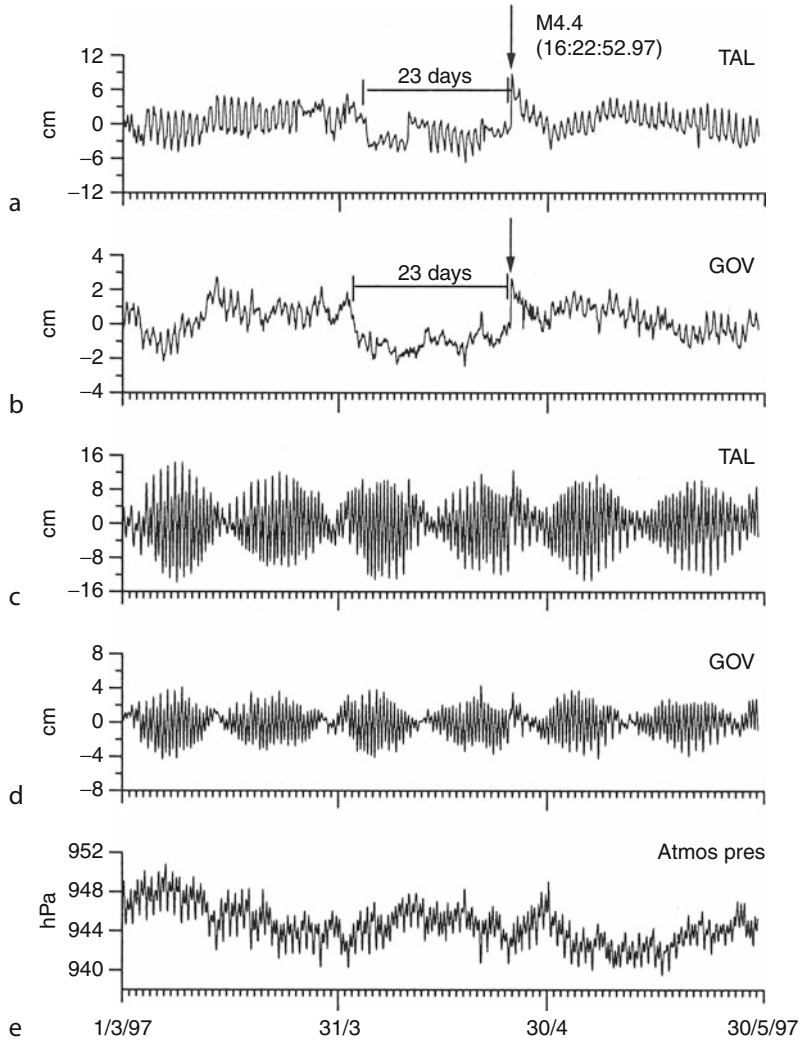
Along the San Andreas fault in the Parkfield area, water levels at 17 wells were monitored continuously as a part of Parkfield earthquake prediction experiment. Rudnicki et al. (1993) analyzed data from a well located 460 m from the San Andreas fault near Parkfield, California during January 1989–July 1990. They demonstrated that recovery rates of water level changes due to fault creep can be used to infer the position of the slipping zone relative to the well. They applied this technique to five slip-related water level changes. The changes were all characterized by a rapid drop (less than 8 h) and a slow recovery (15–30 days). The recoveries modeled by pore fluid diffusion due to a plane strain dislocation in porous, fluid-saturated elastic provided satisfactory agreement with the observations. Calculations were also done for limiting cases of both an impermeable and a permeable fault. They showed that permeability of the fault has little effect on inferences about the slip, but the inferred (horizontal) diffusivity differs for the two cases, 0.15 m^2/s for the impermeable and 0.06 m^2/s for the permeable. Later, Roeloffs (1998) analyzed persistent water level changes data at a well near Parkfield for anomalies caused by local and distant earthquakes.

Chadha et al. (2003) reported four cases of coseismic changes in well around Koyna-Warna region in western India. Koyna region is known to be site of the world's largest Reservoir Triggered Earthquake of M 6.3 in 1967. For the last 5 decades, earthquakes of $M \geq 5.0$ continue to occur in a small source volume of the dimension $30 \times 15 \times 10$ km^3 in this region. To comprehend the cause-and-effect relationship between local earthquakes and water level changes, 21 boreholes were drilled surrounding the seismic source volume. Out of the 21 boreholes, 10 were found to be connected to confined aquifers and showed strong tidal signals. Analysis of data from these wells from 1997 to 2003 revealed four cases of coseismic changes associated with earthquakes of $M \geq 4.2$. Figure 1 shows a coseismic steplike increase in two wells in the Koyna region, which is preceded by precursory drop in water levels prior to the M 4.4 earthquake. While coseismic increase of 2–7 cm in water levels was observed for earthquakes of M 4.3–4.7 in three cases, a troughlike decrease up to 8 cm was observed at seven wells for an M 5.2 earthquake. All these earthquakes occurred within the network of wells drilled for the study. From their studies, Chadha et al. (2003) concluded that the magnitude of the earthquake and epicentral distance to the wells are two vital parameters for recording the hydrological anomalies in well water levels. In Koyna, coseismic anomalies were recorded in wells for earthquakes of $M \geq 4.3$ located up to 24 km distance. Although there were several earthquakes of $M < 4.0$ during the period of study, no anomalous changes were observed in well recordings. Also, few precursory anomalies were also interpreted for local earthquakes that showed coseismic changes.

Using data of M 4.4 earthquake in Koyna, Chadha et al. (2005) tested the hypothesis that "well level fluctuations respond to changes in crustal volume strain that is induced by an earthquake in the form of step like coseismic change." Using Okada's (1992) formulation, they calculated the static volumetric strain at the surface of a homogeneous half space to see whether the coseismic steps observed for this earthquake agree with the observations of Wakita (1975) that the water level in a well shall rise or fall based on the location of the well with reference to the disposition of the fault plane. The results showed that expanding and contracting zones representing the static volumetric strain field agree with the observations of well level changes indicating that well-aquifer system indeed has the potential to reflect coseismic volumetric strain changes, similar as with the tidal fluctuation in volume strain. Further, using the strain sensitivities obtained from tidal analysis, they showed that there was misfit in amplitudes of the observed and calculated coseismic steps. Based on this study, they concluded that coseismic strains may be a function of site effects controlled by local heterogeneity in geological structures. Thus, simple elastic models cannot explain the amplitudes of hydrological anomalies wholly. Huang et al. (1995) have earlier suggested a nonlinear response of water levels to coseismic strains due to local heterogeneities. Earlier, Grecksch et al. (1999) have also observed coseismic well level steps to be higher than predicted from strain sensitivities.

Transient seismic signals

Seismic waves from distant earthquakes can cause changes in well water levels at great distances due to the passing of seismic waves (Rexin et al., 1962). There are several reports of such changes from different parts of the world, following the Sumatra earthquake of Mw 9.3 on December 26, 2004 (Kitagawa et al., 2006; Sil, 2006; Sil and Freymueller, 2006; Wang and Manga, 2006; Chadha et al., 2008). Earthquake-induced water level changes at distant locations were also reported after the Denali earthquake (Brodsky et al., 2003; Harp et al., 2003; Stricherz, 2003; Cassidy and Rogers, 2004; Kayen et al., 2004; Sil, 2006). It is thought that dynamic oscillation in crustal strain in an aquifer due to a seismic wave mainly caused dynamic oscillation in the groundwater level. Seismic oscillations, due primarily to surface waves from distant events, occur in some wells tapping highly transmissive aquifers (Liu et al., 1989; Liu et al., 2006). Earlier, several workers have shown that anomalous



Seismic Signals in Well Observations: Pre, Co, Post, Figure 1 Records of air pressure and well water level in GOV and TAL wells, during March 1–May 30, 1997. (**a**) and (**b**) residual water levels after removing earth tides and atmospheric pressure, (**c**) and (**d**) raw data after removing the trend. Spring and neap tides are clearly seen, (**e**) Atmospheric pressure. Arrow shows origin time of the earthquake on April 25, 1997. Precursory decrease 23 days prior to M 4.4 earthquake is shown by a horizontal line.

well-water level changes occur in response to deformation of the connected aquifers because of seismic waves (Cooper et al., 1965, 1967; Liu et al., 1989), fault creep (Wesson, 1981; Roeloffs, 1996, 1998), tidal strain (Bredehoeft, 1967; Van der Kamp and Gale, 1983), or atmospheric loading (Rojstaczer, 1988). Cooper et al. (1965) and Kunugi et al. (2000) showed that the amplitude of the oscillation in groundwater level is enhanced in a particular period due to the characteristics of the well-aquifer system.

M 9.1 Sumatra earthquake of 2004 and transient seismic signals

Kitagawa et al. (2006) reported water level changes in wells due to Sumatra earthquake of 2004 at a distance of more than 5,000 km in Japan. At 38 of the 45 observation stations, these changes were recorded. Ishii-type borehole strain instruments installed in 10 of the observation stations also recorded changes in crustal strains. Most of these changes in crustal strains and groundwater levels were dynamic oscillations due to a seismic wave. Sil and Freymueller (2006) reported anomalous changes in wells in Fairbanks, Alaska due to the passing of seismic waves of Sumatra earthquake. Chadha et al. (2008) reported large water level changes in six bore wells in the Koyna region in western India, following the Great Sumatra earthquake of Mw 9.3 in December 26, 2004. This earthquake occurred at 00:58:50 coordinated universal time (UTC) off the coast of Sumatra located about 3,000 km from the Koyna region. The arrival time of the *P* wave recorded at the Koyna seismic station was 01:04:24.45 (UTC). The anomalous water level changes were observed at 01:15

(UTC) at all of these wells where the sampling rate was 15 min. No abnormal changes were noticed in the preceding sampling time at 01:00 (UTC), clearly indicating that these changes occurred due to the passage of seismic waves generated by the Sumatra earthquake. However, due to the large sampling interval, it was difficult to correlate the water level changes either to shear or surface waves. No local earthquake was recorded by the network during this period. The anomalous water level changes were of the order of 2–65 cm and showed either a spikelike or a steplike change. These types of changes are attributed to the dynamic strain induced by the passage of seismic waves, most probably long period surface waves.

Summary and conclusion

Earthquakes can cause changes in well water levels in near and far fields. This has been exemplified by several reported cases in the literature during the last 3 decades. Therefore, water level monitoring becomes a valuable tool for earthquake prediction research. Although, the coseismic and transient water level changes are well established, the greatest challenge is to identify precursory anomalous changes that can be identified prior to the occurrence of earthquakes. Very often, these precursory changes that represent the pre-earthquake phase are very small and therefore not very obvious in the raw data. This is due to the response of wells to large atmospheric pressure, significant precipitation, or earth tides, which may obscure these smaller earthquake-related changes. Sophisticated filtering techniques have to be developed to decipher the earthquake related anomalies from non-tectonic effects in the data. Definite patterns of water level anomalies have to be established, both site specific and global, so that predictive capabilities can be developed. This could be done with continuous monitoring of dedicated networks of wells around known seismically active regions in different countries.

At present, three categories of anomalies have been reported, namely, co- and preseismic, aseismic, and transient changes. In the first category, a steplike coseismic rise or fall has been observed. This type of coseismic steps is understood as sudden pore pressure changes related to an alteration in in-situ volume strain caused by the redistribution of stress in the brittle crust (Bodvarsson, 1970; Kuempel, 1992; Muir-Wood and King, 1993). Sometimes, these coseismic steps were found to be preceded by persistent water level drops prior to the earthquakes. According to Sadovsky et al. (1979) and Monakhov et al. (1983), the most common precursor is a water level drop of a few centimeters amplitude several days before the earthquake. Typically, the drop is beginning to recover when the earthquake occurs. This type of anomaly has been referred to as "rebound anomaly" (Igarashi et al., 1992) and is believed to be related to an increase of porosity and permeability due to fracturing, with the subsequent recovery attributable either to influx of fluid or to compression (Roeloffs, 1988). Another type of precursory water level drop that occurs much prior to coseismic steps, but recovers just before the earthquake. This type of water level drops could be due to aseismic creep along a fault plane where the earthquake stress is building up. The third type of precursory change occurs and recovers much before the occurrence of the earthquake. This type of water level drops and recovery is believed to be due to small slips on the hanging wall of a normal fault prior to occurrence of the main earthquake. All these precursory changes are established in the hindsight, that is, after the occurrence of earthquakes. Continuous data sets for long periods will help in establishing these kinds of anomalies.

SEISMIC STRUCTURE AT MID-OCEAN RIDGES

Donald W. Forsyth
Department of Geological Sciences, Brown University, Providence, RI, USA

Definition

Lithosphere. The cool, uppermost layer of the solid earth that moves as a unit and has some long-term elastic rigidity. It usually consists of both crust and the uppermost mantle. The mantle portion is typically characterized by high seismic velocities and low attenuation.
Asthenosphere. A more deformable, low-viscosity layer in the mantle underlying the lithosphere. Characterized by low seismic velocities and relatively high attenuation.
Anisotropy. Physical properties at any one point varying depending on direction; for seismic waves, velocity may depend on direction of propagation and direction of polarization of the wave.

Introduction

Mid-ocean ridges are spreading centers where two oceanic, lithospheric plates move apart. The separation of the plates induces upwelling in the underlying asthenospheric mantle. Because melting temperature decreases with decreasing pressure, as the mantle upwells, it undergoes pressure-release partial melting, producing magma that migrates upward to form new oceanic crust. As the plates move away from the spreading center, heat is lost to the surface conductively by diffusion and convectively by hydrothermal circulation. As the crust and mantle lose heat, the magma solidifies, and the plates thicken and cool with increasing age of the seafloor.

Although the general outline of the processes beneath mid-ocean ridges leading to the formation of new seafloor is well known, there are many questions remaining about the details of the mantle flow, melt generation, and melt migration that have not yet been fully answered. For example, along mid-ocean ridges, spreading centers are offset and segmented by transform faults and overlapping spreading centers. Are there distinct centers of mantle upwelling beneath each ridge segment or is the segmentation a shallow manifestation of stresses within the lithosphere with upwelling a more or less continuous phenomenon in the asthenosphere? How broad and deep is the melt production region?

The propagation of seismic waves through the crust and mantle provides one of the most direct ways of probing the structure beneath the ridges associated with plate separation and crust formation. The velocity, attenuation, and anisotropy of the waves are affected by temperature, composition, the presence of melt or cracks, and the crystal fabric. Tomographic images and maps of crustal and uppermost mantle structure are typically created in active source experiments where artificial sound sources, such as air guns, are recorded by ocean bottom seismometers (OBS) and/or long arrays of hydrophones towed behind ships. Deeper mantle structure is probed using signals generated by distant, teleseismic earthquakes recorded on arrays of ocean-bottom and land seismometers over periods of months to years. The logistical difficulty and expense of such experiments means that relatively few mid-ocean ridges have been studied in detail.

Mantle structure

A cross section of the shear velocity structure beneath the East Pacific Rise spreading center is shown in Figure 1 in comparison to the velocity variations that would be expected for simple conductive cooling of the plates if shear velocity were sensitive only to temperature and pressure. This tomographic image is based on the propagation of Rayleigh surface waves across two OBS arrays deployed for periods of

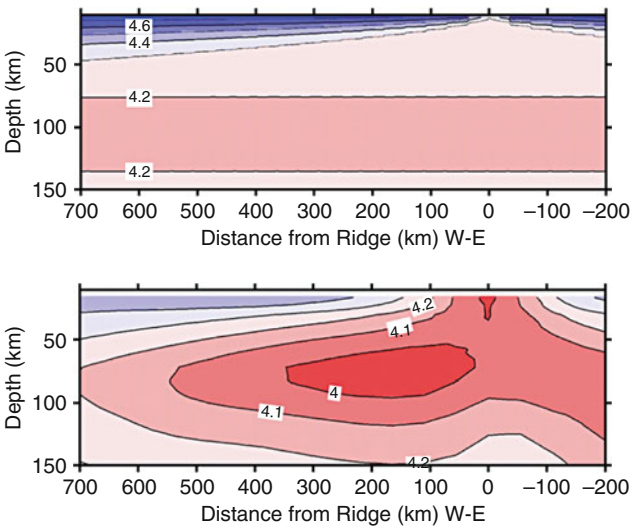
6 and 12 months. The expected thickening of the plate with increasing distance from the ridge axis as the plate cools is clearly observed in the form of increasing shear wave velocity near the surface. Velocity changes extend substantially deeper than is predicted and the shear velocity is lower than expected for the direct effects of temperature variations. Both of these departures from the predictions are indications that partial melt may be present, which could reduce the shear (S) wave velocity.

The lowest velocities are observed at depths of 60–80 km, where petrological models predict maximum melt production. There also are very low shear velocities at shallow depths immediately beneath the ridge axis, which may represent higher melt concentrations in the mantle that accumulated as melt migrates upward and inward to form the new oceanic crust at the ridge axis.

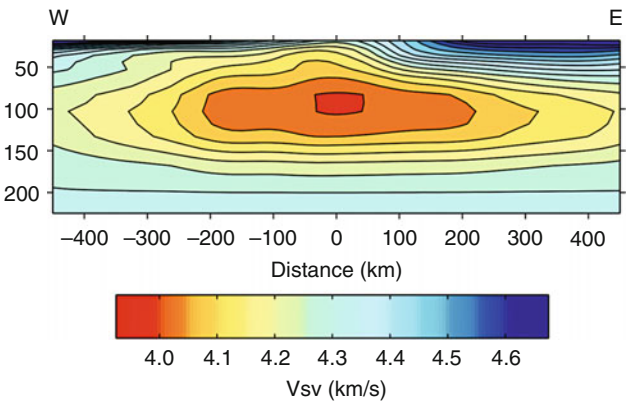
Another important feature of the shear velocity structure is the asymmetry across the ridge axis. To the east, beneath the Nazca plate, the high-velocity surface layer increases in thickness more rapidly and the very low-velocity region is absent. This asymmetry is also observed in the degree of shear wave splitting, an indicator of anisotropy, in delays of compressional (P) and S waves, in electrical conductivity, and in the rate of subsidence of the seafloor away from the ridge axis (MELT Seismic Team, 1998; Evans et al., 1999). S wave tomography indicates that the asymmetry may extend to depths of 200 km or more (Hammond and Toomey, 2003). The asymmetry is probably caused by large-scale mantle flow coming from the hotspot region to the west beneath the Pacific plate, coupled with migration of the spreading center to the west. The fast direction for seismic wave propagation, as indicated by shear wave splitting and Rayleigh wave anisotropy, is perpendicular to the East Pacific Rise, consistent with the alignment of olivine crystals in the mantle expected for plate formation and flow from the west.

The East Pacific Rise is one of the fastest spreading ridges, with full spreading rate of about 14 cm/year. Pronounced asymmetry is also observed across the Reykjanes Ridge south of Iceland (Figure 2), which has a full spreading rate of only about 2 cm/year (Delorey et al., 2007). In this case, the tomographic study took advantage of the existence of arrays of stations on Iceland, which straddles the Reykjanes/Mid-Atlantic Ridge. Like the East Pacific Rise, very low shear velocities (~4.0 km/s) indicative of the presence of melt are found in a broad region beneath the ridge. For both the East Pacific Rise and the Reykjanes Ridge, there is too little attenuation of surface waves to attribute the very low velocities to the effect of high temperature alone. Velocities at depths shallower than 80 km are lower on the west side, beneath the North American plate, perhaps due to the westward migration of the ridge and upwelling in the mantle in the wake of the thicker North American lithosphere farther west. The anisotropy pattern is different than for typical mid-ocean ridges, perhaps indicating that there is along-axis flow away from the Iceland hotspot in the asthenosphere.

To date, there have been no experiments that provide good control of along-axis variations in mantle structure at depths of tens of kilometers or more where melt production is expected to occur. In the Gulf of California, a surface wave study showed that there are along-axis variations in shear velocity with minima spaced at intervals of about 250 km, perhaps indicative of discrete upwelling centers (Wang et al., 2009), but that spreading system is flanked by continental crust on both sides and dominated by long transform faults, so it may not be typical. At shallower depths just



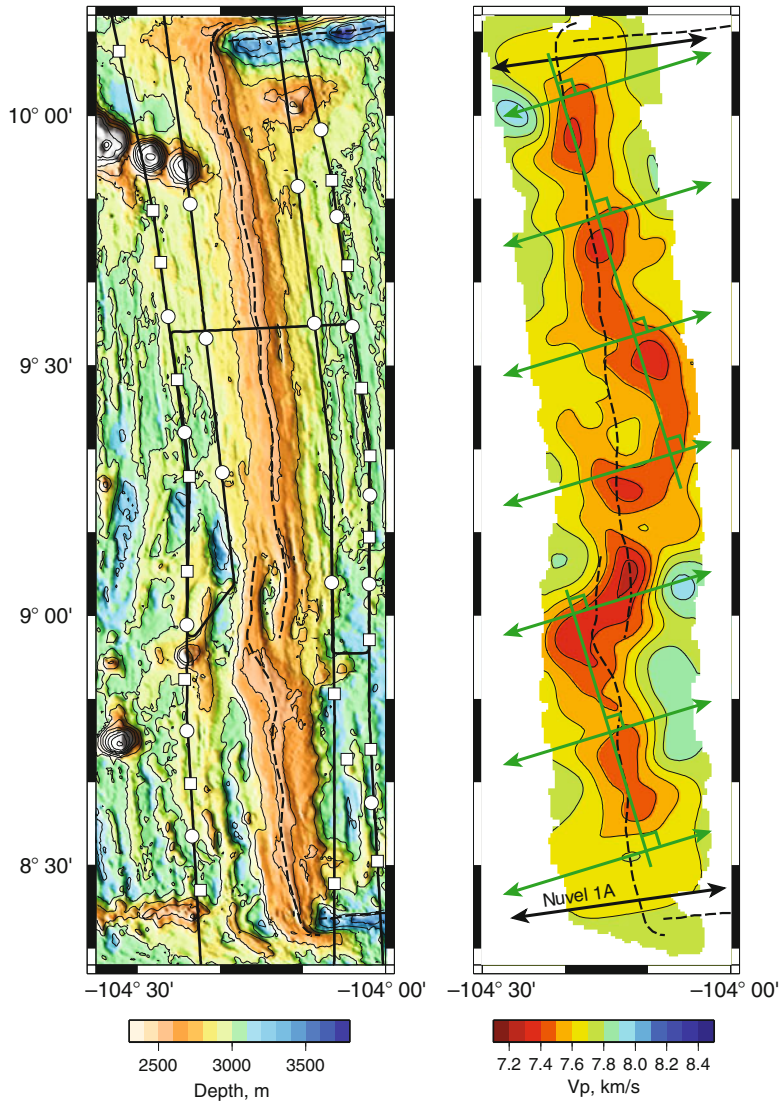
Seismic Structure at Mid-Ocean Ridges, Figure 1 Tomographic cross section of the East Pacific Rise, comparing predicted shear velocity structure (*top*) to observed structure (*bottom*). Contours are labeled in km/s. Velocities are significantly lower than predicted for temperature effects alone, suggesting the presence of partial melt. After Harmon et al. (2009).



Seismic Structure at Mid-Ocean Ridges, Figure 2 Tomographic cross section of shear wave velocity structure across Reykjanes Ridge south of Iceland. Note strong asymmetry in upper 100 km between North American plate (west) and European plate (east). After Delorey et al. (2007).

beneath the Moho (the transition from crust to mantle), there are clearly along-axis variations in P-wave velocity on the northern East Pacific Rise, the boundary between the Pacific and Cocos plates (Toomey et al., 2007). Using long offset arrivals refracting from the Moho (Pn) observed in an active experiment, velocity minima were found spaced about 25 km apart (Figure 3). P-wave velocities in the minima are 7.4 km/s or less, suggesting the presence of 1–3% melt distributed in films or thin sheets (typical P-wave velocities at the Moho are 7.8–8.4 km/s). However, it is not clear whether these apparent centers of melt lie above centers of upwelling mantle or they represent a scale length associated with melt migration.

Most of the centers of melt concentration lie beneath or very close to the spreading center determined from detailed bathymetric surveys, but one at 9° 30' N is displaced several kilometers from the axis. Because the fast direction for P-wave propagation is skewed from the spreading direction and is not perpendicular to the strike of the ridge axis, Toomey et al., inferred that upwelling and mantle flow at depth may also be skewed, controlling the location of the velocity minima just below the Moho.



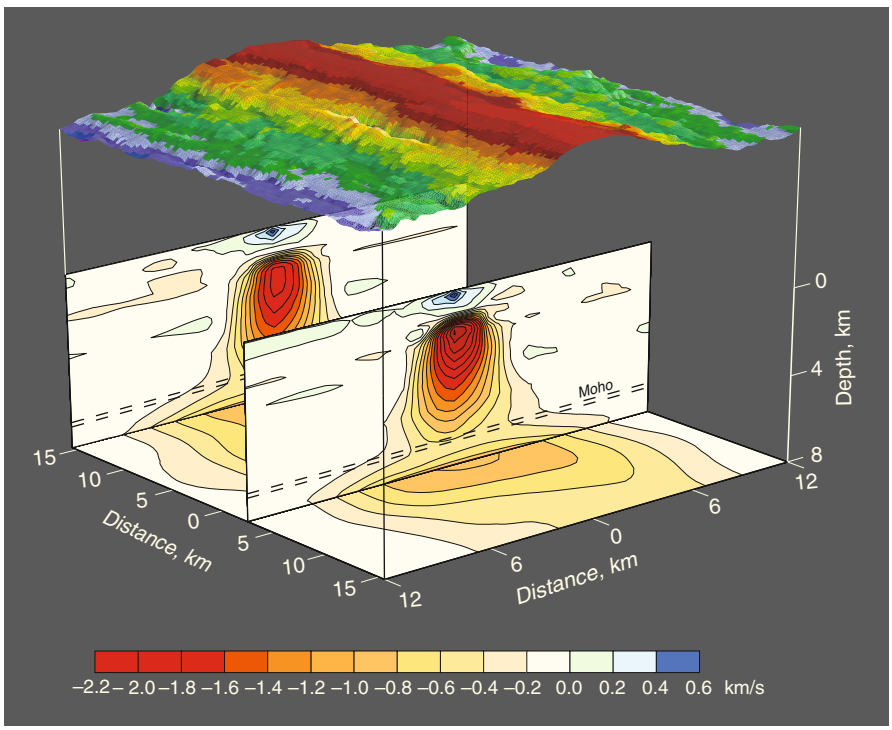
Seismic Structure at Mid-Ocean Ridges, Figure 3 Bathymetry of the East Pacific Rise (*left*) and tomographic image of the mantle 9 km beneath the seafloor (*right*). Dashed lines show plate boundary. Solid lines show locations of air gun shots fired at 500-m intervals. Squares and circles are locations of ocean bottom receivers. Contour interval on tomographic image of P-wave velocity is 0.1 km/s. Green lines with double arrowheads indicate fast direction for anisotropic wave propagation. Black lines with arrows indicate direction of relative motion between the Pacific and Cocos plates. Note that some of the slowest region is displaced from the plate boundary. After Toomey et al. (2007).

