ENCYCLOPEDIA of SOLID EARTH GEOPHYSICS

Edited by
Harsh K. Gupta

Springer

ENCYCLOPEDIA of EARTH SCIENCES SERIES

ENCYCLOPEDIA *of* SOLID EARTH GEOPHYSICS

Encyclopedia of Earth Sciences Series

ENCYCLOPEDIA OF SOLID EARTH GEOPHYSICS

Aims of the Series
The *Encyclopedia of Earth Sciences Series* provides comprehensive and authoritative coverage of all the main areas in the Earth Sciences. Each volume comprises a focused and carefully chosen collection of contributions from leading names in the subject, with copious illustrations and reference lists.

These books represent one of the world's leading resources for the Earth Sciences community. Previous volumes are being updated and new works published so that the volumes will continue to be essential reading for all professional earth scientists, geologists, geophysicists, climatologists, and oceanographers as well as for teachers and students. See the dustjacket of this volume for a current list of titles in the *Encyclopedia of Earth Sciences Series*. Go to http://www.springerlink.com/reference-works/ to visit the "Earth Sciences Series" online.

About the Series Editor
Professor Charles W. Finkl has edited and/or contributed to more than eight volumes in the Encyclopedia of Earth Sciences Series. For the past 25 years he has been the Executive Director of the Coastal Education & Research Foundation and Editor-in-Chief of the international *Journal of Coastal Research*. In addition to these duties, he is Research Professor at Florida Atlantic University in Boca Raton, Florida, USA. He is a graduate of the University of Western Australia (Perth) and previously worked for a wholly owned Australian subsidiary of the International Nickel Company of Canada (INCO). During his career, he acquired field experience in Australia; the Caribbean; South America; SW Pacific islands; southern Africa; Western Europe; and the Pacific Northwest, Midwest, and Southeast USA.

Founding Series Editor
Professor Rhodes W. Fairbridge (deceased) has edited more than 24 Encyclopedias in the Earth Sciences Series. During his career he has worked as a petroleum geologist in the Middle East, been a WW II intelligence officer in the SW Pacific and led expeditions to the Sahara, Arctic Canada, Arctic Scandinavia, Brazil and New Guinea. He was Emeritus Professor of Geology at Columbia University and was affiliated with the Goddard Institute for Space Studies.

Preface

All information about the Earth's interior comes from field observations and measurements made within the top few kilometers of the surface, from laboratory experiments and from the powers of human deduction, relying on complex numerical modeling. Solid Earth Geophysics encompasses all these endeavors and aspires to define and quantify the internal structure and processes of the Earth in terms of the principles of physics, corresponding mathematical formulations and computational procedures. The role of Solid Earth Geophysics has gained prominence with increasing recognition of the fact that knowledge and understanding of Earth processes are central to the continued well being of the global community. Apart from persistent search for natural resources, this research line is linked to basic investigations regarding the mutual relationships between climate and tectonics and on the effects of global change in terms of a wide spectrum of natural hazards. Consequently, the pursuit of this science has seen spectacular progress all over the world in recent decades, both in fundamental and applied aspects, necessarily aided by advancements in allied fields of science and technology.

The ***Encyclopedia of Solid Earth Geophysics***, aims to serve as a comprehensive compendium of information on important topics of Solid Earth Geophysics and provide a systematic and up-to-date coverage of its important aspects including primary concepts as well as key topics of interest. It, however, does not claim to chronicle each and every niche area that in reality is a part of this multidisciplinary and multi-faceted science. Neither does it attempt to describe the basic physics of matter and energy systems, which comprise the underlying tenets of geophysical research. The first edition of this Encyclopedia, edited by Prof. David James, was published in 1989 by the Van Nostrand Reinhold publishing company. The extraordinary growth and diversification of this science over the last twenty years called for a complete revision. This is realized by identifying the necessary topics and bringing together over 200 articles covering established and new concepts of Geophysics across the sub-disciplines such as Gravity, Geodesy, Geoelectricity, Geomagnetism, Seismology, Seismics, Deep Earth Interior and Processes, Plate Tectonics, Geothermics, Computational Methods, etc. in a consistent format. Exceptional Exploration Geophysics and Geotechnical Engineering topics are included for the sake of completeness. Topics pertaining to near Earth environs, other than the classical 'Solid Earth', are not within the scope of this volume as it is felt that the growth of knowledge in these fields justify a dedicated volume to cover them.

Articles written by leading experts intend to provide a holistic treatment of Solid Earth Geophysics and guide researchers to more detailed sources of knowledge should they require them. As basic understanding and application of Solid Earth Geophysics is essential for professionals of many allied disciplines such as Civil Engineering; Environmental Sciences; Mining, Exploration and software industries; NGOs working on large scale social agenda; etc., it would be useful to them to have access to a ready and up-to-date source of knowledge on key topics of Solid Earth Geophysics. Hopefully, this Encyclopedia would prove to be an authoritative and current reference source with extraordinary width of scope, drawing its unique strength from the expert contributions of editors and authors across the globe.

I am grateful to Anny Cazenave, Kusumita Arora, Bob Engdahl, Seiya Uyeda, Rainer Kind, Ajay Manglik, Kalachand Sain and Sukanta Roy, members of the Editorial Board for their constant advice and guidance in developing the framework of this Encyclopedia and help with the editorial work. I am equally grateful to all the authors who readily agreed to contribute and honoured the guidelines and time schedule.

Petra van Steenbergen, Sylvia Blago, Simone Giesler and D. Nishantini from Springer were very co-operative. It has been a pleasure working with Springer. Ms M. Uma Anuradha provided extraordinary assistance in the preparation of this volume. My wife Manju and daughters Nidhi & Benu supported me through the entire project.

Harsh K. Gupta
(Editor-in-Chief)

Acknowledgments

The manuscripts went through several iterations during their development and at each stage the manuscripts were carefully reviewed by well known experts in their respective fields. The following have graciously spent their valuable time in reviewing one or more articles:

A

ABSOLUTE AGE DETERMINATIONS: RADIOMETRIC

Richard W. Carlson
Department of Terrestrial Magnetism, Carnegie Institution of Washington, Washington, DC, USA

Definition

Radiometric dating uses the decay of naturally occurring radioactive elements to determine the absolute age of geologic events.

Introduction

Time is an essential datum in geology. Some geological processes, particularly those responsible for generating natural hazards, occur over time intervals that can be measured with conventional clocks. Most geologic processes, however, occur on timescales beyond human experience – thousands, millions, and even billions of years (see *Continental Drift*; *Continental Rifts*; *Geodynamics*; *Lithosphere, Continental*; *Paleomagnetism, Magnetostratigraphy*; *Paleoseismology*; *Plate Tectonics, Precambrian*). For these, the chronometer of choice is radiometric dating, where the decay of naturally occurring radioactive elements is translated into time (Dickin, 2005; Faure and Mensing, 2005). In its application to geochronology, the most important aspect of radioactive decay is that it occurs at a known, constant rate, independent of environmental factors such as changing temperature and pressure, at least within the ranges of these parameters found outside the interior of stars.

Only 10 years after the discovery of radioactivity, the renowned physicist Ernest Rutherford measured the amount of helium in a uranium ore and derived an age of 500 million years for the ore (Rutherford, 1906). By 1913, radioactive dating of rocks had made important inroads into geologic investigations of Earth history (Holmes, 1913). The discovery of isotopes, also in 1913, and the improvement of the instruments used to measure their abundance (mass spectrometers) over the next decades, allowed radioactive dating to be applied to an increasingly broad range of natural materials, and hence, geologic processes. This, in turn, facilitated the transition of isotopic measurements from physics to geology departments and established radiometric geochronology as a tool of widespread use in the geosciences in the years following World War II.

Radioactivity and the systematics of its use as a chronometer

Radiometric dating is based on the principle of nuclear transmutation, common to alchemy. Some elements have isotopes whose nuclei contain an unstable number of neutrons and protons. The instability is most often remedied by the ejection of material from the nucleus. Alpha decay involves the ejection of two protons and two neutrons (a 4-helium (^{4}He) nucleus or alpha particle). Beta decay occurs through loss of an electron from the nucleus, turning a neutron into a proton. Another form of radioactive decay involves the capture of an electron from those surrounding the nucleus, turning a proton into a neutron. All forms of radioactive decay also release energy, and are thus a heat source in Earth's interior (see *Radiogenic Heat Production of Rocks*; *Energy Budget of the Earth*). The result of radioactive decay is that an isotope of one element is transformed into an isotope of another element. While the path from lead to gold does not occur naturally, if one waits long enough, radioactive decay will eventually transform all uranium and thorium into lead.

Table 1 lists the major radioactive nuclides that have been used for dating various geologic events. Naturally

Absolute Age Determinations: Radiometric, Table 1 Radioactive elements commonly used for absolute age determinations

Parent isotope	Production mechanism	Daughter isotope	Half-Life (Million years)
7-Berylium (^{7}Be)	Cosmogenic	7-Lithium (^{7}Li)	53 days
210-Lead (^{210}Pb)	Uranium decay	210-Bismuth (^{210}Bi)	22.3 years
226-Radium (^{226}Ra)	Uranium decay	222-Radon (^{222}Rn), ^{4}He	1,622 years
14-Carbon (^{14}C)	Cosmogenic, Bomb	14-Nitrogen (^{14}N)	5,730 years
231-Protactinium (^{231} Pa)	Uranium Decay	227-Thorium (^{227}Th), ^{4}He	0.033
234-Uranium (^{234}U)	Uranium Decay	230-Thorium (^{230}Th), ^{4}He	0.25
36-Chlorine (^{36}Cl)	Cosmogenic, Bomb	36-Argon (^{36}Ar)	0.31
26-Aluminum (^{26}Al)	Cosmogenic, Stellar	26-Magnesium (^{26} Mg)	0.73
230-Thorium (^{230}Th)	Uranium Decay	226-Radium (^{226}Ra), ^{4}He	0.75
60-Iron (^{60}Fe)	Stellar	60-Nickel (^{60}Ni)	1.5
10-Berylium (^{10}Be)	Cosmogenic, Stellar	10-Boron (^{10}B)	1.6
53-Manganese (^{53}Mn)	Cosmogenic, Stellar	53-Chromium (^{53}Cr)	3.7
107-Paladium (^{107}Pd)	Stellar	107-Silver (^{107}Ag)	6.5
182-Hafnium (^{182}Hf)	Stellar	182-Tungsten (^{182} W)	9
129-Iodine (^{129}I)	Stellar, Cosmogenic	129-Xenon (^{129}Xe)	15.7
244-Plutonium (^{244}Pu)	Stellar	Various fission products	80
146-Samarium (^{146}Sm)	Stellar	142-Neodymium (^{142}Nd)	103
235-Uranium (^{235}U)	Stellar	207-Lead (^{207}Pb), ^{4}He	704
40-Potassium (^{40} K)	Stellar	40-Argon (^{40}Ar) 40-Calcium (^{40}Ca)	1,270
238-Uranium (^{238}U)	Stellar	206-Lead (^{206}Pb), ^{4}He	4,469
232-Thorium (^{232}Th)	Stellar	208-Lead (^{208}Pb), ^{4}He	14,010
176-Lutetium (^{176}Lu)	Stellar	176-Hafnium (^{176}Hf)	35,700
187-Rhenium (^{187}Re)	Stellar	187-Osmium (^{187}Os)	41,600
87-Rubidium (^{87}Rb)	Stellar	87-Strontium (^{87}Sr)	48,800
147-Samarium (^{147}Sm)	Stellar	143-Neodymium (^{143}Nd), ^{4}He	106,000
190-Platinum (^{190}Pt)	Stellar	186-Osmium (^{186}Os)	450,000

occurring radioactive isotopes are produced through four mechanisms:

1. Stellar nucleosynthesis where the very high temperatures and pressures present in stellar interiors fuse nuclei, creating new elements (Truran and Heger, 2005).
2. Some radioactive elements decay into other radioactive elements. For example, 238-uranium requires eight alpha decays and six beta decays before it reaches stable 206-lead. Along the way, the decay steps include some isotopes with long enough decay lives to be useful in geochronology. These include ^{234}U, ^{230}Th, ^{226}Ra, ^{222}Rn, and ^{210}Pb.
3. High-energy cosmic ray particles collide with atoms in Earth's atmosphere or surface rocks with enough energy to cause nuclear reactions. For example, 14-carbon is created when 14-nitrogen in the atmosphere captures a neutron released by a cosmic ray interaction with some other atom. Other cosmic-ray-produced nuclides include ^{10}Be and ^{26}Al that are made by spallation, which occurs when an energetic cosmic ray proton simply breaks off a fragment from the nucleus of an atom with which it collides. Radioactive isotopes produced in these reactions are known as cosmogenic isotopes.
4. Above-ground detonations of nuclear bombs introduced into the environment substantial quantities of a number of radioactive species that have been used to investigate a number of atmosphere – Earth's surface exchange processes, and for tracing ocean water circulation.

The probability that a radioactive isotope will decay over any time interval is described by the equation:

$$-dN/dt = \lambda N \quad (1)$$

where N is the number of atoms of the radioactive species (parent isotope), t is time, and λ is the rate constant of the decay. Rate constants often are converted to "half-life"; the time needed for half of the radioactive species to decay. The half-life of a radioactive species is equal to ln(2)/λ. Integrating Equation 1 gives:

$$N = N_0 e^{-\lambda t} \quad (2)$$

where N_0 is the number of atoms present when t = 0. This equation can be used to determine ages if one has independent information on the initial abundance of the parent isotope. For example, in ^{14}C dating, if one assumes that the ratio of ^{14}C to stable ^{12}C is constant in the atmosphere, then one need only measure the present day ^{14}C/^{12}C ratio in a material that obtained its carbon from the atmosphere and use Equation 2 in order to determine the material's age. The assumption of a constant atmospheric ^{14}C/^{12}C

ratio is now known to be invalid because the production rate of ^{14}C in the atmosphere depends on issues as diverse as sunspot activity and the varying strength of Earth's magnetic field (see *Paleomagnetic Field Intensity*). Various schemes have been used to correct ^{14}C chronology for variations in the atmospheric ^{14}C production rate including comparison with the carbon in tree rings dated simply by counting the annual growth rings (Friedrich et al., 1999) or, for longer time intervals, to growth rings in corals dated with ^{230}Th and ^{234}U (Fairbanks et al., 2005). Although the variations in ^{14}C production rate complicate ^{14}C dating, they potentially provide information on the variability of Earth's magnetic field, or sunspot activity, and how these parameters may affect Earth's climate (Bard and Frank, 2006).

Because the initial abundance of the parent isotope generally is not known, most radioactive dating schemes measure the increase in the abundance of the decay product (daughter). If no atoms are lost, the abundance of the daughter isotope (D) increases with time at the rate described by:

$$D = N_0 - N = N\left(e^{\lambda t} - 1\right) \tag{3}$$

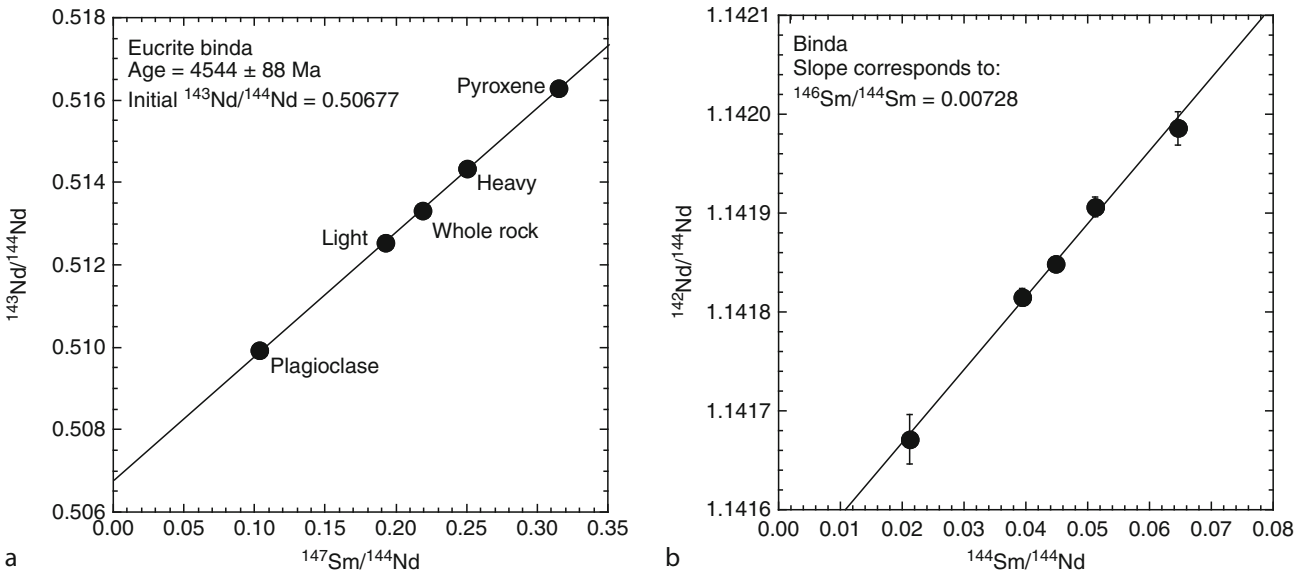
Thus, in an ideal situation where, for example, a mineral forms that contains radioactive ^{40}K, but no ^{40}Ar, the age of the mineral can be determined simply by measuring the abundance of ^{40}K (N) and ^{40}Ar (D) in the mineral after some decay interval has passed. In nature, perfect separation of parent from daughter isotope is rare, so if some atoms of the decay product are present initially (D_0), then:

$$D = D_0 + N\left(e^{\lambda t} - 1\right) \tag{4}$$

Because mass spectrometers can measure isotopic ratios of some elements to precisions of 0.0005% whereas elemental abundances can only be determined to about 0.1–1% precision, Equation 4, using the ^{238}U-^{206}Pb decay scheme as an example, can be expressed as:

$$\left(^{206}Pb/^{204}Pb\right)_m = \left(^{206}Pb/^{204}Pb\right)_0 + \left(^{238}U/^{204}Pb\right)_m\left(e^{\lambda t} - 1\right) \tag{5}$$

where "m" stands for the measured ratio and λ is the decay constant of ^{238}U. Pb-204 is a stable isotope of lead. If two or more samples with different U/Pb ratios are formed at the same time with the same initial Pb isotope composition ($(^{206}Pb/^{204}Pb)_0$), after some time has passed, plotting the measured $^{206}Pb/^{204}Pb$ for each sample against its $^{238}U/^{204}Pb$ ratio will produce a line, called an isochron, whose slope and y-intercept correspond to $(e^{\lambda t} - 1)$, and the initial $^{206}Pb/^{204}Pb$ ratio, respectively (Figure 1a). Thus, the slope of an isochron provides the time when the samples on the line had the same Pb isotope composition. The U–Pb system is unique in that it contains two isotopes of U that decay into two isotopes of Pb.



Absolute Age Determinations: Radiometric, Figure 1 Isochron diagrams for the long-lived ^{147}Sm–^{143}Nd and short-lived, now extinct, ^{146}Sm–^{144}Nd systems. The data shown are for minerals separated from the Binda eucrite, a type of meteorite that is a volcanic rock erupted on some small planetesimal. The meteorite consists primarily of the minerals plagioclase and pyroxene, which have different ratios of Sm to Nd when they form, but the same initial Nd isotopic composition. As Sm decays, it changes the isotopic composition of Nd. Using an equation similar to 5, the slope on the ^{147}Sm-^{143}Nd diagram directly provides the age of the sample, but on the ^{146}Sm-^{142}Nd diagram the slope provides the initial abundance of ^{146}Sm (actually the $^{146}Sm/^{144}Sm$ ratio as illustrated in an equation analogous to Equation 8). Data from Boyet et al. (2010).

Thus, an analogous Equation 5 can be written for the decay of ^{235}U to ^{207}Pb. More importantly, the two equations can be combined to give:

$$\frac{\left(^{207}Pb/^{204}Pb\right)_m - \left(^{207}Pb/^{204}Pb\right)_0}{\left(^{206}Pb/^{204}Pb\right)_m - \left(^{206}Pb/^{204}Pb\right)_0} = \frac{\left(^{235}U/^{238}U\right)\left(e^{\lambda_5 t} - 1\right)}{\left(e^{\lambda_8 t} - 1\right)} \quad (6)$$

where λ_5 and λ_8 are the decay constants for ^{235}U and ^{238}U, respectively. Because the $^{235}U/^{238}U$ ratio is nearly constant in nature at any given time, this equation allows an age to be determined from measurements of lead isotopic composition alone, without the need for concentration determinations of U or Pb. Such ages, called Pb–Pb ages, are obtained by plotting $(^{207}Pb/^{204}Pb)_m$ versus $(^{206}Pb/^{204}Pb)_m$, which will produce a line for two or more samples whose slope is equal to the right hand side of Equation 6. This equation can then be solved numerically to determine "t", the time when the samples formed.

A very active application of radiometric chronology uses the variety of short-lived (half-lives of 10^5–10^8 year) radionuclides that were present when the solar system formed, but have long since decayed away (Carlson and Boyet, 2009). For these systems, the "t" in Equation 2 cannot be referenced to today because $e^{-\lambda t}$ would always be close to zero. Instead, the "t" for these extinct systems must be a time interval referenced to a time when the parent isotope still existed. In this case, using the decay of ^{26}Al to ^{26}Mg as an example, Equation 5 can be rewritten as:

$$\left(^{26}Mg/^{24}Mg\right)_{\Delta t} = \left(^{26}Mg/^{24}Mg\right)_0 + \left(^{26}Al/^{27}Al\right)_0 \left(^{27}Al/^{24}Mg\right)_m e^{-\lambda \Delta t} \quad (7)$$

Plotting the two measurable parameters of this equation ($^{27}Al/^{24}Mg$, $^{26}Mg/^{24}Mg$) for two or more samples will produce a line whose slope gives not the age, but the $(^{26}Al/^{27}Al)$ at the time when the samples formed (Figure 1b). The time interval between the reference time and the time of sample formation is then:

$$\Delta t = -\left(\ln\left[\left(^{26}Al/^{27}Al\right)_{\Delta t} \Big/ \left(^{26}Al/^{27}Al\right)_0\right]\right)/\lambda \quad (8)$$

To convert these relative ages into absolute ages requires cross-calibration with a chronometer that provides absolute ages. For example, a certain type of mineral inclusion within the Allende meteorite provided a Pb–Pb age of 4567.6 ± 0.4 Ma and an Al-Mg isochron whose slope corresponds to $^{26}Al/^{27}Al = 4.96\ (\pm\ 0.25) \times 10^{-5}$ (Jacobsen et al., 2008). This provides a "pinning point" for the $^{26}Al/^{27}Al$ ratio present in the solar system at a known time. Thus, if analyses of some other sample produced an Al–Mg isochron whose slope corresponded to, for example, $^{26}Al/^{27}Al = 2.5 \times 10^{-5}$, this sample would be one half-life of ^{26}Al, or 750,000 years, younger than the other. Extinct radioactive dating systems thus provide not absolute, but relative, ages. If these relative ages are anchored to an absolute age, as done in the example above, then the extinct system can be used to indicate that the hypothetical sample mentioned above is 4566.8 million years old. A good example of the use of extinct radionuclides is the attempt to date the oldest volcanism in the solar system. Several types of meteorites are interpreted to be lavas produced on small planetesimals. One of these, the D'Orbigny meteorite, has provided Al–Mg, Mn–Cr, Hf–W, and Pb–Pb ages of 4562.8 ± 0.5 Ma, 4564.0 ± 0.6 Ma, 4562.8 ± 1.5 Ma, and 4564.42 ± 0.12 Ma, respectively. These results offer the promise of temporal precisions of 0.002% for the earliest events in solar system history.