Crustal structure

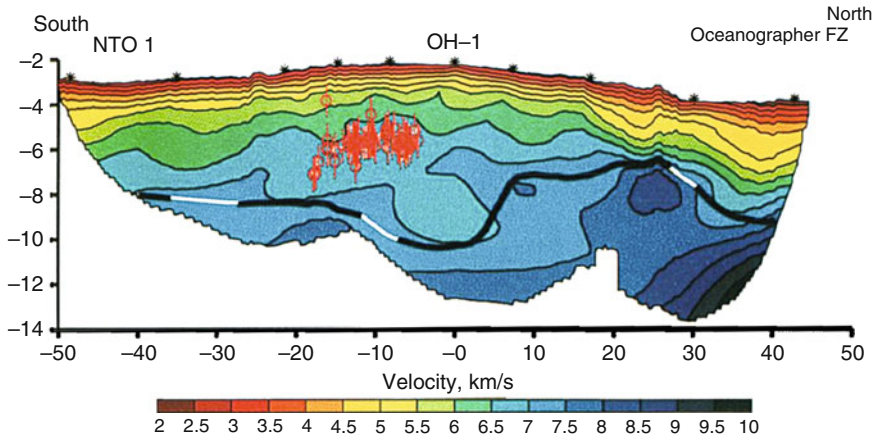
Basaltic melt migrates upward through the mantle and is focused at the ridge axis. The mechanisms for focusing are still not well known: there may be melt-rich channels at the base of the lithosphere that guide the melt upward and toward the ridge axis; there may be pressure gradients within the deforming mantle that help push the melt toward the axis; or there may be anisotropic cracks or dunite channels that form easy paths for melt migration. Once the melt reaches crustal levels, there may be redistribution along axis through dikes or a continuous magma chamber. It is clear from seismic studies, however, that there is very little magmatic addition to the crust outside the immediate vicinity of the ridge axis. The crust is essentially full thickness at the spreading center itself (Detrick et al., 1987).

The classic model of oceanic crust is a layer of extrusive basalts at the surface in the form of porous pillow basalts and sheet flows, underlain by a region of sheeted dikes that feed the extrusive layer from a magma chamber, and the lower crust consisting of gabbros that solidify from the magma chamber or underlying mush zone. The seismic structure has also commonly been described in terms of layers that have often been equated to the lithological layering: layer 2A is a low-velocity layer at the surface several hundred meters thick (layer 1 is sediments that are deposited on top of the basaltic crust); layer 2B is a transition region in which the P velocity increases rapidly downward; and layer 3 has low vertical velocity gradients and high P-wave velocities of 6.5–7.0 km/s. A number of investigations, however, have demonstrated that the seismologic layering does not correspond exactly to the lithological layering and that seismic structure is primarily controlled by porosity. The middle to lower crust, layer 3, contains both dikes and gabbro bodies.

At the axis of fast-spreading ridges, there usually is a low-velocity region only a few kilometers wide at most that represents a zone of partial melting that extends throughout the crust (Figure 4). At the top of this low-velocity region is a very low velocity layer, which is imaged as a prominent reflector in seismic reflection profiles at depths of 1.5–2.5 km on the East Pacific Rise (Detrick et al., 1987). The depth to this reflector tends to increase with decreasing spreading rate or proximity to a fracture zone and it is typically absent at slow-spreading ridges (Singh et al., 2006). The width varies from about 250 m to several kilometers. It is interpreted as the top of an axial magma chamber (AMC) or melt sill, with typical thickness less than 100 m. Modeling of P to S conversions in wide-angle reflections indicates that melt content in the AMC varies from nearly 100% to less than 30% along the ridge (Singh et al., 1998; Canales et al., 2006). Estimates of melt content in the deeper crustal mush zone (consisting



Seismic Structure at Mid-Ocean Ridges, Figure 4 Three-dimensional view of the anomalous P-wave velocity structure of the East Pacific Rise at 9°30′N (a one-dimensional reference model has been subtracted). From Dunn et al. (2000). Overlying bathymetry is shown at top, with red shallow to blue, deep. The red regions below the ridge axis correspond to areas of partial melting. The axial magma chamber is at the top of these anomalously slow regions.



Seismic Structure at Mid-Ocean Ridges, Figure 5 P-wave velocity structure along the Mid-Atlantic Ridge axis from a non-transform offset on the left to the Oceanographer fracture zone on the right. Crustal thickness from wide-angle reflections off the Moho is shown by thick solid line (open where there are gaps in coverage). The crust is thicker and the lower crust has lower velocity near the center of the segment. From Hooft et al. (2000). The red circles are locations of microearthquakes with uncertainties indicated by error bars. Location of ocean-bottom hydrophones indicated by asterisks.

of a mixture of melt and crystals) are of the order of 2–8% in the lower crust and 3–12% near the Moho (Dunn et al., 2000). The fact that the zone in which melt is present is so narrow even at fast-spreading ridges means that hydrothermal circulation must be very efficient in removing heat, as purely conductive cooling of the crust would result in a much wider zone of partial melting.

Although there are variations in structure along-axis at fast-spreading ridges, the along-axis variations are much more pronounced at segmented, slow-spreading ridges. Typically, the crust thins approaching transform offsets. Within the fracture zone itself, the basaltic crust may be as thin as 1 km or less, but seismically there may be an altered, fractured layer that is a few kilometers thick and characterized by unusually low velocities, so that it looks like crust. The low-velocity region in the fracture zone, however, probably is mostly mantle that is altered by interaction with water penetrating down cracks that are repeatedly opened by slip along the transform fault. Near the center of ridge segments between two transform offsets, the crust tends to be thicker and lower in velocity than elsewhere (Figure 5), suggesting that melt is preferentially delivered to the crust from the mantle at that point. The upper crust at slow spreading ridges is anisotropic, with P-waves traveling faster along axis than perpendicular to it, indicating that faults and fissures are preferentially aligned parallel to the spreading center (Barclay and Toomey, 2003).

Summary

The seismic velocity structure of mid-ocean ridges is controlled by crustal thickness, cracking or porosity, temperature, melt, and crystal orientation. Low-velocity regions in the mantle that are caused by high temperatures and partial melt indicate that melt is generated in a broad region beneath spreading centers. Asymmetries in the velocity structure show that upwelling and melting beneath ridges are strongly influenced by global mantle circulation and plate motions. Crustal low-velocity regions are concentrated very near the ridge axis, so melt must migrate both vertically and horizontally to the ridge axis from the broad melt production region. The narrowness of the low-velocity zone in the crust requires that hydrothermal circulation must rapidly cool the crust. Along-axis variations, particularly at slow-spreading ridges, suggest that melt is preferentially delivered to the center of ridge segments.

Definition

The term tomography derives from the Greek τομος, or slice. "Seismic tomography" is used for a variety of methods that use transmitted seismic waves to estimate the spatial variations in properties (wave velocity, density, attenuation) inside the Earth, which are often represented as images of two-dimensional cross-sections or "slices." It is conceptually different from seismic migration, which uses reflected waves to image sharp discontinuities.

History

In 1971, P. Bois at the Institut Français de Pétrole was the first to suggest the tomographic method in order to locate the causes of delays in seismic waves between two boreholes. His paper predates many future developments but was written in French and remained largely unnoticed. In the mid-1970s, Keiti Aki from MIT applied a linear inversion to locate velocity heterogeneities beneath large nuclear monitoring arrays in Norway and Montana, and Harvard's Adam Dziewonski began interpreting the time residuals published by the International Seismological Center (ISC) in the UK in terms of global velocity anomalies.

In 1982, Guy Masters and his colleagues at the Scripps Institution of Oceanography discovered a strong degree-2 component in the geographical distribution of the slight shifts in the spectral peaks of the Earth's normal modes. Since then, the Earth's free oscillations have contributed to constrain the heterogeneity in the Earth at the longest wavelengths and as deep as the inner core. By 1984 John Woodhouse and Adam Dziewonski at Harvard published a first global model for shear velocity in the upper mantle based on long-period surface waves.

However, to image smaller scale anomalies, the shorter wavelengths of P and S-waves are indispensable. In particular, Steve Grand at the University of Texas, Rob van der Hilst and Wim Spakman at Utrecht University and Yoshio Fukao and colleagues at the University of Tokyo pioneered high-resolution body-wave tomography using iterative solvers for the huge systems of linearized equations and established in the early 1990s that some, but not all, subducting slabs are able to sink well into the depths of the lower mantle.

Thermal plumes in the lower mantle were for the first time reliably imaged in 2003 by Raffaella Montelli, using a new technique of finite-frequency tomography developed by Tony Dahlen and Guust Nolet and their collaborators at Princeton University.

For references and a detailed account of the history of seismic tomography see the reviews by Romanowicz (2003) and Rawlinson et al. (2010). Nolet (2008) provides a general introduction into the methods of seismic tomography, including the theoretical aspects that are here discussed only briefly.

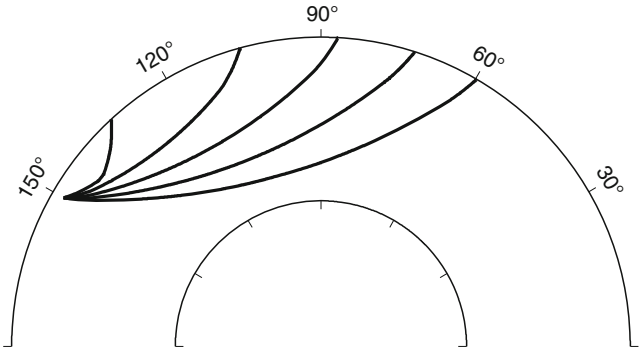
Onset times

Much of seismic tomography is based on estimating the arrival time of a seismic body wave by picking the "onset" of a phase on the seismogram, and interpreting the travel time T using the infinite-frequency approximation of ray theory:

$$T = \int_{\text{raypath}} \sigma(\boldsymbol{r}) \mathrm{d}s \tag{1}$$

where the raypath is determined by Snell's law and where σ is the inverse velocity v^{-1} of the wave at the location $\boldsymbol{r}$. The raypaths may be located between two boreholes, e.g., to monitor the exploitation of an oil or gas field, between several explosive sources and an array of seismographs at the surface (deep seismic sounding), between a seismogenic zone and a local array of seismographs, or between an earthquake and the global network of seismic stations.

The raypath is often approximated by the path calculated for a spherically symmetric Earth or a horizontally



Seismic Tomography, Figure 1 Examples of raypaths for a P wave in an equatorial cross-section from a hypothetical earthquake at a depth of 248 km located at 0°N, 150°E.

layered background model. Examples of global raypaths are given in Figure 1. This approximation is permitted because ray trajectories render the travel time stationary, such that small deviations in the true ray path location only cause second order errors in the travel time calculated with Equation 1, a property of rays known by the name of *Fermat's Principle*. In practice, one usually prefers to invert for the difference between the true Earth and a starting- or background model: $\delta\sigma(\boldsymbol{r}) = \sigma(\boldsymbol{r}) - \sigma_0(\boldsymbol{r})$, and use the difference between observed time T and its prediction T_0 from the background model as datum: $\delta T = T - T_0$:

$$\delta T = \int_{\text{raypath}} \delta\sigma(\boldsymbol{r})\mathrm{d}s \tag{2}$$

For strongly heterogeneous regions such as subduction zones, one may need to use three-dimensional ray tracing and an iterative approach using (Equation 2).

Model parameterization and inversion

The model $\delta\sigma(\boldsymbol{r})$ can be described by a finite number of parameters if it is developed in terms of a basis of M interpolating or "basis" functions $h_k(\boldsymbol{r})$:

$$\delta\sigma(r) = \sum_{k=1}^{M} m_k h_k(\boldsymbol{r}) \tag{3}$$

The basis functions may be represented by homogeneous cells, linear interpolators in a tetrahedral or other mesh, spherical harmonics, or 3D wavelets. Substitution of Equation 3 in Equation 2 gives a formal system of linearized equations for N estimated travel times $\delta T_i, i = 1, \ldots N$, arranged in a vector $\delta\boldsymbol{T}$:

$$\delta\boldsymbol{T} = \boldsymbol{A}\boldsymbol{m} \tag{4}$$

where $A_{ik} = \int_{\text{raypath}_i} h_k(\boldsymbol{r})\mathrm{d}\boldsymbol{s}$. Since many raypaths may overlap, the system (Equation 4) is usually overdetermined and needs to be solved by a least squares solver that minimizes χ^2, the length of the misfit vector weighted by the data standard error e_i:

$$\chi^2(\boldsymbol{m}) = \sum_{i=1}^{N} \left(\frac{\sum_{k=1}^{M} A_{ik} m_k - \delta T_i}{e_i} \right)^2 \tag{5}$$

Mathematically, this is accomplished by first dividing the system (Equation 4) by the standard error of the data (i.e., multiplying by the inverse square root of the covariance matrix $\boldsymbol{C}$ which is generally assumed to be diagonal), and backprojecting the system using the transpose $\boldsymbol{A}^T$ of $\boldsymbol{A}$:

$$\boldsymbol{A}^T\boldsymbol{C}^{-\frac{1}{2}}\boldsymbol{A}\boldsymbol{m} = \boldsymbol{A}^T\boldsymbol{C}^{-\frac{1}{2}}\boldsymbol{\delta T} \tag{6}$$

One often scales the equations a priori such that the data have unit error $e_i = 1$ and $\boldsymbol{C} = \boldsymbol{I}$, which has the same effect. In the following we therefore ignore $\boldsymbol{C}$.

Usually, Equation 6 is at the same time overdetermined for some parameters and underdetermined for others (the determinant of $\boldsymbol{A}^T\boldsymbol{A}$ being zero): there are in that case infinitely many models that satisfy the data within the measurement uncertainty and one needs to regularize the solution. This can be done by choosing the solution that minimizes a weighted penalty of χ^2, model norm and model roughness, by strongly truncating a development in spherical harmonics, or by choosing the sparsest decomposition in wavelets that still satisfies the data. This generally involves a subjective choice between the degree of detail one allows in a model and the goodness of fit to the data. Generally, one aims for a χ^2 approximately equal to the number of data N – in other words, one attempts to fit the data at the level of about one standard deviation. Invariably, a trade-off exists between the detail allowed in the model and the statistical precision with which the model parameters can be determined: the sharper the detail, the more uncertain the m_k.

Regularization can also be done in a fundamentally different way by inverting for local averages in $\delta\sigma(\boldsymbol{r})$ that can be estimated linearly from the data with a specified variance, though this can only be done at the expense of a significant increase in computing time (Backus-Gilbert theory). In this case the trade-off is between the size of the averaging volume and the model variance: averages over larger volumes are determined with smaller statistical uncertainty.

Whatever method is used, the system (Equation 4) may be very large (e.g., 10^6 data for 10^5 unknown model parameters). Local parameterizations (cells, as opposed to spherical harmonics) render $\boldsymbol{A}$ sparse, and the system can be solved efficiently using iterative solvers that adapt to sparse matrices, such as LSQR.

Normal modes and surface waves

The eigenfrequencies ${}_n\omega_\ell^m$ of the Earth are characterized by three quantum numbers ℓ, m and n, related to the number of nodal surfaces in the displacement field of the Earth with latitude, longitude and depth, respectively. For a non-rotating, isotropic, spherically symmetric Earth the spectrum is degenerate in the sense that the frequency is

independent of the azimuthal order m. For the real Earth, a weak dependence on m splits each eigenfrequency into $2\ell + 1$ separate frequencies that are too closely spaced to be resolvable except for the very lowest angular order ℓ. Instead, a composite spectral line or "multiplet" is observed with a peak that depends on the location of the seismic station – a direct consequence of the fact that the $2\ell + 1$ single peaks have amplitudes that depend on geographical location by virtue of their spherical harmonic dependence on latitude and longitude.

Two major strategies exist to exploit the small fluctuations in the spectrum. Decomposing the free oscillation into surface waves traveling in opposite directions, ray theory may be used to establish a linear relationship between the heterogeneity along the great circle between source and receiver and the observed peak shift in the spectral line. At higher frequency we separate single passages of the surface wave and exploit the linear relationship between fluctuations in the observed phase velocity and the Earth's heterogeneity. In both cases, the relationship between the Earth's heterogeneity and the observed datum is a two-dimensional integral along the great circle of the form:

$$\delta\omega = \int_0^a \int_{\text{gc}} K(\boldsymbol{r})\delta\sigma(\boldsymbol{r})\mathrm{d}s\mathrm{d}r, \tag{7}$$

where the kernel $K(\boldsymbol{r})$ is computed using first order perturbation theory of the differential equations governing the Earth's free oscillations.

Alternatively, we may exploit the known distribution of amplitudes of single peaks over the surface of the Earth to invert for the location of these peaks ("mode splitting"). The small frequency shifts $\delta\omega^m$ are themselves the eigenvalues of a splitting matrix $\boldsymbol{H}$ of which the elements are linearly related to the variation of density and elastic parameters in the Earth. We can estimate $\boldsymbol{H}$ from the seismic data using autoregressive filtering techniques. This way we avoid any ray-theoretical approximations and obtain a three-dimensional integral constraint that can be used to solve for the large-scale variations in the Earth's density and elastic properties.

Finite-frequency tomography

Modern, broadband digital instrumentation allows for a robust estimation of the delay of an observed seismic wave $s_1(t)$ with respect to a theoretically predicted ("synthetic") waveform $s_2(t)$ or with respect to the same phase observed elsewhere, by locating the maximum in the cross-correlation $C(t)$ between the two signals:

$$\begin{aligned} \delta T &= \arg \max_{t\in[\tau_1,\tau_2]} C(t), \\ C(t) &= \int_{\tau_1}^{\tau_2} s_1(\tau)s_2(\tau - t)\,\mathrm{d}\tau\,, \end{aligned} \tag{8}$$

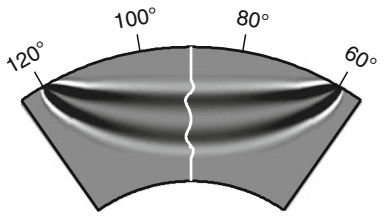
where the integration interval (τ_1, τ_2) extends over all times where the integrand is nonzero. The cross-correlation delay is thus fundamentally different from the delay measured by picking the onset of $s_1(t)$, because it represents an integral measure over a time window that is at least as long as the dominant period of $s_1(t)$. Heterogeneities inside the Earth may influence the integral by scattering waves in the direction of the recording station that arrive within the time window. The most serious consequence is that energy may diffract around a small heterogeneity, thus masking or dominating the slower or faster arrival that has crossed the heterogeneity. This phenomenon of "wavefront healing" biases observed delay times to zero, especially if the anomaly is located at some distance from the source and receiver.

Taking wave diffraction into account leads to a three-dimensional integral constraint of the form:

$$\delta T = \int_V K(\boldsymbol{r})\delta\sigma(\boldsymbol{r})\mathrm{d}^3\boldsymbol{r}\,, \tag{9}$$

where the kernel $K(\boldsymbol{r})$ can be efficiently calculated using ray theory for scattered waves. The effective volume of integration V is roughly equivalent to that of the Fresnel zone of the ray, where the sensitivity is largest. An example of a finite-frequency kernel is shown in Figure 2. Remarkably, the cross-correlation travel time is insensitive to perturbations in the Earth's properties at the location of the ray path. Because of this hole in the sensitivity and their general shape, finite-frequency kernels are often referred to as "banana-doughnut" kernels. Numerical tests have shown that the finite-frequency kernels accurately model the loss of signal caused by "wavefront healing," the gradual reduction of a delay caused by waves diffracting around a small heterogeneity. By estimating delays in different frequency bands, one gains information about the size of the heterogeneity in the Earth.

Though finite-frequency kernels were initially proposed to provide a better theoretical modeling of long-period signals affected by wavefront healing, they offer the advantage of being able to model the healing as a function of frequency, and thus obtain independent information on the size of the heterogeneity. Such "multiple-frequency" tomography may significantly increase



Seismic Tomography, Figure 2 The sensitivity of the cross-correlation time to the earth structure, for a long-period P wave from a surface source at 0°N, 120°E, recorded at a distance of 60°. The kernel is plotted in an equatorial cross-section of the mantle, the *grayscale* runs from large negative values (*black*) to positive (*white*). The sensitivity is zero at the location of the geometrical raypath, forming a "doughnut hole" in the banana-shaped kernel.

resolution (Sigloch et al., 2008). Finite-frequency sensitivity can also be formulated for the amplitude perturbations caused by attenuation and by focusing/defocusing (focusing cannot be handled with ray theory because ray theory does not model amplitudes correctly at low frequency and is very nonlinear at high frequency).

Instead of inverting for a cross-correlation delay or an amplitude perturbation, one can formulate a 3D sensitivity directly for the observed time series, though this has the disadvantage that the observed and predicted waveforms have to be close enough in phase that the phase difference can be adequately modeled by adding a small perturbation to the waveform itself (in fact modeling $e^{i\varphi} \approx 1 + i\varphi$). This limits the inversion to waveforms with small time mismatches, in contrast to the delays estimated through (Equation 8), which remain linear for large anomalies.

All types of data – delays, amplitudes and waveform mismatches – can be iteratively inverted using an adjoint approach, in which the best fitting model is sought along the gradient $\nabla_m \chi^2$ (Tromp et al., 2005), e.g., for delay times scaled to unit variance:

$$\nabla_m \chi^2 = \boldsymbol{A}^T(\boldsymbol{Am} - \delta \boldsymbol{T}) \tag{10}$$

For waveforms, the matrix A is in this case the matrix representation of a finite-difference or spectral-element algorithm that produces the predicted seismograms and A^T is the adjoint operator that projects the seismograms back in time. Since this allows one to backproject all residual seismograms for one earthquake with only one calculation, and since only the product of the adjoint matrix and the residual data vector is needed, this allows us to avoid computing the partial derivatives separately for each datum δT_i with respect to each model parameter m_k. The adjoint approach has some advantages over a direct matrix inversion for large-scale problems, in particular those with few sources and many stations, because it does not require the storage of a large matrix, which is especially important for waveform inversions.

Summary

The equations of seismic tomography are integral equations; the observations are weighted averages of the properties of the Earth (Equation 9). Though often treated as line integrals, assuming ray theory is valid, even a 1 Hz P wave senses a volume or Fresnel zone inside the Earth that is several hundred kilometers wide. The inversion of integral equations demands care to avoid that noise (errors in the data) is interpreted as small differences in such averages which may require large spatial variations in the Earth's properties. This imposes a fundamental limitation to the resolving power of seismic waves that even finite-frequency theory cannot completely avoid. The theoretically best available horizontal resolution, using the highest observable seismic frequencies, is of the order of hundred kilometers in the lower mantle. In practice, this lower limit is not yet reached because of the limited coverage of the Earth's surface with seismic stations. On land, the coverage can be improved markedly using temporary deployments of seismic arrays, but this is much more difficult and expensive to do in the oceanic domain. Major improvements on a global scale are therefore to be expected only if we solve the problem of oceanic seismometry.

SEISMIC VELOCITY-DENSITY RELATIONSHIPS

Kalachand Sain
National Geophysical Research Institute, Council of Scientific & Industrial Research (CSIR), Hyderabad, India

Definition

Seismic velocity is defined as the speed with which a seismic wave travels through a medium and is measured in km/s. The density is the mass per unit volume and is expressed in g/cc.

Types of seismic waves

The *body wave* and the *surface wave* are the main seismic waves. The body waves are the longitudinal (P) and the shear (S) waves in which the particles vibrate parallel and perpendicular to the direction of wave propagation respectively. The velocities of P-wave (V_P) and S-wave (V_S) are related to the density, ρ as

$$V_P = \sqrt{\frac{\kappa + \frac{4}{3}\mu}{\rho}} \quad (1)$$

$$V_S = \sqrt{\frac{\mu}{\rho}} \quad (2)$$

where κ and μ are the bulk and rigidity moduli respectively. It appears that the seismic velocity and density are inversely related, but the denser rocks are characterized by higher velocities compared to lighter rocks because the density also depends on κ and μ. The halite with low density (1.8 g/cc) and high V_P (4.5 km/s) shows an exception. Generally velocities and densities increase with depth. The inversion of this trend also is observed due to pore pressure, fluids, or sediments below volcanics.

General relation between velocity and density

(a) Birch's law – To fit measurements from crustal and mantle rocks, Birch (1961) established a linear relationship between V_P and ρ as

$$V_P = a + b\,\rho \quad (3)$$

where a and b are empirical parameters.

(b) Gardner relation – Gardner et al. (1974) conducted field and laboratory measurements on saturated sedimentary rocks and determined the velocity–density relation as

$$\rho = aV_P^b \quad (4)$$

where $a = 0.31$ and b is 0.25. Major sedimentary rocks fall within a narrow corridor around the Gardner curve. Coals, anhydrite, and salts exhibit large deviations from this trend. The deviation increases with porosity, and becomes higher for lower densities.

Estimation of seismic velocity and density from surface measurements provides important inputs to understand the structure and tectonics of the earth. Since gravity is a potential field, velocity structure is often used to constrain the gravity modeling (Behera et al., 2004) by converting the velocity into density using above formulas. Use of Ludwig et al. (1970) formula to relate V_P with ρ is also very common in crustal studies.

SEISMIC VELOCITY-TEMPERATURE RELATIONSHIPS

Kalachand Sain
National Geophysical Research Institute, Council of Scientific & Industrial Research (CSIR), Hyderabad, India

Definition

The seismic velocities of subsurface rocks decrease with temperature but experience opposite effects due to increase in pressure (depth).