The application of radiometric dating

The relatively simple equations given in the previous section provide the basis by which measurements of radioactive decay products can be translated into absolute ages. Applying these chronometers to natural processes requires matching the distinct properties of the many radioactive systems listed in Table 1 to the problem being investigated. Systems with short half-lives can be used to determine precise ages of geologic events only a few to a few thousand years old. Many of these short-lived nuclides are created either in the atmosphere or upper meter of Earth's surface, which makes them particularly amenable to dating a variety of near-surface processes. The concentrations of ^{10}Be or ^{26}Al in quartz in rocks or sediments can be used to date the time when the rock was exposed to cosmic rays, which can provide information on both uplift and erosion rates (von Blanckenburg, 2005) (see *Paleoseismology*). The rates of water movement from surface through subsurface aquifers can be traced with a number of radiometric chronometers (Bethke and Johnson, 2008). The presence of ^{10}Be in the lavas erupted at convergent margins tracks the subduction of surficial sediments to the 100 km + depths of magma generation (Morris, 1991) (see *Subduction Zones*). Carbon-14 is used to date a huge variety of events from the eruption of young volcanoes, movement along faults (see *Earthquakes and Crustal Deformation*; *Archaeoseismology*; *Paleoseismology*), the rates of ocean water circulation and ocean uptake of atmospheric CO_2, and the death of a living organism with its applications in archeology and paleoecology (Broecker, 2005). The longer-lived radionuclides can be applied to a wide variety of issues concerning the evolution of the solid earth, from dating the formation of crustal rocks (see also *Paleomagnetism, Magnetostratigraphy*), to determining the time of continental assembly and breakup (see *Continental Drift*; *Plates and Paleoreconstructions*), to defining the age of the Earth.

The key point in the application and proper interpretation of radiometric dating is understanding exactly what

event is being dated. What "starts" a radiometric clock is some event that changes the composition of a sample and fixes this new compositional state until the sample is dated in the laboratory. For example, ^{14}C often is used to determine the age of young volcanic eruptions. This system works in this application not by dating the rock itself, but by dating charcoal formed when the lava flowed over, and burnt, a bush or tree. What the ^{14}C age actually dates is the time when the plant stopped exchanging carbon with Earth's atmosphere. In most cases, this happened because the plant was killed by the volcanic eruption, in which case, the ^{14}C age accurately dates the eruption. However, if a 100-year-old lava flow were to flow over a 10,000-year-old bristlecone pine tree trunk lying long dead on the ground, the ^{14}C date of the charcoal would be 10,000 years, not 100 years.

The precision of a radiometric age depends on the amount radioactive decay has changed the isotopic composition of the parent or daughter element. This depends primarily on the time passed relative to the half-life of the system, and in systems where measurement of the daughter element is involved, on the degree to which parent and daughter element are fractionated from one another. Thus, one would use ^{14}C with its 5,730 year half-life to date an organic remain from ancient Rome, but it would be useless to date a million year old limestone because the ^{14}C "clock" stopped measuring time when the ^{14}C decayed away after a few half-lives into the history of the limestone. Similarly, ^{147}Sm, with a 106 billion year half-life, is used to date a variety of materials ranging in age from millions to billions of years old, but would be useless to date very young processes because only 7×10^{-15} g of ^{143}Nd is produced every thousand years per ppm of Sm, and this amount simply is too small to measure accurately.

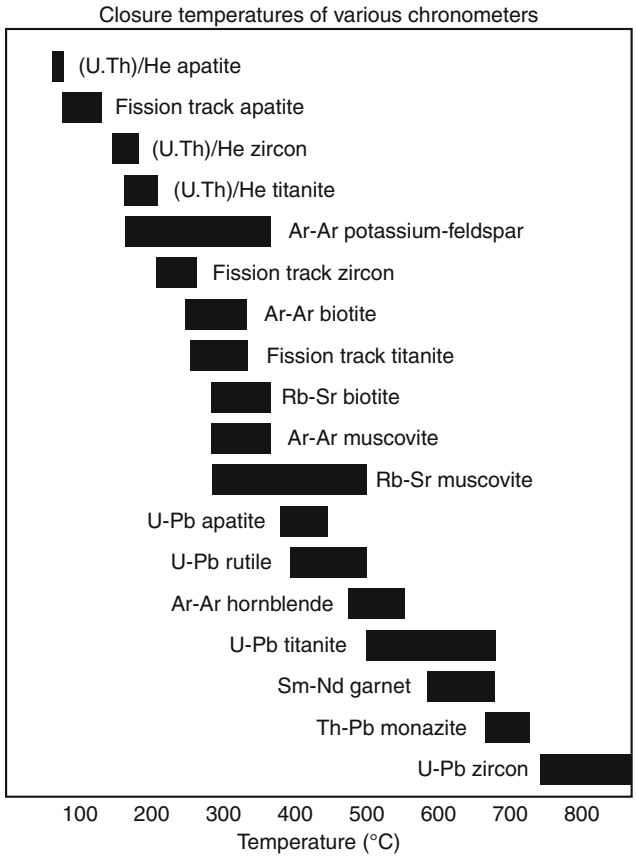
Besides choosing the proper radiometric system for the application, understanding whether a radiometric age is providing an accurate age for the event of interest demands an understanding of the processes that set, and reset, a radiometric clock. For Equation 5 to provide an accurate age demands that the samples used to construct the isochron: (1) all formed at exactly the same time, (2) all had exactly the same initial daughter isotope composition, (3) experienced no change in parent/daughter element ratio between formation of the sample and its measurement in the laboratory, and (4) nothing other than the decay of the parent modified the daughter isotopic composition. In nature, all of these requirements have the potential to fail, but, in some cases, these "failures" can still provide useful information.

A good candidate to meet the requirements above is a volcanic rock. Under conditions ideal for an accurate age, a well-mixed magma will crystallize, over a short time interval after eruption, a variety of minerals with different parent/daughter elemental ratios, but the same initial daughter isotopic composition that they inherit from the magma. Over time, if the minerals experience no chemical exchange with their surroundings, the radioactive decay products will build up allowing their measurement to provide the accurate age of eruption of this volcanic rock. The Apollo 15 basalt 15386 provides evidence that when these criteria are met, ages from many radioactive systems can agree. For this sample, the age (in billions of years) obtained from different radiometric systems are: K-Ar 3.89 ± 0.04, Rb-Sr 3.88 ± 0.01, Sm-Nd 3.85 ± 0.08, and the U–Pb age for zircon from a compositionally similar rock is 3.89.

For volcanic rocks this old, the assumption that the minerals all formed at the same time, at least relative to the ancient age of the rock, likely will be accurate. When one moves to younger volcanic systems, and the use of chronometers with better temporal resolution, the issue of the duration of crystallization becomes important. Several cases have now been presented where different minerals in the same volcanic rock give ages that range from the age of eruption to significantly older. One example is the Coso Volcanic field in California where zircons in one of the rhyolites range in age from the same as a K-Ar date on sanidine from the rhyolite, interpreted as the eruption age, to as much as 200,000 years older (Miller and Wooden, 2004). This result suggests that emplacement and crystallization of distinct magma batches in the crustal magma chamber that eventually fed this eruption is a prolonged process occurring over many thousands of years. Similar results have now been reported in many young volcanic rocks (Cooper and Reid, 2008). Although the age range of the minerals mentioned above is interpreted as reflecting a prolonged magmatic event, another way that an old crystal can get into a young magma is if a crystal from an older rock underlying the volcano is picked up by the magma during its ascent. Finding such "xenocrystic" material, particularly within more viscous, lower melting temperature, silica-rich magmas, is so common that it can be used to detect and even determine the age of older crust buried beneath a volcano, in some cases enabling the identification of older basement where none was previously known to exist (Smyth et al., 2007).

This brings up what is possibly the most insidious cause of an inaccurate radiometric age: the generally poorly-known temperature history of the sample. Because the rate of chemical diffusion within solids increases with temperature, elevated temperatures facilitate chemical changes. Heating a mineral can cause gases, such as He and Ar that are present in a crystal lattice as a result of their production through radioactive decay, to diffuse out of the crystal and escape along grain boundaries. At a temperature of 1,000°C, diffusion will cause a Sr atom in a mineral to move about 2 mm in a million years. If a small grain of a high Rb/Sr ratio mineral, such as mica, is next to a grain of a low Rb/Sr ratio, and high Sr content, mineral like plagioclase, the ingrowth of radiogenic ^{87}Sr in the mica will be diluted by diffusional exchange with the unradiogenic Sr in the plagioclase. Diffusion thus makes all radioactive chronometers "thermochronometers" that date the time when the material of interest reached a low-enough temperature to stop diffusional resetting of

the radiogenic ingrowth. Because rates of diffusion are a function both of the element that is diffusing and the structure of the crystal through which it is diffusing, different radiometric systems, and different minerals, can have different sensitivities to temperature excursions. This gives rise to the concept of "closure" or "blocking" temperature, above which the diffusion rate is too high to allow for the buildup of the radioactive decay product. In other words, the radiometric clock does not start until the mineral falls below its closure temperature. In the Coso example above, the K–Ar age obtained for the sanidine is interpreted as the eruption age because even if this mineral formed well prior to eruption, the 200–400°C closure temperature of the K–Ar system in sanidine (Figure 2) is so low that the radiogenic ^{40}Ar being produced in the sanidine was diffusing out as fast as it was being produced because of magma temperatures in the range of ~750°C.



Absolute Age Determinations: Radiometric, Figure 2 Closure temperatures for various radiometric systems in different minerals. The fission track technique counts the density of damage tracks made in crystals due to the fission of ^{238}U. Coupled with the measurement of U concentration in the crystal, the density of fission tracks can be converted into a radiometric age. Figure modified from (Pollard, 2002 – http://pangea.stanford.edu/~dpollard/NSF/main.html) which was adapted from a figure produced by P. Fitzgerald, S. Baldwin, G. Gehrels, P. Reiners, and M. Ducea.

In contrast, the closure temperature of the U–Pb system in zircon is higher than the magma temperature, so as soon as the zircon first crystallized, its U–Pb clock started to record time. Temperature-induced diffusional resetting of radiometric systems may make interpretations of ages a bit more difficult, but it creates a new field – thermochronometry – that constructs time-temperature histories for various geologic processes (Reiners and Ehlers, 2005). Though many radiometric systems can be used for thermochronometry, the oldest radiometric dating technique, the decay of U and Th to He, has been reenergized (Farley, 2002) because the low closure temperature of the U,Th – He system can be used to address geological processes such as the rate of mountain uplift or surface erosion by telling the time when a rock arrived close enough to Earth's surface to cool below the closure temperature of the radiometric clock (Reiners and Brandon, 2006).

While the appreciation and use of thermochronometry has been the primary growth field in radiometric geochronology in the last decade, other efforts are directed at finding ways to avoid reset ages. The traditional way to do this is to move to sample sizes much larger than diffusion lengths. This is the basis for "whole rock isochrons" where kilogram rock samples are homogenized and measured as an individual point on an isochron. Although this approach has produced some accurate ages, it suffers two main weaknesses. First, deciding whether all the rocks included on an isochron are the same age is not always easy, particularly for ancient, highly deformed, gneisses where this approach often is applied. Second, in order to obtain a sufficient range in parent/daughter ratio to precisely determine an isochron, compositionally distinct rocks are usually included on the isochron. Judging from modern igneous rocks, large compositional distinctions often are associated with variable initial isotope composition, which would violate the requirement that all the samples used to construct an isochron have the same initial isotope composition. Where whole rock isochrons can be useful is in detecting when much older components are involved in the genesis of younger rocks. A good example of this are the Sm-Nd data for lunar basalts where mineral isochrons of individual samples provide eruption ages generally less than 4 billion years, but the whole rock data scatter about a line corresponding to an age near 4.45 Ga (Carlson and Boyet, 2009). The precision of this older age is debatable, as is its interpretation, but it could imply that the younger basalts are made by melting source materials in the lunar interior that formed from some global differentiation event on the Moon that occurred some time near 4.45 Ga. Memory of this event was erased from the minerals in the basalts, that know only of their crystallization from the magma, but the magmas themselves may "remember" the events that led to the formation of their source materials in the lunar interior.

The other approach to avoiding thermally reset ages is to use minerals whose crystal structure allows only very slow diffusion. One curious example is diamond.

Diamond cannot be dated directly because it contains insufficient amounts of the radioactive elements, but it often contains as inclusions minerals that can be dated. Even though these minerals were formed, and have been stored, at temperatures above 1,000°C and depths greater than 150 km in the mantle (see *Lithosphere, Continental: Thermal Structure*), the encapsulation by the diamond does not allow them to communicate through diffusion with their surroundings. As a result, dating of inclusions in diamond show that diamond formation in the mantle has occurred over a good part of Earth history, with the oldest diamonds being approximately 3.5 Ga (Pearson and Shirey, 1999) (see *Lithosphere, Continental*).

By far, the most commonly used and most versatile way to avoid reset ages is with the application of the U–Pb system in zircon (Hanchar and Hoskins, 2003). The strengths of U–Pb zircon dating include: (a) very high U–Pb closure temperature, (b) resistance to chemical modification through alteration and metamorphism, (c) high U concentrations, but initially vanishingly small Pb contents, (d) the U–Pb system includes two independent decay schemes that allow tests to determine whether or not the age has been disturbed (Wetherill, 1956), (e) among the long-lived radioisotopes, the relatively short half-life of ^{235}U allows highly precise ages to be obtained for ancient rocks, (f) both the trace element concentrations and Hf isotope composition in zircon provide information on the nature of the source rock from which the zircon was derived, and (g) U–Pb ages can be obtained in samples as small as fragments of individual grains or even spots, tens of microns in diameter, ablated with either lasers or ion beams. Perhaps the only weakness of zircon is that it is not found in all rock types, occurring primarily in felsic igneous rocks. These characteristics explain the many varied applications of zircon U–Pb dating that include the discovery of the oldest dated material on Earth, 4.36 Ga zircons from quartzites in western Australia (Wilde et al., 2001), to high-precision calibration of the geologic timescale (Bowring and Schmitz, 2003), to the previously described use of zircons to determine the duration of crystallization in the magma chambers of young volcanic rocks.

Summary and conclusions

Continually improving analytical capabilities coupled with expanding appreciation of the physical controls on what sets, and resets, radiometric clocks are allowing ever-increasing expansion of this now century-old approach. The variety of radioactive species now in use provide the ability to determine absolute ages for geologic processes that occur over timescales that range from days to the age of the Earth and solar system.

Magnetic dating, archaeological; Remanence dating

Definition

Archaeomagnetism is the study of all remanent magnetization associated with materials found in, or associated with, an archaeological context. In practice, it is the application of paleomagnetic techniques to archaeological materials, predominantly in terms of their uses in dating or "sourcing" such materials. This generally means that magnetic surveys are not usually considered "archaeomagnetic," other than when used to provide information on the actual directions and intensities of the remanent magnetizations of the materials causing the anomalies.

As most applications of archaeomagnetic studies relate to magnetic dating, these aspects are described first.

Basic features

Most materials within archaeomagnetic contexts contain iron oxide minerals that are capable of carrying a magnetic remanence acquired at some past time. More rarely, iron sulphides and hydroxides can carry such remanences. Even more rarely, a remanence can be carried by pure iron, nickel and cobalt and their alloys, and in very specific conditions, iron sulphates. The commonness of magnetite (Fe_3O_4) and hematite (Fe_2O_3) makes these almost always the dominant minerals involved. Such ferromagnetic (*sensu lato*) minerals can acquire a *thermal remanence* in the Earth's magnetic field (or of nearby magnetic objects) while cooling from higher than ambient temperatures, *chemical remanences* as a result of crystalline or compositional changes. Some archaeological materials can comprise iron objects, but these are generally poor recorders of early remanences, being generally magnetically "soft." All archaeological materials can become comminuted and eventually deposited as sediments (*v.i.* Archaeological sediments) in which the individual magnetic grains can be magnetically aligned during their deposition in aqueous or aeolian conditions, resulting in a *detrital magnetization* (see *Paleomagnetism, Principles* for details).

In an archaeological environment, it is unlikely that only one form of remanence is present. It can also be presumed that some of the originally acquired remanence will have decayed with time, and other time-dependent magnetizations, *viscous magnetizations*, will have been acquired as the materials lay within a geomagnetic field that gradually changes in both direction and intensity. In order to determine the direction and intensity of the geomagnetic field for some specific time in the past (such as when last heated or deposited), it is necessary to remove such viscous magnetization. Where such viscous magnetizations are not associated with chemical changes, they can be removed by partial demagnetization in alternating magnetic fields or heating in zero-magnetic field in nonmagnetic furnaces. Alternating field demagnetization randomizes the low coercivity components of remanence, that is, the viscous remanences, leaving the high coercivity components unchanged. Partial thermal demagnetization reduces the relaxation time of all contained minerals, that is, the time taken for the direction of individual grain magnetization to relax into the ambient field direction. As the ambient field is zero, the grains with low relaxation times (those that carry the viscous magnetizations) thereby become randomized, leaving the high relaxation grains still in original directions. (For further detail, see *Paleomagnetism, Principles*.) Such partial demagnetization procedures are necessary for magnetic dating using directions or intensity. Statistical analyses, initially Principle Component Analyses, are then made to determine the number, direction, intensity, and precision of the magnetic vectors present in any single sample (see *Paleomagnetism, Measurement Techniques and Instrumentation* for details). The isolated individual sample vectors defined within some 5° that are considered to have been acquired originally are then combined, usually using Fisherian Statistics and giving equal weight to each sample vector, to provide a mean site direction. (Where individual oriented hand samples have been subsampled, these subsamples are combined to obtain the sample values that then yield the site mean value.)

Such treatments normally require different instrumentation for dating based on directions than those for dating based on intensity and are described separately. The theoretical bases are the same.

Archaeological site sampling

Directional analyses

Generally between 7 and 20 individually oriented samples are taken. This enables orientation errors to be averaged, as well as measurement errors. Ideally such samples are distributed evenly throughout the structure being sampled, although concentration is made on materials that are most likely to yield meaningful results and where the physical stability (since acquiring remanence) is better established. Sample orientation in situ is preferably undertaken nonmagnetically (sun compass, gyro-theodolite, or by sightings) as the objects themselves commonly distort magnetic compass readings. It is also desirable that the nature and conditions at the site, with the in situ samples, is recorded so that, when completing the analyses, possible causes from anomalous determinations can be better evaluated (see *Paleomagnetism, Measurement Techniques and Instrumentation*).

Paleo-intensity analyses

Samples for such studies do not need to be oriented while in situ nor need the samples be still in their original positions in which their remanence was acquired. However, such orientations can be useful is assisting assessments of samples that show more than one remanent magnetic vector. Generally, some three to five samples are selected for study from any one archaeological site (see *Paleomagnetic Field Intensity*).

Magnetic dating based on the direction of remanence

This dating method depends on the longtime spatial variations ($>\sim$10 years) of the geomagnetic field (see *Geomagnetic Field, Secular Variation*). Analyses of the present-day geomagnetic variations suggest that, at a medium latitude location, the observed geomagnetic field in a circular area of some 550 km radius ($\sim$1 Mkm^2) can be modeled as that of a geocentric inclined dipole field within an error of $\sim$0.5° (solid angle) in direction. At greater distances, the error increases to $>$1° (solid angle) rendering the model increasingly unreliable for comparing the directions of remanence at more distant sites. Such modeling enables "Master Curves" (Paleo-Secular Variation Curves) of directional change to be constructed using previously studied sites for specific regions, usually for a specific country or groups of small countries. In the UK, most English and Welsh observations were corrected to a central location, Meriden, while French observations were generally corrected to Paris.

Master Curves are now more commonly calculated within a far more sophisticated statistical modeling, notably hierarchical Bayesian modeling (Lanos et al., 2005). In such analyses, the Gaussian errors for the date assignments as well as for directional properties are incorporated in the construction of the Master Curves. Such Bayesian statistics similarly incorporate harmonic analyses. Spherical Cap analyses have the objective to determine the geomagnetic field variations attributable to fields at the Earth's core (Pavón-Carrasco et al., 2008). The latter method is therefore more appropriate for geomagnetic field modeling (see *Geomagnetic Field, Theory*).

Relative dating

Nearby sites (within some 50–80 km) that acquired their remanence at the same time will exhibit identical (within 1°) directions of remanence. Consequently, nearby sites with differing directions of remanence can be considered to have acquired their remanence at different times. Conversely, similar directions can indicate similar ages for their remanence acquisition. However, identical geomagnetic directions can occur in the same location at different times. When such repeat directions occur at time intervals of a few 100 years, the archaeological context is often adequate to distinguish between alternative age assignments.

Chronological dating

This dating method is dependent on the secular variation of the geomagnetic field being known for the region being investigated (see *Geomagnetic Field, Secular Variation*). As the current geomagnetic theories for the origin of the geomagnetic field are still evolving (see *Geomagnetic Field, Theory*), this usually requires previously well-dated (by non-archaeomagnetic means) site values to be available. In newly studied areas, the method is clearly inhibited by the lack of such data, but as more and more observations are obtained, the past directions of the geomagnetic field become increasingly well defined. Archaeomagnetic dating is thus an unusual scientific dating technique as its precision increases as more observations accumulate.

Magnetic polarity and polarity excursion dating

This dating application is based on unusual aspects of the long-term geomagnetic behavior. On scales of a few thousand years, the geomagnetic field can undertake major excursions away from its normal direction, geomagnetic events, or excursions. On timescales of a few 100,000 years, the Earth's magnetic field changes polarity – the North magnetic pole becoming the South magnetic pole, and vice versa for the South magnetic pole. Consequently, some geomagnetic excursions occur on archaeological timescales, and the younger polarity changes occur on archaeological-anthropological timescales (see *Geomagnetic Excursions*; and *Geomagnetic Field, Polarity Reversals* for more detailed considerations).

Magnetic dating based on the intensity of remanence

Relative dating can be based on the determination of paleo-intensities of the ancient field in a similar way as for direction (qv). Most current studies are directed toward defining the changes in geomagnetic intensity during archaeological time although sufficient quantities of high quality paleo-intensity determinations are now becoming

available for specific regions, enabling chronological dating to be undertaken. As for directional studies, when past records of the Earth's magnetic field intensity are available, a Master Curve can be constructed for a similar circular area of ~1 Mkm^2, radius of ~550 km, as for directional studies.

Errors

General errors

These apply to both directional and intensity dating techniques.

1. It is usually assumed that any effects of weathering and other environmental changes are minimal and that the magnetic grains carrying the remanence of interest are essentially unaffected. However, some weathering products, such as goethite and hematite, can carry high-stability remanence. It is desirable that, as far as practicable, unweathered materials are collected.
2. During partial demagnetization, it is assumed that no chemical or structural alterations occur to the existing magnetic minerals and that no new magnetic minerals are formed. Such changes are far more likely during thermal demagnetization than by alternating magnetic field techniques and are usually monitored by repeated measurements of the initial susceptibility. This is, however, a coarse measure and magnetic domain changes (see *Magnetic Domains*) which can occur with no clear change in susceptibility.
3. Both directions and intensities can be affected by magnetic anisotropy (shape and crystalline) that may be associated with the sample shape, the shape of contained minerals and the orientations of their crystallographic axes (see *Magnetic Anisotropy*).
4. Lightning strikes at times subsequent to the original acquisition of remanence, and have electromagnetic effects that can drastically alter the magnetic remanence. Although mostly associated with electrical charges that usually travel through surface waters, these effects can penetrate. Such effects can usually be recognized by their high intensities and tendency to be in random directions.
5. The local geomagnetic field direction and intensity may well be distorted if there were nearby magnetized objects, natural or manufactured, at the time of remanence acquisition.
6. The behavior of the geomagnetic field is still poorly defined and, particularly at high magnetic latitudes, can show major diurnal variations. It also appears that secular variations are not necessarily smooth, but may occur in "jerks" (see *Geomagnetic Field, Secular Variation*) although these appear to be mostly within the current experimental error of the technique.
7. The geomagnetic field over time can return to previous direction and intensity values. When such "crossover" points occur in the Master Curves at sufficiently different times, then the archaeological age constraints on the site may enable the most likely chronological age to be applied. However, most extant Master Curves are likely to still be distorted by some studies for which the archaeological or chronological age has subsequently been modified. However, such "anomalous" sites becoming increasingly recognized as databases increase.

Errors specific to directional dating

In addition to the general errors, directional studies are sensitive to the oriented samples having remained in situ since they acquired their remanences. In a solid structure, such loose materials can be readily identified, but individual parts of some structures can have undergone motions relative to the rest of the structure, for example, kiln-wall "fall-out" or "fall-in." On hillside, it is also possible that the whole structure may have undergone motion away from where the remanence was acquired. Thus, a knowledge of the archaeological controls on possible motions of the site is essential.

Errors specific to intensity dating

In addition to the general errors, paleo-intensity studies are sensitive to the "cooling rate" of the acquired magnetic properties. The naturally acquired remanence will commonly have been acquired over times that can be of the order of several days, while the laboratory studies are necessarily on far shorter times scales. The laboratory redox conditions during cooling are normally very different.

Overall error assessment

While there are many potential sources of error in archaeomagnetic dating, in most archaeological sites where the conditions are clear and the materials largely pristine, the errors arising appear to be only rarely of sufficient magnitude to warrant rejection.

Specialized applications

Murals and plaster

Remarkably, it has been shown that pigments can carry a remanence relating to the time when they were applied. Where such pigments have been applied to walls, their remanence has been shown to relate to the time that the pigments were applied, particularly in tempera paintings – either originally or during subsequent retouching. It seems most likely that this remanence is associated with hematite and was acquired "detritally," that is, by rotation of the grains while still fluidized (Lanza et al., 2009). Similar observations have also been shown for plaster work (Soler-Arechalde et al., 2006).

Object reconstruction

Specific artifacts, such as pottery, when fired, obtain a uniform magnetization in the ambient geomagnetic field as they cool within the furnace. If broken, individual shards retain this original remanence and can be reassembled to assist in defining the original shape of the pot (Burnham and Tarling, 1975).

Archaeological sediments

As sediments are deposited within an archaeological site, any contained already magnetized grains are influenced by the ambient geomagnetic field. As these alignment forces are weak (compared with the effects of gravity and flow motions) only a percentage of the magnetic grains are aligned and such alignments can be gravitational flattening during the deposition process. However, the more magnetically stable grains (usually with single-domain dimensions of ~1 μm) can rotate into full alignment while they are still fluidized immediately after deposition. However, such alignments can be modified by meniscus forces as the water table subsequently rises or falls. Sedimentary minerals also undergo a series of chemical reactions as they adjust to their new environment. Consequently, it is often difficult to establish the true direction of the geomagnetic field at the time of deposition with sufficient certainty to assign ages based on the magnetic determinations. However, there are archaeological sites, such as basal sediments, deposited immediately after a ditch had been cut, that appear to be recording the geomagnetic field direction at that time.

Magnetic "sourcing"

Magnetic sourcing attributes an object to a particular location on the basis of its magnetic properties. For example, an obsidian arrowhead can sometimes be sourced to the obsidian outcrop from which it was originally fashioned.

The physical basis for this is that the compositions and grains sizes of the magnetic minerals within a rock can be specific to a particular outcrop. Each outcrop also tends to have a slightly different cooling history and became magnetized by a specific geomagnetic field strength. Several magnetic properties can be rapidly and cheaply measured, such as its initial (low field) susceptibility, its saturation remanence, and its intensity of natural remanence, are sufficient to identify a specific outcrop. Generally, the range of magnetic properties in most sedimentary rocks is too great to allow such assignments, but obsidians, rapidly cooled volcanic glasses, commonly have a range of magnetic properties that are either unique to that outcrop or to only two or three outcrops.

Summary

The study of the magnetic properties of archaeological materials, archaeomagnetism, is particularly significant in geophysics as it enables secular variations in the direction and strength of the geomagnetic field over timesscale that are far longer than those for direct measurement (~400 years). In comparable magnetic studies of rocks, paleomagnetism, these secular variations are commonly averaged out during the processes by which rocks acquire their remanent magnetization. Conversely, archaeomagnetic records provide an additional dating tool for archaeologists. As a comparative dating tool, archaeomagnetism enables relative dating between nearby samples (100–200 km) within ~10–20 years. As a dating tool, it is mainly dependent on the validity of the ages used to compile the regional Master Curve. It is thus unique, as a scientific dating method, in that as more data are acquired, age "outliers" can be identified and their age reassessed. Consequently, the Master Curves are continually improving and, ultimately, could have the same precision as for relative dating. There are also interesting applications in using such observations in conservation studies and establishing past environmental conditions.

Earthquake archeology

Definition

The study of pre-instrumental earthquakes that, by affecting locations of human occupation and their environments,

have left their mark in ancient structures uncovered by means of archaeological excavations or pertaining to the monumental heritage (Buck and Stewart, 2000; Galadini et al., 2006).

Introduction

Ever since man-made structures have been erected, earthquakes have left their marks on these constructions. However, damages in archaeologically excavated buildings or continuously preserved monuments are often hard to unravel in terms of the causative effects. The use of archaeological data to investigate unknown or poorly known historical earthquakes and descriptions of earthquake effects recorded in the archaeological heritage started in the nineteenth and early twentieth century (e.g., De Rossi, 1874; Schliemann, 1881; Evans, 1928). Since the 1980s, the increased interest in the subject led to the publication of special volumes and articles in seismological and geological journals (e.g., Guidoboni, 1989; Stiros and Jones, 1996; McGuire et al., 2000; Galadini et al., 2006; Reicherter et al., 2009). While earlier investigations were dominated by the qualitative description of damage records, more recent studies take a quantitative approach. The main questions to be answered by archaeoseismic investigations are (1) how probable are seismic ground motions, or secondary earthquake effects, as the cause of damage observed in man-made structures from the past, (2) when did the damaging ground motion occur, and (3) what can be deduced about the nature of the causing earthquake.

Archaeoseismic observations

The marks in ancient structures relevant for archaeoseismology fall into four main categories: (1) displacements along shear planes directly linked to the earthquake fault plane or side branches of it. In particular, earthquakes with a strike slip mechanism can leave distinctive traces in buildings and lifelines such as aqueducts, roads, and sewer systems. Case studies (e.g., Ellenblum et al., 1998; Meghraoui et al., 2003) show that under favorable conditions the amount of slip and in case of repeated events the slip rate of the faults can be revealed. (2) Off-fault-shaking effects including fractured building elements, tilted walls, shift of building elements, lateral warping, breaking and overthrow of walls, rotations of vertically oriented objects (tomb stones, columns, monuments). For most of these features, a seismogenic origin is not the only possible interpretation. Therefore, alternative causes must be taken into account in the damage analysis. (3) The secondary shaking affects lateral spreading and cyclic mobility as a consequence of liquefaction of the subsurface. Liquefaction always requires a certain level of dynamic excitation. So secondary damages in buildings and monuments due to liquefaction help exclude alternative causes from a damage scenario. (4) Archaeologically detected abandonment of a site and evidence of repair and rebuilding. These observations are mainly of interest in connection with the reasons mentioned before because as a single observation in general they do not give enough evidence for the conclusion of a seismogenic cause (Galadini et al., 2006).

While the first category is limited directly to the linear features of active faults, off-fault shaking affects a much larger area and is more common but harder to prove. Ancient structures show deformations related to seismic shaking similar to those observed in recent earthquakes. Typical earthquake effects on masonry walls are (1) cross fissures, due to stress concentrations often nucleating at corners of doors and windows, driven by shear forces, (2) corner expulsion of walls caused by differential movements in orthogonal directions, (3) horizontal and independent lateral and rotational shift of wall blocks, best visible in uncemeted walls made of rectangular blocks, (5) spall of block corners due to stress concentrations, (6) height reduction by vertical crashing, (7) movement of keystones and rupture of arch piers, (8) rotation of vertically oriented objects, (9) domino-like toppling of structured columns and walls. Examples are shown in Figure 1. Following the term seismite, used for seismically disturbed sediment layers, the above-mentioned deformations may be called archaeoseismites. Several of these deformations may also originate without dynamic earthquake excitation. In these cases, a single piece of evidence or at a single edifice only cannot be considered a conclusive archaeoseismite. If damages are identified as archaeoseismites, intensities can be derived following the classical macroseismic methods.

Methods

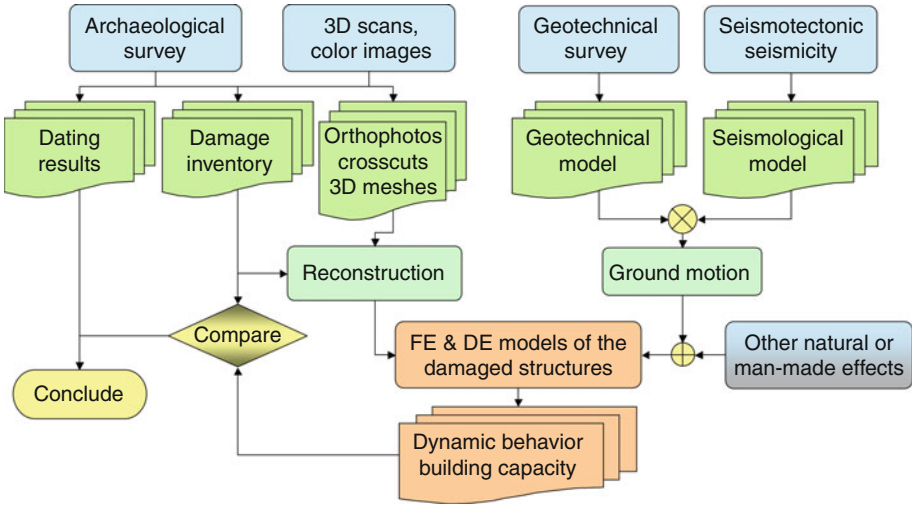
Archaeoseismology requires the integration of several scientific disciplines. Figure 2 shows a scheme of workflow in a quantitative archaeoseismic study. Besides archaeological and seismological methods, input from geodesy, pure and applied geology, and civil engineering is needed (Ambrasyes, 2006). Physical absolute dating techniques including radiometric methods, luminescence methods, and dendrochronology are necessary to determine a time window for the damaging event. In case of multiple events, the rough dates are crucial for seismicity models and hazard analysis.

The first step in studying field cases is the documentation and analysis of damages to the archaeologically excavated buildings or objects. In addition to the important traditional excavation techniques and classical measurements and drawings, 3D imaging techniques have proved their usefulness in archaeoseismic field cases. Photogrammetry and laserscanning are fast in the field and allow detailed analysis and post processing, especially a quantification of deformations, fractures, etc. In cases where building parts are fragile and cannot be conserved in the original finding situation, successive laser scans during the excavation offer the possibility to build virtual 3D models. In ideal cases, the seismological relevant data can be acquired during an ongoing excavation. Important

Archaeoseismology, Figure 1 Examples of deformations and damages which possibly are earthquake effects: (**a**) Horizontally deformed wall of a crusader fortress build on top of the Dead Sea Transform Fault in the Jordan Valley; (**b**) deformed vault of a Roman sewer in Cologne, Germany; (**c**) toppled columns of a Byzantine church in Sussita located above the Sea of Galilee; (**d**) toppled column of the great palace in Patra, Jordan; (**e**) moved block in an arch of the Nimrod fortress in the Golan Heights; (**f**) shifted blocks of an analemma of a Roman theatre in Pınara, SW Turkey; (**g**) moved blocks of a corner wall of a Roman monument in Patara, SW Turkey; (**h**) shifted blocks of a Roman grave house in Pınara, SW Turkey; (**i**) spall of block corners, same object as in (**g**);(**j**) broken and horizontally displaced fortification wall of the Roman Tolbiacum (Zülpich, Germany); (**k**) rotated Lycien sarcophagus in Pınara, SW Turkey.

is the complete documentation of the stratigraphy of debris layers, which can reveal the decay rate of structures (Galadini et al., 2006). Building collapse may be sudden, progressive, or a combination of both. The progressive deterioration of walls results in accumulations having maximum thickness close to the wall feeding the material. The thickness decreases a short distance from the wall. In case of height reduction of walls or buildings due to earthquake effects, the debris is more distributed. Sometimes even complete walls topple to one side; in this case, the impact pattern can help to constrain ground motion amplitudes. However, if the findings of previous excavations are archaeoseismologically analyzed, the current situation and available excavation reports form the database. Possible alterations of the excavated objects since the first excavation and shortcomings in the documentation, especially if earthquake actions were not considered at the time of the original excavation, might hinder the interpretation.

Depending on site conditions, exploration, and modeling of the properties of the local geology at the site is an important second step. Several of the above-mentioned deformations can also be caused by slow, quasi-static deformations of the subsoil, and ground amplification due to shallow soft sediments can significantly amplify seismic shaking. If the latter is not taken into account, the size of the damaging earthquake can easily be overestimated.



Archaeoseismology, Figure 2 Schematic work flow in a quantitative multidisciplinary archaeoseismic study. The dynamic behavior is studied by finite element (FE) or discrete element (DE) methods.

Only on rare occasions, site-specific strong motion records from recent earthquakes will be available and help to prove or disprove proposed damage scenarios. To overcome this lack of information, the calculation of synthetic seismograms based on models of the capable faults and local geology have been used to better ascertain the probability of a seismogenic cause of the damages and name faults on which the damaging earthquake occurred. When other natural forces (flooding, storm, mass movement) or even human action also come into consideration, their action on the excavated objects has to be tested as well.

Reconstructions of the damaged archaeological objects are the basis for determining the dynamic behavior and the vulnerability of the ancient buildings. Common earthquake engineering techniques including finite element and discrete element modeling are used to analyze the reaction of the buildings to the estimated seismic loading functions. Results from such models are compared to the damages observed in situ.

The most challenging task of an archaeoseismic study is the determination of source parameters of the earthquake which caused the analyzed damages. While timing of the earthquake has to be done by archaeological techniques, including classical archaeological stratigraphy and the above-mentioned physical dating, location and strength of the earthquake can only by narrowed down with seismological models. A territorial approach (Galadini et al., 2006), in which the collected information from the surroundings of an archaeological site are taken into account, is the most promising tool to determine earthquake source parameters.

Summary

In the past decades archaeoseismology has evolved as a new branch of seismological sciences. While palaeoseismology focuses on the marks left by earthquakes in the geological record, archaeoseismologists analyze and interpret marks in the archaeological record and in preserved monuments.

The use of quantitative methods in archaeoseismology, including calculation of synthetic site-specific strong motion seismograms, modeling of natural non-earthquake-related forces, anthropogenic forces, and finite or discrete element models of structures, supports conclusive discrimination between potential damage scenarios. However, if model parameters cannot be well constrained, modeling result uncertainties might still be too large to draw definite conclusions. Common sense interpretations of archaeoseismites as solitary evidence are generally too vague to complement earthquake catalogs for a seismic hazard analysis. Recent advances in ground motion simulation methods and computational possibilities promise to refine quantitative archaeoseismological methods and establish them at levels equal to historical and palaeoseismologial methods. Finally, even if an archaeoseismic study does not deliver the often-requested improvement of hazard determination, it can still advance our picture of the past by attempting to answer open archaeological, historical, and geologic questions in a scientific manner. And following Ambrasyes (2006): "Surveying and mapping an archaeological site is an art, verifying the cause of damage is science."

ARTIFICIAL WATER RESERVOIR TRIGGERED EARTHQUAKES

Harsh K. Gupta
National Geophysical Research Institute, Council of Scientific & Industrial Research (CSIR), Hyderabad, Andhra Pradesh, India

Definition and Introduction

Under certain suitable geological conditions, anthropogenic activity can trigger or induce earthquakes. The triggered/induced earthquakes are known to have occurred due to gold and coal mining, petroleum production, filling of artificial water reservoirs, high-pressure liquid injection into ground, and natural gas production. The largest scientifically accepted triggered earthquake of magnitude 6.3 occurred on December 10, 1967 in the vicinity of Koyna Dam near the west coast of India. It is debated whether the M 7 Gazli earthquakes of May 1976 and March 19, 1984 were induced due to the production of large quantities of gas at the Gazli Oil Field in Uzbekistan. There is an argument that the Sichuan, China, M 7.9 earthquake of May 12, 2008, that claimed over 80,000 human lives was triggered due to filling of the nearby Zipingpu reservoir. It has been also proposed that flooding of a river near San Andreas fault in California caused at least two M $\sim$ 6 earthquakes. A good account of triggered/induced seismicity can be found in a review by McGarr et al. (2002). Hudyma and Potvin (2005) has extensively dealt with mining-induced seismicity. Gupta (2002) has reviewed artificial water reservoir triggered seismicity.

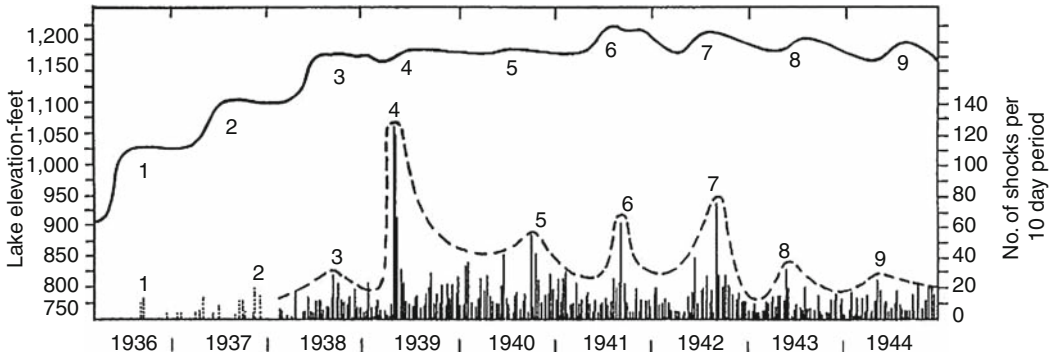
Here we present cases of artificial water reservoir triggered earthquakes that occurred all over the world, with a special emphasis on earthquakes in the Koyna region near the west coast of India. This is a classical case where triggered earthquakes have been occurring since the impoundment of reservoir in 1962.

Triggered vis-à-vis induced earthquakes

For a long time, the adjectives "induced" and "triggered" were used interchangeably whenever one talked of artificially simulated earthquakes. McGarr and Simpson (1997) have addressed this question and suggested that it would be important to draw a distinction between the two. They proposed that the adjective "triggered seismicity" should be used only when a small fraction of stress change or energy associated with earthquakes is accounted for by the causative activity. The term 'induced seismicity' should be used where the causative activity is responsible for a substantial part of the stress change. In case of triggered seismicity, tectonic loading plays an important role. The stress-level changes associated with filling of some of the deepest artificial water reservoirs are only of the order of 1 MPa or so, whereas the stress drop associated with the earthquakes is much larger. Therefore, all cases of earthquakes occurring subsequent to filling of the artificial water reservoirs fall in the category of "triggered earthquakes," and hence it is appropriate to call it "reservoir triggered seismicity" (RTS).

Artificial water reservoir triggered earthquakes

Generation of hydroelectric power, flood control, and irrigation necessitates creation of huge artificial water reservoirs globally. Triggering of earthquakes was for the first time pointed out by Carder (1945) at Lake Mead in USA. Figure 1 depicts Lake Mead water levels and local seismicity for the period 1936 through 1944. The rise in water level and corresponding bursts of seismic activity are numbered. The correspondence is indeed remarkable. Damaging triggered earthquakes exceeding magnitude six occurred at Hsingfengkiang, China (1962); Kariba, Zambia–Zimbabwe border (1963); Kremasta, Greece (1966); and Koyna, India (1967). Koyna earthquake of M 6.3 that occurred on December 10, 1967 is so far the largest scientifically accepted



Artificial Water Reservoir Triggered Earthquakes, Figure 1 Lake Mead water levels and the local seismicity. For 1936 and 1937, only the felt shocks are plotted. The rises in water levels and the corresponding bursts of seismic activity are numbered. General trend of tremor-frequency variation is shown by dotted lines (After Carder, 1945).

triggered earthquake. It claimed over 200 human lives, injured about 1,500, and rendered thousands homeless. The occurrence and potential of triggered earthquakes has caused major modification of civil works and engineering projects. Anticipating a large triggered earthquake, the Hsingfengkiang Dam was strengthened twice before the occurrence of M 6.1 earthquake on March 20, 1962 (Shen et al., 1974). The disposal of waste fluid through injection into the ground at Rocky Mountain Arsenal had to be discontinued due to triggered earthquakes (Evans, 1966). The possibility of high magnitude triggered seismicity was responsible for terminating the Auburn Dam project in California (Allen, 1978). There is a general reluctance on the part of Engineering Community, globally, to accept the significance or even the existence of the phenomenon of triggered seismicity (Allen, 1982; Simpson and Leith, 1988). What Allen (1982) said a quarter century back: "From a purely economic point of view, not to speak of public safety, the problem of reservoir induced earthquakes deserves far more attention than it currently is receiving in most parts of the world", is still true.

Reservoir triggered seismicity (RTS): global distribution

Globally there are about 100 sites where RTS is reported to have occurred (Table 1). These could broadly be grouped in the following categories:

1. Sites where largest earthquake exceeded M 6.0 (4 sites)
2. Sites where the largest earthquake M was 5.0–5.9 (10 sites)
3. Sites where the largest earthquake M was 4.0–4.9 (29 sites)
4. Sites where the largest earthquake M was less than 4.0 (55 sites)

Table 1 gives a global list of artificial water reservoir sites where triggered earthquakes of M $\geq$ 4 are known to have occurred.

Important factors for RTS

Several studies examined the correspondence among possible correlates like rate of loading, highest water level reached, and the duration of retention of high water levels and the occurrence of RTS. The most important correlate is the depth of water column in the reservoir (Baecher and Keeney, 1982). Figure 2 demonstrates that when the water column depth exceeds 200 m, about one in five reservoirs have experienced RTS. A review of recent global examples gives support to this observation. It must also be noted that a reservoir with a water volume exceeding 1 km^3 and/or a water depth exceeding 100 m is called a large reservoir. Globally, there are more than one thousand such reservoirs and only a small percentage has evidenced RTS.

Common characteristics of RTS sequences

By early 1970s, over a dozen cases of RTS were known. In a couple of detailed studies, Gupta et al. (1972a, b) discovered several common characteristics of RTS sequences, which discriminated them from the normal earthquake sequences occurring in close by regions but not associated with reservoirs. These characteristics are:

1. In the earthquake frequency-magnitude relation ($\log N = A - b\,M$, where N is the number of earthquakes with magnitude $\geq$ M, and A and b are constants), the foreshock and aftershock *b* values of the RTS sequences are higher than the *b* values for natural earthquake sequences in the regions concerned, and the regional *b* values.
2. In addition to high *b* values, the magnitude ratio of the largest aftershock to the main shock is also high.
3. Aftershock activity decays slowly compared to normal earthquake sequences.
4. The foreshock–aftershock sequence pattern belongs to Type II of Mogi's Model (Mogi, 1963), where as the natural earthquake sequence pattern belongs to Type I of Mogi's Model.

Artificial Water Reservoir Triggered Earthquakes, Table 1 Reported cases of reservoir triggered seismicity (RTS) where M ≥ 4 earthquake occurs

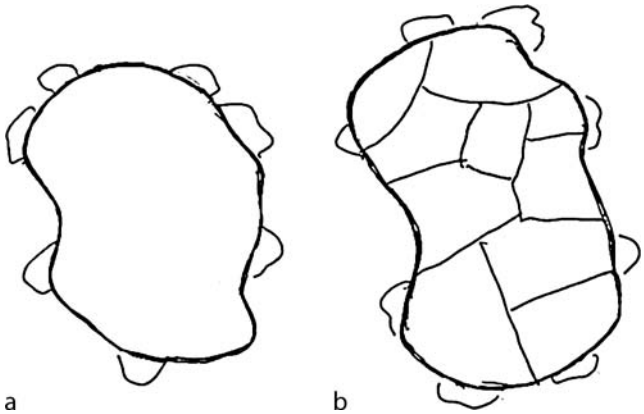
Artificial Water Reservoir Triggered Earthquakes, Figure 2 Height of water column is the most important correlate (After Stuart-Alexander and Mark, 1976).



Artificial Water Reservoir Triggered Earthquakes, Figure 3 Impoundment of water reservoir increases heterogeneity. (**a**): Homogeneous rock volume before impoundment. (**b**): After impoundment. For **a**, earthquake sequence falls under Type 1 of Mogi's (1963) models: no foreshocks and a few aftershocks. For **b**, earthquake sequence falls under Type 2 of Mogi's (1963) models: considerable foreshock activity. For details see text.

The above-mentioned observations are governed by the mechanical properties of the media, and their deviation from the normal implies changes in these properties consequent to impoundment of the artificial water reservoir. It can be best illustrated by a sketch shown in Figure 3. "A" in this figure is a homogenous media rock volume. When the stress exceeds the strength of the rock, there would be a major event releasing most of the strain, followed by peripheral adjustment aftershocks. In such a sequence, there would not be any foreshocks before the major event. The aftershock activity would be over in a short time, the ratio of the largest aftershock to the main event would be low, and the *b* value would be low. This is typically the situation with the earthquake sequences in stable continental regions not associated with the reservoir loading. Due to filling of the water reservoir, the heterogeneity of the media increases ("B" in Figure 3), and the rock volume gets fragmented, and the accumulated stress is released by smaller rock volumes. In such a situation, the events would start occurring as and when the strength of an individual rock volume is exceeded. The main event would correspond to the largest rock volume and there would be events before it and after it, changing the pattern from Type I of Mogi's Model to Type II. The ratio of the magnitude of the largest aftershock to the main shock would be high, and the *b* value of the foreshock sequence as well as the aftershock sequence would be high. This is what is observed with RTS sequences.