Velocity–temperature equation

On an average, the pressure increases at a rate of 30 MPa/km and the temperature raises at a rate of 25°C/km from surface to a few tens of kilometers. Further deep down, this increasing rate of temperature gradient decreases to small values. Since seismic velocity (V) decreases with temperature (T) and increases with pressure (P), we need to know the combined effects of P and T for interpreting seismic velocities at different depths. The generalized relation for the variation of velocity with depth, Z can be expressed as

$$\frac{dV}{dZ} = \left(\frac{\partial V}{\partial P}\right)_T \frac{dP}{dZ} + \left(\frac{\partial V}{\partial T}\right)_P \frac{dT}{dZ} \quad (1)$$

where $\left(\frac{\partial V}{\partial P}\right)_T$ denotes the change in velocity with pressure at constant temperature (isotherm) and $\left(\frac{\partial V}{\partial T}\right)_P$ is the change in velocity with temperature at constant pressure (isobar). $\frac{dP}{dZ}$ and $\frac{dT}{dZ}$ are the vertical pressure and temperature gradients respectively.

To make petrological inferences, the crustal and lithospheric seismic velocities are to be corrected to the experimental reference values (i.e., constant pressure of 100 MPa and room temperature of 20°C). Rybach and Buntebarth (1984) have defined the correction factor (f) to the P-wave velocity (V_P) at a given P and T as

$$V_P(20^\circ\text{C}, 100\text{ MPa}) = V_P(P,T)f = V_P\left[1 + \Delta T\frac{\partial V_P}{V_P \partial T} - \Delta P\frac{\partial V_P}{V_P \partial P}\right] \quad (2)$$

As per Equation 2, the corrections to the field velocities at depths from 1 to 50 km are of the order of ±0.1 km/s.

Velocity variation with temperature for some reservoir rocks

The change in seismic velocities with temperature also depends on the saturation of rock. The results of Wang and Nur (1990) in heavy oil sands and hydrocarbon-saturated

rocks show that both V_P and V_S decrease with increasing temperature. Since V_S is not affected by fluids, the decrease in V_S is due to changes in rock frame and in rock fluid interactions. The V_P in heavy oil sands (Tosaya et al., 1987) shows a dramatic decrease. As temperature increases from 25°C to 125°C, V_P can drop by 35% to almost 90%. Heavy oils are highly viscous and a strong interfacial force exists between oil and rock grains. The viscosity of oil and interfacial force decrease due to rise in temperature, which decreases the rigidity and bulk modulus leading to reduction in seismic velocities. For temperature up to about 150°C, changes in pore fluid properties play dominant role in changing the velocity.

Elastic waves in homogeneous and inhomogeneous media

Definition

The Earth is a complex medium containing heterogeneities and scattering structures over many scales. The influence of heterogeneities on seismic wave propagation is therefore studied intensively by numerical modeling to explain observations. Coming along with the enormous increase of computational power, the development of numerical techniques for the accurate calculation of synthetic seismograms in three-dimensional (3-D) models of the Earth has been the subject of a continuous effort in the last 30 years. This chapter presents a glimpse of several of these numerical methods.

Introduction

In 1969, Keiiti Aki first focused attention on the appearance of continuous wave trains (called coda), in the tail portion of individual seismograms of local earthquakes as a direct evidence of the random heterogeneity of the lithosphere. Models for seismic wave propagation through inhomogeneous elastic media have been developed using deterministic approaches such as model theory for layered media. In 1954, Norman Haskell made a great contribution to theoretical geophysics with his famous paper in which he showed how seismic surface waves could be computed for an Earth modeled by an arbitrary number of plane parallel layers, each one with arbitrarily prescribed physical properties. His work was based on Thomson's work and it is now known as the Thomson–Haskell method. In his pioneering work Claerbout (1968) recognized the solution to the inverse problem of determining the medium from the seismogram. Numerical modeling of seismic wave propagation in an inhomogeneous media is becoming more important in seismic exploration. A wide variety of recent numerical strategies are concerned with treating Earth models of successively increasing complexity. The realistic computational models can include anisotropic media, nonplanar interfaces between layers and blocks, velocity/density/quality-factor gradients inside layers, and often with free-surface topography. In particular, the rheology of the medium should allow for realistic attenuation. We can divide the different approaches to numerically solve the wave equation in complex media into three main classes: *direct methods*, *integral equation methods*, and *ray tracing methods*, see Table 1 and Carcione et al. (2002). In order to solve the wave equation using *direct methods*, the geological model needs to be approximated by a numerical mesh. There are no restrictions about material variability and different rheologies can be implemented. These methods give solution to the wave equation in the time domain. They can be very accurate provided a sufficiently fine grid, but they are computationally more expensive than analytical or ray tracing methods. *Integral equation methods* are based on Huygens' principle. These methods formulate the solution of a problem in terms of values at the domain's boundary. Integral equation methods have an interesting conceptual advantage over direct methods, which is the reduction of one space dimension. Moreover, integral equation methods (in the frequency domain) do not need absorbing boundaries. They match easily the boundary conditions and do not suffer from grid

Seismic Wave Propagation in Real Media: Numerical Modeling Approaches, Table 1 Classification of numerical methods to model seismic wave propagation in real media

Direct methods	Finite differences (FD), pseudospectral (PS), finite element (FE), spectral element method (SEM), finite volume (FV), discontinuous Galerkin (DG), discrete element method (DEM)
Integral equation methods	Boundary element method (BEM), indirect boundary element method (IBEM), fast multipole method (FMM), domain integral methods (DIM)
Asymptotic or ray tracing methods	Gaussian beams

dispersion. However, these methods require the knowledge of Green's function which is limited to a few cases (see Kausel, 2006). *Ray tracing* or *Asymptotic methods* are approximative because they do not take into account the complete wavefield. The wavefield is considered as an ensemble of certain events, each arriving at certain traveltime and having certain amplitude.

Finite-difference method

Among direct methods we have those that solve the strong form of the wave equation (FD, PS) and those that solve the weak form, which are also known as variational methods (such as FE). The strong formulation works directly with the equation of motion and the boundaries are prescribed in their differential form. The weak formulation instead uses an integral form of the equation of motion weighting the error by trial functions. The natural boundary conditions are automatically satisfied in the weak formulation. The basic idea of finite-difference methods is to compute the partial derivatives by an approximation based on Taylor series expansions of functions near the point of interest. Forward and backward time derivatives lead to implicit or explicit schemes. In general, an implicit method is computationally more expensive than an explicit method, due to the requirement of solving large matrix equations. When applying finite differences in the implicit scheme only for 1-D problems, the matrix to be inverted is tridiagonal, which is very convenient in terms of computational cost. However, this is not the case for 2-D problems. Nevertheless, using the method of dimensional splitting, one can replace the multi-dimensional problem by a succession of much simpler one-dimensional problems and as a result it is possible to build tridiagonal matrices and combine their results to compute the desired time derivative. This ingenious approach is described in Bayliss et al. (1986), Mufti (1985) and Emerman et al. (1982). More recently Liu & Sen (2009) have obtained implicit finite-difference formulae derived from fractional expansion of derivatives which form a system of equations that form a tridiagonal matrix. Obviously, the explicit schemes are computationally simpler. Therefore a vast majority of earthquake ground motion modeling and exploration seismology studies use explicit FD schemes. Virieux in a couple of papers (1984) and (1986) for SH and P-SV cases, respectively, was the first to introduce explicit time domain staggered FD in seismology. This method is easy to implement, to introduce different kinds of sources, and to consider viscoelasticity. In addition, the local nature of finite-difference operators makes the method suitable for parallelization. In seismic applications, the following velocity-stress formulation is widely used:

$$\begin{aligned} \frac{\partial \sigma_{ij}}{\partial x_j} + f_i &= \rho \frac{\partial v_i}{\partial t} \\ \frac{\partial \sigma_{ij}}{\partial t} &= c_{ijkl} \frac{\partial e_{kl}}{\partial t} \end{aligned} \tag{1}$$

where the first time derivative of the displacement u is the velocity v, σ_{ij} is the stress, $\partial_t e_{kl} = (v_{k,l} + v_{l,k})/2$, e_{kl} being the strain, c_{ijkl} is the fourth-order stiffness tensor with elastic coefficients for linear elastic solids, and f_i is the ith component of the body force vector $\mathbf{f}$ that can be written in terms of the moment tensor as follows:

$$\mathrm{f} = -\mathbf{M} \cdot \nabla \delta(x - x_s) S(t) \tag{2}$$

where x_s denotes the source position δ is the Dirac delta and $S(t)$ denotes the source time function. Evaluating the second time derivative of Equation 1, i.e., $\ddot{u} = \partial_t v$ (double dot denotes twice time derivative), at times $(n + 1)\Delta t$ and $(n–1)\ \Delta t$ by a Taylor expansion yields

$$\frac{\partial^2 u^n}{\partial t^2} = \frac{1}{(\Delta t)^2} \times \left[u^{n+1} - 2u^n + u^{n-1} - 2 \sum_{l=2}^{L} \frac{(\Delta t)^{2l}}{(2l)!} \frac{\partial^{2l} u^n}{\partial t^{2l}} \right] \tag{3}$$

when applied Equation 3 to numerically approximate spatial and time derivatives in the 1-D scalar wave equation

$$\frac{1}{\beta^2} \frac{\partial^2 u}{\partial t^2} = \frac{\partial^2 u}{\partial x^2} \tag{4}$$

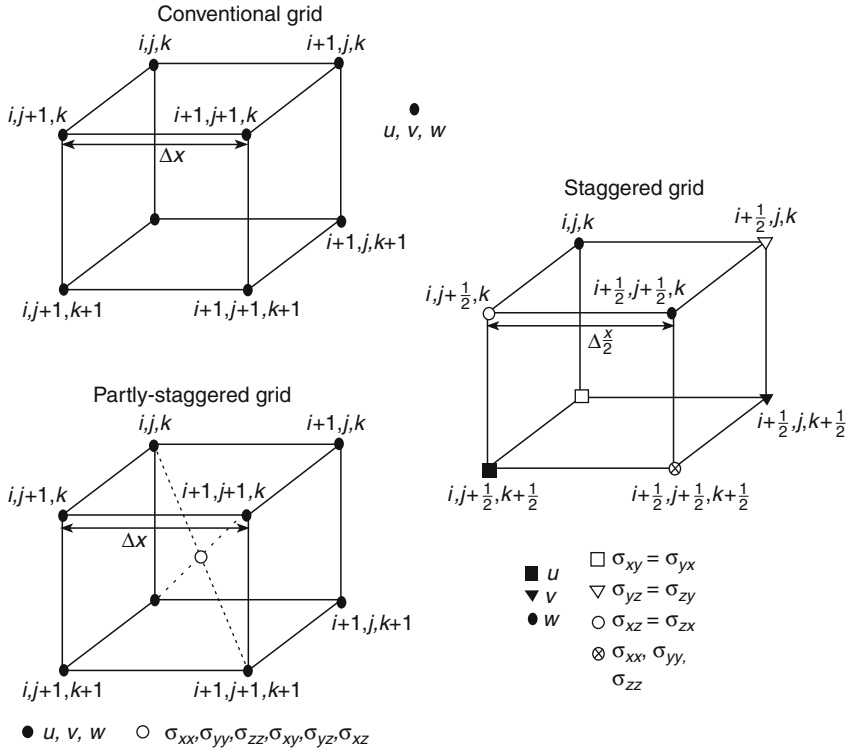
we obtain the Lax-Wendroff scheme

$$\frac{1}{\beta^2} \frac{u_i^{n+1} - 2u_i^n + u_i^{n-1}}{(\Delta t)^2} = \frac{u_{i+1}^n - 2u_i^n + 2u_{i-1}^n}{(\Delta x)^2} \tag{5}$$

This equation represents the discretization of Equation 4 taking into account that we have a Cartesian system of coordinates (x,y,z) with a fourth-order computational domain taking into account the time, i.e., (x,y,z,t). Considering the spatial-time grid given by a set of discrete points (x_i,y_j,z_k,t_n) given by $x_i = x_0 + i\Delta x$, $y_j = y_0 + j\Delta y$, $z_k = z_0 + k\Delta z$, $t_n = t_0 + n\Delta t$; $i,j,k,n = 1,2,...$ The spatial increments Δx, Δy, and Δz are usually referred to grid spacings, (x_0, y_0, z_0, t_0) are initial values for these variables, while Δt is the time step. The value of a function u at a grid position (x_i, y_j, z_k, t_n) is given by $u_{i,j,k}^n = u(x_i, y_j, z_k, t_n)$. It is possible to have nonuniform grids and the other important consideration is whether all functions are approximated at the same grid positions. The conventional, partly staggered, and staggered grids are illustrated in Figure 1. An important observation is pointed out for finite differences solutions of hyperbolic equations. Accuracy increases with increasing Δt, for central differences, up to a limit defined by the Courant-Friederickson-Lewy stability condition (assuming $\Delta x = \Delta z$, in 2-D):

$$\frac{V_{\max} \Delta t}{\Delta x} \leq \frac{1}{\sqrt{2}} \tag{6}$$

where $V_{\max}$ is the maximum velocity considered in the model.



Seismic Wave Propagation in Real Media: Numerical Modeling Approaches, Figure 1 Spatial grid cells in the conventional, partly staggered, and staggered grids (see Moczo et al., 2007).

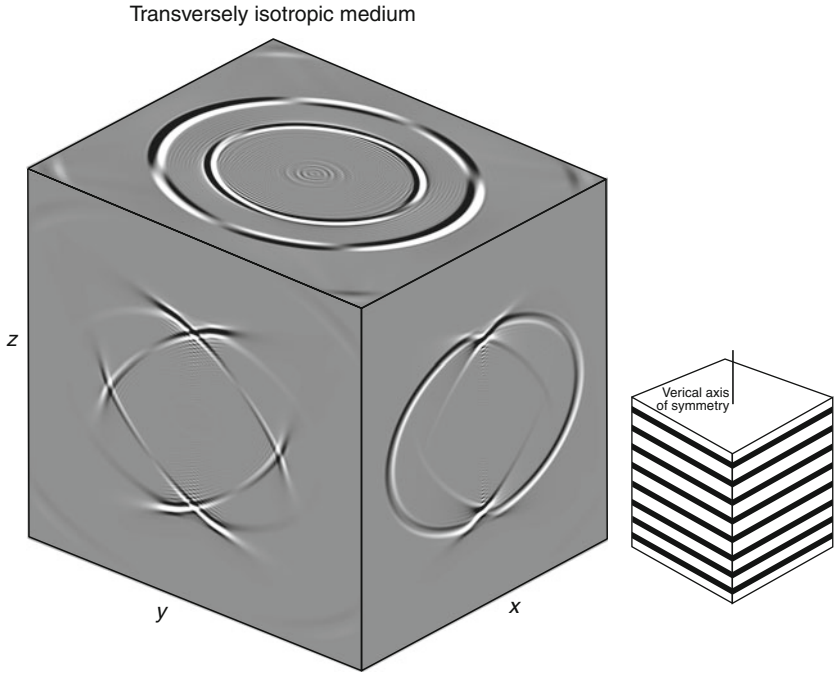
The choice among the different schemes is made to improve accuracy, reduce memory requirements, and to deal with anisotropy media. Recently, the use of the partly staggered grid was upgraded by Saenger et al. (2000) and Saenger & Bohlen (2004). The authors called the grid rotated staggered grid since they obtained the spatial FD operator by the rotation of the standard staggered-grid operator. They used this scheme to successfully simulate media with heterogeneities (cracks, pores, free surface, and anisotropy). Rotated staggered grids have been also used to model planar and nonplanar dynamic rupture models, see Cruz-Atienza et al. (2007). The main limitations of FD are the extensive consumption of computational resources in terms of both core memory and CPU time. However, Furumura and Chen (2005) performed large-scale parallel FD simulations of seismic wave propagation to model strong ground motions during damaging earthquakes. Parallel FD simulation allowed Saito and Furumura (2009) to successfully simulate tsunami generation. A complete review of FD methods can be found in Moczo et al. (2007).

Anisotropy

Anisotropy is caused by structural alignment of elements that are smaller than the wavelength employed for seismic data acquisition. Examples of structures that cause anisotropic effects are fine layering, tectonic grain, and orientation and intensity of cracking. One way to include these effects in the model is to consider that elastic properties at a given point might vary with direction. Therefore, by including anisotropy in the model, alignments of small scale hetegoeneities are captured. The alignment effects might lead to important petrophysical information. To consider anisotropy in a FD simulation one needs to define c_{ijkl} the fourth-order stiffness tensor in Equation 1. For example, to model the effect of layering (see Figure 2) one can consider the following stiffness tensor:

$$C = \begin{bmatrix} c_{11} = 66.6 & c_{12} = 19.7 & c_{13} = 39.4 & 0 & 0 & 0 \\ c_{12} & c_{11} & c_{13} & 0 & 0 & 0 \\ c_{13} & c_{13} & c_{33} = 39.6 & 0 & 0 & 0 \\ 0 & 0 & 0 & c_{44} = 10.9 & 0 & 0 \\ 0 & 0 & 0 & 0 & c_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{66} \end{bmatrix} \tag{7}$$

where $c_{66} = (c_{11} - c_{12})/2$, the density given by $\rho = 2590\ \mathrm{Kg/m^3}$, and the units for the elastic constant are in GPa. The example represents the Mesaverde clay shale (see Thomsen, 1986 and Carcione et al., 1992). This kind of stiffness tensor with these five elastic constants characterizes a medium of class IV according to the classification given by Payton (1983) and it is called transversely



Seismic Wave Propagation in Real Media: Numerical Modeling Approaches, Figure 2 (*Left*). Illustration of a transversely isotropic medium. The example represents the Mesaverde clay shale. The six elastic constants (for the stifness tensor in Equation 1) that generate this medium are given by c_{11} = 66.6 GPa, c_{12} = 19.7 GPa, c_{13} = 39.4 GPa, c_{33} =39.9 GPa, c_{44} = 10.9 GPa., with $c_{66} = (c_{11} - c_{12})/2$ and the density ρ = 2590 Kg/m^3. (*Right*) A layered medium that represents the anisotropic effect.

isotropic medium (since it has the vertical z-axis as a symmetrical axis). Notice that due to the anisotropy, in Figure 2, and the wave fronts do not propagate at the same speed in all directions (see the different wave fronts in plane cuts: xy-plane, xz-plane and yz-plane).

Pseudospectral method

The pseudospectral method (PS) is base mainly on Fourier and Chebyshev differential operators. The spatial derivative is computed in the frequency-wavenumber domain as follows:

$$\frac{\partial u(x,t)}{\partial x} = \frac{1}{2\pi} \int_{-\infty}^{\infty} u(x,t) ike^{ikx} dk \tag{8}$$

see Kreiss and Oliger (1972), Kosloff and Baysal (1982), Furumura et al. (1998). The PS with Fourier has the disadvantage of periodic properties, called wraparound. Both Fourier and Chebyshev are accurate up to the maximum wavenumber of the mesh that corresponds to a spatial wavelength of two grid points (at maximum grid spacing for the Chebyshev operator). Like FD methods, they are also unable to model surface waves with the same accuracy as body waves because of the one-way treatment that needs to be performed in order to implement the free-surface condition (e.g., Carcione, 1994).

Finite element and spectral element methods

The finite element (FE) method is more efficient than FD or PS when dealing with complex geometries (irregular interfaces), heterogeneous media, and handling boundary conditions. This method is also applicable with inelastic constitutive models. Recently, Bielak et al. (2005) have developed an efficient FE-based computational platform for large-scale ground motions. Low approximation orders may lead to a large numerical dispersion, see Marfurt (1984). As a result, mesh refinement is required to reduce numerical dispersion but may lead to a large numerical cost even if parallelization is possible. High-order FE methods became more efficient when the spectral element method (SEM) appeared using Chebyshev polynomials as interpolating functions, see Seriani et al. (1992), Priolo et al. (1994). Komatitsch and Villotte (1998), and Komatitsch and Tromp (1999). This method introduced the use of the Lagrange polynomials as interpolating functions which produces a diagonal mass matrix when using the Gauss-Lobatto-Legendre quadrature.

Discontinuous Galerkin method

The Discontinuous Galerkin method (DG) is a technique that uses discontinuous basis functions to formulate a Galerkin approximation. Given a mesh of the analysis domain, the DG method approximates the solution within each element by a function from a low-dimensional vector

space of functions, e.g., as a linear combination of basis functions like polynomials. For a pair of adjacent mesh elements, the approximate solution computed in the interior of the elements does not have to agree on their common boundary. Some of the advantages of this method are:

- It can sharply capture solution discontinuities relative to a computational mesh.
- It simplifies adaptation since inter-element continuity is neither required for mesh refinement and coarsening.
- It conserves the appropriate physical quantities (e.g., mass, momentum, and energy) on an element-by-element basis.
- It can handle problems in complex geometries to high order.
- Regardless of order, it has a simple communication pattern to elements sharing a common face that simplifies parallel computation. With a discontinuous basis, the DG method produces more unknowns for a given order of accuracy than traditional finite element or finite volume methods, which may lead to some inefficiency. The DG method is harder when applied to unstructured meshes; in particular, it is harder to formulate limiting strategies to reduce spurious oscillations when high-order methods are used. Nevertheless, Käser & Dumbster (2006) have successfully implemented the method for elastic wave propagation on unstructured meshes.

For an introduction to the key ideas, basic analysis, and efficient implementation of discontinuous Galerkin methods and a review of the state of the art, we refer the reader to the book by Hesthaven & Warburton (2008).

Integral equation methods

Boundary element and indirect boundary element methods (BEM & IBEM)

Among Integral equation methods it is the boundary element method. The formulation of direct boundary integral equation method (BIE) in elastodynamics is back to the pioneering work of Somigliana (1886). Considering a volume of elastic material V bounded by a surface S, the displacement field u_i at a point $\mathbf{x}$ and time t can be expressed as a function of the values of the displacement and traction t_j along the boundary through Somigliana's representation theorem:

$$cu_i(\xi,t) = \int_0^t \mathrm{d}\tau \int_s \left[t_j(\xi,\tau)G_{ij}(\xi,t,x,\tau) - u_j(\xi,\tau)\Sigma_{jik}(\xi,t,x,\tau)n_k(\xi)\right]\mathrm{d}S(\xi) \tag{9}$$

where $G_{ji}(\xi,t,\mathbf{x},\tau)$ and $\Sigma_{jik}(\xi,t,\mathbf{x},\tau)$ are the responses in terms of displacement and stress, time t and point ξ of an infinite homogeneous medium to a unit force impulse, applied at time τ at point $\mathbf{x}$ in the direction i, $n_k(\xi)$ is the normal boundary pointing outside V. The volumetric body sources are assumed to be null, but if present, their contribution can be easily added as follows:

$$cu_i(\xi,t) = \int_0^t \mathrm{d}\tau \int_s \left[t_j(\xi,\tau)G_{ij}(\xi,t,x,\tau) - u_j(\xi,\tau)\Sigma_{jik}(\xi,t,x,\tau)n_k(\xi)\right]\mathrm{d}S(\xi) + \int_v^t \mathrm{d}\tau \int_V G_{ij}(\xi,t,x,\tau)f_i(x,\tau)\mathrm{d}V \tag{10}$$

where

$$c = \begin{cases} 1, & \xi \in \mathrm{V} \\ 1/2, & \xi \in \mathrm{S} \\ 0, & \xi \notin \mathrm{V} \end{cases} \tag{11}$$

and assuming that S has a smooth boundaries. The values of c come from the volume integration of the product $\delta(\mathbf{x}-\xi, t\text{-}\tau)\,\mathbf{u}_j(\xi,\tau)$ and the value accounts for the integration of the Dirac's delta and its position. The Green's function for the homogeneous, isotropic, elastic media can be found in Aki & Richards (1980).