Mechanism of triggered earthquakes

In the following we give a gist of major milestones in comprehending the phenomenon of triggered earthquakes.

The foundation of understanding the phenomenon of triggered earthquakes was laid by the study of the waste-fluid-injection-induced earthquakes in the vicinity of Rocky Mountain Arsenal Well near Denver, Colorado, USA, in early 1960s (Evans, 1966). There are three main effects of reservoir loading relevant to triggering of earthquakes as pointed out by Gough and Gough (1970b) and several others:

1. The elastic stress increase following filling of the reservoir
2. The increase in pore fluid pressure in saturated rocks, basically due to decrease in pore volume due to compaction, in response to increase in elastic stress
3. Pore-pressure changes related to fluid migration

Gough and Gough (1970a, b) provided the first definitive quantitative analysis of the role of the load of the water reservoir in triggering earthquakes at Lake Kariba. The role of reservoir load was also considered by Bell and Nur (1978) and Roeloffs (1988). They pointed out that reservoir-load-induced stresses at seismogenic depths are very small and can only perturb the ambient stress field. Gupta et al. (1972a, b) identified the rate of increase of reservoir water levels, maximum water levels reached, and the duration of retention of high water levels as factors affecting the frequency and magnitude of triggered earthquakes. The influence of pore fluid pressure in inducing earthquakes in very simple 1 D reservoir models was presented by Snow (1972). More sophisticated models were dealt by Withers and Nyland (1976), Bell and Nur

(1978), and Roeloffs (1988) based on Biot's (1941) consolidation theory, which later on is generalized by Rice and Cleary (1976) by recognizing that the fluids too may be compressible. Very interesting results related to modeling of pore-pressure diffusion have been reported for Acu Reservoir in Brazil (Do Nascimento et al., 2004).

Pore-pressure diffusion plays a very important role in the triggering of the earthquakes. However, there are a very few direct measurements of diffusivity, and it is mostly inferred from the temporal migration of seismicity. Talwani et al. (1999) have reported in situ measurements of hydrological diffusivity and Skempton's coefficient at the Bad Creek Reservoir in South Carolina, USA. At an observation well located 250 m away from the reservoir, a change in the water level of the well had a direct correspondence with the changes in the water level of the reservoir, initially with a delay of 98 h, which later stabilized at 72 h. This led to a frequency independent estimate of diffusivity of $\sim$0.076 $m^2\ s^{-1}$ and Skempton's coefficient of 0.66 for an undrained response of the reservoir. Later, Talwani et al. (2007) analyzed more than 90 case histories of triggered seismicity and found diffusivity to vary between 0.1 and 10 $m^2\ s^{-1}$. This range of diffusivity values corresponds to a range of intrinsic permeability between 5×10^{-16} and 5×10^{-14} m^2. Talwani et al. (2007) referred this range of the permeability of fractures as seismogenic permeability. Seismogenic permeability is an intrinsic property of fractures where pore-pressure diffusion is associated with seismicity.

The in situ measurements of physical properties and examination of physical mechanism controlling triggered seismicity at Monticello Reservoir, South Carolina, USA, provided the much needed field verification of the theoretical and model developments of concept of triggered seismicity (Zobak and Hickman, 1982). The effect of changes in lake levels and other derived parameters on triggered earthquakes have been dealt by Simpson and Negmatullaev (1981) for the Nurek Dam, and by Gupta (1983) for the Koyna Dam. The part played by pore-pressure diffusion in triggering earthquakes has been dealt by Talwani and Acree (1984/1985). The effect of inhomogeneities in rock properties on triggering earthquakes was addressed by Simpson and Narasimhan (1990).

Most of the theoretical models discussed the effect of pore fluid pressure in isotropic rocks. Chen and Nur (1992) point out that deviatory effects of pore fluid pressure in anisotropic rocks have wide applications in comprehending triggered seismicity, earthquake precursors, and aftershocks. This approach needs to be applied to a few cases of RTS.

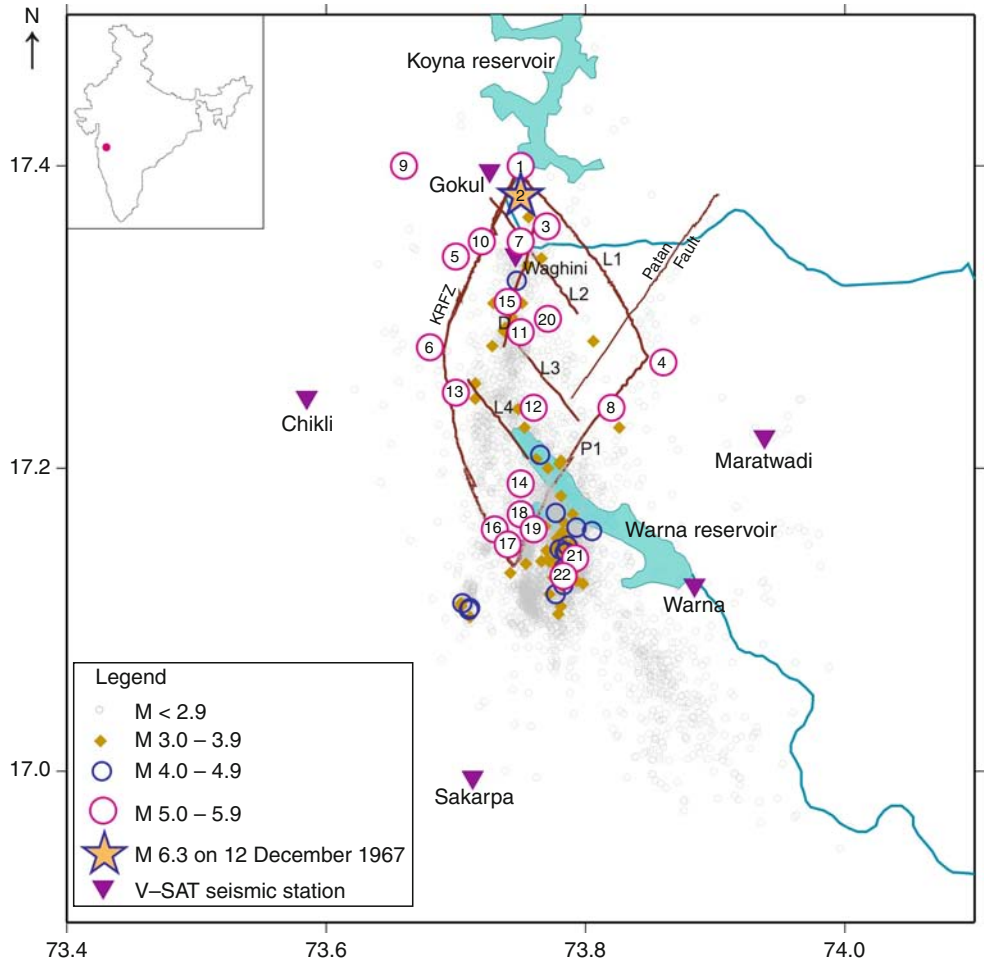
Other interesting studies include the notion of fault stability as a measure of the interplay of frictional stresses mobilized and the resolved shear stresses acting on a fault Chander and Kalpna (1997). Kalpna and Chander (2000) have developed an algorithm for simulation of stresses and pore pressure for more realistic laterally finite 3D models of reservoirs.

Koyna, India

Koyna reservoir located close to the west coast of India continues to be the most significant site of triggered earthquakes. Earthquakes began to occur soon after the impoundment of the Shivaji Sagar Lake created by the Koyna Dam in 1962. So far, globally, the largest triggered earthquake of M 6.3 on December 10, 1967; 22 earthquakes of $M \geq 5$; about 200 earthquakes of $M \geq 4$; and several thousand smaller earthquakes have occurred in the region. Talking to residents in the region in the 1960s revealed that they had not experienced any earthquake in the region in their living memory. There is a seismic station operating at Pune, about 120 km away from Koyna. A scrutiny of the seismograms revealed no earthquakes that could be assigned to the Koyna region. Another water reservoir, Warna, was impounded in 1985. This reservoir is located 35 km SSE of Koyna (Figure 4). After the impoundment of Warna reservoir, the triggered activity got enhanced. For convenience, we shall call the Koyna and the Warna reservoirs region as the Koyna region. Major bursts of seismic activity associated with the Koyna reservoir occurred in 1967, 1993, 1980, 1993–1994, 2005, and 2009.

How long triggered earthquakes will continue at Koyna?

Koyna is indeed a unique site where triggered earthquakes have been occurring since the impoundment of the reservoir in 1962. Gupta et al. (2002) have examined in detail the question as to how long the triggered earthquakes would continue at Koyna. The maximum credible earthquake for the Indian shield region has been estimated to be M 6.8. It is hypothesized that the region between Koyna and Warna was stressed close to critical before the impoundment of the Koyna reservoir, and was capable of generating an M 6.8 earthquake. As demonstrated through the study of b values in earthquake magnitude-frequency relation, foreshock–aftershock patterns, the ratio of the magnitude of the largest aftershock to the main shock and the decay of aftershock activity in earthquake sequences at Koyna, the heterogeneity of the media has increased. None of the $M \sim 5$ earthquake has occurred at the same location. $M \sim 5$ earthquakes occur in Koyna region when the previous water maximum in the reservoir has been exceeded. Long time ago, Kaiser (1953) had reported that acoustic emission, under monotonically increasing stress, shows an appreciable increase after the applied stress exceeds the previously applied stress maxima. This approach has been successfully used by Yoshikawa and Mogi (1981) to estimate crustal stresses from cored samples. For the Nurek Dam also, it was reported that major triggered events occurred when water level in the reservoir reached the previous maximum and exceeded it (Simpson and Negmatullaev, 1981). Gupta et al. (2002) had concluded that as of 2002, about one-half of an M 6.8 earthquake energy has been released in the



Artificial Water Reservoir Triggered Earthquakes, Figure 4 Earthquakes in Koyna region of Western India.

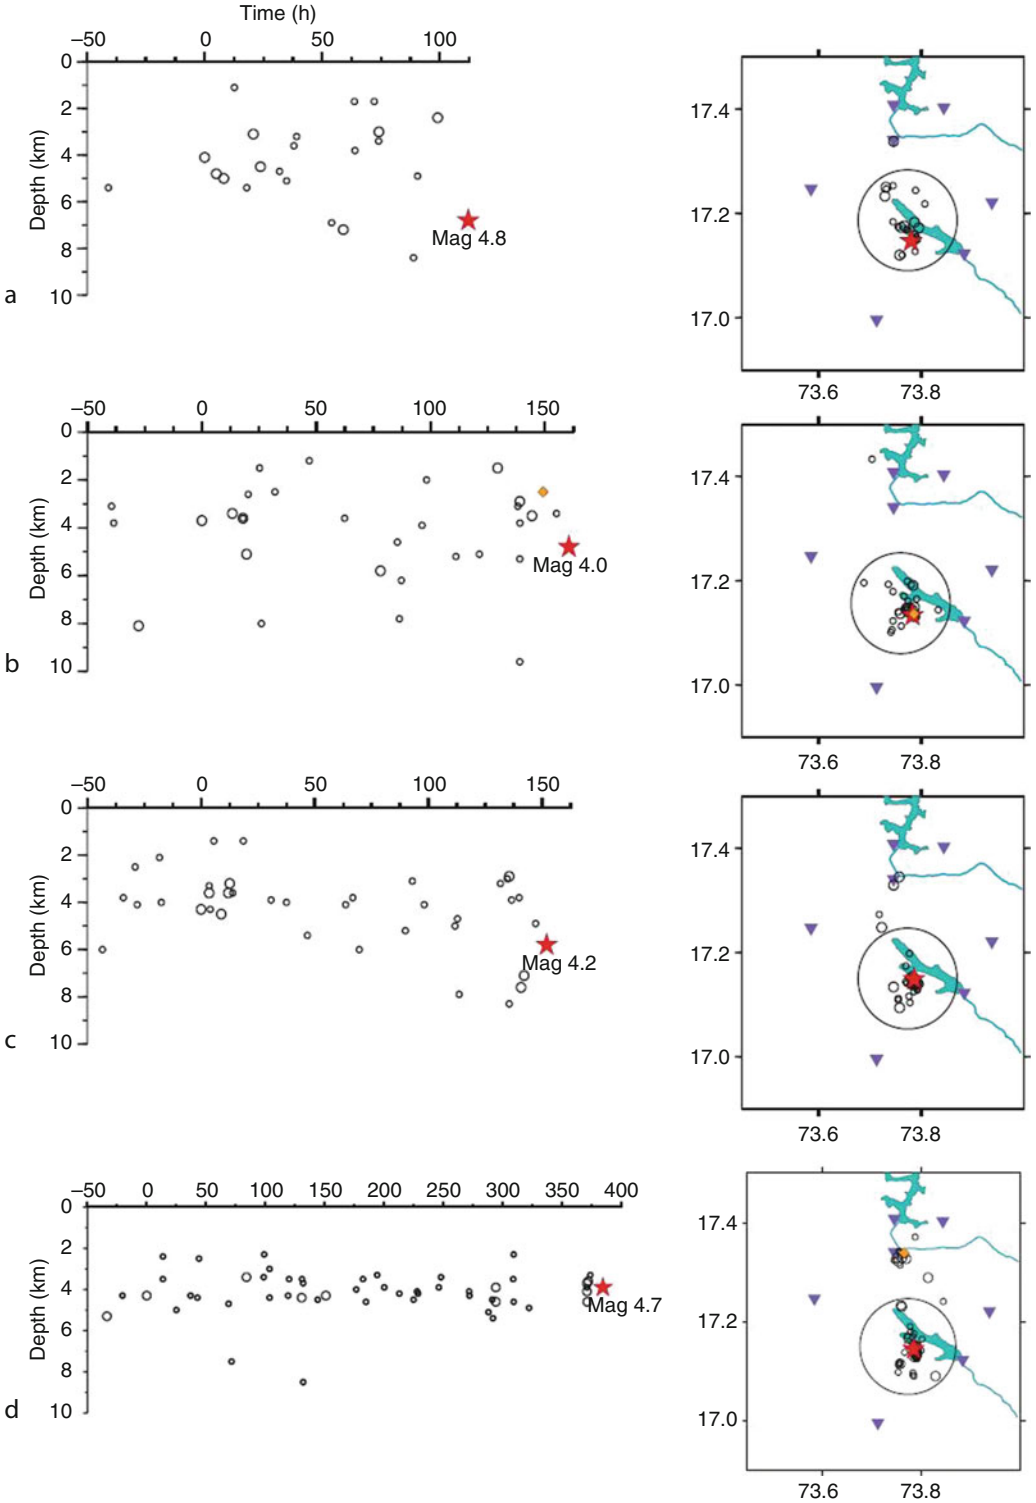
Artificial Water Reservoir Triggered Earthquakes, Table 2 Events preceding M $\geq$ 4.0 earthquakes in Koyna region

Main earthquake	Duration of nucleation period (h)	No. of events before the main earthquake				
		M 1.0–1.9	M 2.0–2.9	M 3.0–3.9	Largest earthquake	50 h prior to beginning of nucleation period
30th August 2005 M 4.8	110	13	8	0	2.6	2
13th November 2005 M 4.0	160	18	8	1	3.0	3
26th December 2005 M 4.2	150	22	8	0	2.9	6
17th April 2006 M 4.7	380	40	10	0	2.7	2

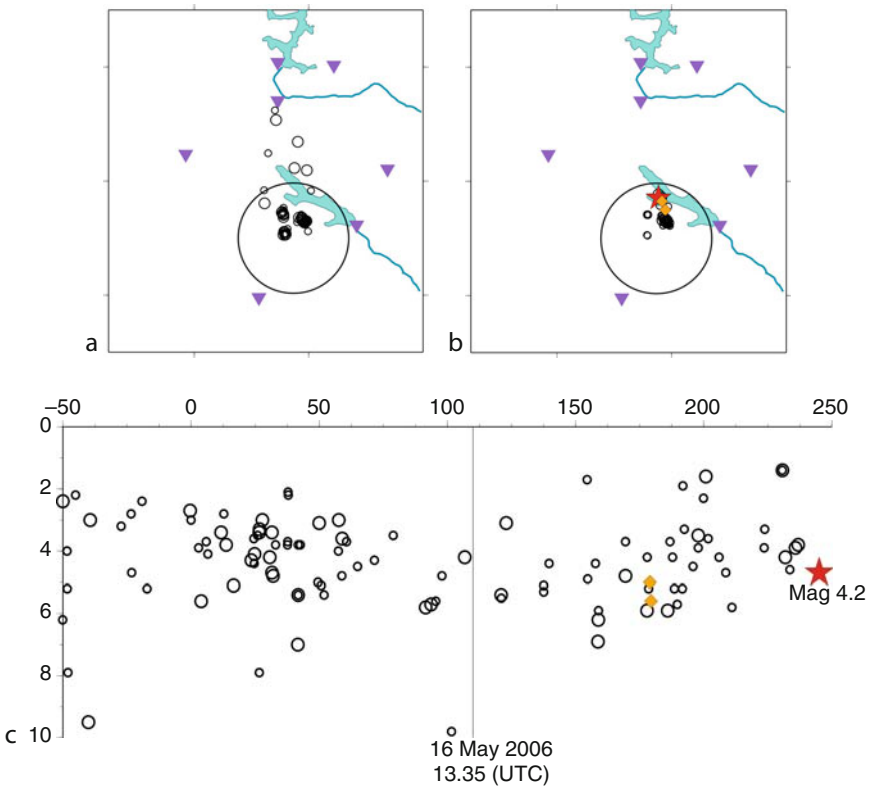
Koyna region, and the activity should continue for another 3–4 decades. Due to increase in heterogeneity, no fault segment long enough to generate an M > 6 earthquake is left intact; so an earthquake like the December 10, 1967, may not occur. The occurrence of M ~ 5 earthquakes would be governed by the fact whether the previous water maximum has been exceeded, and other factors such as the rate of loading, the highest water levels reached, and the duration of the retention of high water levels.

Short-term earthquake forecast at Koyna

A case was made that short-term earthquake forecast may be feasible at Koyna (Gupta, 2001). This was based on the fact that the shallow (depth $\leq$ 10 km) seismic activity in the vicinity of the Koyna is confined to an area of 20 $\times$ 30 km^2, and there is no other seismic source within 50 km radius. Every year, following the rainy season, the reservoirs get filled and there is an enhancement of seismic



Artificial Water Reservoir Triggered Earthquakes, Figure 5 Seismic activity for the period 50 h before the start of nucleation till the occurrence of M $\geq$ 4 earthquakes in Koyna region during August 2005–April 2006. Foreshocks clustering before the main shocks in a region of 10 km radius (*Right*). Temporal distribution of events within the circle with the depth. ◦, ○, ♦ and ★ are events in M 1.0–1.9, 2.0–2.9 and 3.0–3.9 ranges, and main earthquake respectively (*Left*). Onset of identified nucleation period is given "0" time mark. Nucleation period lasted for 110, 160, 150 and 380 h for (**a**) 30th August, (**b**) 13th November and (**c**) 26th December 2005 (**d**) 17th April 2006 earthquakes respectively (Table 2).



Artificial Water Reservoir Triggered Earthquakes, Figure 6 Symbols as in Figure 5. (**a**), Events that occurred during 107 h (11–16 May) preceding identification of nucleation. (**c**), Temporal-depth plot of the events within the 10 km radius circle. Nucleation was inferred to have started 107 h before, where 0 h is put on the time axis. (**b**), Seismic activity from 13:35 UTC on 16 May till the occurrence of the M4.2 earthquake on 21st May 2006, on the right side of (**c**).

activity. From among earthquake precursors, foreshocks are important and have a potential in forecasting earthquakes (Dodge et al., 1996; Helmestetter et al., 2003). Ohnaka (1992) has noted that immediate foreshock activity is a part of the nucleation process leading to main-shock dynamic rupture. Gupta et al. (2007) have reported successful earthquake forecast in Koyna based on identification of nucleation in real time. The seismic activity in the Koyna region is monitored by a closely spaced network of seven modern seismic stations. Table 2 from Gupta et al. (2007) is the learning phase where four earthquakes of M 4.0 to M 4.8 were found to be preceded by well-defined nucleation where several events occurred in a tight cluster of less than 10 km radius (Figure 5a–d). It was realized that if the formation of nucleation could be identified in real time before the occurrence of the main shock, it may be possible to make a short time forecast.

During the middle of May 2006, an interesting situation developed. The events in the Koyna region for the period 11–16th May, 2006, are depicted in Figure 6a (Gupta et al., 2007). By the afternoon of 16th May, 2006, some 50 events of $M \geq 1.0$, the largest being M 2.7, had occurred in the preceding 107 h in a small area, the focal depth being between 2 and 8 km. It was inferred that the region is going through a nucleation phase. Based on the experience of previous nucleation, the following forecast was made at 19:05 IST and communicated to the Editor of *Current Science*, Secretary, Ministry of Earth Sciences of the Government of India, and the President of the Geological Society of India: "On the basis of the data available from seven seismic stations operating in the Koyna region, we have identified a nucleation which started on 12th May 2006. This may lead to the occurrence of an $M \sim 4$ earthquake in the next 15 days. This shallow earthquake (focal depth less than 8 km) will occur within

Artificial Water Reservoir Triggered Earthquakes, Table 3 Forecast of 21st May, 2006, M 4.2 earthquake in Koyna on 16th May, 2006

	Forecast parameters	Occurrence
Epicenter	Within 10 km radius of 17.1°N, 73.8°E	17.171°N, 73.777°E
Magnitude	~4	4.2
Time	Within 15 days of 16th May 2006, i.e., until 31st May 2006	20:29:01 UTC On 21st May 2006
Focal depth	Less than 8 km	4.7 km

a radius of 10 km centered at 17.1°N, 73.8°E. On the basis of our previous experience of studying nucleation-preceding earthquakes in the Koyna region, we expect this earthquake to occur over the next 15 days time (till 31st May, 2006), with a 50% probability." An earthquake of M 4.2 occurred on 21st May. Table 3 gives the comparison of forecasted parameters and that of 21st May, 2006, earthquake. Since 2005, six similar short-term forecasts have been made in the Koyna region and all have come true.

Summary

In this article, we provide a thumbnail review of studies of global occurrence of artificial water reservoir triggered earthquakes, with a special emphasis on Koyna, India. Considering the small changes in the stress regime caused by filling of the deepest reservoirs compared to the stress drop of the associated earthquakes, it is appropriate to replace "reservoir-induced seismicity" by "reservoir triggered seismicity."

Koyna continues to be the most significant sight of RTS globally. The latest $M > 5$ earthquake occurred on December 12, 2009 (M 5.1).

At Koyna, earthquakes of M 4–5 are often preceded by well-defined clusters of foreshocks of $M \leq 3$, referred as nucleation that is found to last typically 100–400 h. Identification of nucleation in real time has led to successful short-term forecasts of $M \sim 4$ earthquakes.

Study of RTS provides exceptionally good input to comprehend physics of earthquakes, finding safer sites of creating artificial water reservoirs and bringing us closer to accurate short-term earthquake forecasts.

Biogeophysics. Sub-discipline of exploration geophysics focusing on the geophysical signatures resulting from microbial interactions with geologic media.

Introduction

Geophysical imaging techniques have the potential to measure not just the subsurface physical and chemical properties, as geophysics is conventionally used, but also microbes, microbial processes, and microbe-mineral interactions. "Biogeophysics" is defined here as a rapidly evolving discipline of exploration geophysics concerned with the geophysical signatures of microbial interactions with geologic media that combines the fields of Microbiology, Biogeoscience, and Geophysics (Atekwana and Slater, 2009) (Figure 1). Within this context, biogeophysics examines the links between dynamic subsurface microbial processes, microbial-induced alterations to geologic materials, and geophysical signatures. We note that the term biogeophysics is also used in other disciplines (a) to describe research into the origins of life, and (b) to describe fluxes of energy, water, and momentum between earth surface and the atmosphere. Our use of the term describes how it has been adopted by the exploration geophysics community in recognition of the geophysical signatures of microbial activity.