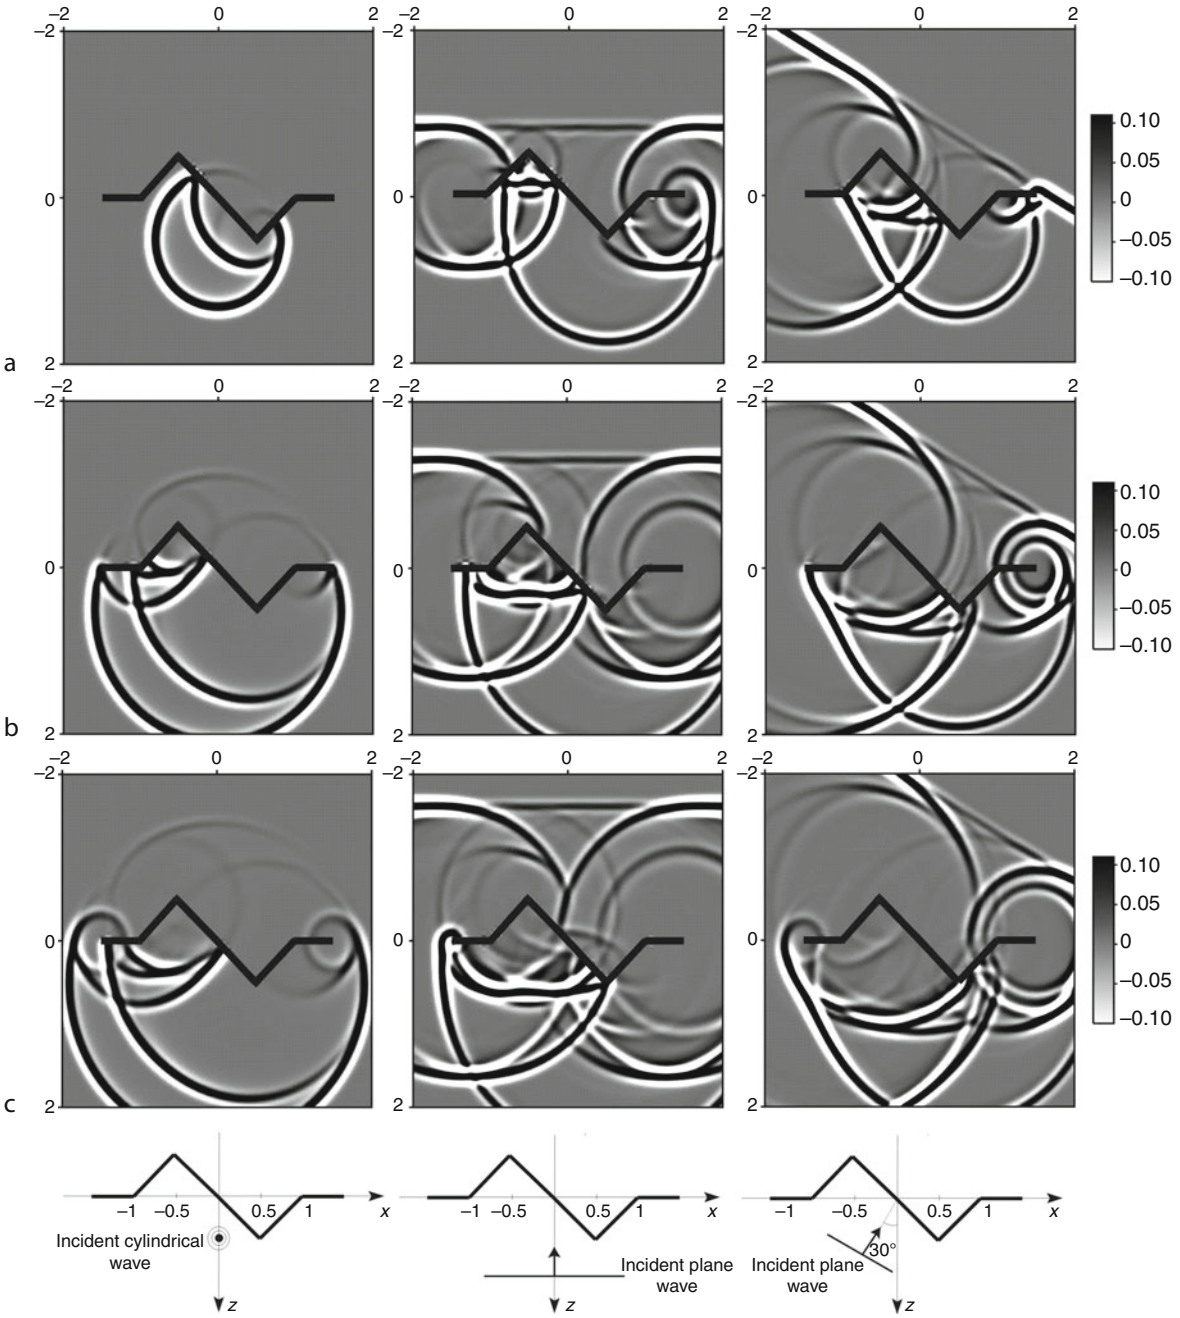
The indirect formulation of the elastodynamic problem expresses the wavefield as an integral over the boundary of elementary source radiations as follows:

$$u_i(x,t) = \int_0^t \mathrm{d}\tau \int_s \phi_j(\xi,\tau)G_{ij}(x,t,\xi,\tau)\mathrm{d}S(\xi) \tag{12}$$

where $\phi_j(\xi,\tau)$ denotes τ the force density distribution applied at time t at point ξ of the surface S. In this equation we have assumed that the volumic forces are null. If present, their contribution needs to be added. Equation 10 can be seen as the mathematical transcription of Huygens' principle, which states that each point of diffracting boundary acts as a secondary source of wave radiation. This principle applies to any wavefront as well. Equation 12 is also the mathematical expression of the exploding reflector concept widely used in seismic exploration (see Claerbout, 1985). The fictitious distribution ϕ_j is an intermediate variable which needs to be solved in the boundary integral equations before the wavefield can be computed. This is the reason why this formulation is called indirect.

The discretization of the boundaries leads to the discretization of the BIE, and the application of boundary conditions transforms BIE into a system of linear equations which in general is not symmetric. The resolution of this system is usually done implicitly and in the frequency domain. Comprehensive intorduction of integral equation methods can be found in the books by Bonnet (1999), Dominguez (1993), and Manolis & Beskos (1988). In seismology, the BEM is used to study the effect of irregular topography on earthquake ground motion, in

2-D some other works deal with 3-D problems. This method has been also used to simulate elastic wave propagation in media with cracks, for example, on Figure 3 we have an irregular crack strike by a cylindrical SH incident wave (first column) and the same crack strike by a plane SH incident wave with 0^o and 30^o, measured with respect to the z-axis (second and third columns, respectively), see Iturrarán-Viveros et al., 2005; Pointer et al., 1998. A complete review on the use of BEM for seismic problems can be found in Bouchon and Sánchez-Sesma (2007).



Seismic Wave Propagation in Real Media: Numerical Modeling Approaches, Figure 3 Snapshots of displacements for: (*left*) A cylindrical SH wave striking an irregular crack. (*middle*) A plane SH wave with incident angle 0^o striking an irregular crack. (*right*) A plane SH wave with incident angle 30^o striking an irregular crack. The set of snapshots are taken at (**a**) $t = 1.25$ s (**b**) $t = 1.71$ s and (**c**) $t = 2.03$ s.

Fast multipole method in elastodynamics

Two types of fast multipole method (FMM) are available for elastodynamics in the frequency domain. The first one is the low frequency FMM. As for static cases, the complexity of this algorithm is $O(N)$. This complexity is due to the fact that the wavelength is much larger than the domain size. On the other hand, if the wavelength is shorter than the geometrical feature, the complexity of low frequency FMM increases to $O(N^2)$ and the method is not efficient any longer. For this reason, computational efficiency of fast BEMs in the mid-frequency regime is enhanced by using the so-called diagonal form for the Helmholtz Green's function, proposed by Rokhlin (1990), with a complexity of O (N log N). The upper limit stems from the fact that the size N becomes intractable at high frequencies, but the diagonal form also breaks down at very low frequencies and must be replaced with other types of expansions. The method for low frequencies was developed by Fujiwara (1998). The first 3-D implementation was proposed by Fujiwara (2000) using a multi-level and diagonal form. The author presents some low frequency seismic oriented examples. More recently Chaillat et al. (2009) also addressed problems in 3-D. Yoshida (2001) proposed a low frequency FMM for crack problems in 3-D.

Analytic solutions for nonhomogeneous media

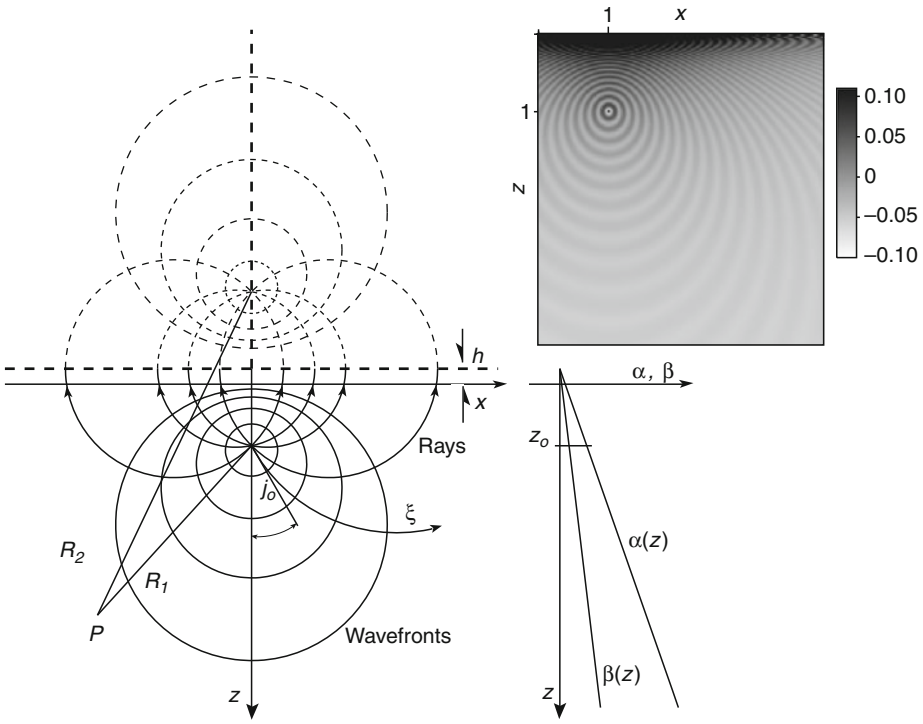
Since analytic solutions help to assess numerical methods, some attempts to develop analytic solutions for particular cases of mildly anisotropy media are briefly described. In Sánchez-Sesma et al. (2001) authors developed an approximate analytical formula for elastic 2-D Green's functions for a constant-gradient propagation velocity medium. These solutions correspond to unit line forces per unit length: the antiplane SH line source and the in-plane P-SV line sources, respectively. They are based on the asymptotic ray theory and account for both near-source effects and low frequencies. The orthogonal bipolar coordinates are depicted in Figure 4.

The approximate solution for the 2-D scalar case is given by

$$G_{22}(\omega,\tau) \approx \Lambda \frac{1}{4\mu_0} H_0^{(1)}(\omega\tau) \tag{13}$$

where Λ is defined as follows:

$$\Lambda = \left(\frac{1+\gamma z_0}{1+\gamma z}\right)^{\frac{1+n}{2}} \left[2\ln\left(\frac{R_2+R_1}{R_2-R_1}\right)\frac{(z_0+h)(z+h)}{R_1 R_2}\right]^{1/2} \tag{14}$$



Seismic Wave Propagation in Real Media: Numerical Modeling Approaches, Figure 4 (*Left*). Schematic illustration of the bipolar coordinate system. Both rays and wave fronts are circular. Rays depend upon take-off angle j_0. $t = \xi t_0$, where $t_0 = h/\beta(0)$ and ξ is one of the bipolar coordinates (the other is j_0). The distances R_1 and R_2 from the poles to point P are displayed. The plane for which $z = -h$ corresponds to null propagation velocities. (*Top right*) This solution is used to compute the Green's function for the scalar case in the time domain with a source located at (1,1), $\beta(0)$ = 500 m/s, and $\beta(z_{max})$ = 3,000 m/s. Wave fronts depend on traveltime.

where z_0 = depth of the source, β_0 = shear wave velocity at the source level, $\beta(0)$ = shear wave velocity at $z = 0$, ρ_0 = mass density at source level, $\gamma = 1/h$, h = distance from depth $z = 0$ to the level where the propagation velocity is null ($z = -h$), $j_0 = \sin^{-1}[2x(z_0 + h)/R_1R_2]$ = take-off angle, $R_1 = (x^2 + (z-z_0))^{1/2}$, and $R_2 = (x^2 + (z + z_0 + 2h)^2)^{1/2}$. The traveltime t is given by

$$\tau = t_0 \ln\left(\frac{R_2 + R_1}{R_2 - R_1}\right) = 2t_0 \tanh^{-1}\left(\frac{R_1}{R_2}\right) = t_0\xi \qquad (15)$$

In Watanabe & Payton (2002, 2006) Green's functions are obtained exactly for radially symmetric waves and for transient and time-harmonic SH-waves in inhomogeneous anisotropic elastic solids, respectively. Since time-harmonic conditions have been assumed, viscoelastic material behavior can be captured through the introduction of complex-valued wave speeds.

Equivalent media theories

When one wishes to model highly heterogeneous media, one possibility is to make the continuum hypothesis (see Christensen, 1979; Hudson, 1991). A real material with its atomic and molecular structure is replaced by an equivalent continuum model, which remains a continuum no matter how much it is subdivided. The macroscopic mechanical properties of the material remain unchanged. This hypothesis works as long as the scale of observation is much larger than the scale-length of the molecular structure (Rayleigh scattering regime). Micro fractures, pores, and other heterogeneities with uniform statistical distributions can be replaced by an equivalent or effective medium provided that the scale of the observation is much larger than the scale of the heterogeneities. This is an attractive approach in exploration seismology since the scale of the observation, or seismic wavelengths, is much larger than the scale length of the heterogeneities present in the subsurface. The concept of equivalent media clearly implies that, if the stress, strain or displacements are measured on a large enough scale, the values obtained and the relationship between them will be that of homogeneous continuum. This implies some kind of spatial averaging process. Nevertheless, scales much smaller than the minimum wavelength (used in the numerical model) are present in the earth model. Therefore effective media theories allow to average small scales of the original medium without losing the accuracy of the wavefield computation that are needed. In Capdeville and Marigo (2007), authors applied two-scale homogenization technique to the wave equation in layered media. The order 0 homogenization provides the same result as the one given by Backus (1962). The order 0 is not enough to obtain an accurate solution especially for surface waves. Higher order homogenization terms (up to 2) allowed them to obtain accurate surface waves. Lately Capdeville et al. (2010) proposed original nonperiodic homogeneization technique in 1-D. The extensions to 2-D and 3-D are foreseen.

Asymptotic ray tracing methods

An accurate estimation of traveltime is needed to map heterogeneities in the Earth's subsurface. Traveltime computation schemes fall within one of these two categories: First-arrival traveltime, and ray-theory based traveltime. The first-arrival traveltime corresponds to the first arrival of the complete wavefield at a specified receiver position and it is not a function of the type of wave (e.g., head wave, direct wave). Most of the schemes, which estimate first-arrival traveltimes, are based on the solution of eikonal equation. Vidale (1988, 1990) proposed different versions of finite-difference solution of the eikonal equation along expanding square (in 2-D) and along an expanding cube (in 3-D) to compute first-arrival traveltimes in isotropic media. Schneider et al. (1992) proposed a method based on Fermat's principle for traveltime computation in isotropic media that uses a local ray-trace solution of the eikonal equation. Ray tracing can be classified into two categories: (1) Initial-value ray tracing, and (2) Boundary value ray tracing. In initial-value ray tracing, a fan of rays is shot from the source in the model and some kind of extrapolation scheme is used to estimate the traveltime at a particular point in the model. Paraxial extrapolation (Cêrvený, 1985) is one of the most popular methods of traveltime extrapolation. An excellent review on ray theory can be found in (Cêrvený, 2001).

Poroelastic media

In addition to complex geometries, different rheologies and anisotropy, current numerical techniques are concentrating efforts to include porosity and fluid saturation in their models. Reservoir-rocks can be modeled as a porous solid matrix where the pore space is fully saturated with a pore fluid. The analysis of wave propagation in fluid saturated porous media is different in nature than that of elastic wave propagation. Biot's model is generally used to describe this effect (Biot 1956; Biot 1962). Two approaches exist to derive the poroelastic equations of motion and the constitutive laws. One method is to use homogenization methods. The laws to describe the medium are first derived on the microscopic scale of porosity. Then they are passed to macroscopic scale by homogenization. Pride et al. (1992) used an averaging procedure to derive the poroelastic equations similar to Biot (1956) and Biot (1962). We refer the reader to the book by Carcione (2007).

Boundaries

When modeling the propagation of elastic waves in any medium, the waves that reach the neighborhood of the boundaries will create reflected waves. This a nonphysical phenomena that we want to avoid. On top of the model we would like to impose a free surface. Therefore, for the top boundary, we need a reflected boundary and for the other three boundaries (in 2-D) we need a nonreflecting absorbing boundaries. In most of the numerical schemes described here, there are boundary

conditions to be imposed or it is necessary to implement absorbing boundaries conditions to eliminate spurious reflections due to the finite computational domain. The free-surface boundary condition is implemented by adding fictitious line of grid nodes next to the top boundary and use the one-side differences to approximate normal derivatives and centered difference to approximate tangencial derivatives, see Kelly et al. (1976) and Graves (1996). The simplest and more effective absorbing boundary conditions consist of a sponge along the artificially truncated edges of the domain. Clayton and Enquist (1977) proposed a kind of absorbing boundary conditions based on replacing the wave equation in the boundary region by one-way wave equation that do not allow energy to propagate from the boundaries to the numerical domain. An alternative scheme suggested by Cerjan et al. (1985) is based on gradual reduction of the amplitudes in a strip of nodes along the boundaries for the mesh. Bérenger (1994, 1996) first introduced Perfectly Matched Layers (PMLs) for electromagnetism. The main idea is to define a selective attenuation of the fields propagating in one prescribed direction. PMLs for elastic wave propagation were developed by Basu and Chopra (2003, 2004), Komatitsch and Martin (2007). The velocity-stress formulation of PMLs for elastic wave equations has been introduced by Collino and Tsogka (2001). It was applied to viscoelastic (Martin & Komatitsch, 2009) or poroelastic (Zeng et al., 2001; Martin et al., 2008) media. Recently Meza-Fajardo and Papageorgiou (2008) demonstrated that for any anisotropic media, the classic PML exhibits instabilities. In addition, they presented a generalization of the classical Perfectly Matched Layer (PML) (called multiaxial Perfectly Matched Layer M-PML) to a medium in which damping profiles are specified in more than one direction.

Summary

Modeling the Earth is a challenging task. With the increase of computational power, direct modeling techniques start to open the door to inversion problems. All numerical methods share at the same time their own disadvantages and weaknesses (high computational costs and storage requirements, poor accuracy, nonstructured grids, hard implementations, system matrix full) with the agreeable flavor of equivalent advantages (reduction of one dimension of the problem, system matrix diagonal or sparse, no need for absorbing boundaries, easy implementation, easy to model topographies or complex geometries). The nature of the problem gives us the appropriate guide to choose one method over others. In this article we briefly cover some numerical techniques to model elastic waves in heterogeneous media. However, the literature on all available methods is very extensive and we include only some references.

Definition

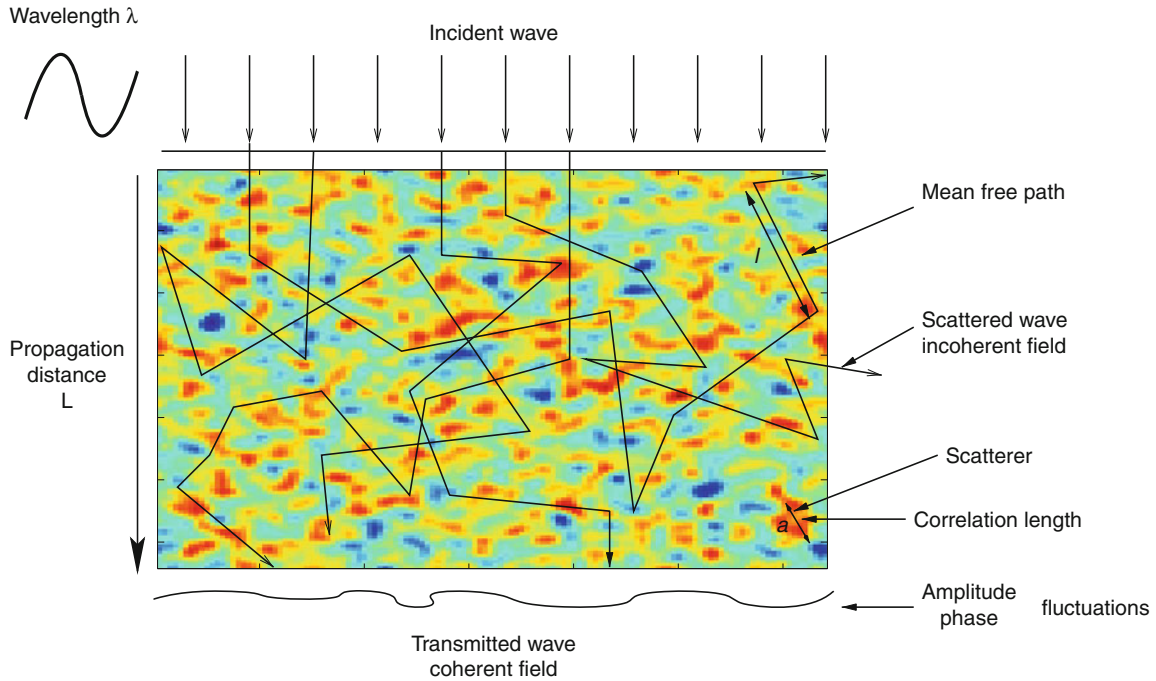
Scattering of seismic waves is best defined by reference to a laterally homogeneous or slowly varying medium where the wave fronts can be perfectly tracked and the propagation of waves can be successfully described by geometrical methods such as ray theory. In the presence of obstacles, or lateral variations of elastic parameters, wave fronts are distorted and seismic energy can be deflected in all possible directions: a phenomenon known as wave scattering. Specific to seismic waves are the possible mode conversions between various polarizations: compressional, shear, and Rayleigh waves.

Introduction

The scattering of seismic waves is intimately related to the heterogeneous nature of Earth materials on a variety of spatial scales. Well-logs data or geological maps offer direct but limited access to the nature of heterogeneities in the Earth. As elastic waves can propagate all the way through the Earth, they constitute the primary tool to sound deep heterogeneities. While the pioneering studies of seismic scattering were largely focused on the lithosphere, the presence of scatterers in the mantle and solid core has been confirmed in a number of recent studies (see Shearer and Earle, 2008, for a review). Hence, the field of seismic scattering has become of interest in global seismology too. For a thorough review of pre-1990s works in seismic scattering, we refer the reader to Wu (1989). A comprehensive reference on the topic is the book by Sato and Fehler (1998). Reviews of recent methodological and observational developments are given in Sato et al. (2008).

Statistical description of the Earth

To introduce the various scale lengths that enter in the modeling of seismic scattering, it is convenient to consider a thought-experiment such as the one shown in Figure 1. We imagine an incident plane wave propagating through a heterogeneous medium. As evidenced by the analysis of well-logs (see for instance Wu et al., 1994), the density and the elastic constants fluctuate in the Earth in a very complicated way. In such a situation, it is convenient to think of the Earth as a particular realization of an ensemble of random media sharing similar statistical properties. The goal of the stochastic imaging methods is to infer some information on the nature of the randomness from the statistical fluctuations of the wavefield. This is a difficult task because the statistical properties of the Earth are nonhomogeneous: they are expected to depend on the geological setting and on the depth. In addition, in the case



Seismic Waves, Scattering, Figure 1 Basic concepts of seismic scattering. We consider a thought-experiment where an incoming plane wave propagates through a chunk of random medium with typical dimension *L*. As the plane wave progresses through the heterogeneous medium, scattering operates and deflects energy in all space directions. The transmitted wavefield is distorted and attenuated.

of the Earth, the random fluctuations are superimposed on a deterministic background, usually represented by a 1-D reference model such as PREM (Dziewonski and Anderson, 1981). It is customary to assume that the spatial variations of the background velocities are slow compared to the typical scale length of the random medium. In this limit of separation of spatial scales, it is possible to consider the scattering medium as locally homogeneous. We may therefore hope to characterize large-scale variations of small-scale heterogeneities.

If we think of the medium as random and continuous, the fluctuations of a parameter such as the density ρ are characterized to lowest order by a correlation function (Rytov et al., 1989b):

$$\psi(\mathbf{x}) = \langle \rho(\mathbf{r} - \mathbf{x}/2)\rho(\mathbf{r} + \mathbf{x}/2)\rangle, \tag{1}$$

where the brackets denote an average over the ensemble of random media. In Equation 1, we have used an assumption of statistical homogeneity. In the case of a locally homogeneous medium, the correlation function may be allowed to vary slowly with the variable $\mathbf{r}$. $\psi(\boldsymbol{x})$ is maximum for $x = 0$, where it is equal to the total variance of the fluctuations denoted by ϵ^2 and goes to zero over a typical spatial scale a which is known as the correlation length. Common choices for ψ are Gaussian and exponential functions but a wide range of other possibilities exist (Klimeš, 2002). An equivalent description of the medium fluctuations is provided by the power spectrum of heterogeneities $\Phi(\mathbf{k})$ defined as:

$$\psi(\mathbf{x}) = \frac{1}{(2\pi)^3} \iiint_{-\infty}^{+\infty} \Phi(\mathbf{k}) e^{i\mathbf{k}\cdot\mathbf{x}} d^3k \tag{2}$$

$\Phi(\mathbf{k})$ quantifies the distribution of the total variance of the fluctuations over all possible length scales. A very useful tool to represent the heterogeneity of fluid or solid geophysical media is the Von-Karman correlation function, whose power spectrum can be written as (Sato and Fehler, 1998):

$$\Phi(\mathbf{k}) = \frac{8\pi^{3/2}\varepsilon^2 a^3 \Gamma\left(\kappa + \frac{3}{2}\right)}{\Gamma(\kappa)(1 + k^2a^2)^{\kappa+3/2}}. \tag{3}$$

In Equation 3, ϵ denotes the RMS fluctuations, a is the correlation length and $\kappa > 0$ is the Hurst exponent which acts as a cutoff of the small-scale features in the medium. The power spectrum (Equation 3) shows a plateau at small wave numbers up to a corner value $k_c \sim 1/a$. For k much larger than k_c, the power spectrum decreases algebraically as $k^{2\kappa+3}$. Note, however, that this description does not apply to Gaussian random media. This is not a severe restriction, since Gaussian media are often regarded as too smooth to represent faithfully the heterogeneities in the Earth. This point of view is confirmed by the analysis

of well-logs (Shiomi et al., 1997), which further shows that only the parameter κ can usually be recovered from observations.

The coherent and incoherent fields

Following the statistical approach, it is natural to characterize the propagation in the random medium by calculating the moments of the wavefield u. This yields a simple classification of the various components of the random field. The first moment $\langle u \rangle$ defines the coherent wave (Rytov et al., 1989a; Sheng, 1995) and corresponds to the part of the field which survives after an average over the statistical ensemble has been performed. In a typical seismological experiment, the measured field is the sum of two terms: the ensemble average $\langle u \rangle$ and a fluctuating part u_f. The coherent field mostly contributes in a time window around the seismic primaries, which may also be termed the ballistic waves. Although the coherent field is an important component of the ballistic field, it has to be carefully distinguished from it (Derode et al., 2001). Statistical wave theory shows that the mean field decays like $e^{-L/2l}$, where L is the propagation distance and l is known as the mean free path (Sheng, 1995). The mean free path gives the typical spatial scale over which a significant amount of energy has been transferred from the coherent to the incoherent or fluctuating part of the wavefield. The incoherent part of the wavefield contributes to all portions of the seismogram and forms the coda of the earthquake records. It is important to realize that the term "incoherent" just indicates the generation of waves that propagate in a direction which differs from that of the incident wave. It does not imply that the phase information has been lost. In section Interferometry with scattered waves, we will demonstrate that the so-called incoherent field is in fact highly "coherent" in the sense that it gives rise to very useful interference effects.

The propagation regimes

The distinction between the fluctuating and ensemble average part of the wavefield is useful to characterize the propagation regime. For propagation distances typically less than the mean free path, the measured field is dominated by the coherent wave: this is the weak fluctuation regime (Rytov et al., 1989a). As shown in Figure 1, after propagating through several inhomogeneities, the most important observation is the distortion of the incident plane wave front. This gives rise to fluctuations of both phase and amplitude, from which information on the statistical properties of the medium can be extracted. For propagation distances much larger than the mean free path, the coherent wave completely vanishes and one is left with the fluctuating part only: this is the strong fluctuation regime (Rytov et al., 1989a). Since by definition the ensemble average of the fluctuating part u_f is zero, it is only through the consideration of the second moment of the field that one can model the propagation of scattering when fluctuations are strong. Specific approaches will be developed in sections Envelope modeling: Markov approximation and Envelope modeling: radiative transfer.