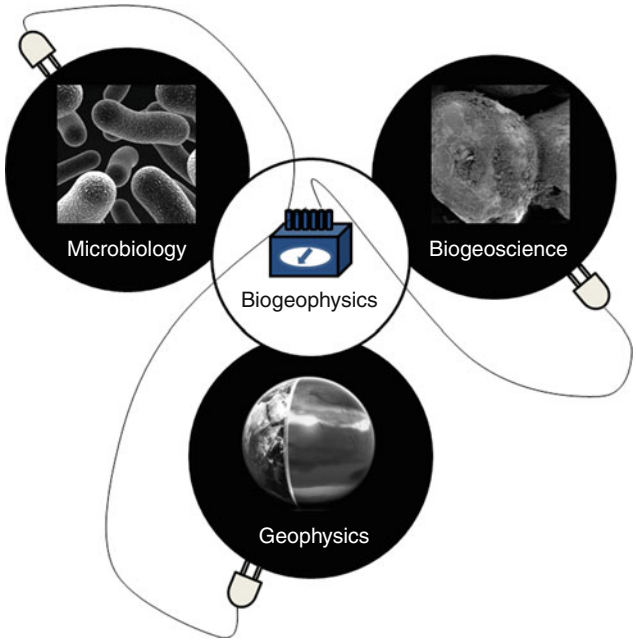
These geophysical signatures may arise from, (1) microbial cells and extracellular structures themselves, (2) growth of microorganisms (production of biomass) and biofilm formation, (3) generation of metabolic by-products and the interactions of these metabolites with the host material, and (4) microbially mediated processes. The geophysical signatures arising from each of these four source mechanisms are described below.

Geophysical detection of cells and biofilms

Microbial cells and biofilms exhibit distinct electrical properties, and certain (magnetotactic) bacteria also display unique magnetic characteristics. The membrane potential (the voltage drop across the membrane due to the negatively charged molecules inside cells) of live cells results in an accumulation of mobile electric-charge carriers at membrane surfaces. When live cells are placed in time-oscillating electric fields, these charges move on the surface of the membrane, giving rise to high polarizations for cellular suspensions that are readily measured with dielectric spectroscopy. As the mobility of these surface charges is relatively small, this effect is manifested at low frequencies, such that the relative dielectric permittivity of live-cell suspensions can be as high as 10^6 (Prodan et al., 2004; Stoy et al., 1982). The outer and inner cell radii, diffusion constants, and membrane potential all have a very distinct effect on broadband dielectric spectroscopy data (Prodan et al., 2008). Polarization enhancement is also observed when microbial cells are present in high concentrations in porous media (Ntarlagiannis et al., 2005), although additional polarization mechanisms associated with mineral surfaces may obscure the signal. This polarization is enhanced when cells are more preferentially adsorbed onto mineral surfaces (Abdel Aal et al., 2009).

The magnetic properties of soils and rock are altered by a diverse group of prokaryotes that exert a significant control over magnetite formation in two ways that differ mechanistically: biologically induced mineralization

Harsh K. Gupta (ed.), *Encyclopedia of Solid Earth Geophysics*, DOI 10.1007/978-90-481-8702-7,



Biogeophysics, Figure 1 Primary disciplinary themes encompassing biogeophysics.

(BIM) and biologically controlled mineralization (BCM) (Jimenez-Lopez et al., 2010). Biologically induced magnetite formation is indistinguishable from magnetite formed by inorganic processes; however, biologically controlled magnetite formation is distinct and produced by magnetotactic bacteria (Jimenez-Lopez et al., 2010). These magnetotactic bacteria biomineralize intracellular, membrane-bound, single-magnetic-domain crystals of the magnetic minerals magnetite and/or greigite called magnetosomes (Bazylinski and Frankel, 2004). Magnetotactic bacteria are typically found in a wide variety of aquatic environments (e.g., fresh water lakes) with the highest numbers occurring mostly at oxic–anoxic interfaces. The presence of magnetotactic bacteria in sediments is often used as a proxy for paleoenvironmental/climatic conditions, and the presence of magnetosomes in sediments and other secondary magnetic minerals produced by microbial activity likely impacts the magnetic properties of the subsurface recorded with magnetic geophysical techniques as has been demonstrated at hydrocarbon contaminated sites (Rijal et al., 2010).

Biofilms (an attached state of cell growth, whereby cells are closely packed and firmly attached to each other) further alter the geophysical properties of soils. Low-frequency electrical measurements respond to self-limiting microbial growth/cell attachment and biofilm formation in porous media, as well as death and lyses of cells (Davis et al., 2006). Electrical polarization may result from the electrical properties of the biofilm itself or from the modification of grain surfaces due to cell attachment. Biofilms also alter the acoustic properties of porous media, with biofilm growth in soil columns resulting in spatial complexity of acoustic amplitudes (Davis et al., 2009). Such variations likely arise from a non-uniform distribution of microbial activity or heterogeneity in the biomass distribution and biofilm morphology (e.g., variations in biofilm thickness, roughness, hydration, etc.).

Geophysical detection of metabolic by-products and mineral weathering

Microbial metabolism enhances the weathering of minerals through the attachment, growth, and colonization of mineral surfaces by microorganisms (Bennett et al., 1996). Metabolic by-products, including biogenic gasses (e.g., CO_2, H_2S, CH_4, etc.), organic acids, and biosurfactants, all affect electrical properties of porous media. Microbial production of organic acids and biosurfactants adds ions to solution, increasing electrolyte concentration of pore fluids (Cassidy et al., 2001). Organic acids enhance mobility of sparingly soluble metals and also increase the number of reaction sites, thus accelerating mineral weathering (Hiebert and Bennett, 1992). Enhanced mineral dissolution catalyzed by increased organic acid concentration can lead to physical changes in grain surface morphology, surface area, surface roughness and the generation of secondary porosity and increased permeability (McMahon et al., 1992). These changes in porosity affect acoustic wave propagation by altering grain contact coupling, and changes in surface area/roughness drive changes in electrical polarization. Biogenic gasses reduce bulk electrical conductivity and enhance attenuation of seismic signal amplitudes.

The effects of metabolic by-products on geophysical properties have been recorded in hydrocarbon contaminated environments (Abdel Aal et al., 2004; Werkema et al., 2003). Such sites are natural bioreactors where excess organic substrates stimulate microbial activity. Enhanced mineral weathering in hydrocarbon contaminated aquifers (Hiebert and Bennett, 1992; McMahon et al., 1995), increases pore fluid conductivity and thereby bulk conductivity sensed with a range of electromagnetic methods (Abdel Aal et al., 2004; Atekwana et al., 2004; Sauck et al., 1998). Elevated bulk conductivity is therefore found where intrinsic bioremediation and enhanced mineral weathering are occurring. These zones of highest bulk electrical conductivity may coincide with the highest percentages of oil degrading microbial populations, with spatial heterogeneity in the microbial community structure and shifts in the microbial community concomitant with vertical changes in bulk electrical conductivity (Allen et al., 2007). Biogenic methane production by archea in anaerobic soils can result in extensive free-phase gas production that reduces dielectric permittivity and electrical conductivity (Comas and Slater, 2007).

Geophysical detection of microbially mediated redox processes

Microbial metabolic activity is a critical driver of redox chemistry because microbes derive energy from

oxidation-reduction reactions (the transfer of electrons from one reactant to the other). Terminal electron acceptors (TEAs) govern nutrient utilization by microbes during the breakdown of organic carbon (Cozzarelli et al., 1999). Microbial respiration consequently results in reduced conditions, and strong redox gradients in the Earth typically develop in the presence of heterotrophic bacteria. Significant changes in Eh and pH result in new mineral stability fields in which some minerals become unstable and are dissolved and mobilized, whereas others may precipitate from solution. As TEAs are consumed, changes in pore fluid chemistry may drive changes in pore fluid conductivity, thereby affecting bulk electrical conductivity.

Strong electrical potentials associated with current sources in the Earth are correlated with redox gradients recorded at sites where microbial degradation of hydrocarbons is occurring (Minsley et al., 2007; Naudet et al., 2003). Such large potentials require geobatteries traditionally invoked to explain very large (~1.0 V) potential gradients due to internal current sources recorded over electronically conductive ore bodies straddling the large redox gradient provided by the water table (Sato and Mooney, 1960). Biogeobatteries may occur in conjunction with a strong redox gradient between highly reducing conditions below the water table within a contaminant plume and an oxidized zone above the water table if microbial activity can generate the required electron bridge (Revil et al., 2010). Possible mechanisms facilitating electron migration include iron oxides, clays, and conductive biological materials (Revil et al., 2010). Metal reducing organisms, such as *Shewanella* and *Geobacter*, produce electrically conductive appendages called bacterial nanowires that may facilitate electron transfer to solid-phase electron acceptors (Reguera et al., 2005). However, the ability of biofilms to facilitate electron transport over the scale of the groundwater interface is unknown although new evidence suggests that such electron transfer can take place at millimeter scales (Nielsen et al., 2010). Nonetheless, more studies are needed to confirm this new finding.

Geophysical detection of microbe-mineral transformations

Biogeochemical processes result in mineral precipitation that alters the physicochemical properties of the grain surfaces. When microbial-induced precipitation is extensive, the volumetric physical properties of porous media are modified. In anaerobic environments, iron-reducing bacteria and sulfate-reducing bacteria can use Fe(III) and sulfate respectively as terminal electron acceptors. Ferrous iron produced by iron reducing bacteria promotes the precipitation of electrically conductive secondary minerals such as siderite ($FeCO_3$), magnetite (Fe_3O_4), and goethite (FeOOH) (Fredrickson et al., 1998). Sulfide produced during microbial sulfate reduction can react with iron (II) produced by iron reducing bacteria to precipitate iron sulfide minerals. Strong seismic and electrical signatures are generated as a result of microbe-induced ZnS and FeS precipitation (Williams et al., 2005). Decreases in seismic wave amplitude result from the development of differential elastic moduli associated with accumulation of metal sulfide-encrusted microbes within pores (Williams et al., 2005). Electrical signals result from the formation, movement and dissolution of electronically conductive biominerals that profoundly enhance the polarization of a porous medium. These electrical signals may be diagnostic of both the concentration and the distribution of the biominerals throughout a porous medium (Slater et al., 2007).

Geophysical signals also result when microbial processes involve the precipitation of semi-metallic or non-metallic minerals, e.g., metabolically induced calcite precipitation by bacterial hydrolysis of urea (Ferris et al., 1995). Relative to metallic minerals, smaller electrical signals result from changes in pore volume/pore tortuosity and/or surface area/surface roughness driven by precipitation of non-metallic minerals (Wu et al., 2010). Calcite precipitation induced by bacteria has been shown to form cements in porous media and affect subsurface fluid flow (Ferris et al., 1995). Such cements profoundly change the elastic properties of soils and rocks, particularly when ureolysis is stimulated to form calcite cement that acts to stiffen the soil matrix (DeJong et al., 2010). Shear waves are well suited to monitoring changes in the particle soil matrix due to precipitation as shear velocity (Vs) is largely unaffected by pore fluid composition and directly dependent on void ratio, coordination number (average number of surrounding particles a given particle is in contact with) and confining stress (DeJong et al., 2010). Large changes in shear-wave velocity accompany stiffening result from initial binding of microbes to the soil matrix, suggesting that relatively small volumes of precipitates can generate large geophysical signals.

Summary

Only a decade ago it seemed inconceivable to suggest that microbial processes could potentially impact geophysical signatures. However, today is it clear that geophysical signatures result from a range of microbial processes covering the scale of an individual cell to the scale of contaminant plumes in the Earth. A pressing question in Biogeophysics is how to quantify the geophysical signatures of microbial processes through the development of appropriate modeling frameworks. Success in this venture will likely involve multidisciplinary research between geophysicists, biogeochemists, and microbiologists.

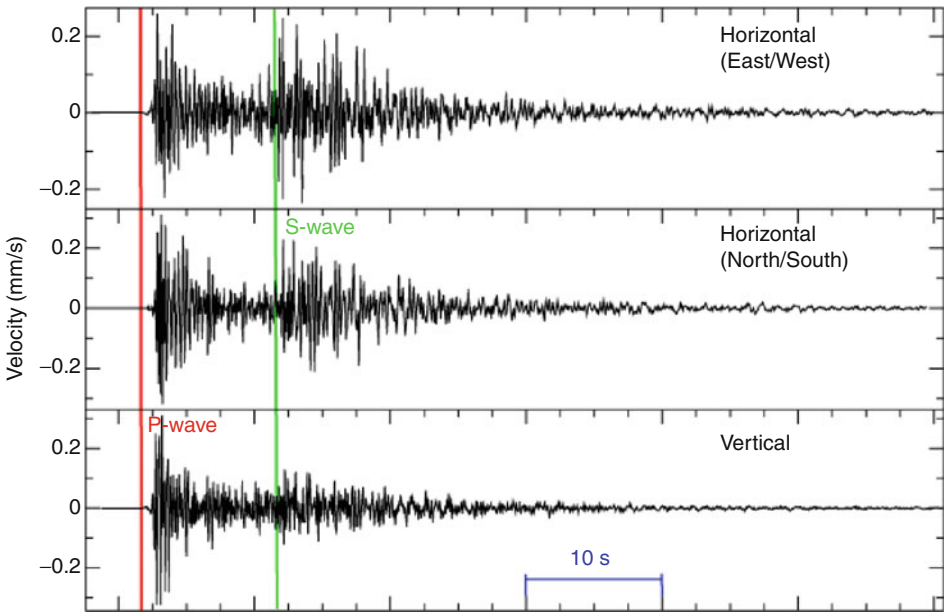
Energy waves generated by an earthquake or an artificial explosion

Definition

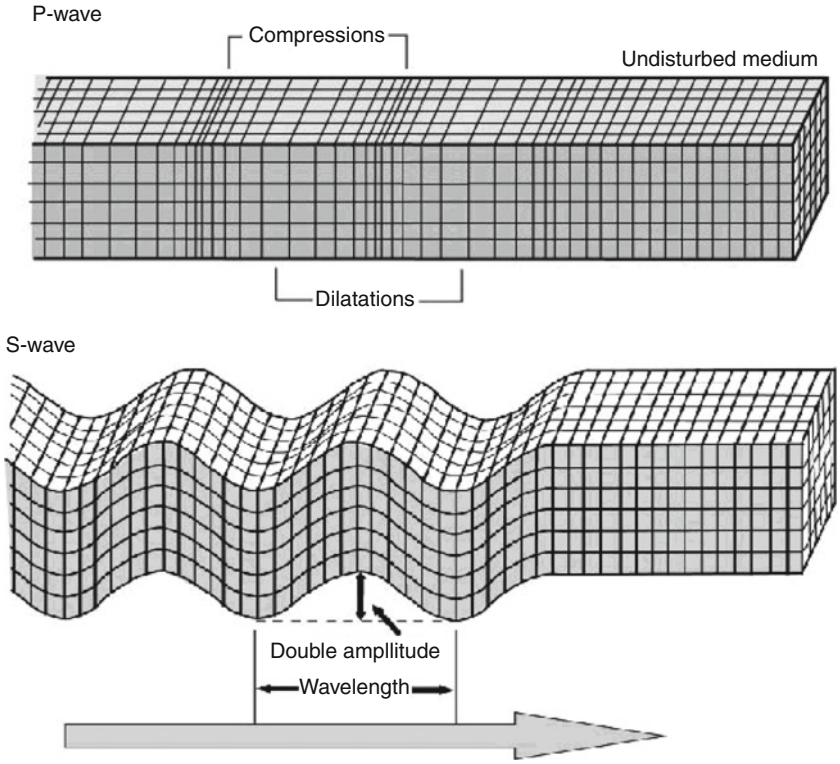
Waves consist of a disturbance in materials (media) that carries energy and propagates. However, the material that the wave propagates in generally does not move with the wave. The movement of the material is generally confined to small motions, called particle motion, of the material as the wave passes. After the wave has passed, the material usually looks just like it did before the wave, and, is in the same location as before the wave. When stress builds up in the Earth to such a level that rapid slip occurs on a fracture (i.e., an earthquake takes place) or when an explosion or mechanical device is used to initiate a seismic disturbance artificially, a complex field of seismic waves is generated. This wave field propagates much like the waves that travel away from the point at which a stone is thrown into a pond. Waves that travel through the interior of the Earth are called body waves. Body waves travel through the interior of the Earth. They follow ray paths bent by the varying density and modulus (stiffness) of the Earth's interior. The density and modulus, in turn, vary according to temperature, composition, and phase. These waves are usually observed at higher frequency.

Types of body waves

There are two main kinds of body waves: P-waves and S-waves, so-named because they are the primary and secondary waves detected by a seismograph (Figure 1). The P-wave is always the first wave to arrive at a seismometer, closely followed by its reflection from the surface and S-waves arrive next. P-waves, or compressional waves, are longitudinal waves (wave motion in the direction the wave is traveling). S-waves are transverse waves or shear waves, involving a back-and-forth shearing motion at right angles to the direction the wave is traveling (Figure 2). Body waves are reflected and transmitted at interfaces where the seismic velocity and/or density changes, obeying Snell's Law. At such an interface, or discontinuity, some of the energy of an incident body wave is reflected as a P-wave, some as an S-wave, some is



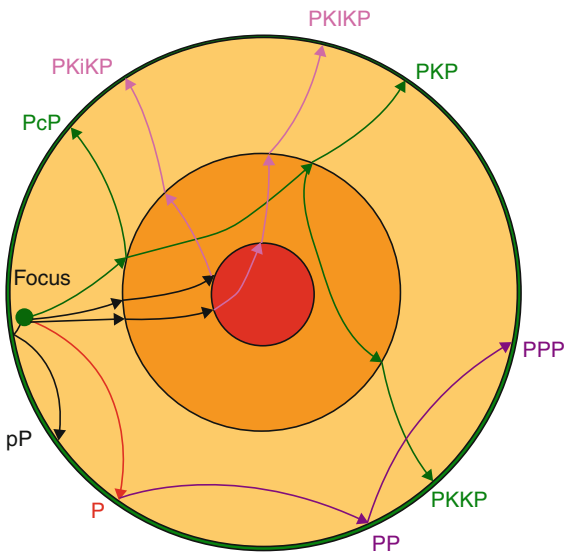
Body Waves, Figure 1 P- and S-wave recorded in a three-component seismograph. P- and S-waves are shown.



Body Waves, Figure 2 P- and S-waves motion. The *arrow* shows the direction that the wave is moving.

transmitted as a P-wave and some as an S-wave. The notation for the various seismic ray paths within the Earth are as follows:

When an earthquake occurs, seismic waves are emitted from the focus (hypocenter); there are several paths that it can take through the Earth before emerging again at the surface. These paths (refer to Figure 3) are symbolized by the letters: p = P-wave arrival from a path that traveled upward from the focus (hypocenter); pP = P-wave arrival from a path that traveled upward from the focus, reflected off the surface of the Earth, then arrived back at the surface; P = P-wave arrival from a path that traveled downward from the focus (hypocenter); PP = P-wave reflected off the surface once; PPP = P-wave reflected off the surface twice; c = a reflection off the outside of the outer surface of the outer core – note that this is the principle cause of multiple arrivals of P- and S-waves right at the epicenter; K = a travel path (refraction) through the outer core; KK = one reflection on the inside outer surface of the outer core; KKK = two reflections off the inside outer surface of the outer core; i = a reflection off the outside of the outer surface of the inner core; I = a travel path (refraction) through the inner core. These letters can be used to indicate the path of a seismic wave through the Earth (Figure 3). For example PKiKP indicates that the wave traveled downward from the focus, refracted through the outer core, reflected off the surface of the inner core, traveled through the outer core, and then traveled through the mantle to arrive at the surface. SKiKS is the same path, but an S-wave. Because liquids have no resistance to shear and cannot sustain a shear wave, S-waves cannot travel through liquid material. The Earth's outer core is believed



Body Waves, Figure 3 P- and S-wave paths in the Earth's interior.

to be liquid because S-waves disappear at the mantle–core boundary, while P-waves do not.

Wave propagation

Seismic body waves propagate through the Earth's interior. Because of the elastic properties of the Earth's materials (rocks) and the presence of the Earth's surface, four main types of seismic waves propagate within the Earth. Compressional (P) and Shear (S) waves propagate through the Earth's interior.

Waves on a seismogram

If we look at a seismogram, we expect to see the first wave to arrive to be a P-wave (the fastest), then the S-wave, and finally, the Love and Rayleigh (the slowest) waves. As you might expect, the difference in wave speed has a profound influence on the nature of seismograms. Since the travel time of a wave is equal to the distance the wave has traveled divided by the average speed the wave moved during the transit, we expect that the fastest waves arrive at a seismometer first. The fact that the waves travel at speeds that depend on the material properties (elastic moduli and density) allows us to use seismic-wave observations to investigate the interior structure of the planet. We can look at the travel times, or the travel times and the amplitudes of waves to infer the existence of features within the planet, and this is an active area of seismological research. To understand how we "see" into Earth using vibrations, we must study how waves interact with the rocks that make up Earth. Several types of interaction between waves and the subsurface geology (i.e., the rocks) are commonly observable on seismograms. We will examine the two simplest types of interaction refraction and reflection.

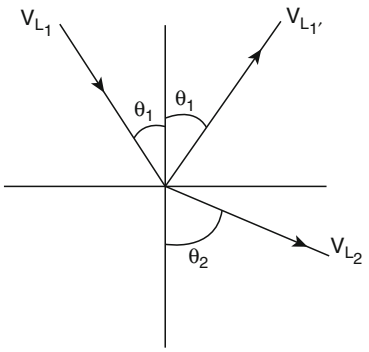
Refraction

As a wave travels through Earth, the path it takes depends on the velocity. Perhaps you recall from high school a principle called Snell's law, which is the mathematical expression that allows us to determine the path a wave takes as it is transmitted from one rock layer into another. Snell's law describes the relationship between the angles and the velocities of the waves. Snell's law equates the ratio of material velocities V_1 and V_2 to the ratio of the sines of incident (θ_1) and refracted (θ_2) angles, as shown in the following equation:

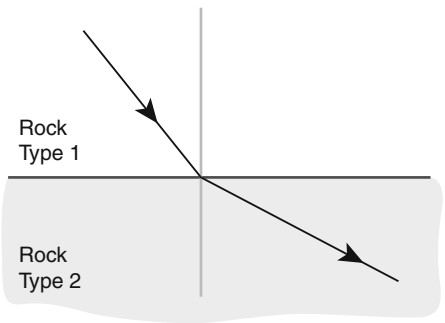
$$\frac{\sin\theta_1}{V_{L_1}} = \frac{\sin\theta_2}{V_{L_2}} \tag{1}$$

where V_{L_1} is the longitudinal wave velocity in material 1 and V_{L_2} is the longitudinal wave velocity in material 2.

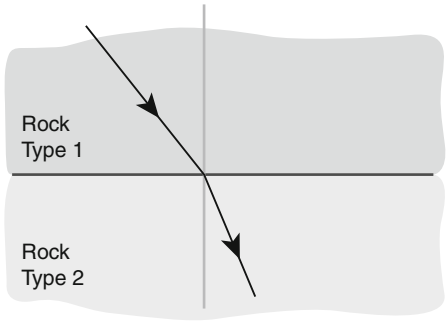
Note that in Figure 4, there is a reflected longitudinal wave ($V_{L_{1'}}$) shown. This wave is reflected at the same angle as the incident wave because the two waves are traveling in the same material, and hence have the same velocities. This reflected wave is unimportant in our explanation of Snell's law, but it should be remembered that some of the wave energy is reflected at the interface. When a longitudinal wave moves from a slower to a faster material, there is an incident angle that makes the angle of refraction for the wave 90°. This is known as the first critical angle. The change in direction depends on the ratio of the wave velocities of the two different rocks. When waves reach a boundary between different rock types, part of the energy is transmitted across the boundary. The actual interaction between a seismic wave and a contrast in rock properties is more complicated because an incident P-wave generates transmitted and reflected P- and S-waves and also an incident S-wave generates transmitted and reflected P- and S-waves, so five waves are involved. The transmitted wave travels in a different direction, which depends on the ratio of velocities of the two rock types (Figures 5 and 6). Part of the energy is also reflected backwards into the region with rock type 1, but we have not shown that on these figures. Refraction has an important effect on waves that travel through Earth. In general, the seismic velocity in Earth increases with depth (there are some important exceptions to this trend) and refraction of waves causes the path followed by body waves to curve upward (Figure 7).



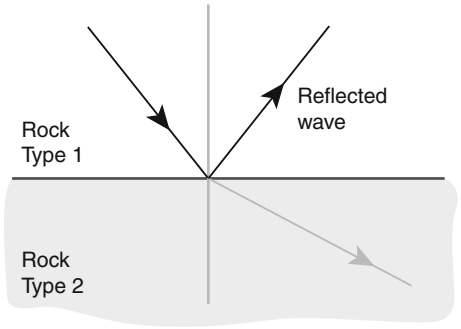
Body Waves, Figure 4 Reflected ($V_{L_{1'}}$) and refracted (V_{L_2}) longitudinal waves.



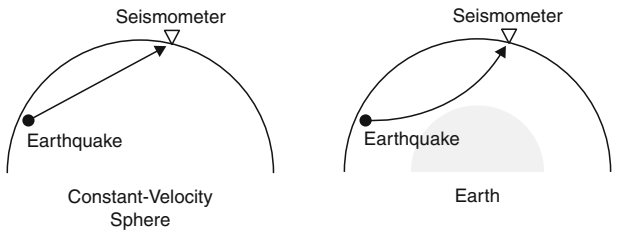
Body Waves, Figure 5 Velocity in rock type 2 is greater than velocity in rock type 1.



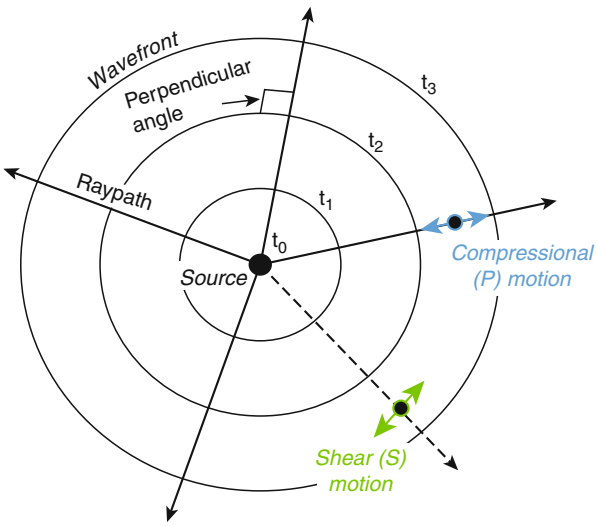
Body Waves, Figure 6 Velocity in rock type 2 is less than velocity in rock type 1.



Body Waves, Figure 8 When a wave encounters a change in material properties (seismic velocities and or density), its energy is split into reflected and refracted waves.



Body Waves, Figure 7 The overall increase in seismic-wave speed with depth into Earth produces an upward curvature to rays that pass through the mantle. A notable exception is caused by the decrease in velocity from the mantle to the core. This speed decrease bends waves backwards and creates a "P-wave shadow zone" between about 100° and 140° distance (1° = 111.19 km).



Body Waves, Figure 9 Wave fronts and ray paths in seismic-wave propagation.

Reflection

The second wave interaction with variations in rock type is reflection. I am sure you are familiar with reflected sound waves: we call them echoes. And your reflection in a mirror or pool of water is composed of reflected light waves. In seismology, reflections are used to prospect for petroleum and investigate Earth's internal structure. In some instances, reflections from the boundary between the mantle and crust may induce strong shaking that causes damage about 100 km from an earthquake (we call that boundary the "Moho" in honor of Mohorovicic, the scientist who discovered it). A seismic reflection occurs when a wave impinges on a change in rock type (which usually is accompanied by a change in seismic-wave speed). A part of the energy carried by the incident wave is transmitted through the material (that is the refracted wave described above), and a part is reflected back into the medium that contained the incident wave (Figure 8). The amplitude of the reflection depends strongly on the angle that the incident wave makes with the boundary and the contrast in material properties across the boundary. For some angles, all the energy can be returned into the medium containing the incident wave. An incident P-wave generates transmitted and reflected P- and S-waves and so five waves are involved. Likewise, when an S-wave interacts with a boundary in rock properties, it too generates reflected and refracted P- and S-waves. Because major boundaries between different rock types within the Earth are normally approximately parallel to the Earth's surface, S-wave particle motion is commonly in the SV (perpendicular to the ray path and vertical) and SH (perpendicular to the ray path and horizontal) directions. P-waves travel faster than S-waves, so there will be separate wave front representations for the P- and S-waves (Figure 9). If the physical properties of the material through which the waves are propagating are constant, the wave fronts will be circular (or spherical in three dimensions). If the physical properties vary in the model, the wave fronts will be more complex shapes. In the transverse or shear wave, the particles oscillate at a right angle or transverse to the direction of propagation. Shear waves

require an acoustically solid material for effective propagation, and therefore, are not effectively propagated in materials such as liquids or gases. Shear waves are relatively weak when compared to longitudinal waves. In fact, shear waves are usually generated in materials using some of the energy from longitudinal waves.

Velocity

Among the properties of waves propagating in isotropic solid materials are wavelength, frequency, and velocity. The wavelength (λ) is directly proportional to the velocity of the wave (C) and inversely proportional to the frequency (f) of the wave. The phase velocity of a seismic wave can be written as:

$$C = \omega/k, \tag{2}$$

where $\omega = 2\pi f$ is the angular frequency and $k = \lambda/2\pi$ is wave number.

Velocity of P- and S-waves

Seismic waves travel fast, of the order of kilometers per second (km/s). The precise speed that a seismic wave travels depends on several factors, the most important of which is the composition of the rock. We are fortunate that the speed depends on the rock type because it allows us to use observations recorded on seismograms to infer the composition or a range of compositions of the planet. But the process is not always simple, because sometimes different rock types have the same seismic-wave velocity, and other factors also affect the speed, particularly temperature and pressure. Temperature tends to lower the speed of seismic waves and pressure tends to increase the speed. Pressure increases with depth in Earth because the weight of the rocks above increases with increasing depth. Usually, the effect of pressure is larger and in regions of uniform composition, the velocity generally increases with depth, despite the fact that the increase of temperature with depth works to lower the wave velocity. When the different seismic-wave types are described below, I will quote ranges of speed to indicate the range of values we observe in common terrestrial rocks. But you should keep in mind that the specific speed throughout Earth will depend on composition, temperature, and pressure.

P-waves

P-waves are the first waves to arrive on a complete record of ground shaking because they travel the fastest (their name derives from this fact –P is an abbreviation for primary, first wave to arrive). They typically travel at speeds between ~1 and ~14 km/s. The slower values corresponds to a P-wave traveling in water, the higher number represents the P-wave speed near the base of Earth's mantle. The velocity of a wave depends on the elastic properties and density of a material. If we let κ represent the bulk modulus of a material, μ the shear modulus, and ρ the density, then the P-wave velocity, which we represent by C_P, is defined by:

$$C_P = \sqrt{\frac{\lambda + 2\mu}{\rho}} \tag{3}$$

A modulus is a measure of how easy or difficult it is to deform a material. For example, the bulk modulus is a measure of how a material changes volume when pressure is applied and is a characteristic of a material. For example, foam rubber has a lower bulk modulus than steel. P-waves are sound waves, it is just that in seismology we are interested in frequencies that are lower than humans' range of hearing (the speed of sound in air is about 0.3 km/s). The vibration caused by P-waves is a volume change, alternating from compression to expansion in the direction that the wave is traveling. P-waves travel through all types of media – solid, liquid, or gas.

S-waves

Secondary, or S-waves, travel slower than P-waves and are also called "shear" waves because they do not change the volume of the material through which they propagate – they shear it. S-waves are transverse waves because they vibrate the ground in a direction "transverse," or perpendicular, to the direction that the wave is traveling.

The S-wave speed, call it C_S, depends on the shear modulus and the density

$$C_S = \sqrt{\frac{\mu}{\rho}} \tag{4}$$

Even though they are slower than P-waves, the S-waves move quickly. Typical S-wave propagation speeds are of the order of 1–8 km/s. The lower value corresponds to the wave speed in loose, unconsolidated sediment, the higher value is near the base of Earth's mantle. An important distinguishing characteristic of an S-wave is its inability to propagate through a fluid or a gas because fluids and gases cannot transmit a shear stress and S-waves are waves that shear the material. The velocity of seismic waves depends on the elastic properties and density of a material in which the wave is traveling. P-waves are sound waves, it is just that in seismology we are interested in frequencies that are lower than humans' range of hearing (the speed of sound in air is about 0.3 km/s). The vibration caused by P-waves is a volume change, alternating from compression to expansion in the direction that the wave is traveling. In general, earthquakes generate larger shear waves than compressional waves and much of the damage close to an earthquake is the result of strong shaking caused by shear waves.

Attenuation

Near the source of a strong disturbance, such as a large explosion or earthquake, the wave-generated deformation

can be large enough to cause permanent deformation, which will be visible as cracks, fault offsets, and displacements of the ground after the disturbance has passed. A source of energy creates the initial disturbance and the resulting waves propagate (travel) out from the disturbance. Because there is finite energy in a confined or short-duration disturbance, the waves generated by such a source will spread out during propagation and become smaller (attenuate) with distance away from the source or with time after the initial source, and thus, will eventually die out (Figure 10). Knowledge of attenuation can be very useful in seismic data processing, as its removal increases resolution.

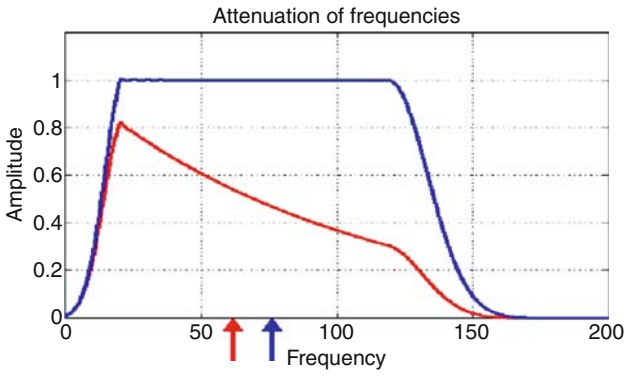
Attenuation often serves as a measurement tool that leads to the formation of theories to explain physical or chemical phenomenon that decreases the body wave's intensity. The amplitude change of a decaying plane wave can be expressed as:

$$A = A_0 \mathbf{e}^{-\alpha z} \tag{5}$$

In this expression A_0 is the unattenuated amplitude of the propagating wave at some location. The amplitude **A** is the reduced amplitude after the wave has traveled a distance **z** from the source. The quantity α is the attenuation coefficient of the wave traveling in the z-direction. The more common unit of the attenuation value is Decibels. Attenuation is generally proportional to the square of the frequency. Quoted values of attenuation are often given for a single frequency, or an attenuation value averaged over many frequencies may be given. The quoted values of attenuation only give a rough indication of the attenuation and should not be automatically trusted. Generally, a reliable value of attenuation can only be obtained by determining the attenuation experimentally for the particular material being used.

Summary: results of regional and global studies

The study of seismic body waves permits us to derive important knowledge about the internal constitution of the Earth. The problems related to propagation of elastic seismic body waves has been discussed in a number of books and in numerous papers (e.g., Bromwich, 1898; Sezawa, 1927; Haskell, 1953; Ewing et al., 1957; Brekhovskikh, 1960; Bullen, 1963; Bath, 1968; Achenbach, 1975 and others). Attenuations of seismic waves have been investigated by many authors (e.g., McDonald et al., 1958; Knopoff and Macdonald, 1958; Kolsky, 1963; White, 1965; Kuster and Toksoz, 1974; Shoenberger and Levin, 1974; Kennett, 1983; Hong and Kennett, 2003 and others). The asymptotic theory of body-wave propagation in anisotropic media is also well developed (e.g., Crampin, 1984; Thomsen, 1986; Tsvankin, 1997; Cerveny, 2001; Chapman, 2004).



Body Waves, Figure 10 Amplitude spectrum in red is for signal after attenuation.

The effect of initial stresses present in the medium is not considered in the above studies. Recently, Dey and Dutta (1998) have been studying the problem of propagation and attenuation of seismic waves, taking the effect of initial stresses present in the medium into account. Biot incremental deformation theory has been used (Biot, 1965) in their study. Selim and Ahmed (2006) have studied the velocities of propagation, damping, and attenuations of seismic body waves in compressible and dissipative medium under the effect of both initial and couple stresses.

Body-wave modeling

Seismological methods for determining Earth structure are often classified as being either active or passive in nature. Passive methods involve waiting for an earthquake to occur and provide the seismic source for recording. In contrast, controlled-source seismology refers to active methods where the experimenter provides the source by an explosion or a mechanical device such as a hammer, a weight that is dropped, or a vibrator. Active methods can, in turn, be divided into two basic classifications. The first is seismic reflection profiling, which is a clearly defined approach in which the goal is to produce an image of the subsurface in which structures can be seen directly, in the way that an X-ray image reveals features inside an object. Other active seismic methods infer seismic velocities and the presence of discontinuities in velocity and structure (such as faults) using a variety of approaches that analyze the arrival times and sometimes the shape of seismic waves traveling along different paths through the Earth. As a consequence of advances in seismic instrumentation and national programs increasing the number of instruments available, there have been many recent developments in these techniques that do not directly image the Earth. A convenient aspect of the theoretical basis for virtually all active-source techniques is that they are largely independent of scale. Thus, detailed studies to address environmental problems and regional studies to determine deep Earth structure employ the same basic techniques of analysis (Hancock and Skinner, 2000). Recently, several efforts have been made to complete our knowledge of the structure of the Earth's upper mantle by detailed observation of seismic body waves, especially by their amplitude–distance curves.

CHARACTERISTIC EARTHQUAKES AND SEISMIC GAPS

David D. Jackson, Yan Y. Kagan
Department of Earth and Space Sciences, University of California Los Angeles, Los Angeles, CA, USA

Definitions

Fault slip. Relative motion, either steady or sudden as in earthquakes, between rock units on either side of a fault.
Rupture. Sudden fault slip in an earthquake.
Elastic rebound. Sudden release, as by an earthquake, of slowly accumulated strain energy.
Segment. A section of a fault or plate interface bounded by features thought to serve as strong barriers to earthquake rupture. Features postulated to form such barriers include changes in fault orientation or in rock type across parts of the fault, and intersections with other faults.
Characteristic earthquake. An earthquake rupturing an entire fault segment. Alternately, one of a sequence of earthquakes rupturing the same area of fault.
Recurrence interval. The time between characteristic earthquakes on a given segment or fault area.
Quasiperiodic. Occurring at approximately equal recurrence intervals.
Seismic cycle. A sequence of events on a segment starting with a large earthquake, followed by aftershocks, then by steady stress accumulation, and culminating with another large earthquake. The term "cycle" is sometimes but not always meant to imply quasiperiodic recurrence.
Seismic gap. A segment for which the time since the previous characteristic earthquake approaches or exceeds the average recurrence interval.

Introduction

The seismic gap hypothesis holds that most long-term geologic slip on faults or plate boundaries is accomplished by characteristic earthquakes on segments. Such quakes are presumed to reduce the stress substantially, necessitating a substantial recurrence time for elastic stress to recover before the next characteristic earthquake. The dates and rupture extent of past earthquakes may be determined by modern seismic networks; by historic reports of faulting, damage, or strong shaking; or by paleoseismic investigation of trenches across faults. The average recurrence time may be determined either from a sequence of dates of past characteristic earthquakes, or by the time required for steady slip on a fault to accumulate the slip experienced in a characteristic earthquake (Working Group on California Earthquake Probabilities, 1988, 1990).

History

Well before plate tectonics became accepted in the 1960s, Gilbert (1884) argued that large earthquakes should be separated by substantial time intervals. Reid (1910, 1911) proposed that faults slowly accumulate energy later released suddenly by earthquakes ("elastic rebound"), and that the time to a future earthquake could be estimated by surveying the strain released by a previous one. Fedotov (1965) noticed that most of the Kamchataka–Kurile trench in the northwest Pacific had been ruptured by earthquakes in the early twentieth century, with the exception of one zone southeast of Hokkaido. He concluded that a future earthquake was likely in that area, a forecast realized in 1973 when the Nemuro-oki earthquake struck with magnitude about 7.5 (Kasahara, 1981, 182).

Plate tectonics now provides a compelling, steady source of the strain energy driving elastic rebound, and

Harsh K. Gupta (ed.), *Encyclopedia of Solid Earth Geophysics*, DOI 10.1007/978-90-481-8702-7,

that fact led many to conclude that occurrence of large earthquakes must be separated by enough time to allow recharge. Scholz (1990, 260) remarked that "A tenet of plate tectonics is that the rates of plate motion must be steady over geologic time periods and must be continuous along plate boundaries. If it is assumed further that a significant portion of this motion must be released seismically, then it follows that segments of plate boundaries that have not ruptured for the longest time are those most likely to rupture in the near future. These places are called seismic gaps." The seismic gap hypothesis was celebrated when Nishenko, 1989 published a list of 13 earthquakes that fit, at least approximately, the descriptions of previously expected earthquakes.

The seismic gap model has been applied to long-term forecasting of earthquakes in many regions (Sykes, 1971; Kelleher, 1972; Kelleher et al., 1973; McCann et al., 1979; Working Group on California Earthquake Probabilities, 1988, Nishenko, 1991). The model and its definition have evolved along with the quality and quantity of data that go into it. Fedotov (1965) defined the Nemuro-oki gap as the last remaining unbroken segment. McCann et al. (1979) used elapsed time and a color code to label segments around the Pacific Rim: more than 100 years had elapsed in red gaps, between 30 and 100 years in orange gaps, and less than 30 years in apparently safe green zones. In the most comprehensive forecast ever using the seismic gap model, Nishenko (1991) actually made testable probabilistic forecasts for about 125 plate boundary segments around the Pacific Rim. In that study he estimated the mean recurrence time and the elapsed time for each segment, and assumed that their ratio obeys a log-normal probability density function. With that information, he calculated the probability that each zone would be ruptured by a characteristic earthquake whose magnitude he also listed for each zone within 5-, 10-, and 30-year periods. A very similar model was used by the Working Group on California Earthquake Probabilities (1988) in its official earthquake probability estimates.

Assumptions

All the applications mentioned above share several important assumptions. First, their authors assume that faults and plate boundaries are segmented and that rupture does not cross segment boundaries. Second, they assume that each characteristic earthquake ruptures to both ends of its segment, reducing the stress to a uniform base level and beginning the process of stress recharge. Third, they assume that the time to the next characteristic earthquake depends almost entirely on the time of the previous one: not on other earthquakes, nonelastic stress redistribution, or other causes. To make useful forecasts, scientists must obviously be able to distinguish characteristic earthquakes from all others in order to know the elapsed time since the last one.

Small characteristic earthquakes

Recent studies in California (e.g., Nadeau and McEvilly, 1999), Japan (e.g., Igarashi et al., 2003; Okada et al., 2003), and elsewhere have identified sequences of small earthquakes fitting the alternative definition of "characteristic earthquake" above. In each sequence, the events are approximately the same size, and rupture approximately the same fault area. They recur at nearly equal time intervals or in some cases variable intervals consistent with variations in their size or in fault slip rate. In most cases, the slipped areas appear to be surrounded by areas where displacement occurs by steady slip rather than earthquakes. Because of that special circumstance, these small repeating earthquakes are not relevant to the discussion of seismic gaps.

Modified seismic gap hypothesis

As time, earthquake experience, and theoretical sophistication have accumulated, earth scientists have modified the seismic gap theory to rely less on the assumptions above. The Working Group on California Earthquake Probabilities (1990) allowed adjustments to account for stresses from earthquakes not on the relevant segment. The 1992 Landers, California earthquake (magnitude about 7) presented a particularly important observation. In that event, rupture jumped segment boundaries and even faults, making use of up to five faults mapped as separate before 1992. In a seismic hazard model produced by the Southern California Earthquake Center (Working Group on California Earthquake Probabilities, 1995), the seismic gap model was modified to allow rupture to jump segment boundaries with a modest probability. Later uses of the seismic gap model in California for official hazard estimates employ increasingly complex assumptions, especially about conditions under which rupture is likely to involve more than one segment (Working Group on California Earthquake Probability, 2002, 2008).

The more complex versions of the model raise interesting questions. What truly constitutes a segment? How effective are weak barriers in stopping rupture, and what controls their strength? Are the boundaries fixed in space, or can they move as stress conditions change? When rupture crosses a boundary, does it consistently continue to the next? If not, does it reset the stress and the clock on the partially ruptured segment? Do the elapsed times on adjacent segments control the probability that rupture will jump the barrier between them? If so, which segment is most important? Modelers must answer these questions, implicitly or explicitly, to forecast using the modified gap models. So far, there is no clear consensus on the answers.

Challenges to the seismic gap model

Despite some reported successes, the seismic gap hypothesis has often been questioned. Critics point to the difficulty of verifying the rather strong assumptions behind the hypothesis, and to its limited success in forecasting earthquakes.

The basic assumption that faults and plate boundaries are segmented has provoked significant debate. Even the few apparent successes (e.g., Loma Prieta, CA, 1989;

Parkfield, CA 2004; Chile, 2010), are equivocal at best. The rupture of the Loma Prieta earthquake was about the length of the nearest segment mapped by the Working Group on California Earthquake Probabilities (1988), but it shifted south and spilled over the southern segment boundary. Moreover, the event occurred near, but not actually on the San Andreas Fault for which the segment was defined. Before 2004, the Parkfield segment was defined in several different ways, so its location at Parkfield does not confirm the segmentation hypothesis (Jackson and Kagan, 2006). The 2010 Chile earthquake went well beyond the segment boundaries specified by Nishenko (1991). In addition, several events have clearly violated preassigned boundaries. The 1992 Landers quake was mentioned above, and the great Sumatra tsunami earthquake of 2004 breached several boundaries along its 1,300-km rupture zone (Nalbant et al., 2005).

The assumption that earthquakes rupture to both ends of segment boundaries also lacks verification. A basic problem is that the locations of segment boundaries are usually estimated inaccurately from the extent of past earthquake ruptures. For earthquakes identified by paleoseismic investigations, rupture can generally be pinpointed at only a few widely spaced locations. For historical earthquakes, rupture extent is typically estimated with great uncertainty from the extent of damage or reported shaking. Even for modern instrumentally recorded earthquakes, the extent of the aftershock zone or fault scarp may not accurately represent the rupture at depth where the elastic rebound occurs. In many cases, the extent of rupture for older earthquakes is assumed to be similar to that of the most recent event, a clear case of circular reasoning.

The connection between plate tectonics and earthquake recurrence referred to in the words of Scholz above depends on the assumption that characteristic earthquakes release most of the slowly accumulated fault slip. However, that assumption fails in many examples. For instance, the cumulative slip of the Parkfield, CA earthquakes since 1857, often regarded as an archetypical characteristic sequence, accounts for only a small fraction of expected slip at the long-term geological rate (Jackson and Kagan, 2006). In such cases, the alternative definition of characteristic earthquakes listed above, and the times of past events, may provide valuable information on the causes of some earthquakes but the direct link to plate tectonics is lost.

Proponents of the seismic gap theory cite many examples in which identified gaps have been filled by earthquakes. The positive examples are appealing but insufficient for two reasons. First, the definitions of gaps and forecasted earthquakes were quite general, making the target easier to hit at random. Second, they included only successes; a fair evaluation needs to consider failures as well.

Kagan and Jackson (1991, 1995), and Rong et al. (2003) applied statistical tests to the seismic gap theory as articulated by McCann et al. (1979) and Nishenko (1991). Earthquakes were actually more frequent in McCann's green zones than in the red ones, opposite to what the gap theory assumes. The 1991 gap model implied far more earthquakes, in different places, than actually occurred. Kagan and Jackson (1995) and Rong et al. (2003) also tested a simple alternative to the gap model, assuming that earthquakes occur randomly in time and near past earthquakes. The alternative model fits the total number and the locations of future earthquakes much better than the 1991 gap model.

These statistical tests necessarily applied to the earlier versions of the gap hypothesis, in which segments were assumed to be independent of one another. Since then, more complex versions of the model have been applied. Most of these applications involve one or a few purported gaps with estimated recurrence times of decades or centuries. Published models generally do not provide probabilities for multi-segment ruptures, and they cannot be effectively evaluated until several seismic cycles have elapsed. To be rigorously testable, such a model must forecast a few tens of well-defined earthquakes. Unfortunately, no systematic, well-specified version of the more complex seismic gap model has been applied broadly enough to be tested.

Conclusions

The intuitively appealing seismic gap model encompasses the virtually unassailable principle that earthquakes release strain energy accumulated over a long time. Although many large events have occurred in previously identified gaps, the same is true of locations outside them. Simple versions of the gap theory, in which characteristic earthquakes occur on independent segments, are no longer tenable. Modified versions of the gap theory have not yet been formulated in a rigorously testable way.

CONTINENTAL DRIFT

Alan G. Smith
Department of Earth Sciences, University of Cambridge, Sedgwick Museum, Cambridge, UK

Definition

Continental drift. The name given to the relative movement between continents.