At this stage, it is natural to raise the following question: How can we measure the mean free path in the Earth? First, it is important to note that one has to consider at least two different mean free paths since both longitudinal and transverse waves propagate through an elastic medium. In the laboratory, there are well-calibrated techniques to measure the mean free path based on ensemble averaging. Unfortunately, these methods cannot be transposed to field experiments. Instead, the common seismological practice consists in correcting the seismograms for the travel-time fluctuations caused by long wavelength variations of the velocity before stacking or averaging the records. The field obtained after such a processing is called the traveltime-corrected mean field. Sato (1982, 1984) and Wu (1982) have demonstrated that this field decays exponentially on a scale which is much larger than the mean free path, because the traveltime correction in fact removes the long wavelength components of the medium fluctuations. A theoretical discussion of various averaging procedures and their application to seismic data is given by Shapiro and Kneib (1993).

Analysis of transmission fluctuations

As announced in introduction, we now review the various approaches that have been developed to infer the statistical properties of the Earth from an analysis of seismic wave scattering. We will first introduce a method which is well adapted to the analysis of fluctuations of amplitude and phase of teleseismic P waves recorded on a dense array. Such an approach has been pioneered in the seventies by Aki (1973) and has been subsequently developed by Wu and coworkers (Wu and Flatté, 1990; Zheng et al., 2007; Zheng and Wu, 2008). In this approach, one considers a small time window around the direct P-wave at teleseismic distance. It is usually assumed that at sufficiently large distance from the source, the wave front incident from the mantle can be approximated locally by a plane. By using sufficiently deep earthquakes, it is possible to avoid the effects of strong heterogeneities in the vicinity of the source. As the plane wave progresses through the lithosphere, the wave front is distorted and the amplitude and phase of the ballistic waves measured on the array fluctuate. Zheng and Wu (2005) have very carefully discussed the correct measurement practice. The main pulse recorded on the vertical component of the seismometer is first isolated from the rest of the signal. After Fourier transformation, the amplitude A and the phase ϕ of the pulse is obtained at a given frequency. This operation is repeated at all stations of the array, and the phase field is subsequently unwrapped spatially, i.e., possible phase discontinuities are removed. It is not correct to measure the phase of the field by picking the first arrival since, as a consequence of scattering, the medium is dispersive and the first arrivals propagate with the group velocity.

Basic observables are the fluctuations of the phase and of the logarithm of the amplitude. The reason why one considers the logarithm of the amplitude is that this quantity enters in the Rytov representation of the wavefield Rytov et al. (1989a):

$$u = u_0 e^{\psi}, \tag{4}$$

where u_0 is the reference plane wavefield in the background medium and ψ is a complex phase:

$$\mathrm{Re}\psi = \ln\frac{A}{A_0} \quad \mathrm{Im}\psi = \phi - \phi_0 \tag{5}$$

Scattering theory based on the Rytov representation is more accurate than the standard Born approximation in the transmission geometry. In Equation 5, A (resp. A_0) and ϕ (resp. ϕ_0) denote the amplitude and unwrapped phase of the field (resp. reference field). From the array measurement, one can estimate the transverse coherence function of the phase field which is defined as:

$$C_\phi(\boldsymbol{r}) = \langle \phi(\boldsymbol{x})\phi(\boldsymbol{r}+\boldsymbol{x})\rangle, \tag{6}$$

where the points $\boldsymbol{x}$ and $\boldsymbol{x} + \boldsymbol{r}$ lie on the surface of the Earth. More generally, one can consider the transverse angular coherence function of the two phase fields corresponding to two incoming plane waves with different incident wavevectors $\boldsymbol{k}$ and $\boldsymbol{k}'$ (Wu and Flatté, 1990; Chen and Aki, 1991).

The interpretation of the phase coherence function is based on two major theoretical approaches, with different domains of validity. These approaches rely on the basic physical assumption that the medium fluctuations have a spatial scale, a, which is much larger than the probing wavelength, λ. In this regime, the scattering occurs preferentially in a small angular cone around the forward direction. As a consequence, one can usually neglect the backscattered waves and consider one-way propagation only. The crucial nondimensional parameter that governs the properties of the phase is known as the wave parameter, D, which is defined as (Rytov et al., 1989a):

$$D = \frac{\lambda L}{a^2} \tag{7}$$

In the numerator of Equation 7, the length $\sqrt{\lambda L}$ provides the typical size of the first Fresnel zone which can be interpreted as the typical volume sampled by the waves around a ray of length L. The region $D \ll 1$ can be conveniently treated with the methods of geometrical optics. In this regime, there are some well-established results for the phase coherence function of a single plane wave with vertical incidence: (1) The variance of the phase is proportional to the total variance of the medium fluctuations and increases linearly with the propagation distance L. (2) The typical correlation length of the phase is proportional to the correlation length of the random medium. This result makes sense physically, since parts of the incident wave front which are located a distance a apart – a, the correlation length– will visit different inhomogeneities. This provides a very useful method to map the typical scale of heterogeneities. The geometrical optics approach is rather flexible and allows the treatment of more complex situations. Kravtsov et al. (2003) have adapted the method to the reflexion geometry usually encountered in exploration geophysics.

The method of geometrical optics usually breaks down for $D > 1$ as caustics may develop for sufficiently large propagation distances. In order to account properly for diffraction effects, it is important to use a wave-based approach. As in the problem of transmission fluctuations in which the propagation is essentially one-way, it is convenient to consider the depth variable z as an evolution variable and to neglect the backscattered waves. In this case, the usual Helmholtz equation can be replaced by the following parabolic approximation for the wavefield:

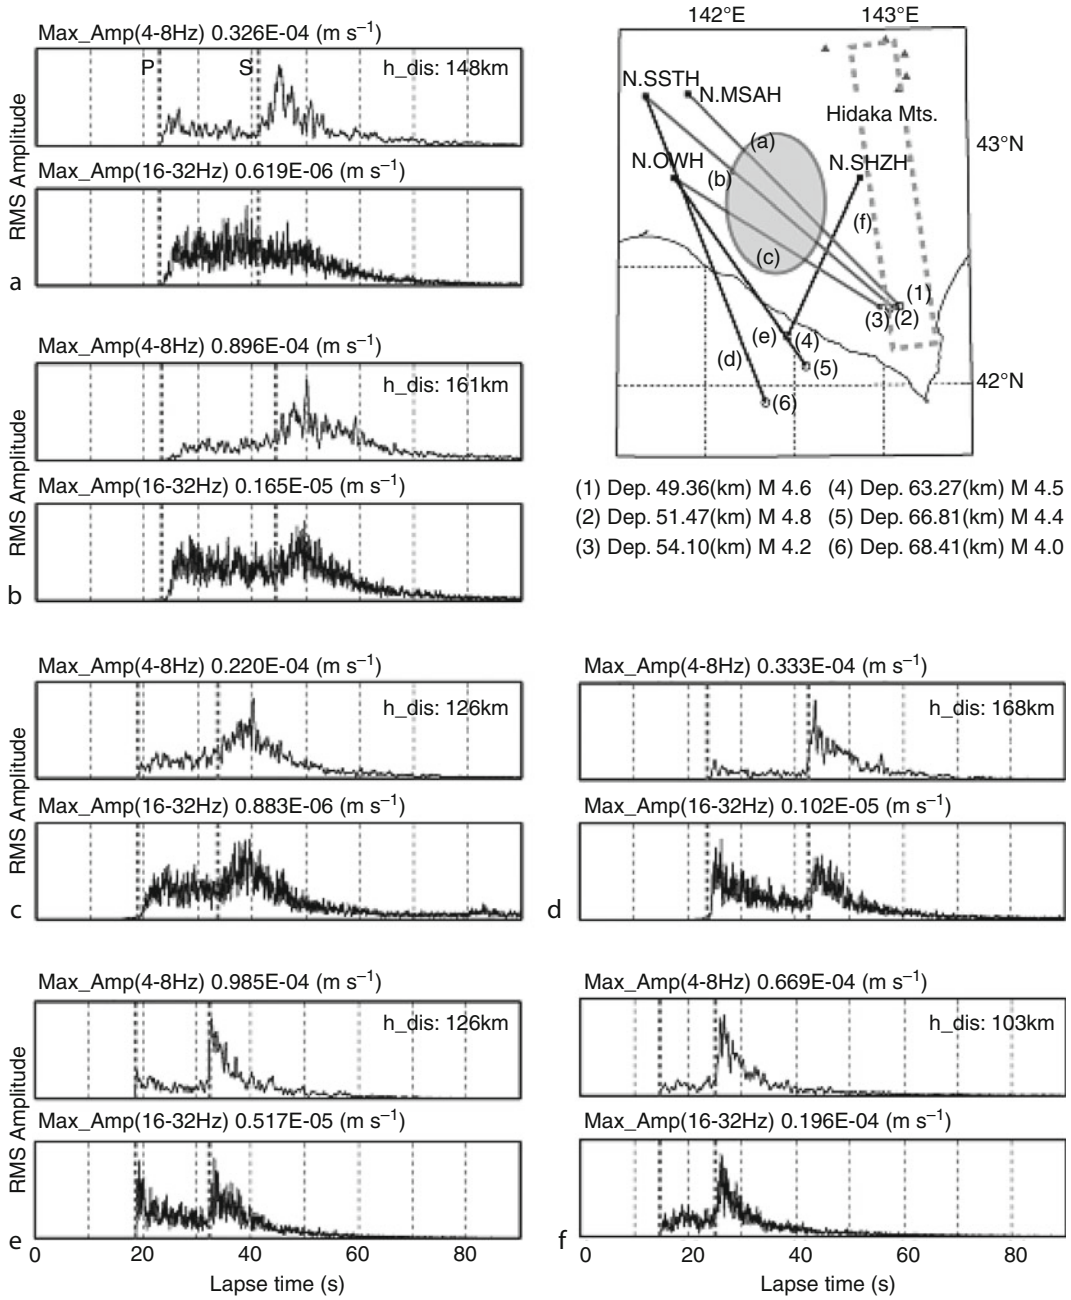
$$2ik_0\frac{\partial u}{\partial z} + \Delta_\perp u - 2k_0^2\frac{\delta c}{c_0}u = 0, \tag{8}$$

where $\Delta_\perp = \partial_x^2 + \partial_y^2$ represents the Laplace operator in the plane perpendicular to the main propagation direction. The parabolic approximation is accurate for low-angle scattering only, which is consistent with the scaling $\lambda/a \ll 1$. In this regime, a very powerful approach couples scattering theory and the Rytov representation of the wavefield to obtain expressions for the coherence function that extend the results of geometrical optics to the region $D > 1$. We refer to Wu and Flatté (1990) for further details on the derivation.

The first application to data was made by Aki who estimated the correlation length and total variance of the velocity fluctuations from the cross-coherence of amplitude and phase under the LASA array (Aki, 1973). In this pioneering work, he further approximated the correlation function of the medium with a Gaussian function. It was later realized that this choice was not always the most appropriate since many studies revealed that the more general Von-Karman correlation function could be used to describe a broad class of random media. Flatté and Wu (1988) developed a two-layer model of heterogeneity of the upper mantle based on observed transverse and angular correlation functions at NORSAR. By superimposing a layer with Hurst exponent 1/2 extending from 15 to 250 km depth upon a layer with flat power spectrum extending from 0 to 200 km depth, they were able to explain satisfactorily the joint measurements of phase and amplitude fluctuations. The most recent developments by Zheng et al. (2007) and Zheng and Wu (2008) allow the treatment of velocity gradient in the reference medium. Their general formalism offers the possibility to perform a nonparametric inversion, i.e., the full power spectrum of the fluctuations at depth can in principle be mapped from the surface measurements of angular correlation functions. For a complete description of the method as well as numerous references to the literature, we refer to the review by Zheng and Wu (2008).

Envelope modeling: Markov approximation

We now consider a regime of propagation where the fluctuating part of the field is larger than the coherent part. In this regime, an interesting phenomenon termed "envelope broadening" can be used to retrieve information on the statistical fluctuations of velocities in the medium. Enveloped broadening is illustrated in Figure 2, where small earthquakes have been recorded at epicentral distances of the order of 150 km in eastern Japan. On these data, we can observe a delay between the onset of the direct shear wave and the maximum of the amplitude. Such a delay is characteristic of the strong forward-scattering regime where the waves follow "snake-like" paths around the ballistic trajectory between source and station. As clearly shown in



Seismic Waves, Scattering, Figure 2 Example of earthquake records showing the phenomenon of envelope broadening. Paths a, b, c propagate through a very heterogeneous volcanic region. A large delay between the onset of *S* waves and the maximum amplitude is clearly observed. This phenomenon further depends on the frequency band considered. Paths d, e, f do not cross the heterogeneous region and show more impulsive envelopes with small onset to peak delay time (Reproduced from Takahashi et al. (2007)).

Figure 2, envelope broadening depends on propagation distance and frequency band. It is also noticeable that very heterogeneous regions such as volcano areas give rise to much stronger envelope broadening than the usual crust. The clear path dependence suggests the possibility to use regional variations of the onset to peak delay time to map heterogeneities in the crust, in order to develop a stochastic tomography in the strong fluctuation regime.

Such an approach has been pioneered by Sato in the late 1980s. A recent review of the topic in seismology is given by Sato and Korn (2009). Based on the parabolic approximation, Sato (1989) derived an equation for the two-point, two-frequency coherence functions of the wavefield for incident plane waves. This technique which was originally introduced in astrophysics has been termed "Markov approximation." In the case of regional propagation, it is preferable however to consider the radiation from a point source. Following Saito et al. (2002), we write the coherence function of the field as follows:

$$\Gamma(\mathbf{r}_{\perp 1},\ \mathbf{r}_{\perp 2},\ r,\ \omega_d, \omega_c) = \langle U(\mathbf{r}_{\perp 1},\ r,\ \omega_1)\langle U(\mathbf{r}_{\perp 2},\ r,\ \omega_2)^*\rangle, \tag{9}$$

where ω_c and ω_d denote the central $(\omega_1 + \omega_2)/2$ and modulation $\omega_1 - \omega_2$ frequency, respectively. The introduction of two frequencies is demanded by the nonstationarity of the envelope records. The source station distance is denoted by r and the points $\mathbf{r}_{\perp 1}$ and $\mathbf{r}_{\perp 2}$ lie in a plane perpendicular to the wave front. The time dependence of the observed coda envelopes around the frequency ω_c is obtained by setting $\mathbf{r}_{\perp 1} = \mathbf{r}_{\perp 2}$ and taking a Fourier transform over ω_d.

The basic idea of the so-called Markov approximation is to consider one-way propagation and to neglect backscattering. The different slices of the medium perpendicular to the main propagation direction independently perturb the local ray direction in a random fashion. As a consequence, the distribution of ray directions at a distance r_0 from the source depends solely on the heterogeneities that have been met for $r < r_0$ (Sato, 1989; Sato and Korn, 2009). Such an approximation is valid for strong forward-scattering, i.e., when the relation $\lambda > a$ applies. This does not mean that the Markov approximation cannot be used if the medium contains heterogeneities with scale lengths shorter than the wavelength. Indeed, the large-scale fluctuations contribute predominantly to the field measured in the transmission geometry. Scattering at large angles caused by small-scale fluctuations mainly plays the role of an apparent energy loss which adds to the intrinsic losses (Sato, 1989). In order to quantify the typical validity region of the Markov approximation, it is useful to introduce a quantity known as the transport mean free path (Sheng, 1995) and defined as:

$$l^* = \frac{l}{1 - \langle \cos\theta \rangle}, \tag{10}$$

where $\langle \cos\theta \rangle$ is the mean cosine of the scattering angle. The transport mean free path can be interpreted as the typical length beyond which the waves have lost memory of their initial propagation direction. In the case of large-scale fluctuations, the transport mean free path l^* is typically one or two orders of magnitude larger than the scattering mean free path l. For propagation distances of the order of the transport mean free path, backscattering can no longer be ignored and one must appeal to other methods to be described in section Envelope modeling: radiative transfer.

As carefully explained in the paper of Sato (1989), there are two basic phenomena that contribute to the observed envelope shape. The first one is termed "the wandering effect" and is purely statistical in nature. It corresponds to the small arrival time fluctuations in the line-of-sight propagation direction. It leads to a Gaussian spread of an initially delta-like pulse. This reshaping can only be observed upon ensemble averaging and is therefore not of primary importance in seismology. The second phenomenon is the increase of the typical duration of the seismogram with propagation distance which has been termed "pulse" – or may be more appropriately – "envelope broadening." It reflects the angular spreading of the wave propagation directions as they interact with the medium heterogeneities. For a general Von-Karman correlation function, a time scale t_m characterizes the typical duration of the seismogram (Saito et al., 2002):

$$t_m = C\left(\varepsilon^{1/(p-1)} a^{-1}\right)^{2-2/p} \omega^{-2+4/p} r_0^{1+2/p}, \tag{11}$$

where ϵ denotes the root mean square fluctuations, ω is the central frequency of the signal, r_0 is the hypocentral distance and C is a numerical pre-factor which depends on the wavespeed, and on the Hurst exponent κ. The parameter p is an increasing function of κ and varies from 1.2 to 2 for $0 < \kappa \leq 1$. Formula (11) reveals interesting characteristics of the envelope broadening phenomenon. For a smooth medium, i.e., a medium poor in small-scale features, the parameter p is close to 2 and, as a consequence, the typical envelop duration is frequency-independent. Such a result also holds for the Gaussian correlation function and is in sharp contradiction with observations. As a consequence, the frequency dependence of envelope duration offers access to the degree of roughness of Earth's heterogeneities. Accurate measurements of the exponent κ requires that absorption and – to some extent – scattering losses caused by small-scale heterogeneities be incorporated in envelope modeling (Saito et al., 2002).

In practical applications to data, a characteristic time, t_q, is measured as a function of frequency and hypocentral distance: $t_q = t_p + t_{1/2}$, where t_p is the duration from onset to peak and $t_{1/2}$ is the decay time of the envelope from the peak to RMS half-peak value. Note that the observations are usually focused on the S wave train for which pulse broadening is usually much clearer than for P waves. The observations are then compared to those numerically obtained by the Markov approximation for a wide range of correlation lengths, RMS perturbations and intrinsic quality factor. In general it is not possible to estimate

independently ϵ and a since various combinations of these two parameters may yield the same characteristic time t_m. However, by analyzing separately the distance and frequency dependence of t_q, the intrinsic quality factor Q_s, the parameter p, and in turn, the Hurst exponent κ can be estimated. For applications to seismic observations, we refer to, e.g., Scherbaum and Sato (1991); Obara and Sato (1995); Saito et al. (2005).

As illustrated in Figure 2, for comparable hypocentral distances and frequency bands, the envelope shapes may strongly depend on the direct ray path. Such an observation calls for the introduction of large-scale variations of small-scale heterogeneities. Such an approach has been taken by Takahashi et al. (2007) who mapped strongly heterogeneous regions beneath quaternary volcanoes in northeastern Japan from the observed path dependence of the characteristic broadening time t_q. A complete tomographic approach to estimate the power spectrum of small-scale heterogeneities from envelope broadening data was further developed and applied to northeastern Japan by Takahashi et al. (2009).

Gusev and Abubakirov (1999a, b) developed a tomographic method to map the transport mean free path in the Earth based on body wave envelope broadening. Their approach is simpler since they consider the inversion of a single parameter. From the knowledge of the frequency dependence of the the transport mean free path, it is possible to put constraints on the parameters ϵ, a, and κ. The Markov method has recently been extended to the case of vector waves by Sato (2006, 2007, 2008). The theoretical approach relies on the introduction of scalar and vector potentials for P and S waves, respectively. The employed Helmholtz decomposition neglects the conversions between P and S waves, which is justified in the high-frequency regime $\lambda \gg a$, up to a characteristic coupling time τ^{PS} between P and S waves. Extensions of the Markov method to the vectorial case allow the modeling of the observed energy envelopes of the transverse components of the wavefield after the onset of the direct P-wave. The observation of such transverse energy is another manifestation of the randomization of the ray directions in a scattering medium. Alternative explanations for this phenomenon are mode conversions or anisotropy. In the case of a statistically homogeneous Gaussian medium with thickness h, Sato (2006) showed that the ratio between the peak total intensity and the peak intensity on the transverse component of the P pulse scales like $\epsilon^2 h/a$. Interestingly, this relation is free from absorption, since it cancels out in the intensity ratio. Based on this approach Kubanza et al. (2007) made a global study of energy envelopes of transverse components in the P wave train observed at teleseismic distances and found good correlation between the strength of heterogeneity and the tectonic setting.

Envelope modeling: radiative transfer

When the propagation time and distances become very large compared to the ballistic time, or when the acquisition geometry is in the reflection mode, it becomes crucial to take into account scattering at large angle. A powerful approach to model seismogram envelopes in scattering media in such cases is provided by radiative transfer theory. In seismology, radiative transfer was introduced in the mid-1980s by Wu (1985) with a first application to data by Wu and Aki (1988). Physically, the equation of transfer is a local statement of energy conservation in a random medium and incorporates an arbitrarily high number of scattering events. The radiative transfer equation also takes into account the anisotropy of the scattering process, in particular large-angle scattering. Therefore, it enables the complete modeling of seismogram envelopes including coda waves, i.e., the late arrivals of the seismogram. A review of the radiative transfer approach in seismology is given by Margerin (2005).

The study of coda waves has been pioneered by Aki (1969) and Aki and Chouet (1975). In this last reference, the authors developed two famous models of scattering: the single-scattering approximation and the diffusion approximation. The single-scattering model applies for propagation distances of the order of, or less than the mean free path. This model has been very popular until studies by Gusev and Abubakirov (1987) and Hoshiba (1991) pointed out the importance of multiple scattering. Recently, the diffusion model has known a revived interest in connection with seismic experiments on volcanoes (Wegler and Lühr, 2001; Wegler, 2004). The single-scattering and diffusion models are respectively short-time and large-time asymptotics of the radiative transfer equation. Mathematically, radiative transfer takes the form of an integro-differential equation for an angularly resolved energy flux known as the specific intensity $I(\mathbf{r}, \hat{\mathbf{k}}, t, \omega)$. The specific intensity quantifies the amount of energy flowing around the direction $\hat{\mathbf{k}}$ in a small frequency band $[\omega, \omega + \delta\omega]$ during a time interval $[t, t + \mathrm{d}t]$ through a small surface element located at $\mathbf{r}$. Although the concept of specific intensity was first introduced on a phenomenological basis, it is now well understood that it is in fact connected to the Wigner-Ville distribution of the wavefield (Ryzhik et al., 1996):

$$I(\mathbf{r},\hat{\mathbf{k}},t,\omega) = C \iint \langle u(t-\tau/2,\mathbf{r}+\mathbf{x}/2)u(t+\tau/2,\mathbf{r}-\mathbf{x}/2)^*\rangle e^{-i\mathbf{k}\cdot\mathbf{x}+i\omega\tau} d^3x d\tau, \tag{12}$$

where the brackets denote an ensemble average. The key to understand this definition is the notion of separation of scales. In Equation 12, one must think of the intensity as a slowly varying function of the time t, as compared to the fast oscillations of the wavefield described by the frequency ω. Similarly, the average intensity varies slowly in space as compared to the wavelength. Such a separation of scales is well satisfied by high-frequency seismograms and guarantees that the Wigner distribution can be interpreted as a local power spectrum of the wavefield.

It is important to note that interference effects are neglected in the transfer approach. This can be justified on the basis of the small phase shifts that occur upon scattering and which will be different for waves visiting different heterogeneities.

An important step in the development of radiative transfer was the introduction of the Monte Carlo method, which is a flexible numerical technique to solve the transfer equation. It has been introduced in seismology by Gusev and Abubakirov (1987). The Monte Carlo method simulates the random walk of particles, which change direction of propagation at the end of each step. The step length has an exponential distribution with parameter the scattering mean free path, and the change of direction upon scattering is provided by a probabilistic interpretation of the differential scattering cross-section. The latter quantity can be obtained from the Born approximation at frequencies below the geometrical optics limit. The validity of this approximation has been discussed by Wegler et al. (2006a) and Przybilla and Korn (2008). The Monte Carlo method can be shown to yield an exact solution of the transfer equation (Papanicolaou et al., 2000). The variance of the result typically decreases like the square root of the number of simulated random walks.

An important application of the radiative transfer approach was developed by Fehler et al. (1992) and Hoshiba (1993) who proposed a method to infer the mean free path and intrinsic quality factor in the crust from the space time dependence of the energy radiated by small earthquakes. The method is based on the estimation of the energy in three successive time windows starting with the direct *S* wave arrivals. Such multiple lapse-time window analysis has been applied in various regions of the world to give estimates of the level of heterogeneity in the crust. Typically, the mean free path of the crust around 1 Hz ranges from a few tens to a few hundred kilometers. The method has some limitations since it assumes isotropic scattering and a uniform distribution of scatterers in a half-space.

It was pointed out by Gusev and Abubakirov (1987), Abubakirov and Gusev (1990) and Hoshiba (1995) that the observed shape of envelopes of body waves is incompatible with isotropic scattering, since no broadening occurs in this case. Based on the comparison between modeled and observed *S* wave seismogram envelopes, Gusev and Abubakirov (1996) were able to infer a Hurst exponent ranging between 1/4 and 1/2 in the crust. In the case of crustal propagation at regional distances, the field is dominated by guided waves. To take into account the role of stratification and scattering in the Earth, Hoshiba (1997), Margerin et al. (1998), and Yoshimoto (2000) have shown how to incorporate depth-dependent velocity and mean free path in the Monte Carlo method. Margerin et al. (1999) numerically solved the radiative transfer equation in the crustal geometry and confirmed the importance of the leakage of energy at the Moho to explain the decay of the coda, as first proposed by Korn (1990).