Introduction

Apparently, continental drift was first postulated by Abraham Ortelius, who made one of the first atlases, in the third edition of his *Thesaurus Geographicus* (Ortelius, 1596) to account for the similarity between the coastlines of western Africa, western Europe, and the eastern Americas. During the next three centuries or so, several other thinkers used this morphological similarity to come to the same conclusion.

Alfred Wegener

Although Ortelius speculated that earthquakes and floods had torn the continents apart, Alfred Wegener, an Austrian meteorologist, was the first to systematically gather the geological evidence for continental drift in his synthesis (Wegener, 1929a), also translated into English (Wegener, 1929b), parts of which had been published as early as 1912 (Wegener, 1912).

Wegener was puzzled in particular by the present-day distribution of former ice-age deposits, or tillites, of Permo-Carboniferous age, now known to be about 300 million years old that are found today in South America, Africa, Antarctica, India, and Australia. Wegener's meteorological background led him to assume that the present-day climatic zones, with cold polar regions and a hot tropical belt, was a fundamental property of the Earth's atmosphere that had been established before these glacial deposits had formed and had persisted to the present-day. He realized that if all the southern continents had been joined together to form a supercontinent lying near the south geographic pole, then the *present-day* distribution of all the Permo-Carboniferous tillites would have a logical explanation. This supercontinent is known as Gondwana. But Wegener went further and postulated that the northern continents had also been joined to form a northern supercontinent known as Laurasia, which, with Gondwana, formed a huge continental area incorporating all the major continents, known as Pangea.

Wegener's solution to the tillite distribution had a compelling elegance about it, partly because it also placed the Carboniferous forests of Europe and North America, (whose compressed remains gave the name to the Carboniferous period) in what would have been the tropical region of that time. However, elegance is not a scientific proof, and Wegener's ideas were rejected by most geophysicists and many geologists, principally

because there were no physical measurements that demonstrated drift and there was also no known *physical* mechanism that could move continents independently of one another [e.g., Jeffreys (1929)].

Wegener (1929a) made the reassembly by positioning the continents at where he presumed the edges of the continents lay, that is, somewhat beyond the present-day coastlines, but his maps were rather schematic. A more convincing Gondwana map, supported by much geological evidence, was made by Du Toit (1937), but the best precomputer map showing the excellence of the fit between the continental edges of South America and Africa was made by Carey (1958). Jeffreys (1964) denied that there was a fit, and it was his denial that in part led Bullard and others to examine how well the continental edges fitted together (Bullard et al., 1965; Everett and Smith, 2008). These ideas were supported by the changes in the Earth's magnetic field preserved in rocks (see *Paleomagnetism, Principles*) determined by workers such as Irving (1964), but the results were *not fully accepted by the geoscience community* until after the plate tectonic revolution.

Conclusions

It is now established that the Earth's lithosphere is divided into a number of rigid *Plate Tectonics, Precambrian* in relative motion. Tracing these motions back in time shows that Gondwana, Laurasia, and Pangea did exist in the past, *vindicating Wegener's idea completely.*

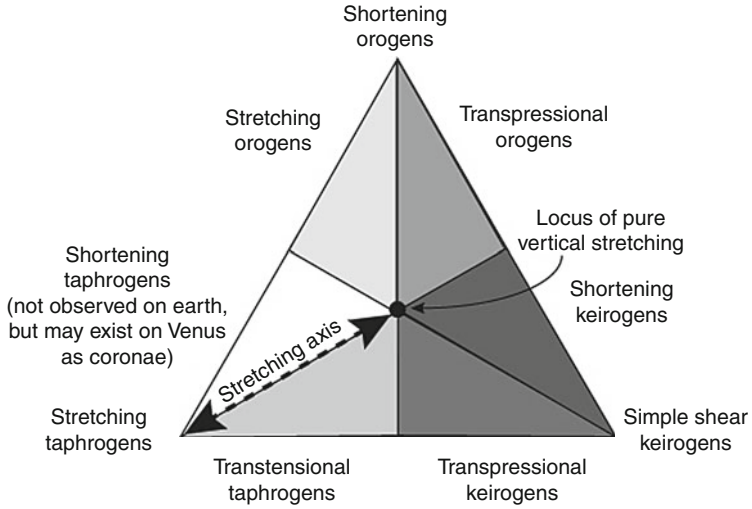
Definition

A continental rift (Gregory, 1894; Quennell, 1982, 1985) is a fault-bounded elongate trough under or near which the entire thickness of the lithosphere (see *Lithosphere, Continental*; *Lithosphere, Mechanical Properties*) has been reduced in extension during its formation. Just as old mountain ranges may no longer have any topographic expression because of tectonic and/or erosional events, some, especially old, rifts may no longer appear as troughs for the same reasons, but their original trough shape is recognized by their stratigraphically younger fills, or metamorphically lower grade of their down-dropped central blocks (see *Sedimentary Basins*).

Introduction

Rifts form one of the three main categories of lithospheric-scale structures resulting from differential motion of parts of the lithosphere. Lithospheric shortening creates orogens, simple shear creates keirogens, and stretching creates taphrogens that are collections of rifts (Figure 1). However, at present, only 20.5% of the active plate boundaries show normal convergence and 21% normal divergence. Some 8% show pure dextral strike-slip and some 6% pure sinistral strike-slip. The remaining 58.5% display some deviation from the three end-members, with relative motion vector angles to bountary strikes varying between 0° and 67° (Woodcock, 1986). Plate boundaries must have shown a similar behavior in the past, so only about half of all the rifts a geologist may encounter is likely to show normal extension



Continental Rifts, Figure 1 A ternary diagram of strain showing the three lithospheric megastructure categories resulting from various strains.

(see *Plate Motions in Time: Inferences on Driving and Resisting Forces*; *Plates and Paleoreconstructions*).

Rifts are important structures from the viewpoints of our understanding of the behavior of our planet and our exploitation of its resources. They record evidence of continental fragmentation in diverse tectonic settings, including all three types of plate boundaries and in plate interiors (see *Plate Motions in Time: Inferences on Driving and Resisting Forces*; *Plates and Paleoreconstructions*). Also, at different stages of their evolution, they present opportunities of studying the continental crust (and in extreme cases even the upper mantle) from its surficial sedimentary rocks down to the crust-mantle interface (see *Lithosphere, Continental*). Especially the lacustrine sedimentary sections of rifts are useful for studies on the past climates (e.g., Olson and Kent, 1999; Kravchinsky et al., 2003; Felton et al., 2007) and they have enabled geologists to refine stratigraphic correlations down to thousands of years, as far back as in the early Mesozoic (e.g., Olsen and Kent, 1999).

Rifts house important economic reserves such as hydrocarbons (the Sirt rift in Libya being the most productive with about 45 billion barrels of oil and 33 trillion cubic feet of gas; for the hydrocarbon potential of rifts, see Harding, 1983; MacKenzie and McKenzie, 1983: a classic on hydrocarbon genesis in rifts; Ziegler, 1994a; Lambiase, 1995), hydrothermal and stratiform copper, copper-nickel, molybdenum, giant lead-zinc, and even uranium deposits (for metallogenesis in rifts, see Sawkins, 1990). Most of the geothermal areas in the world are located in active rifts (e.g., Jaffé, 1971; figure 1) (see *Geothermal Heat Pumps*). At present, one fifth of the entire fresh-water reserve of the earth resides in a rift basin, namely Lake Baykal. Rifts are thus significant not only for increasing our geological knowledge, but also for contributing to our well-being. It is perhaps of some interest in this context to remember that our genus and species were born in a rift, namely in the East African.

For good overviews of rifts and rifting, see Burke and Dewey (1973), Burke and Wilson (1976), Coward et al. (1987), McKenzie (1978) (a "must" read for understanding the evolution of rifts), Manspeizer (1988), Ziegler (1992, 1994b), Landon (1994), Şengör (1995), Şengör and Natal in (2001) (a detailed catalog of the world's rifts with tabulated summaries of origin and history and references) and Ring and Wernicke (2009). For the geology of some of the classic rift regions of the world, with increasing age, see Africa as a whole: Kampunzu and Lubala (1991), Burke (1996), and Burke and Gunnell (2008). East Africa: Frostick et al. (1986), Frostick (1997) (a good introduction for beginner), Schlüter (1997) (this book has a bibliography of some 1,300 items), Morley (1999) (has an excellent collection of seismic sections). Basin-and-Range: Wernicke (1990), Beratan (1996), Faulds and Stewart (1998), Snow and Wernicke (2000), Dickinson (2002) (best introduction for an outsider) and McQuarrie and Wernicke (2005) (best kinematic reconstruction of any rift I know). Rio Grande rift, USA: Ingersoll (2001). The Upper Rhine rift: see the special issue on it in the *International Journal of Earth Sciences (Geologische Rundschau)*, vol. 94 (2005); also: Hüttner (1991), Schumacher (2002), Rotstein et al. (2006). The Lake Baykal rift: Crane et al. (1991), Kuz'min et al. (2001), ten Brink and Taylor (2002), Kravchinsky et al. (2003). The West Siberian Basin: Surkov et al. (1994). The North Sea Basin with the North German (Lower Saxony) Basin: Blundell and Gibbs (1990), Evans et al. (2003) (this lavishly illustrated and richly documented mammoth book makes all earlier publications on the subject either obsolete or redundant; also available as a two CD-ROM set), Wilson et al. (2004), Littke et al. (2008). The Mediterranean region: Durand

et al. (1999), Corti et al. (2006) (an excellent paper about a little-known rift cluster).

Rift, graben, and taphrogen

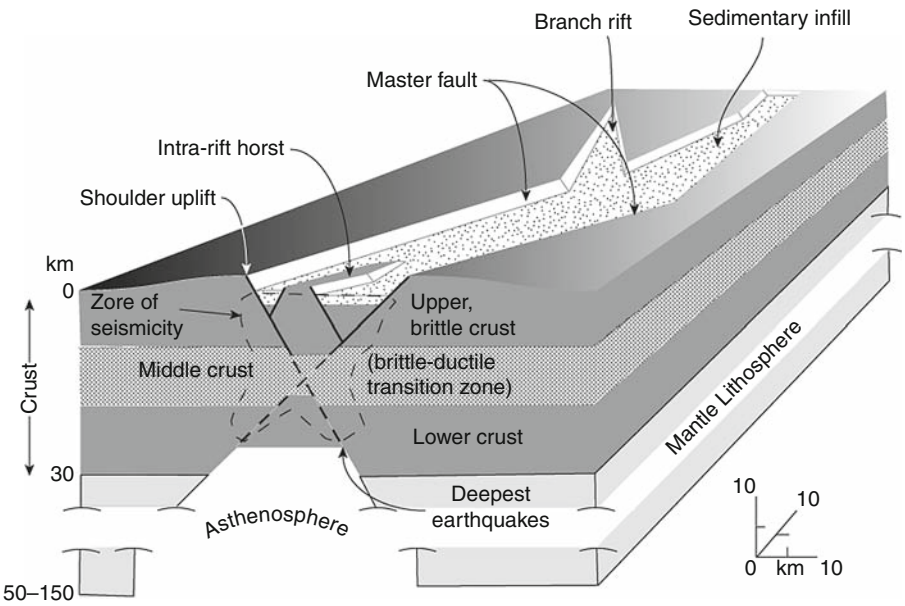
"Rift" and "graben" are two words used interchangeably in the international literature designating elongate troughs bounded by normal faults. However, not all such troughs are parts of structures that rupture, or even thin by rock creep, the entire lithosphere. Some normal-fault-bounded troughs result from sliding and stretching of surficial rocks over lubricating sedimentary horizons such as evaporites or shales. The normal-fault-bounded basinets that formed during a landslide associated with the March 27, 1964, Prince William Sound earthquake in Alaska or the similar troughs in the Canyonlands National Park in Utah formed by sliding and stretching the sedimentary section above the Upper Carboniferous evaporites are examples. Such structures have nothing to do with lithospheric stretching and thus they do not fit the definition of rift given above. Şengör (1995) therefore suggested that the word rift be confined to those structures that actually disrupt or otherwise (by creep) thin the lithosphere and graben be reserved for those that do not. His usage is what is recommended and followed in this entry. In rifts, when the extension factor β, the ratio of extended width to unextended width (McKenzie, 1978), goes beyond 3 the continental lithosphere generally ruptures completely, and ocean generation begins by seafloor spreading (Le Pichon and Sibuet, 1981) (see *Seafloor Spreading*) either by dyke injection or by cold extrusion of subcontinental mantle in the form of ultramafic "core complexes" as seen in such places as along the boundary between the Upper Penninic and the Lower Austroalpine units of the Alps (Bernoulli et al., 2003 and the references therein) or along the South Galicia Bank (Boillot et al., 1987). For obvious reasons, this cannot happen to grabens, however much they may be extended.

Large regions of localized extension exist on our planet where many rifts and grabens occur together. It is inappropriate to call such regions simply rifts. It would be like calling whole orogens simply "thrust wedges." These large regions of extension are the extensional counterparts of orogens (Figures 1 and 9) and therefore it is appropriate to use for them the term "taphrogen," derived from Krenkel's term "taphrogeny."

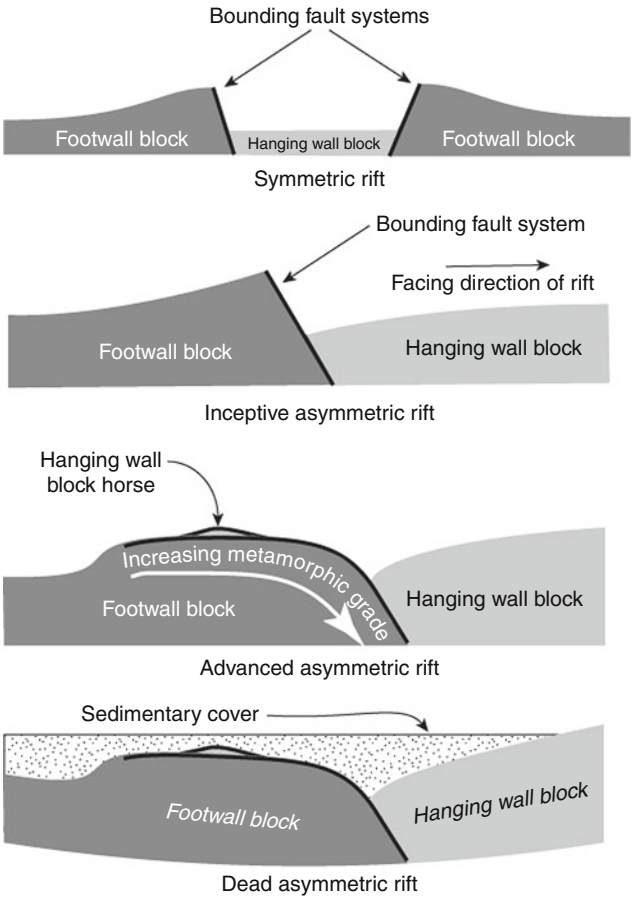
General properties of rifts

Structure of rifts

Figure 2 is an idealized and highly simplified block diagram of a rift. Rifts have two fundamental structural entities: a main hanging wall block and one or two footwall blocks depending on whether the rift is symmetric (as in Figure 2) or asymmetric (see Figure 3). In symmetric rifts, the extension represented by the rift is almost entirely localized between two master bounding normal (or oblique extensional) fault systems, and it is these two systems that take up much of the extension, although the hanging wall block delimited by them is also intensely broken up by smaller normal faults with strikes largely parallel with those of the major bounding fault families (Figure 4). The hanging wall is commonly dropped down because of crustal thinning affecting it and in the basin thus formed sediments accumulate whose thicknesses can be in excess of 15 km in large rifts such as the Dneper-Donetz rift in the Ukraine (Ulmishek et al., 1994), which is very close to the maximum possible



Continental Rifts, Figure 2 A highly schematic block diagram of an "ideal" rift drawn to emphasize the main architectural elements of rifts. The straight marginal faults, e.g., do not mean that all rifts must have straight faults or that they are single faults instead of fault families.



Continental Rifts, Figure 3 Some properties of symmetric and asymmetric rifts.

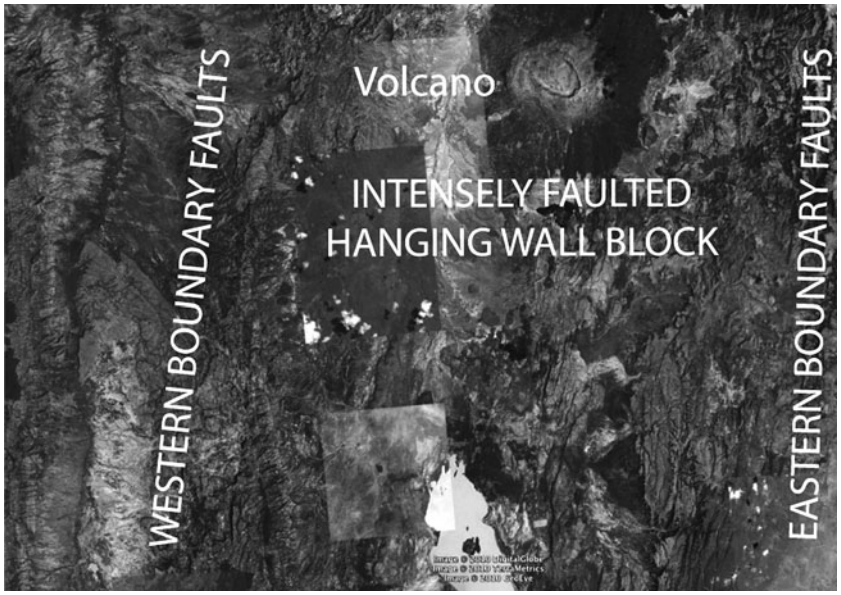
thickness (17 km) of sediment accumulation on continental crust (Dewey, 1982) Most rifts of average size, however, have sediment thicknesses ranging from 2 to 5 km. Individual rift lengths vary from about 1,000 to 100 km and widths from about 150 to 10 km. Rift size is a function not only of the amount of extension, but also the thickness of the lithosphere it disrupts. The thicker the lithosphere, the wider the rift. On Figure 5, the distribution of continental rifts on earth is shown. In areas of thick lithosphere (e.g., in the North American craton, eastern Europe, and Siberian craton), the rifts are very wide, whereas in areas of thin lithosphere such as the western USA or in the Aegean they are very narrow, in places less than 10 km wide.

The bounding faults of the rifts have long been thought to be listric (shovel-shaped), i.e., flattening with depth, although studies on earthquakes have not supported this. Wherever precise hypocenter location is possible and where the earthquake has caused a surface rupture (see *Earthquake, Focal Mechanism*; *Earthquakes and Crustal Deformation*; *Earthquake, Location Techniques*), it is seen that the associated fault is planar down to depths of 8–10 km. Eyidoğan and Jackson (1985) documented that the March 28, 1969, Demirci earthquake in western Turkey consists of two discrete sub-events: one along a northerly-dipping planar normal fault and another one on a horizontal surface north of, but at the same depth as, the hypocenter of the first one. The horizontal rupture is believed to be located in a region that deforms ductiley under long-term strain rates, but ruptures when that rate is suddenly increased as in an earthquake (Figure 2). This suggests a kinked cross-section for the master fault. Such "kinked" faulting events may be the explanation of why hanging wall blocks in some rifts are so much more disrupted than the rift shoulders. In areas of thicker lithosphere, however, hypocenters along the master faults of rifts may be as deep as 30 km as exemplified by the March 10, 1989, Malawi earthquake in east Africa (Figure 2; Jackson and Belkinsop, 1993) (see *Seismicity, Intraplate*).

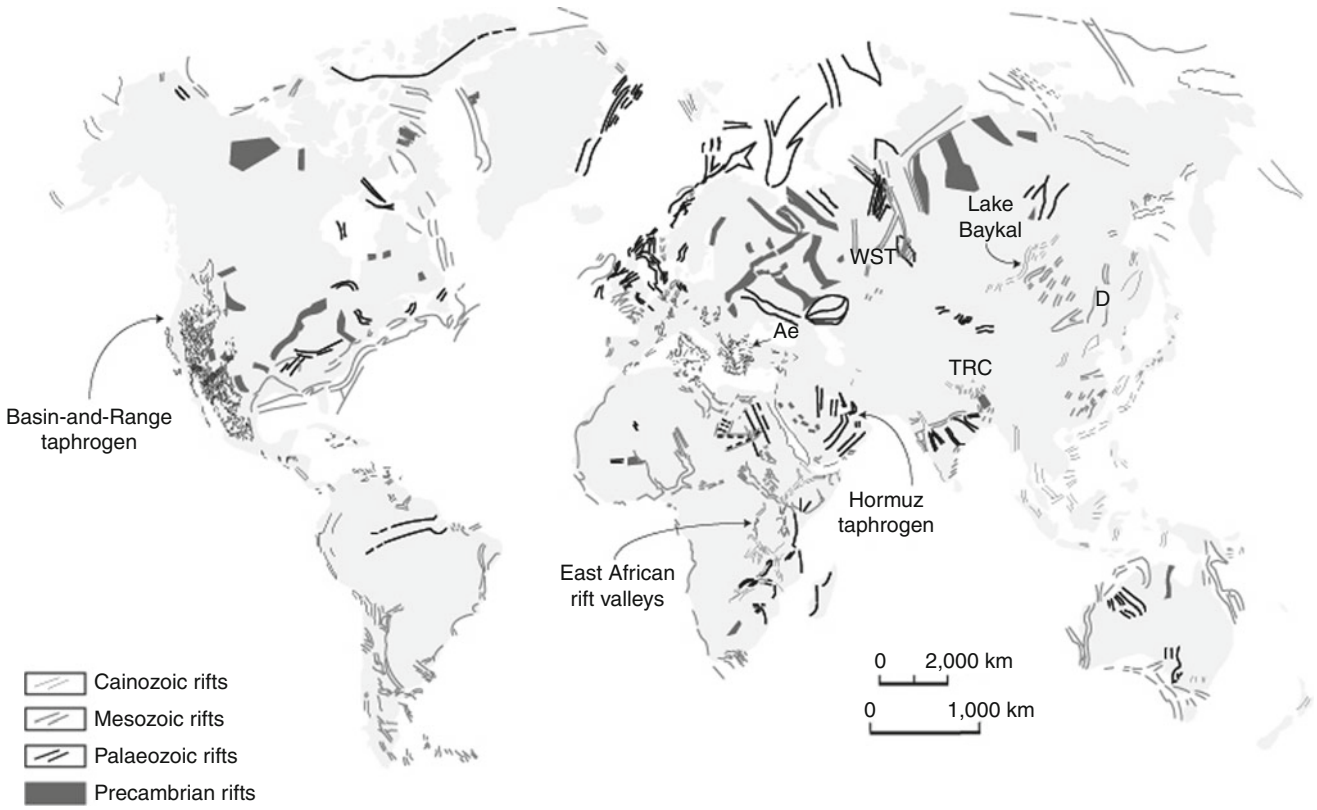
The straight fault hypothesis is difficult to generalize, especially where the master fault families bounding rifts are strongly curved in map view such as those that created the Lake Tanganyika rift system (Burgess et al., 1988). It is possible that individual segments of large faults rupture as straight fractures, but eventually the entire fault acquires a listric geometry. This seems supported by the fact that in Lake Tanganyika, where the rift floor has deeply subsided, faulting within the hanging wall block is less intense (Burgess et al., 1988). This is incompatible with a major kink of the master fault at depth. Wernicke and Burchfiel (1982) pointed out that where numerous, parallel-striking planar normal faults have rotated in unison around horizontal axes, one listric fault at the head of the series is a kinematic necessity to allow the others to rotate.

Asymmetric rifts are said to "face" in the direction of the dip of their master faults (Figure 3). Many major rifts are made up of half rifts that change their facing along the strike. In such cases, "transfer" or "accommodation zones" form along their boundaries that take the form of areas of complex oblique faulting and crustal block rotations (see especially the excellent discussions on transfer and accommodation zones in Faulds and Stewart, 1998; also Derer et al., 2005). Smaller and shallower transfer faults, essentially tear faults disrupting the hanging wall block with complicated displacement histories, form where the hanging wall is differentially stretched along the strike of the rift (cf. Şengör, 1987).