Other applications of radiative transfer pertain to the study of the seismic source. Nakahara et al. (1998) proposed a method based on radiative transfer theory to infer the distribution of high-frequency radiation on the fault plane of large earthquakes. They considered the different part of the fault to be independent and modeled the propagation using a multiple isotropic scattering model. Sens-Schönfelder and Wegler (2006a) devised a method to infer the seismic moment of small crustal earthquakes recorded at regional distance. Another important application concerns the modeling of wave propagation in very heterogeneous structures such as volcanoes, where the mean free path can become as small as a few hundred meters. A review of recent development in the field is provided by Del Pezzo (2008). It is to be noted that in cases where the typical propagation distance is much larger than the mean free path, the radiative transfer equation can be simplified to a simple scalar diffusion equation for the total energy density of *P* and *S* waves. The diffusion approach to the modeling of seismic energy propagation in volcanoes has been advocated by Wegler (2004).

Radiative transfer theory is still in an active stage of development. A radiative transfer equation for elastic waves has been introduced in seismology by Zeng (1993); Sato (1994); and Ryzhik et al. (1996). This equation takes into account in a rigorous way the coupling between *P* and *S* waves. A Monte Carlo method to solve this elastic transfer equation was developed by Margerin et al. (2000). A comparison of finite-difference and Monte Carlo simulations by Przybilla and Korn (2008) demonstrated the accuracy of the radiative transfer approach to simulate the coupling and multiple scattering of *P* and *S* waves. An extension of the radiative transfer equation to incorporate the coupling between surface and body waves is a major challenge. An important step in this direction was made by Maeda et al. (2007) who incorporated the coupling between Rayleigh and body waves in the single-scattering approximation. The impact of anisotropic scale lengths has been studied by Margerin (2006) who derived a radiative transfer equation with an angular-dependent scattering mean free path.

Global-scale scattering

The subject of seismic scattering at the global scale was first developed in the early 1970s in connection with short-period precursors to phases such as *PP* (King et al., 1975) and *PKP* (Cleary and Haddon, 1972). Accompanying the improvement of the global seismic network and the availability of high-quality data, evidences for the importance of scattering in the deep Earth have accumulated in recent years. The study of precursors to deep phases such as *PKP* (Hedlin et al., 1997) and *PKKP* (Earle and Shearer, 1997) has been used to put constraints on the heterogeneities in the deep mantle and core. Observation and modeling of anomalous propagation of seismic waves in the subducting lithosphere have put forward the role of scattering by elongated heterogeneities in slabs

(Furumura and Kennett, 2005). The presence of strong scatterers in Earth's inner core has been revealed by a number of studies (Vidale and Earle, 2000; Koper et al., 2004; Poupinet and Kennett, 2004). Vidale and Earle (2000) used data from nuclear explosions recorded on the LASA array to demonstrate that the long-lasting signal following the ballistic *PKiKP* phase was not caused by the response of the crust but were genuine scattered waves radiated from the inner core. They showed examples of slowly-emergent and long-lasting *PKiKP* signals recorded at an epicentral distance of about 60°. This last point is particularly important, since it corresponds to incidence angles of *P* waves at the inner core boundary such that the reflection coefficient vanishes. The coda of *PKiKP* thus provides a direct proof of the presence of scatterers in the inner core.

Since the deep Earth interior is usually thought to be much less heterogeneous than the lithosphere, much of the modeling work has been focused on the single-scattering approximation (Hedlin et al. (1997); Vidale and Earle (2000); Leyton and Koper (2007)). The radiative transfer approach was introduced in global seismology by Margerin and Nolet (2003a, b) to improve the modeling of the precursors to the *PKP* wave. In particular, they demonstrated the ability of radiative transfer to incorporate complicated ray geometry such as the one imposed by the severe drop of velocity at the core–mantle boundary. The Monte Carlo method was further developed by Shearer and Earle (2004) who proposed a scheme to simulate the multiple scattering of elastic waves at the global scale, including the coupling between *P* and *S* waves. Their method was applied to the study of the coda envelopes of teleseismic *P* waves. To explain the observations, they proposed a 1-D model of Earth small-scale heterogeneity composed of a heterogeneous 200 km top-layer (4% RMS perturbations) overlying a less heterogeneous 400-km layer (3% RMS perturbations). At the base of the mantle, a 600 km thick layer with 0.5% RMS perturbations is required to achieve a good fit to the data. Shearer and Earle (2004) concluded that attenuation is dominated by scattering in the upper-mantle and by absorption in the lower mantle.

In addition to global studies of scattering of short-period waves, an interest in the scattering of long-period surface waves has recently arisen. Maeda et al. (2006) performed an (*f,k*) analysis of the vertical components of three large earthquakes recorded on the Japanese Hi-Net in the 90–180 s period band. They find that the signals recorded between the first multi-orbiting Rayleigh wave arrivals are composed of waves coming from all directions with phase velocities of the order of the Rayleigh wave fundamental mode. This suggests that in the period band of interest, scattered Rayleigh waves are present in the data at short lapse time. After typically 30,000 s, the multi-orbiting Rayleigh waves have strongly decayed. The (*f,k*) analysis demonstrates that the signal is dominated by waves with very large phase velocities, thereby implying the dominance of higher-mode Rayleigh waves. Such a phenomenon is to be expected on the ground that higher modes sample the deeper parts of the Earth with high intrinsic quality factor. To model the coda of multi-orbiting Rayleigh waves, Sato and Nishino (2002) developed a radiative transfer equation on the sphere assuming the multiple isotropic scattering of the fundamental mode Rayleigh wave. In their approach, the coupling with higher modes is neglected. They observe a systematic discrepancy between observed and modeled seismogram envelopes which also suggests that higher modes dominate the data at lapse times larger than 30,000 s.

Interferometry with scattered waves

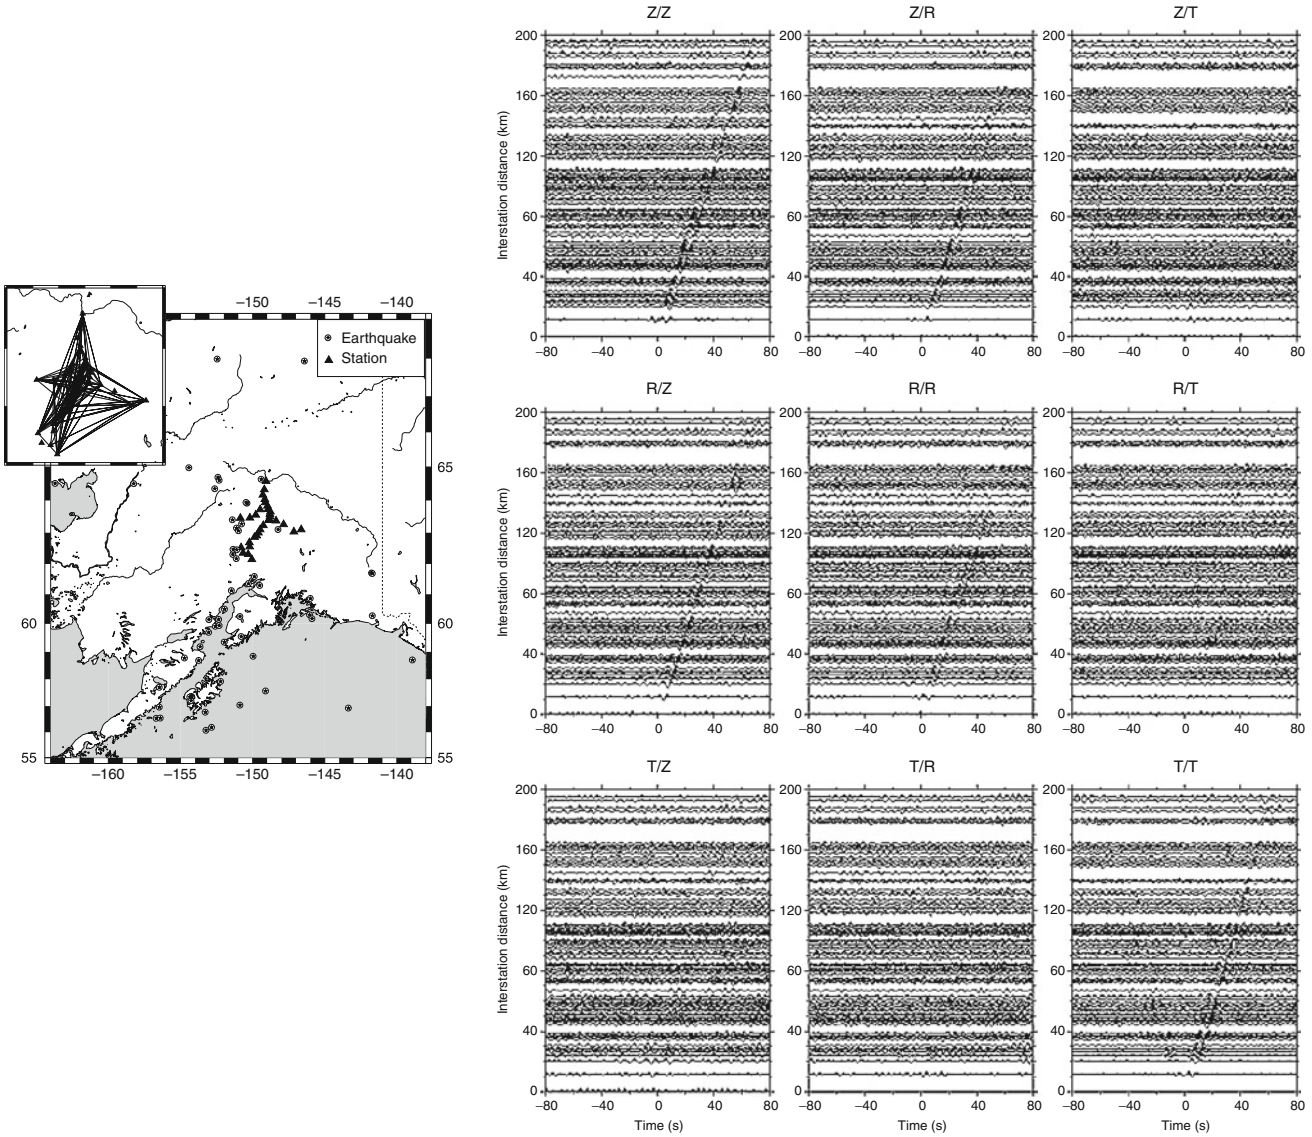
Green function retrieval

As explained in section Introduction, the incoherent field refers to the waves that average out when a mean over an ensemble of random media is performed. These waves are incoherent in the sense that, at a given point of the medium, they propagate in space directions that differ from that of the mean field. But "incoherence" does not imply that the phase information has been lost (Campillo, 2006). Campillo and Paul (2003) were the first to demonstrate the existence of correlations between the coda waves recorded at two distant points in the heterogeneous crust. Such correlations emerge after sufficient temporal and source averaging. Following Lobkis and Weaver (2001), Campillo and Paul (2003) proposed that the correlation tensor of the coda wavefields recorded at two points *A* and *B* is in fact proportional to the Green's tensor G_{ij} between these two points. In the frequency domain, such a relation can be mathematically formulated as follows:

$$\left\langle u_i(B,\omega)u_j(A,\omega)^*\right\rangle \propto \mathrm{Im}G_{ij}(B,A,\omega). \tag{13}$$

The proportionality factor depends on the details of the source spectrum. The occurrence of the imaginary part of the Green's function on the right-hand side of Equation 13 physically means that the correlation of two wavefields is proportional to a combination of the retarded and advanced Green's functions. The appearance of the advanced Green's function is most easily understood by noting the equivalence between correlations and time-reversal experiments. We will not discuss this analogy, but the interested reader can refer to Derode et al. (2003).

In seismology, the brackets in Equation 13 usually denote an average over time windows in the coda and over earthquake sources. An example of emergence of the retarded and advanced Green's function in the correlation of coda waves recorded on a temporary network deployed in Alaska is illustrated in Figure 3. The maximum of the correlation is always shown for positive times, but it is nevertheless possible to distinguish some coherent arrivals at negative times. The reconstruction of the Green's function from coda waves is intimately related to the concept of equipartition, which is a fundamental consequence of multiple scattering. Loosely stated, equipartition stipulates that plane *P, S*, Rayleigh, and Love



Seismic Waves, Scattering, Figure 3 Example of Green's function reconstruction from coda waves recorded in Alaska. A location map of the experiment is shown on the *left*. The inset shows all the station pairs analyzed in this study. On the *right*, all possible terms of the correlation tensor are represented as a function of the correlation time on the horizontal axis and the epicentral distance between the two stations on the vertical axis. For each station pair, the three components of the seismometers have been rotated onto the radial (R), transverse (T), and vertical (Z) reference frame (Reproduced from Paul et al. (2005)).

waves coming from all possible directions compose the wavefield. That the Green's function of the medium is recovered if the equipartition state is reached has been shown for an infinite elastic medium by Sánchez-Sesma and Campillo (2006). Based on the single-scattering approximation for scalar waves, Sato (2009) demonstrated that the correlation of coda waves recorded at two stations enables the reconstruction of the ballistic Green's function between the two stations. Snieder (2004b) derived the reconstruction of the Green's function from coda waves based on the stationary phase approximation. An experimental verification of the equipartition principle has been performed by Hennino et al. (2001). In Figure 3, we can observe a clear time asymmetry in the reconstructed Green's function. This seems to contradict the equipartition principle. Such a time asymmetry has been studied by Paul et al. (2005). These authors demonstrate that a flux of energy directed from the earthquake source to the station can persist even at very large lapse time in the coda. Such an energy flux breaks the temporal symmetry of the correlations unless the distribution of earthquakes around the station covers all azimuths.

Monitoring temporal variations

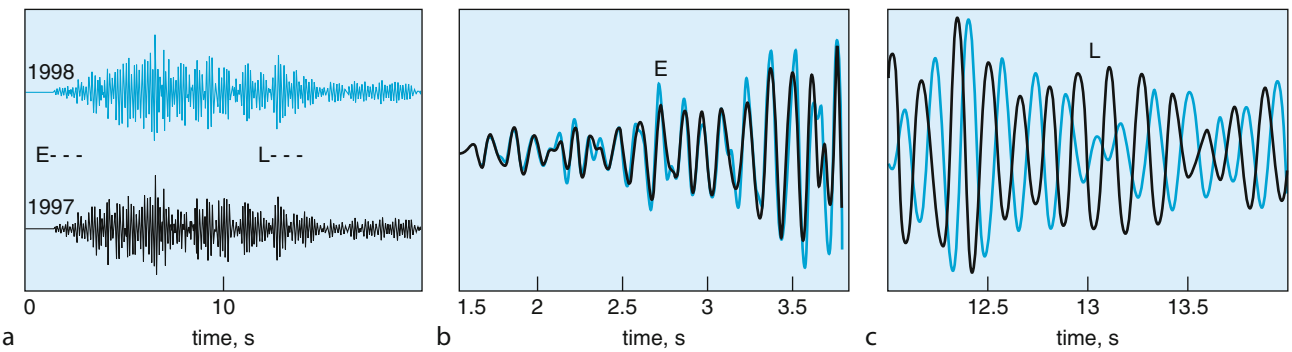
An interesting application of wave multiple scattering pertains to the detection of weak changes in dynamic media, i.e., media evolving with time. The methods which make use of scattered waves to probe changes in complex media have been termed "diffusing acoustic wave spectroscopy" in acoustics and "coda wave interferometry" (CWI) in seismology. In this article, we focus on applications to seismic waves. A theoretical approach of the method is provided by Snieder (2006). For a very accessible review of this broad topic in physics, we refer to Snieder and Page (2007). A comprehensive review of monitoring applications in seismology is given by Poupinet et al. (2008).

The key idea of CWI is to take advantage of the long propagation paths of scattered waves, which accumulate small phase differences on their way from source to station. An example of monitoring the medium changes at the Merapi volcano is shown in Figure 4. In this experiment, a repeatable source is used to generate seismic waves that propagate through the volcano. The fact that the source is highly reproducible is important, as any small difference between seismograms recorded at different time instants can be interpreted as a change of the propagating medium. Natural repeating sources such as earthquake doublets can also be exploited to probe medium changes. The doublets correspond to small earthquakes breaking the same fault patch at different times of occurrence (Poupinet et al., 1984). As shown in Figure 4, the changes are virtually undetectable on the first arrivals. In the coda, the medium changes are manifested by a small time delay between two very similar waveforms. In the case of the Merapi data shown in Figure 4, an analysis of the delay times as a function of the time lag in the coda reveals that the two seismograms are nearly stretched versions of one another. This means that the two waveforms can be related by a similarity transformation $t \rightarrow t(1+\epsilon)$ of the time variable. Such an observation can be interpreted as a very small change of the wave velocity δv in the propagating medium. The relation between the stretching parameter ϵ and the velocity variation reads (Sens-Schönfelder and Wegler 2006b):

$$\epsilon = -\frac{\delta v}{v} \tag{14}$$

In practice, the velocity change can be estimated by measuring the delay time which maximizes the correlation between the two signals. Such a procedure can be applied to moving time windows in the coda, of typical duration, a few central periods. The relation (14) is valid for acoustic waves only. A formula valid for elastic coda waves in the equipartition regime has been derived by Snieder (2002). Ratdomopurbo and Poupinet (1995), and Wegler, et al. (2006b) found that the shear velocity increases prior to eruptions at the Merapi volcano, an observation interpreted as a pressurization effect due to the magma ascent. Typically, relative velocity changes of the order of 10^{-5}–10^{-4} can be detected (Poupinet et al., 2008). This makes coda wave interferometry the ideal tool to study the rheology of materials (Snieder et al., 2002).

As a final example of the use of scattered waves, we consider a method which has been termed "passive image interferometry" (Sens-Schönfelder and Wegler, 2006b) which combines coda wave interferometry with the principle of Green's function reconstruction from coda waves. Passive interferometry uses ambient noise – instead of coda waves – to reconstruct the Green's function. The coda part of the reconstructed Green's function is subsequently used to monitor temporal variations in the medium. A great advantage of this method as compared to the usual coda wave interferometry lies in the fact that noise records allow a continuous reconstruction of the Green's function over very long time periods. Brenguier et al. (2008) demonstrated the possibility to detect very



Seismic Waves, Scattering, Figure 4 Illustration of the principle of coda wave interferometry. A controlled and repeatable source is used to probe the Merapi volcano with seismic waves. The signals recorded at a time interval of 1 year are shown by *blue and black lines*. The insets show the comparisons of waveforms in the early part of the signal (E) and in the late part of the signal (L). In the later portion, a clear time shift between the two traces can be observed (Reproduced from Snieder (2004a)).

small medium changes at Le Piton de la Fournaise volcano in la Réunion Island. Applications to the study of the recovery phenomena in sediments affected by strong ground motion are developed in Sawazaki et al. (2009).

Summary

This article presents a nontechnical introduction to the various phenomena and methods pertaining to the scattering of seismic waves. The basic concepts of seismic scattering are introduced with the aid of a thought-experiment. The topics covered include the interpretation of transmission fluctuations, the broadening of envelope at regional distances, the interpretation of coda waves at local and global scales, and the use of scattered waves in seismic interferometry. The methods developed in seismic scattering offer powerful tools for the stochastic imaging of Earth's structure at spatial scales that cannot be resolved by traditional tomographic methods. In addition, scattered seismic waves are extremely sensitive to slight temporal changes of the medium. Using the interferometric approach, multiply-scattered coda waves can be used to monitor the evolution of the dynamic Earth.

Definition

Seismic zonation. The process of subdividing the territory into regions with respect to the level of seismic hazard. The result of seismic zonation is usually presented as a map, which is based on seismic hazard map.

Introduction

Seismic zonation is useful for hazard reduction such as earthquake-resistant design of structures, risk analysis, land-use planning, etc. Many earthquake-prone countries developed seismic zonation maps. Seismic zonation map is usually revised or updated periodically with the progress in methodology and accumulation of new data. Seismic intensity (see *Earthquakes, Intensity*) or ground motion parameters such as peak ground acceleration (PGA), peak ground velocity (PGV), and spectral acceleration at specific natural period are mostly adopted in seismic zonation map. In the early stage, most seismic zonation maps were in terms of intensity, but since the 1980s, ground motion parameters have become popular. More commonly, such maps take the exceeding probability of 10% within 50 years (return period 475 years) as standard.

Methodology

The basic method to develop seismic zonation map is the seismic hazard analysis (see *Seismic Hazard*) approach. Both deterministic and probabilistic approaches are adopted. Although some new deterministic approaches based on the computation of synthetic seismograms are used in recent years in developing seismic zonation maps (Parvez et al., 2003), nevertheless probabilistic approaches are more popular. The seismic zonation maps, based on seismic hazard maps (see *Seismology, Global Earthquake Model*), of many countries are developed by the use of probabilistic approach. The well-known USGS National Seismic Hazard Maps (Algermissen and Perkins, 1976; Algermissen et al., 1990; Frankel et al., 1996; Frankel et al., 2002; Petersen et al., 2008) and the Global Seismic Hazard Assessment Programme (GSHAP) are the typical (see *Seismic Hazard*) ones. In this article, only probabilistic method is briefly introduced.

The probabilistic method (usually referred to as PSHA – probabilistic seismic hazard analysis) was first introduced by Cornell (1968) and since then widely adopted and modified (McGuire, 1978; Bender and Perkins, 1982). There are four basic steps for assessment of PSHA (Figure 1):

Step 1: Definition of seismic sources. Sources may range from small faults to large seismotectonic provinces with uniform seismicity. The type of seismic source can be both line or area sources.

Step 2: Definition of seismicity recurrence characteristic for the sources, where each source is described by an earthquake probability distribution, or recurrence relationship. A recurrence relationship indicates the chance of an earthquake of a given magnitude to occur anywhere inside the source during a specified period of time. An upper bound earthquake is chosen for each source, which represents the maximum event to be considered.

Step 3: Development of ground motion attenuation relationships. This is usually done empirically from strong motion records (see *Earthquakes, Strong-Ground Motion*).

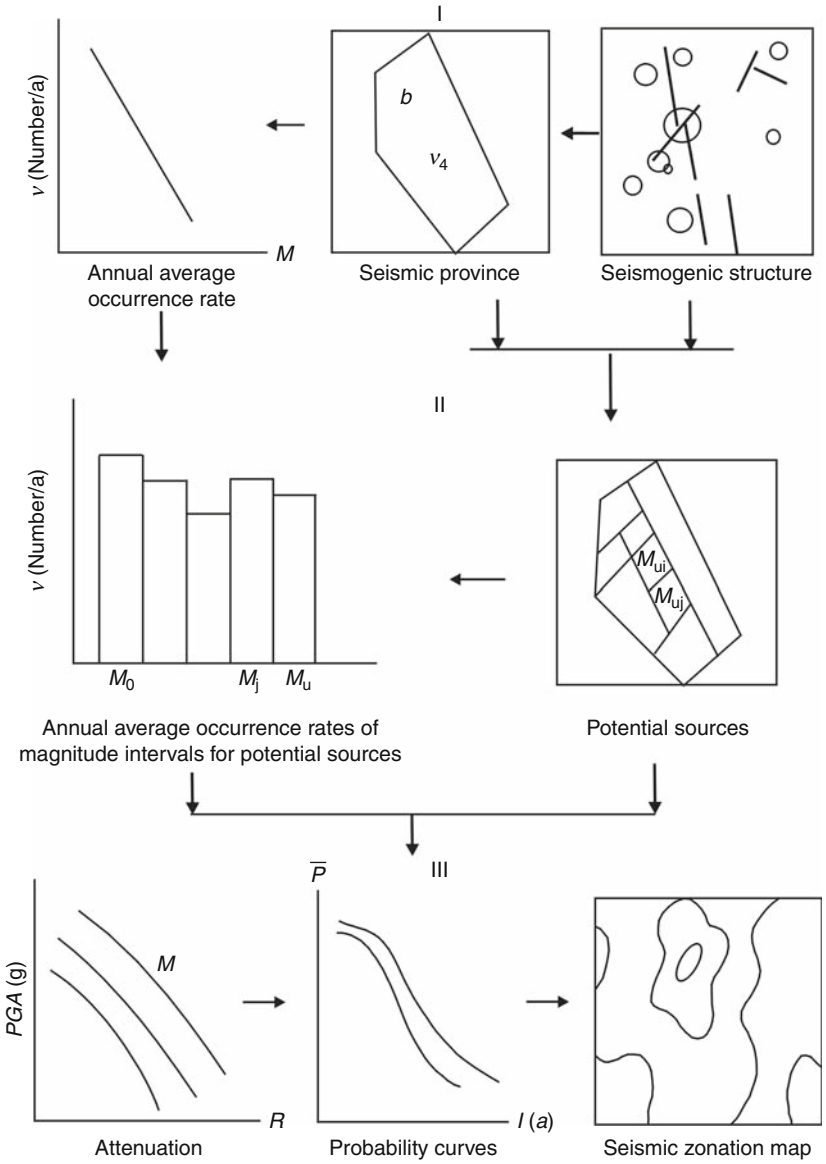
Step 4: Determination of the hazard at each site. In this case, the effects of all the earthquakes of different sizes occurring at different locations in different earthquake sources at different probabilities of occurrence are integrated into one curve that shows the probability of exceeding different levels of ground motion level (such as PGA) at the site during a specified period of time.

There are two basic assumptions in the seismic hazard analysis method at present: (a) Seismicity in the region around the site in the past indicates that in future, the recurrence rate of given site is the same as that of historic period. (b) Seismicity of the region can be expressed by tectonic earthquakes in the region, i.e., the seismic activities distribute homogeneously in a certain tectonic area or an active fault.

The two assumptions accord with the two principles of historic earthquake repeatness and tectonic extrapolation. The difference is that the PSHA adds a new concept of magnitude interval recurrent rate and the hazard is evaluated with probabilistic analysis method. The method can provide the exceedence probability of different ground motion extent (intensity, acceleration, etc.) at the site in specific time intervals, so that the earthquake resistant parameters can be selected with different exposure period, risk level, and various engineering structures.

Example: seismic zonation map of china (2001)

The first seismic zonation map of China was compiled by Wong (1921) after the Haiyuan earthquake, which occurred in 1920. After that, three versions of seismic zonation map were developed in 1957, 1977, and 1990 (Shi et al., 1992). The 1957 version demonstrated the maximum affected intensity of China. The 1977 version was provided by using the methodology of long-term and middle-term earthquake prediction. This version of seismic zonation map demonstrated the maximum encountered intensity in the forthcoming 100 years. This map was adopted by the building code. The 1990 version used probabilistic method. The seismic intensity with exceeding probability of 10% within 50 years was given in the map. It was used in the building code and other regulations related with seismic design. In 2001, a new seismic zonation map of China was issued. This map also used probabilistic method. The PGA and characteristic



Seismic Zonation, Figure 1 Approaches of probabilistic seismic hazard analysis.

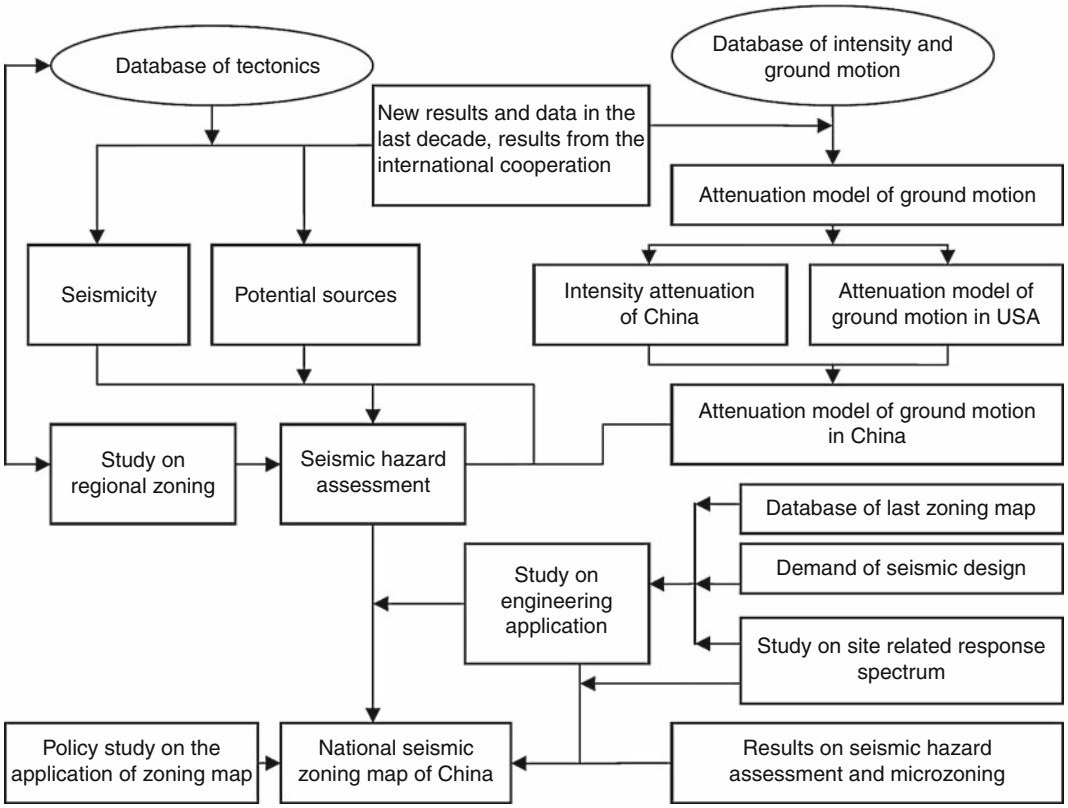
period of response spectrum Tg with exceeding probability of 10% within 50 years were given in the map. The probabilistic method used in developing seismic zonation of China (2001) was a little bit different from PSHA.

Most earthquakes in China are intraplate earthquakes (see *Seismicity, Intraplate*). Their non-homogeneity in space, non-stationarity in time were shown in the historical earthquake catalogs. The PSHA method applied in China can reveal non-homogeneity in space, non-stationarity in time. The approaches applied differ from PSHA in two aspects:

1. Evaluating seismicity and determining magnitude distribution, total annual occurrence rate of the province are on the basis of the seismic tendency estimation and the seismic characteristics analysis.
2. Annual rates of sources in all magnitude intervals are determined by spatial distribution functions, which describe relative risk among sources in the province.

The technical approach developing the national seismic zonation map of China (2001) is shown in Figure 2 (Gao, 2003).

The key scientific problems in compiling this map are: (a) how to treat the uncertainties in the evaluation of seismicity parameters and the delineation of potential sources as well as the attenuation relationship; (b) how to select the suitable parameters in the zonation map to fit the need of seismic design; and (c) how to use the domestic data and the data from the world to get the attenuation of the ground motion parameters.



Seismic Zonation, Figure 2 Technical approach of developing national seismic zonation map of China (2001).

The logic tree method is adopted to treat the uncertainties in seismic hazard analysis. The multi-set of potential source delineations was used. Four groups of scientists participated in the work of potential sources delineations based on the independent background and database. There are four sets of potential sources adopted in the logic tree analysis. Figure 3 is one of the potential source set.

Site-related seismic response spectrum is the base of seismic design for ordinary industry and civil construction. The site-related response spectrum is not only closely related to the earthquake environment, but also related to the soil condition. It is very difficult to decide site-related response spectrum by a single parameter such as intensity or peak acceleration. According to the results form seismic hazard assessment and the building code, the basic parameters used in the seismic zoning map to provide site-related response spectrum are PGA and the characteristic period of the response spectrum.

The attenuation relationships for the acceleration response spectrum platform value Sa and the velocity response spectrum platform value Sv were developed by modifying corresponding attenuation relations in the western United States according to the differences of intensity attenuation relations. Then the PGA and the characteristic period of response spectrum of acceleration Tg were defined as:

$$PGA = \frac{Sa}{2.5}$$
$$Tg = 2\pi \frac{Sv}{Sa} \quad (1)$$

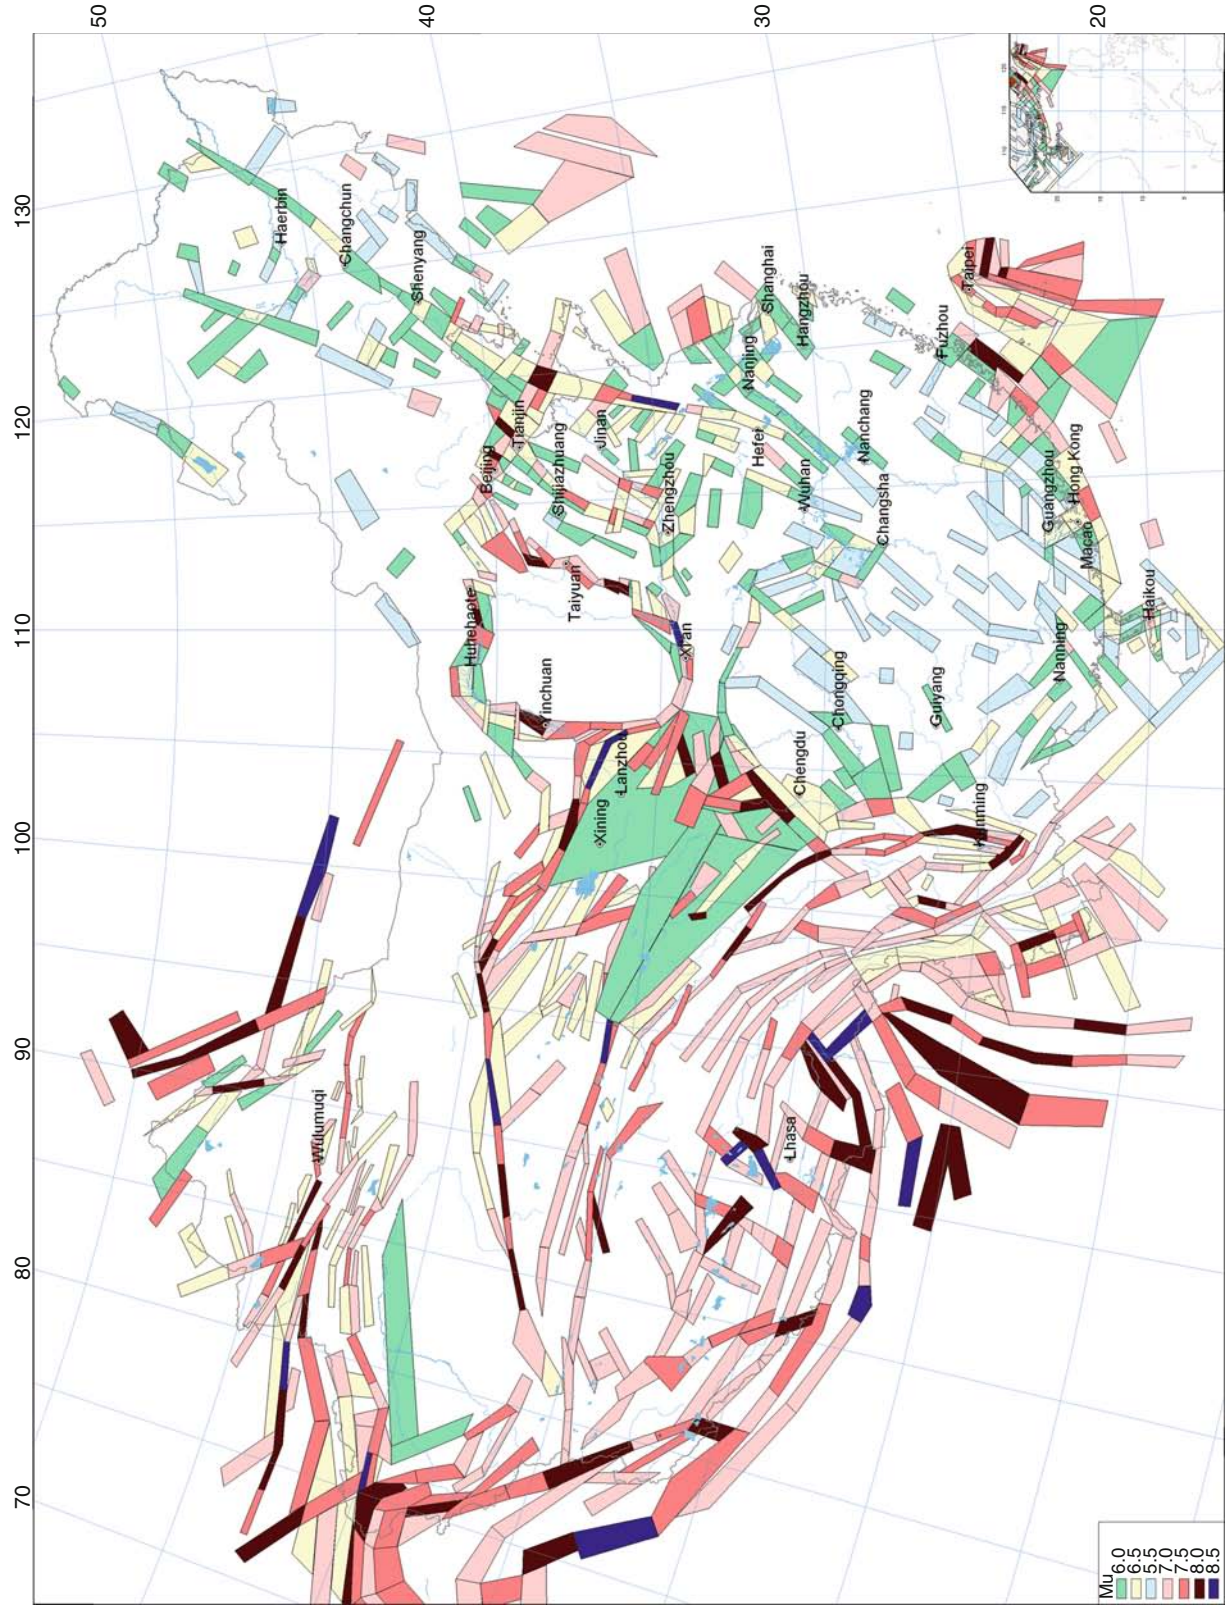
The country was divided into 40,000 grids. The probabilistic seismic hazard analysis for every grid was performed. The ground motion parameters with exceeding probability 10% within 50 years (return period 475 years) were determined.

The new zoning map includes two specific maps. One is PGA in gravity unit g (Figure 4) and the other is Tg in second (Figure 5). The scale of the maps are 1:4,000,000. The soil condition is medium hard soil. From these two parameters, the design response spectrum can be determined easily by (Equation 2):

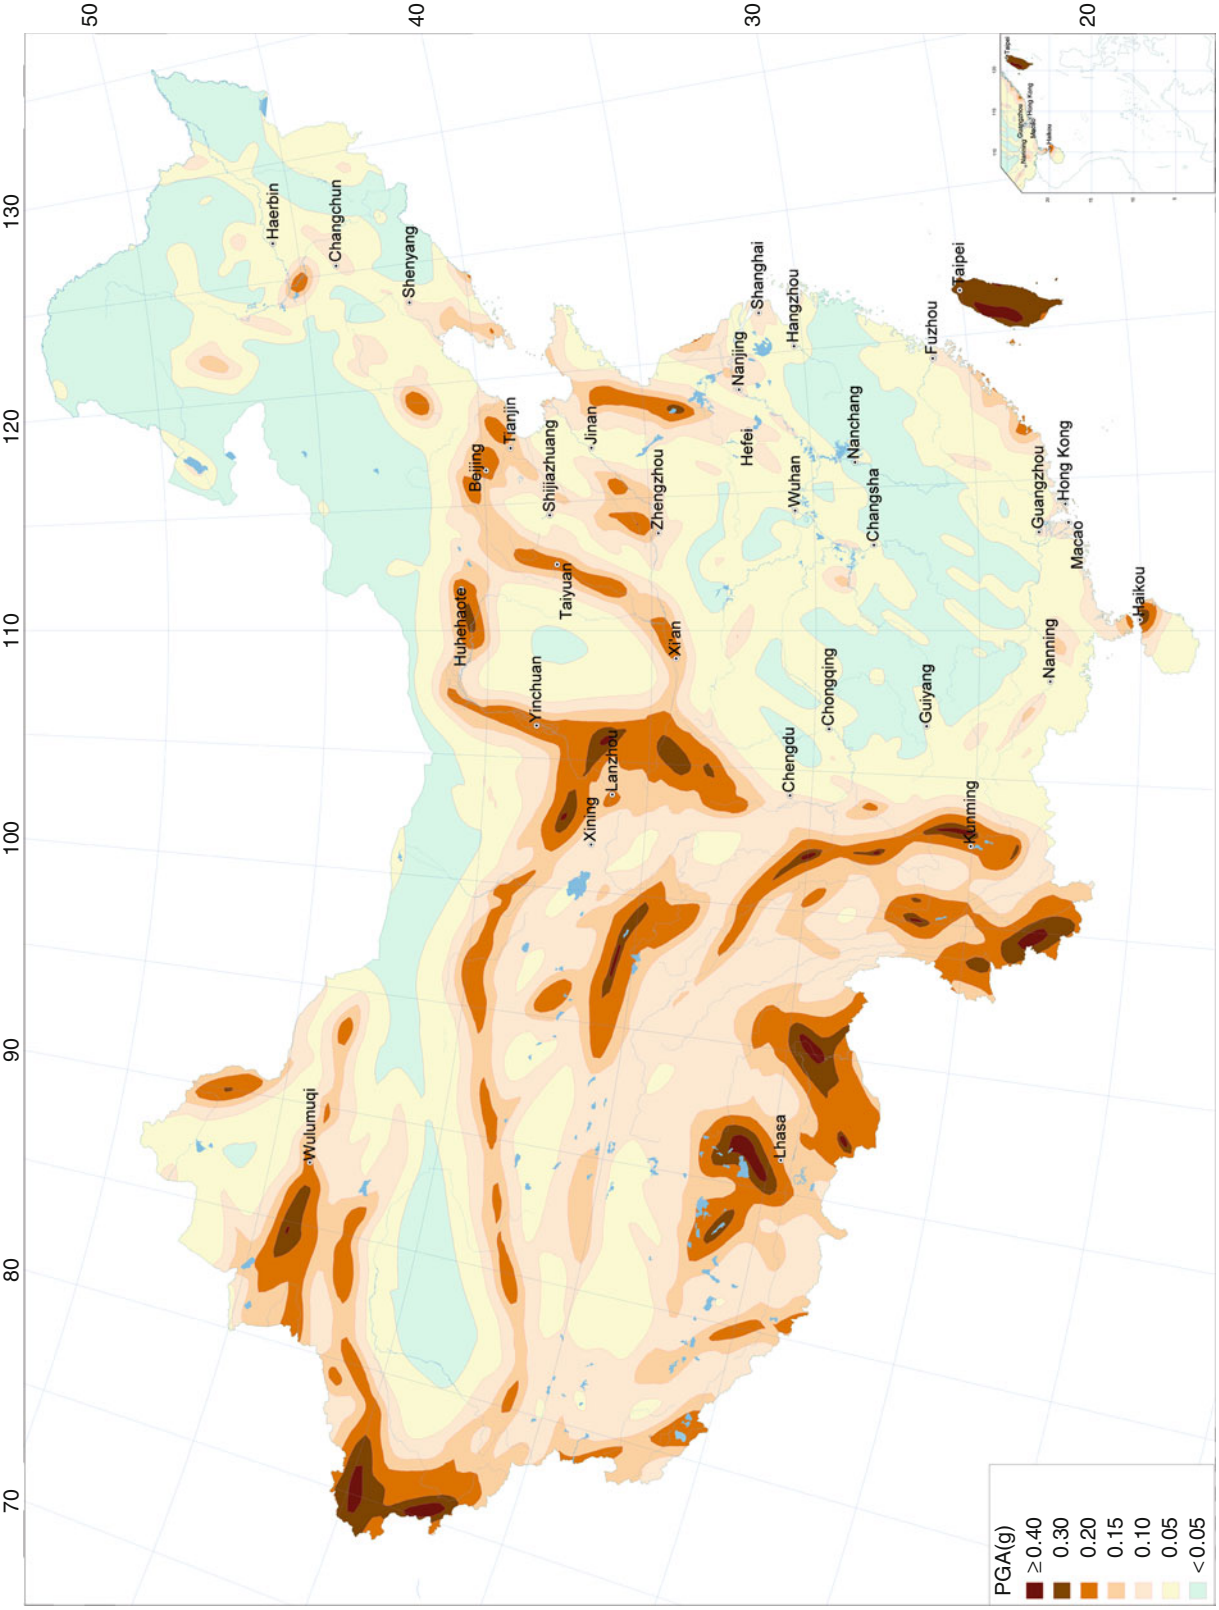
$$Sa(T) = 2.5a \begin{cases} 6T + 0.4 & 0 \le T < 0.1 \\ 1 & 0.1 \le T < Tg \\ Tg/T & T \ge Tg \end{cases} \quad (2)$$

where a is PGA in g, T is the natural period in second.

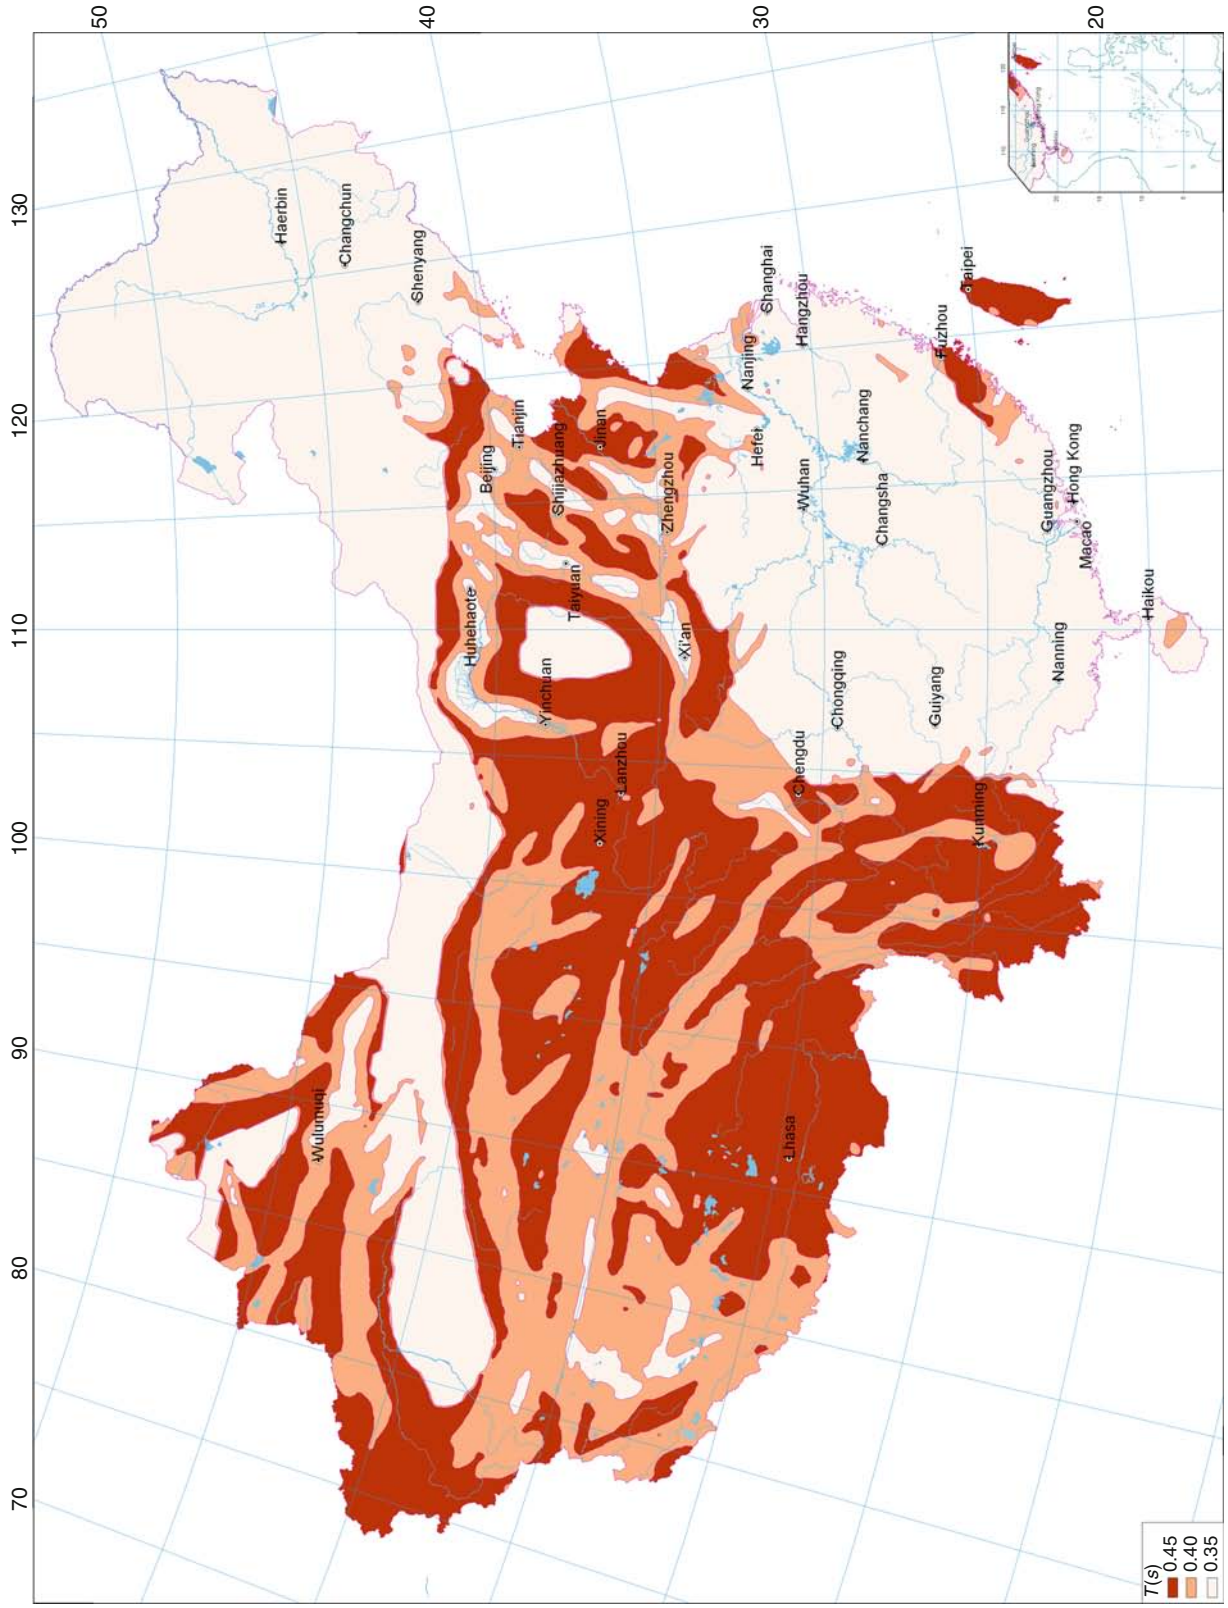
In the acceleration map (Figure 4), the territory is divided into seven zones. The acceleration for the seven zones are 0.05, 0.05, 0.10, 0.15, 0.20, 0.30, and $\geq$0.40 g, respectively.



Seismic Zonation, Figure 3 One of the seismic potential source set used in developing national seismic zonation of China (2001).



Seismic Zonation, Figure 4 Illustration of acceleration zonation map of China.



Seismic Zonation, Figure 5 Illustration of characteristic period of seismic response spectrum zonation map of China.

Seismic Zonation, Table 1 Tg value for different soil conditions (unit: second)

Zone	Soil conditions			
	Hard	Medium hard	Medium soft	Soft
1	0.25	0.35	0.45	0.65
2	0.30	0.40	0.55	0.75
3	0.35	0.45	0.65	0.90

In the characteristic period zoning map (Figure 5), the territory of China is divided into three zones. Zone 1 is the region with Tg = 0.35 s, zone 2 with Tg = 0.40 s, and zone 3 with Tg = 0.45 s.

For different soil conditions, the Tg value should be adjusted as Table 1, but the PGA value does not change with soil conditions.

The new national seismic zonation map of China serves as the obliged state standard, which took into effect in August 1, 2001. For the ordinary new constructed buildings, the standard must be followed.

Summary

Seismic zonation is a process of estimation of the seismic hazard in terms of parameters of ground motion for a certain area. Assessment results in seismic zonation map compilation, which reflects territorial distribution of the seismic hazard (see *Seismic Hazard*). Seismic zonation map is useful for hazard reduction such as earthquake-resistant design of structures, risk analysis, land-use planning, etc. Many countries apply seismic hazard maps in anti-seismic codes. Recently, the probabilistic seismic hazard analysis method is more commonly used in compiling seismic zonation map. The seismic zonataion maps take the exceeding probability of 10% within 50 years (return period 475 years) as standard. Seismic zonation will develop with the development of seismic hazard assessment methodology and anti-seismic policy.

Definition

Seismic noise: permanent motion of the Earth surface that is not related to earthquakes or specific controlled sources.

Introduction

Traditional observational methods in seismology are based on earthquake records. It results in two main shortcomings. First, most techniques are based on waves emitted by earthquakes that occurred only in geologically active areas, mainly plate boundaries. This results in a limited resolution in all other areas where earthquakes are not present. Second, the repetition of earthquakes is rare, preventing the study of continuous changes within active structures such as volcanoes or faults.

Also at smaller scales in the context of geophysics prospecting, the resolution is limited by the number and power of sources, making it difficult to image large areas and/or deep structures. Similarly, reproducible sources

are necessary for time-lapse monitoring leading to long-duration surveys that are difficult to achieve.

Nowadays, the seismic networks are producing continuous recordings of the ground motion. These huge amounts of data consist mostly of so called seismic noise, a permanent vibration of the Earth due to natural or industrial sources. Passive seismic tomography is based on the extraction of the coherent contribution to the seismic field from the cross-correlation of seismic noise between station pairs.

As described in many studies where noise has been used to obtain the Green's function between receivers, coherent waves are extracted from noise signals even if, at first sight, this coherent signal appears deeply buried in the local incoherent seismic noise. Recent studies on passive seismic processing have focused on two applications, the noise-extracted Green's functions associated to surface waves leads to subsurface imaging on scales ranging from thousands of kilometers to very short distances; on the other hand, even when the Green's function is not satisfactorily reconstructed from seismic ambient noise, it has been shown that seismic monitoring is feasible using the scattered waves of the noise-correlation function.

Theoretical basis for the interpretation of noise records at two stations

Passive seismology is an alternative way of probing the Earth's interior using noise records only. The main idea is to consider seismic noise as a wave field produced by randomly and homogeneously distributed sources when averaged over long time series. In this particular case, cross-correlation between two stations yields the Green's function between these two points. In the case of a uniform spatial distribution of noise sources, the cross-correlation of noise records converges to the complete Green's function of the medium, including all reflection, scattering, and propagation modes. However, in the case of the Earth, most of ambient seismic noise is generated by atmospheric and oceanic forcing at the surface. Therefore, the surface wave part of the Green's function is most easily extracted from the noise cross-correlations. Note that the surface waves are the largest contribution of the Earth response between two points at the surface.

Historically speaking, helioseismology was the first field where ambient-noise cross-correlation performed from recordings of the Sun's surface random motion was used to retrieve time-distance information on the solar surface. More recently, a seminal paper was published by Weaver and Lobkis (2001) that showed how, at the laboratory scale, diffuse thermal noise recorded and cross-correlated at two transducers fastened to one face of an aluminum sample provided the complete Green's function between these two points. This result was generalized to the case where randomization is not produced by the distribution of sources, but is provided by multiple scattering that takes place in heterogeneous media.

By summing the contributions of all sources to the correlation, it has been shown numerically that the correlation contains the causal and acausal Green's function of the medium. Cases of non-reciprocal (e.g., in the presence of a flow) or inelastic media have also been theoretically investigated. Derode et al. (2003) proposed to interpret the Green's function reconstruction in terms of a time-reversal analogy that makes it clear that the convergence of the noise-correlation function towards the Green's function is bonded to the stationary phase theorem. For the more general problem of elastic waves, one could summarize that the Green's function reconstruction depends on the equipartition condition of the different components of the elastic field. In other words, the emergence of the Green's function is effective after a sufficient self-averaging process that is provided by random spatial distribution of the noise sources when considering long-time series as well as scattering (e.g., Gouédard et al., 2008 and references herein).

Applications in seismology

For the first time, Shapiro and Campillo (2004) reconstructed the surface wave part of the Earth response by correlating seismic noise at stations separated by distances of hundreds to thousands of kilometers, and measured their dispersion curves at periods ranging from 5 s to about 150 s. Then, a first application of passive seismic imaging in California (e.g., Shapiro et al., 2005; Sabra et al., 2005) appeared to provide a much greater spatial accuracy than for usual active techniques. More recently, the feasibility of using the noise cross-correlations to monitor continuous changes within volcanoes and active faults was demonstrated (e.g., Brenguier, 2008a, b). These results demonstrated a great potential of using seismic noise to study the Earth interior at different scales in space and time. At the same time, the feasibility of both noise-based seismic imaging and monitoring in every particular case depends on spatio-temporal properties of the available noise wavefield. Therefore, a logical initial step for most of noise-based studies is to characterize the distribution of noise sources. Also, in many cases, knowledge of the distribution of the noise sources can bring very important information about the coupling between the Solid Earth with the Ocean and the Atmosphere. So far, we can identify three main types of existing seismological applications related to noise correlations: (1) studies of spatio-temporal distribution of seismic noise sources, (2) noise-based seismic imaging, and (3) noise-based seismic monitoring.

Noise source origin and distribution

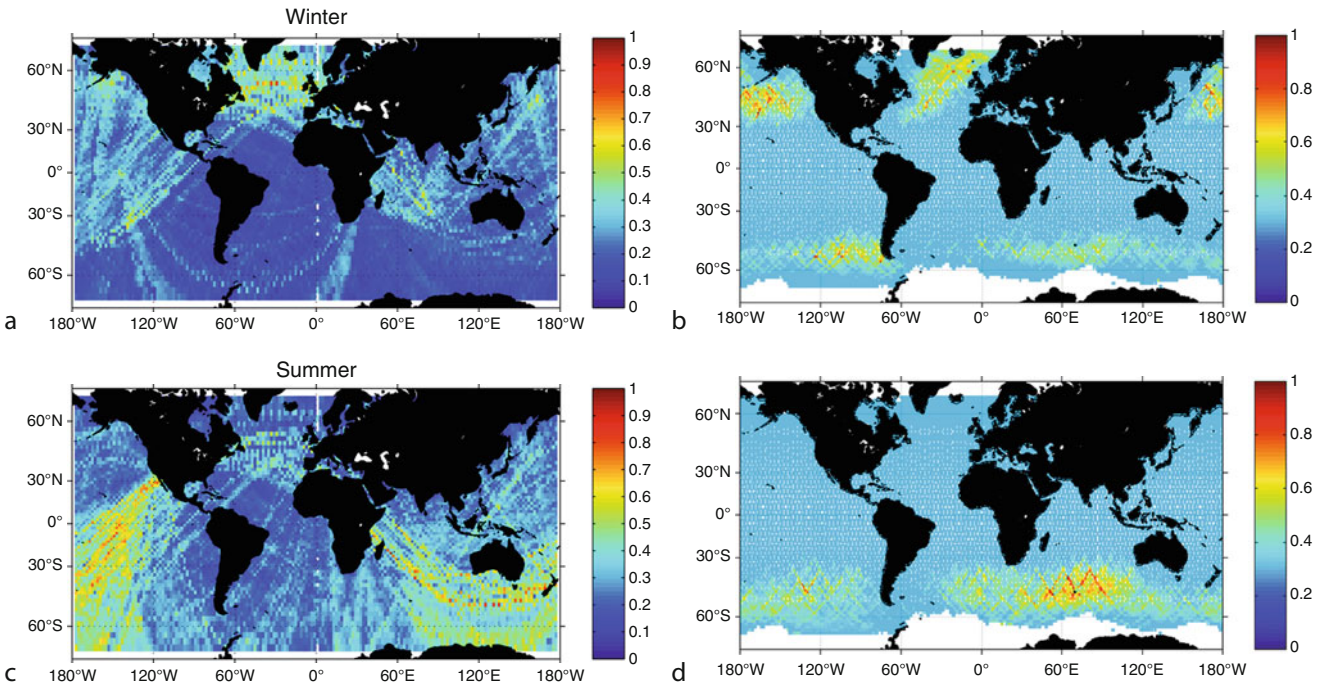
Distribution of noise sources strongly depends on the spectral range under consideration. At high frequencies (> 1 Hz), the noise is strongly dominated by local sources that may have very different origins and are often anthropogenic. At these scales, the properties of the noise wavefield should be studied separately for every particular case and no reasonable generalization can be done. At

longer periods, noise is dominated by natural sources. In particular, it is well established that two main peaks in the seismic noise spectra in so-called microseismic band (1–20 s) are related to forcing from oceanic gravity waves. It has been also argued that at periods longer than 20 s, the oceanic gravity and infragravity waves play a major role in the seismic noise excitation. The interaction between these oceanic waves and the solid Earth is governed by a complex non-linear mechanism (Longuet-Higgins, 1950) and, as a result, the noise excitation depends on many factors such as the intensity of the oceanic waves but also the intensity of their interferences as well as the seafloor topography (e.g., Kedar et al., 2008). Overall, the generation of seismic noise is expected to be strongly modulated by strong oceanic storms and, therefore, to have a clear seasonal and non-random pattern.

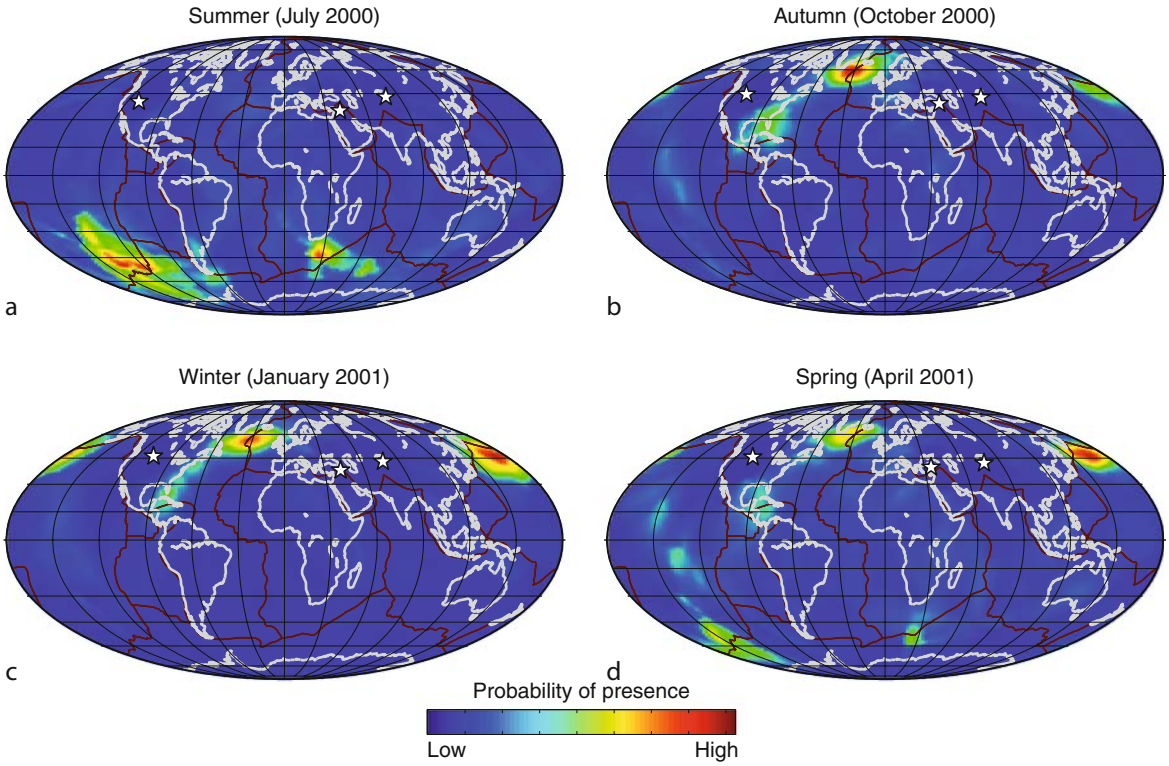
Seismic noise in the microseismic spectral band is dominated by fundamental mode surface waves. It is currently debated whether the surface wave component of microseisms is generated primarily along coastlines or if it is also generated in deep-sea areas. Inhomogeneous distribution and seasonality of microseismic noise sources is clearly revealed by the amplitude of the Rayleigh wave reconstructed in noise cross-correlations (e.g., Stehly et al., 2006) as shown in Figure 1. At the same time, body waves were detected in the secondary microseismic band and can be sometimes associated with specific storms. Figure 2 shows that sources of microseismic P waves are located in specific areas in deep ocean and exhibit strong seasonality as determined from the analysis of records by dense seismic networks (Landes et al., 2010).

Noise-based seismic imaging

Numerous studies has demonstrated that, when considered over sufficiently long times, the noise sources become sufficiently well distributed over the Earth's surface and that dispersion curves of fundamental mode surface waves can be reliably measured from correlations of seismic noise at periods between 5 and 50 s for most of interstation directions. This led to the fast development during recent years of the ambient-noise surface wave tomography. It consists of computing cross-correlations between vertical and horizontal components for all available station pairs followed by measuring group and phase velocity dispersion curves of Rayleigh and Love waves (e.g., Bensen et al., 2007). This dispersion curves are then regionalized (e.g., Lin et al., 2009) and inverted to obtain three-dimensional distribution of shear velocities in the crust and the uppermost mantle. After first results obtained in southern California (Shapiro et al., 2005; Sabra et al., 2005), this method has been applied with many regional seismological networks (e.g., Yao et al., 2006; Lin et al., 2007; Yang et al., 2008a). At smaller scales, it can be used



Seismic, Ambient Noise Correlation, Figure 1 Comparison between seasonal variations of the location of seismic noise sources and significant wave height. (**a**) and (**c**) Geographical distribution of the apparent source of the Rayleigh waves detected in the 10–20 s noise cross correlations during the winter and the summer, respectively. (**b**) and (**d**) Global distribution of the square of wave height measured by TOPEX/Poseidon during the winter and the summer, respectively (From Stehly et al., 2006).

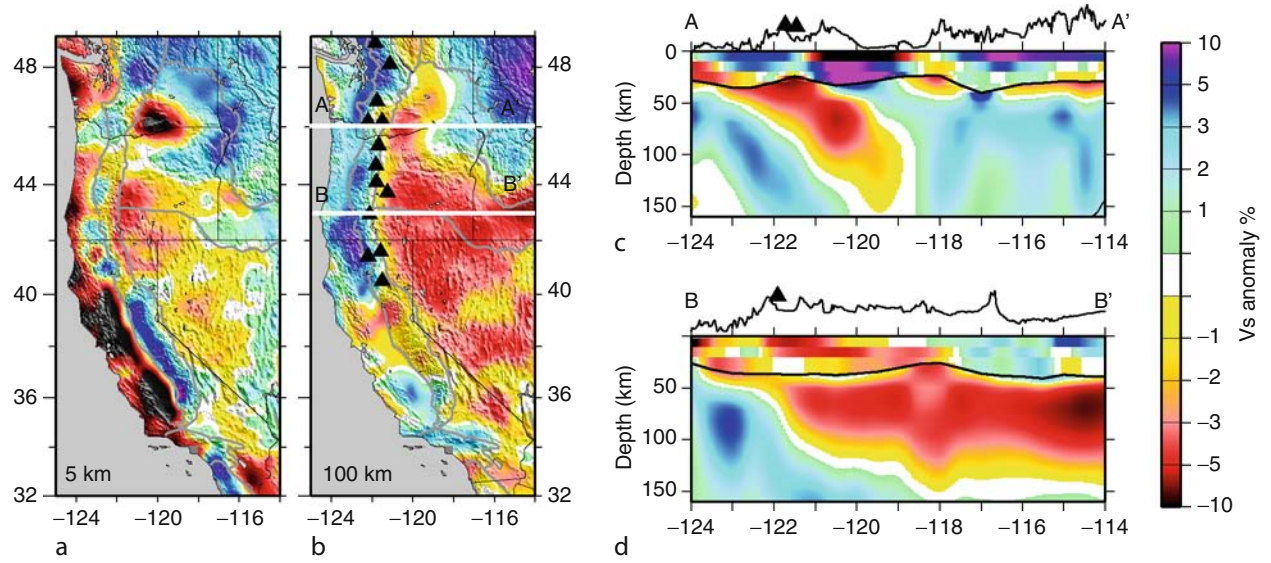


Seismic, Ambient Noise Correlation, Figure 2 Seasonal variation of the location of P-wave seismic noise sources in the secondary microseismic band (0.1–0.3 Hz) determined from the analysis of records at the three seismic networks indicated with white stars (From Landes et al., 2010).

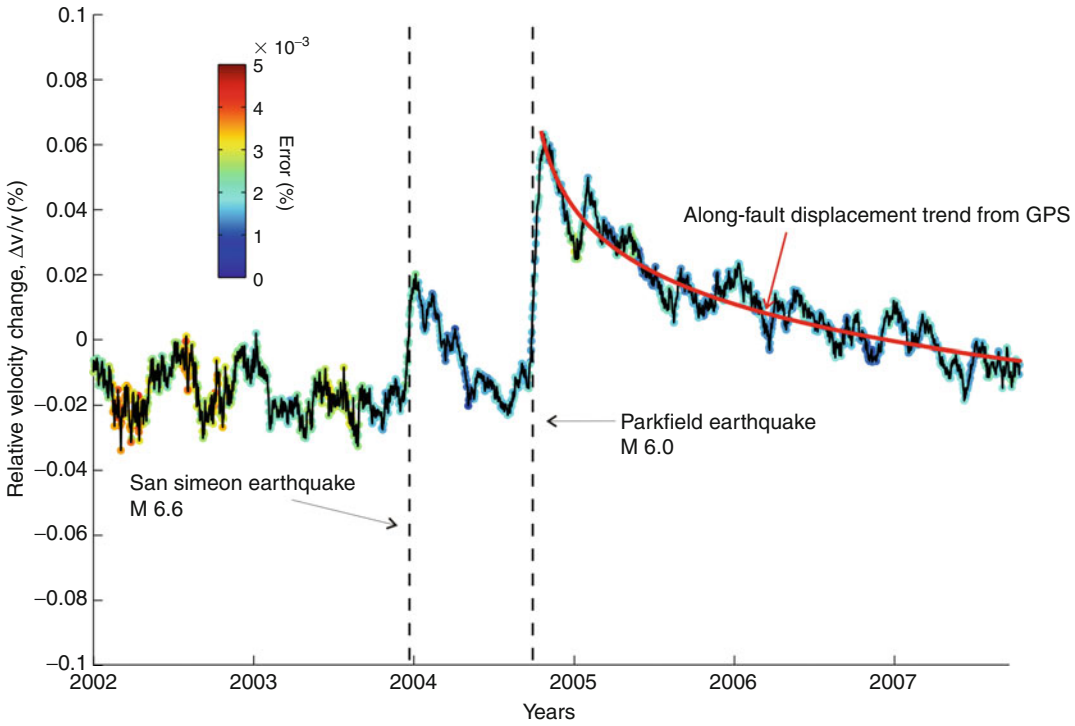
to study shallow parts of volcanic complexes (e.g., Brenguier et al., 2007). The ambient-noise surface wave tomography is especially advantageous in context of dense continent-scale broadband seismic networks such as available in USA (e.g., Moschetti et al., 2007; Yang et al., 2008b) and Europe (e.g., Stehly et al., 2009). At these scales, noise-based imaging can be used to obtain high-resolution information about the crustal and the upper mantle structure including seismic anisotropy (e.g., Moschetti et al., 2010) and can be easily combined with earthquake-based measurements to extend the resolution to larger depths (e.g., Yang et al., 2008b). An example of results obtained from combined noise and earthquakes based surface wave tomography in western USA is shown in Figure 3.

Noise-based monitoring

One of the advantages of using continuous noise records to characterize the earth materials is that a measurement can easily be repeated. This led recently to the idea of a continuous monitoring of the crust based on the measurements of wave speed variations. The principle is to apply a differential measurement to correlation functions, considered as virtual seismograms. The technique developed for repeated earthquakes (doublets), proposed by Poupinet et al., 1984, can be used with correlation functions. In a seismogram, or a correlation function, the delay accumulates linearly with the lapse time when the medium undergoes a homogeneous wave speed change, and a slight change can be detected more easily when considering late arrivals. It was therefore reasonable, and often necessary, to use coda waves for the measurements of temporal changes. Noise-based monitoring relies on the autocorrelation or cross-correlation of seismic noise records (Sens-Schönfelder and Wegler, 2006; Brenguier et al., 2008a, b). When data from a network are available, using cross-correlation take advantage of the number of pairs with respect to the number of stations. It is worth noting that the use of the coda of the correlation functions is also justified by the fact that its sensitivity to changes in the origin of the seismic noise is much smaller than the sensitivity of the direct waves. Several authors noted that an anisotropic distribution of sources leads to small errors in the arrival time of the direct waves, which can be evaluated quantitatively (e.g., Weaver et al., 2009). While in most of the cases, they are acceptable for imaging, they can be larger than the level of precision required when investigating temporal changes. The issue of the nature of the tail (coda) of the cross-correlation function is therefore fundamental and was analyzed by Stehly et al. (2008). These authors showed that it contains at least partially the coda of the Green function, i.e., physical arrivals which



Seismic, Ambient Noise Correlation, Figure 3 Shear-velocity structure of the crust and the upper mantle obtained from the inversion of the USArray data. Black lines outline the Moho. Topography is superimposed above individual cross sections. The black triangles represent active volcanoes in the Cascade Range (From Yang et al., 2008b).



Seismic, Ambient Noise Correlation, Figure 4 Relative seismic velocity change during 6 years measured from continuous noise correlations in Parkfield. The dashed lines indicated two major earthquakes: the San Simeon event that occurred 80 km from Parkfield and the local Parkfield event (Modified from Brenguier et al., 2008b).

kinematics is controlled by the wave speeds of the medium. It can therefore be used for monitoring temporal changes. As an illustration of the capability of this approach, we present in Figure 4 a measure of the average wave speed change during a period of 6 years in the region of Parkfield, California. Two main events occurred in this region during the period of study: the 2003 San Simeon and 2004 Parkfield earthquakes. In both cases, noise-based monitoring indicates a co-seismic speed drop. The measured relative variations of velocity before de San Simeon earthquake are as small as 10^{-4}. The changes of velocity associated with earthquakes are associated with at least two different physical mechanisms: (1) the damage induced by the strong ground motions in shallow layers and fault zone, as illustrated by the co-seismic effect of the distant San Simeon event, and (2) co-seismic bulk stress change followed by the post-seismic relaxation, as shown with the long-term evolution after the local Parkfield event, similar in shape to the deformation measured with GPS.

Summary

Continuous recordings of the Earth surface motion by modern seismological networks contain a wealth of information on the structure of the planet and on its temporal evolution. Recent developments shown here make it possible to image the lithosphere with noise only and to detect temporal changes related to inner deformations.

Definition

Seismic migration. A set of techniques for transforming recorded (elastic-wave) seismic reflection data into an image of reflecting boundaries in the earth's interior. In simplest form, these are intended to correct certain distortions present in recorded wavefields. The distortions can be caused by: diffractors inside the earth, which scatter the incident energy to a range of receiver locations; geometric effects caused by dipping reflectors; and velocity effects, which cause the seismic waves to change direction as they propagate from source to reflector to receiver. Migration is also used to estimate seismic velocity and to provide amplitudes for rock property analysis.

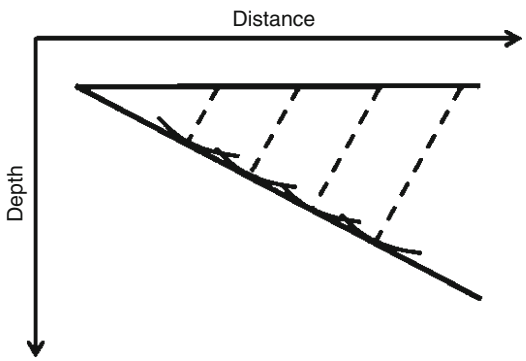
The migration heuristic assumes that subsurface reflectors are made up of point diffractors (Trorey, 1970). The response of a reflector to input seismic energy is the sum of responses to all the diffractors, and migration transforms this response to the actual reflector shape by collapsing each diffractor response to a point (diffraction stack).

History

Mapping using pencil and paper; mechanical migration

The first migrations were performed in the 1920s as a manual operation. A single-fold reflection profile was acquired with sources and receivers on the surface of the earth, and two-way travel times for events from a shallow dipping reflector were picked on the recorded traces. The extent of the lateral offset between source and receiver locations was neglected, which is equivalent to assuming that sources and receivers were colocated, or at zero offset. Then circular arc segments were drawn, centered at the source-receiver midpoints and with radii equal to one-half the product of the picked travel times and the velocity of propagation in the overburden. The envelope of these mapped arcs gave a rough picture of the reflecting interface (Figure 1).

This technique reveals principles and problems of migration. First, reflection events move sideways, or *migrate*, from their picked time locations on the recording surface (the source-receiver midpoints) to subsurface locations at the reflection interface. When reflectors in the earth are not flat, the lateral position of a subsurface reflector is different from that of the recording location of the same event. Second, the assumption of colocated sources and receivers is problematic. As the use of seismic data increased, reflection profiles were typically acquired using higher fold, or multiplicity: for each source, a spread of many receivers recorded reflection data in order to provide a greater multiplicity of observations. Some of the receivers were a considerable distance from the source locations, violating the zero-offset assumption. Later, the common-midpoint (CMP) stack (Mayne, 1962) performed approximate corrections intended to shift each event on a nonzero-offset recorded trace to its zero-offset time, once again allowing the use of the zero-offset assumption in migration (poststack migration). In areas of complicated geologic structure, however, the time corrections used in the CMP stacking process are not accurate, requiring that each recorded trace be migrated using its actual source and receiver location (prestack migration). Third, if more than one reflector exists inside the earth, the various migrated events can interfere with one another as the circular arcs that build up their envelopes overlap. This problem is solved by the more recent application of wave theory to migration. This allows the



Seismic, Migration, Figure 1 Schematic illustration of early pencil-and-paper migration. Assuming constant velocity and zero-offset source and receiver, an event on a seismic trace is swung out along an arc of a circle. Repeating this for the corresponding event on all traces produces an image of a reflector, which lies along the envelope of all the arcs.

rigorous migration of waveforms, with energy buildup near reflector locations, and energy cancellation away from reflector locations. Fourth, if the velocity used in the migration process is incorrect, the image of a subsurface reflector will be located incorrectly. This fundamental velocity problem persists today.