Rift shoulders are commonly uplifted. In symmetric rifts, both shoulders go up because of isostatic adjustment of the crustal wedges that are formed by the master faults dipping towards the rift (see *Isostasy*). Such uplift not only rotates the land surface on the shoulders away from the rift thus guiding much of the regional drainage in the same direction, but it rotates also the bounding normal faults (Buck, 1988). Each increment of faulting further rotates the shoulder and further rotates the previously formed fault segment. In Figure 3, in the case of a young asymmetric rift, the fault is shown to be straight. As the rift age and extension advance, the fault surface curves away from the rift as a result of incremental rotations and finally its oldest parts acquire a flat position, possibly with "horses" of the hanging wall block stuck on it as



Continental Rifts, Figure 4 A part of the eastern ("Gregory") rift in Kenya showing the intense faulting of the down-dropped hanging wall block between the master fault families. (Google Earth image.)



Continental Rifts, Figure 5 Distribution of continental rifts in the world. (Updated from Şengör and Natal'in, 2001.)

"extensional allochthons" (Figure 3). This seems to be the origin of many near-horizontal normal faults in areas of thin lithosphere and large amounts of extension such as the extensional metamorphic core complexes of the North American Cordillera (Armstrong, 1982), or those of the Tethysides (Verdel et al., 2007), although the existence of "primary" low-angle normal faults is also known both from detailed field studies (e.g., Miller and John, 1988) and from the seismicity (Eyidoğan and Jackson, 1985; Abers et al., 1997). The amount of extension in many rifts, especially those that are symmetric, do not go that far, however, and their bounding faults rarely dip less that 30°.

In places where intracontinental rifting along a narrow rift valley has advanced far, as, e.g., along the Wonji Fault Belt in Ethiopia, it has been noted that faulting is driven by dyke injection below the brittle upper carapace of about 10 km thickness and that segments with active deformation at the surface correlate with those of active magmatism (Kendall et al., 2005; Casey et al., 2006).

Cloos (1939) believed that the shoulder uplift in symmetric rifts resulted from the original doming that had led to keystone drop of the hanging wall block, but it was quickly realized that the observed angles of slope on crustal domes rarely exceed 1°, whereas to give rise to substantial rifts one needs about 10° dome slopes, which are excessive. Table 1 lists values of extension and shoulder uplift in some selected rifts. In none, except possibly in the Española Basin, is the shoulder uplift sufficient to cause the estimated amount of stretching.

Sedimentation in rifts

Because rifts form elongate basins they are ideal sediment receptacles. The type of sediment to be found in a rift varies according to the size and geometry of the rift, the climatic zone(s) in which it is located and its evolutionary history. Although most rifts are filled slowly by sedimentation in the sea, lakes, rivers and, in a subordinate degree, subaerially by wind, some are catastrophically invaded by the sea by breaching the barriers of sub-sea-level rift complexes (e.g., the Permian North Sea or the medial Cretaceous South Atlantic). In such cases, either vast evaporite deposits (as in the Aptian of the South Atlantic: Burke and Şengör, 1988) or thick shales (as in the late Permian of the North sea: Evans et al., 2003) are laid down in rift troughs.

Subaerial rifts are normally fed by rivers that locally create lakes within them because of endorheic conditions. Near the fault-bounded shoulders, stream valleys are commonly short (as the crest of the shoulder often is also the water-divide) but the streams in them are energetic because of the steep slopes. They thus carry clastic sediments of a variety of sizes that are horizontally sorted in large alluvial fans at the feet of the fault-escarpments. Along these escarpments, many alluvial fans form and coalesce and ongoing subsidence leads to the accumulation of large thicknesses of fanglomerates, sandstones, and shales near the faulted rift margin(s). Because of rotation towards the fault plane of the basin floors, the sedimentary thicknesses systematically decrease away from rift shoulders towards rift median lines. Steep slopes and catastrophic rain in both tropical and desert climates frequently lead to slope failures resulting in landslides complicating the sedimentary record. Permanent or ephemeral lakes may occupy the middle parts of rift floors. Ephemeral lakes commonly occur in dry climates in the form of playas and deposit evaporites and clays that may interfinger with marginal alluvial fan deposits. Permanent and deep lakes are important sediment repositories in rifts. They may accumulate very thick sedimentary sections in them, exhibiting complex facies dictated by the evolution of the geomorphology of the rift and its surrondings. Such lakes can be very deep (Lake Baykal in Sibearia: with 1,637 m, the world's deepest lake in addition to an 8 km rift sedimentary fill; Lake Tanganyika in

Continental Rifts, Table 1 The amount of stretching and shoulder uplift in some selected rifts (From Şengör, 2001)

Name of rift	Amount extended (km)	Uplift of shoulder area (km)
N Kenya	35–40	>1.4–1.7
Gregory	10	2
Malawi	7.5 (from transfer fault offset)	2.8 (strike-slip affected?)
Suez N	16.3	1.5
Central	17.7–32.6	1
S	29.3 (all from fault geometry)	~500 m
Upper Rhine	17 (from crustal configuration), 5–7 (from fault geometry)	2.2
Oslo	28–36 (from crustal configuration), 11–13 (from fault geometry)	1
Viking	100–130 (from crustal configuration), 30 (from fault geometry)	3
Central (North Sea)	100–105 (from crustal configuration), 15 from fault geometry)	1.5
Benue	100[a]	?
Baykal	15–20 (from crustal configuration), 10 (from fault geometry)	2–3
Española basin	5.5	1.5
Albuquerqe basin N	10 (from fault geometry)	~1
Albuquerqe basin S	16 (from fault geometry)	0.9

[a]Benkhelil et al. (1988) established at least 10 km of shortening during the following compression

East Africa: 1,457 m, but with half the sediment thickness of Lake Baykal). They are well-aerated in cold climates because the cold upper layers of the lake waters make convection and overturning possible (as in Lake Baykal), but they are stratifed with anoxic deeps in hot regions because hot surface waters cannot sink and thus inhibit overturning (as in Tanganyika). As the anoxic conditions in Lake Tanganyika exemplify, deep rift lakes in hot climates may generate good hydrocarbon source rocks in reducing environments. This is corroborated by ancient rift fills that formed under similar conditions such as the Permian oil-bearing sequences in the Junggar and Turfan rift basins in Central Asia (e.g., Graham et al., 1990; Miao et al., 2006) or the organic-rich (up to 8% organic C) Triassic-Jurassic lacustrine sediments of the Newark-type rifts of the eastern USA (Manspeizer and Olsen, 1981).

Rift valley floors are seldom level along the strike of the master bounding faults and this commonly induces longitudinal drainage in rifts. In fact, most of world's major rivers flow in two kinds of valleys: those that are located in rift troughs or in depressions inherited from them and those that are placed in fore- and hinterland basin troughs (cf. Audley-Charles et al., 1977). The Rhine in Europe, the Irrawady in Asia, flow along their almost entire lengths in active rift troughs. Along the western arm of the East African rift valleys, Lake Tanganyika receives (surface elevation at 773 m a.s.l.) the excess waters of Lake Kivu (at 1,460 m) by means of the south flowing river Ruzizi that came into being only 10,600 years ago and may have stopped flowing between 8 and 6,000 years ago (Felton et al., 2007), showing the sensitive dependence of rift sedimentation on the global climate. Farther north, just beyond Kivu, Lake Edward (at 912 m) is connected to Lake Albert (at 619 m) through the northerly flowing river Semliki. Lake Albert in turn feeds the Nile northwards via the river Albert Nile (White Nile or "Bahr al Jebel," i.e., "the river of the mountain").

In the sedimentary record, the rift facies is commonly characterized by thick (2–15 km) clastic sequences with rapid thickness and facies changes both laterally and vertically. If the rifts are underwater and far from clastic sources, they may house carbonate and even siliceous sedimentary sections as illustrated by the Alpine Triassic-early Jurassic facies. There, a continuous passage from late Triassic shallow water carbonates via a horizon of extensional-faulting-related neptunian dykes filled with progressively deepening facies and finally covered entirely by radiolarian cherts indicates a stretching basin floor as it deepened. That no shoulder uplift is indicated by any unconformities suggests that the Alpine rift was asymmetric with a major south-dipping detachment, and that the rocks on the hanging wall block never experinced normal-fault-related upheaval. If catastrophic marine invasion occurs, then sediments at once blanket the preexisting topography.

For good reviews of sedimentation in rifts, see Frostick et al. (1986), Lorenz (1988), Olsen and Schlische (1990), Leeder (1995), Şengör (1995), Beratan (1996), also the section entitled "Rift Basins" in Einsele (2000, pp. 543–560).

Magmatism in rifts

Rift magmatism is extremely variable because the tectonic environments in which rifts form are so diverse (see below). Rifts that form above mantle plumes (see *Mantle Plumes*) in plate interiors away from plate boundaries may begin their activity with restricted volumes of alkalic basalts indicating limited partial melting of mantle material at depth and may evolve towards abundant tholeiitic effusions as the temperature at depth increases and more and more mantle rock is melted, as, for example, illustrated by the evolution of the Afar plume in east Africa. Most geologists take alkalic to peralkalic magmatism as indication of extensional tectonics. The frequent association of nepheline syenites, kindred alkaline igneous rocks, and carbonatites (alkalic rocks and carbonatites [ARCs]) with intracontinental rifts has been taken by Burke et al. (2003, 2008) to argue that deformed rocks of the same compositions (deformed alkalic rocks and carbonatites [DARCs]) that have been shown to characterize suture zones in regions in Asia, Europe, Africa, and North America are nothing but ARC rocks that erupted into intracontinental rifts that became involved in a Wilson cycle of ocean opening and closing. This has been shown to form a powerful tool to map suture zones where other suture indicators such as ophiolites or subduction-related rocks may be missing. However, to think that rifts generate only alkalic magmatic rocks is clearly too simplistic. Those rifts that form along magmatic arc systems, for instance, inevitably have calc-alkalic magmas and those that form above recently thickened continental crust may generate vast quantities of calc-alkalic andesitic/rhyolitic melts. Rifts forming in back-arc regions, such as those in the Aegean, contain volcanic rocks showing evidence for a metasomatised mantle beneath them (e.g., the so-called Kulaites, i.e., hornblende basalts, in western Turkey: Richardson-Bunbury, 1996). Large amounts of silica-rich magmatic rocks may be generated if mantle plumes manage to melt large quantities of continental crust while ascending or if fractional crystallization is allowed to proceed undisturbed (e.g., the Cretaceous tin granites in Nigeria or the Cainozoic granites in Scotland; see Wiart and Oppenheimer, 2004 for an acitve example in Afar). Some rifts such as Tanganyika or Baykal are almost entirely devoid of magmatism, while others such as the late Palaeozoic Oslo Rift have floors made up entirely of magmatic rocks. Some Atlantic-type continental margins, which grew out of disrupted rifts, are called "volcanic," whereas others, "non-volcanic," because they descended from rifts with similar magmatic characteristics.

It is naive to think that lithospheric extension generates only certain kinds of magmatic rocks without considering the tectonic environments that gave rise to the extension and in which the extension proceeds. It is therefore

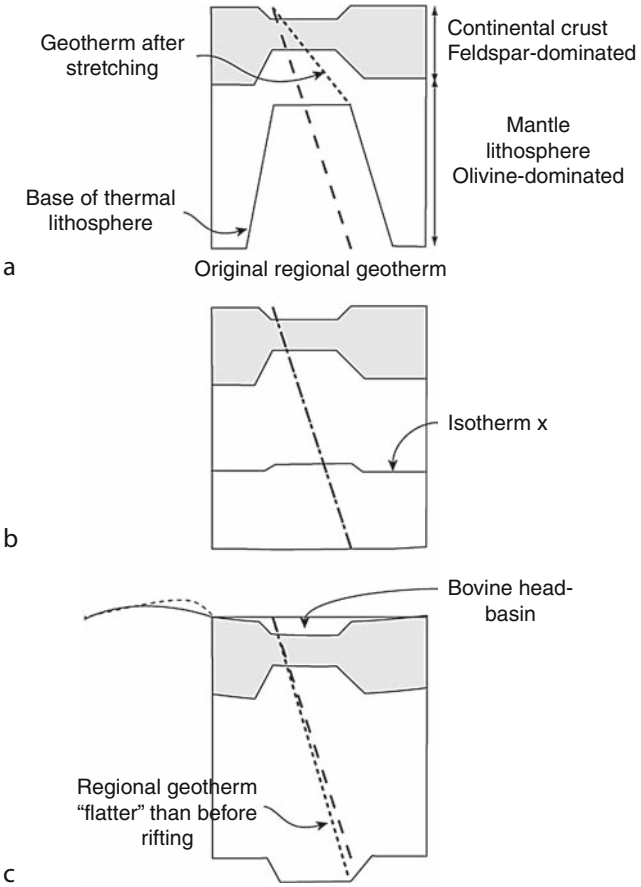
imperative to look at the diversity of the environments which generate rifts.

For good reviews of magmatism in rifts, see Kampunzu and Lubala (1991), Kinnaird (1998), Ulrych et al. (1999), Burke et al. (2003, 2008), Wilson et al. (2004), Yirgou et al. (2006); also the special section on magmatism and extension in *Journal of Geophysical Research*, vol. 100 (1995).

Metamorphism in rifts

Continental rifts are not commonly thought of as prime loci of metamorphic events, but four different kinds of metamorphic rocks do occur in them. In increasing importance: (1) contact metamorphic rocks around rift-related magmatic rocks, (2) hydrothermal metmorphism around vents, (3) burial metamorphism due to large sediment thicknesses, and (4) metamorphic rocks that form within the continental crust and are brought to surface by rifting.

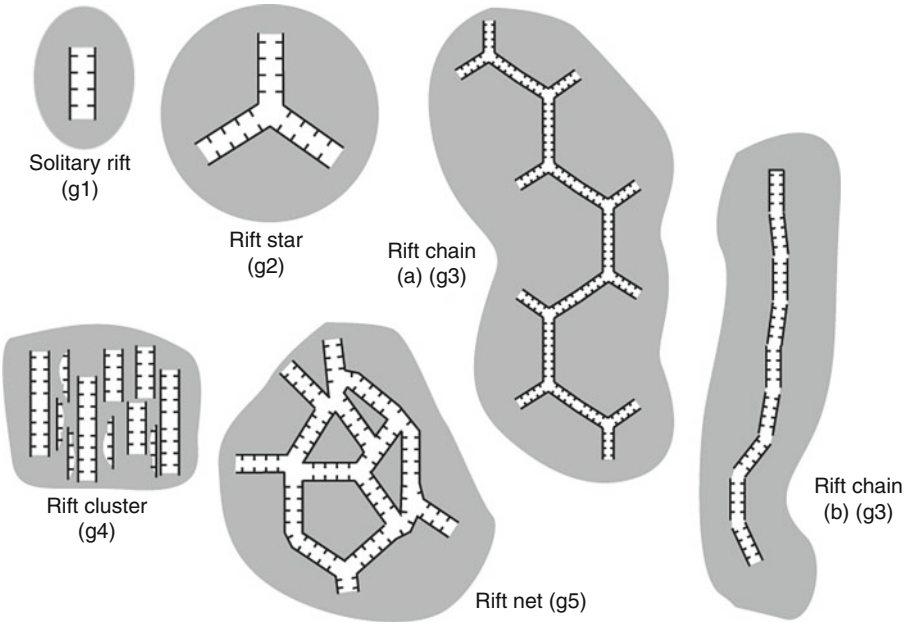
There is little to say about the first kind of metamorphic rocks in rifts as they are no different from any other contact metamorphic rock. Hydrothermal metamorphism is important in many rifts because of the high heat flow and the continuous opening of extensional fractures allowing hot waters to circulate (e.g., Crane et al., 1991). Burial metamorphism is not common in rifts unless they accumulate very large thicknesses of sediment quickly, sufficient to raise the temperature and pressure conditions to initiate metamorphism. If we assume a normal geothermal gradient (~3°C/100 m; see *Heat Flow, Continental*), an accumulation of about 4 km of sediment would be sufficient to initiate metamorphism by raising the temperature beyond 120°C. Jackson (1987) argued, however, that because earthquake hypocenters in rifts are seldom deeper than 10 km, at least beyond that depth rocks must be metamorphic. But since there are earthquakes down to 30 km in the east African rifts system, it is questionable how sound an argument that is. It is true, however, that rift sediments are seldom metamorphosed beyond greenshist grade because they are seldom stretched enough and seldom accumulate sufficient thicknesses of sediment to heat the rocks beyond 320°C. Smith (1976) pointed out, for example, that at the bottom of the about 16 km-thick Gulf Coast sediment pile, the temperature may be just about 320°C under 4 kb pressure. But this ignores both the radioactive heating of the pile (see *Radiogenic Heat Production of Rocks*) and raising the geotherm by stretching. However, even when the crust is stretched, every particle in the stretched crust must cool, unless the rift trough is rapidly sedimented (Figure 6; McKenzie, 1978; Jackson, 1987). Although it has been suggested that some high-grade metamorphic rocks did form in a rift environment (Wickham and Oxburgh, 1985), it was a result of mistaking an orogenic environment for a taphrogenic one, although from elsewhere allegedly rift-related metamorphism creating high-grade gneisses has been reported on the basis of condensed metamorphic zones and absence of associated plutonism



Continental Rifts, Figure 6 Thermal regime of rifts with a simple geotherm. (**a**) Immediately after the stretching, both the crust and the lithospheric mantle thin and isotherms become crowded under the rift increasing the heat flow in the rift. Although no particle in the rift basement will become any hotter. (**b**) After stretching ceases, isotherms begin to subside. (**c**) When the lithosphere "recovers," the rift will end up with more lithospheric mantle beneath it and will have a heavier substratum that will subside and pull its surroundings with it creating an "intracratonic basin" overlying the rift. This is called a "bovine head" cross-section because of its resemblance to a long horn ox. While the basin subsides, its margnis will be elastically uplifted (solid line above **c**), but may relax viscoelastically in time (dotted line above **c**). Here the margins are shown only on one side for graphic convenience, but naturally the events will take place all around the basin.

(e.g., St-Onge and King, 1987). However, I am unaware of any well-documented metamorphic terrane that formed as a consequence of rift burial.

By contrast, large normal faults of the kind shown for the advanced asymmetric rifts in Figure 3 may pull up rocks from the lower continental crust that may have been metamorphosed even up to granulite facies as shown by many extensional metamorphic core complexes. But in this case, the metamorphism is not *caused* by rifting, but it is *exposed* by rifting. In fact, as the rocks ascend



Continental Rifts, Figure 7 The geometric classification of taphrogens. (After Şengör, 1995.)

in the footwall, they get retrograded, which is directly caused by rifting.

For metamorphism in rifts, see Armstrong (1982), Jackson (1987), Lister and Davis (1989), Block and Royden (1990), Verdel et al. (2007).

Kinds of rifts

A classification of rifts must serve to answer the questions: how many different sorts of environments lead to lithospheric extension and what kinds of rifts form in these environments? In essence, one must specify where and how taphrogens commonly form. If taphrogeny stops before producing ocean, it causes subsidence and creates large basins (called "koilogens" by Spizaharsky and Borovikov, 1966, pp. 113ff.) overlying taphrogens (Figure 6; cf. McKenzie, 1978; Şengör, 1995). A comprehensive synthesis of various taphrogen types does not yet exist. Below is a restatement of Şengör's (Şengör, 1995; Şengör and Natal'in, 2001) classification of types of rifts that make up the main elements of taphrogens. That classification is hierarchical and goes from pure geometry to dynamics (Figure 8). Its hierarchical nature allows the environment and the path of formation of a given rift to be determined. For numerous examples of each of Şengör's categories, see Şengör and Natal'in (2001). In this section, references already given in Şengör (1995) and in Şengör and Natal'in (2001) are not repeated.

Şengör's classification has three different categories that do not completely overlap, namely *geometric*, *kinematic*, and *dynamic*. In the following, the three different categories are identified with their initials, i.e., *g*, *k*, and *d*, respectively.

Geometric classification of rifts

Rifts or groups of rifts forming individual taphrogenic units display five kinds of fundamental map patterns (see Figures 7 and 8). From simplest to more complex, these are:

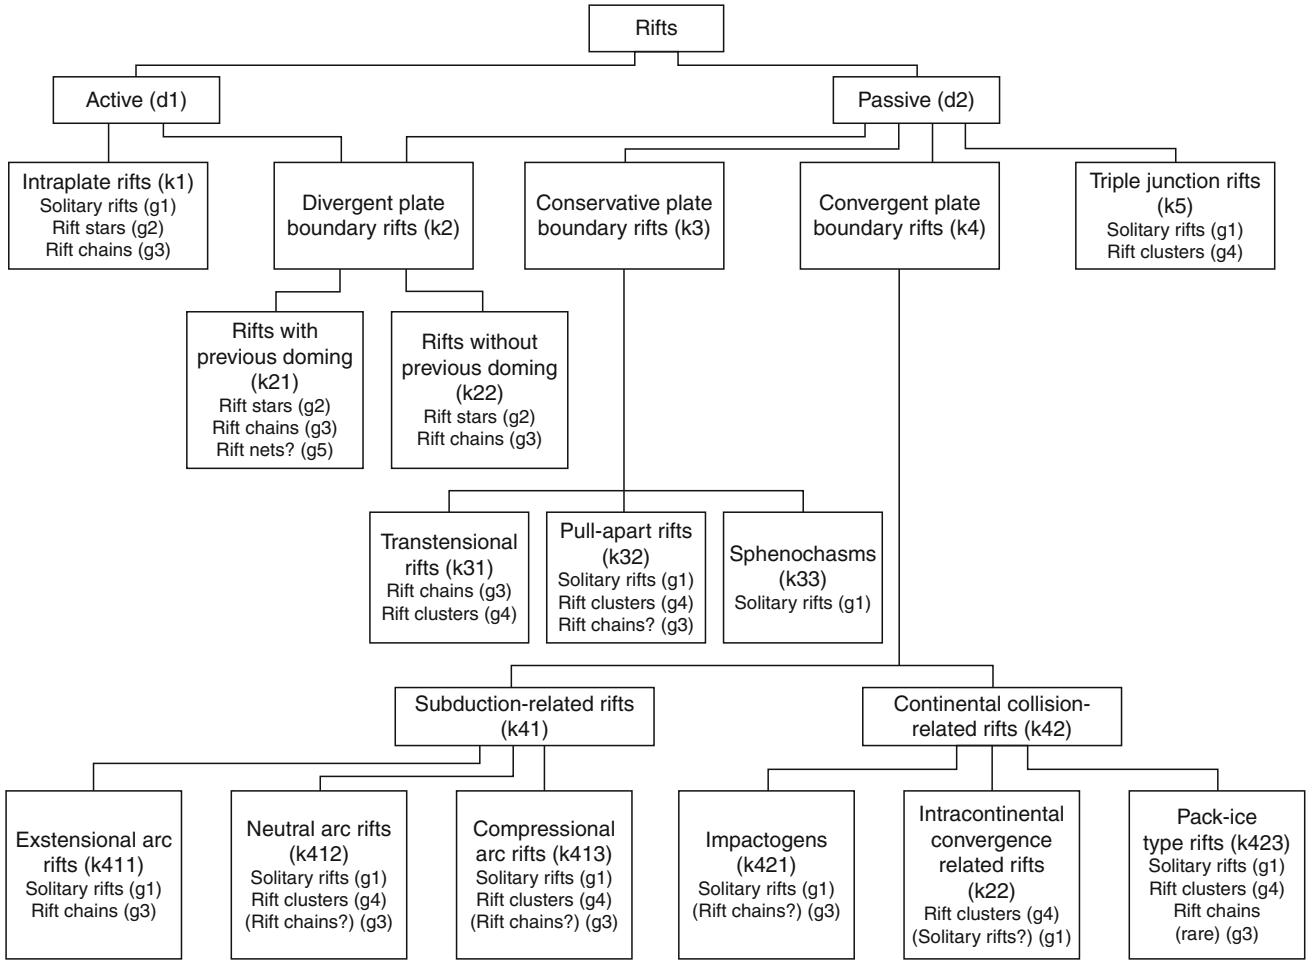
g1 – Solitary rifts: Solitary rifts form small, fairly insignificant, and very rare taphrogens and are extremely difficult to ascertain in the geological record because it is commonly hard to tell whether a given rift fragment is isolated or part of a larger taphrogen (for a comparable difficulty in shortening structures, imagine a big solitary fold or a large thrust fault!).

g2 – Rift stars: Rift stars form when more than two rifts radiate away from a common center, building a roundish taphrogen. Rift stars are very common features of the structural repertoire of our planet today.

g3 – Rift chains: When several rifts are aligned end-to-end along linear/arcuate belts of rifting, they form *rift chains*. The East African Rift System constitutes the best-known active rift chain in the world. Solitary rifts or rift stars or combinations of these may be connected to form different kinds of rift chains (e.g., Figure 7 rift chains a or b).

g4 – Rift clusters: When several subparallel rifts occur in roughly equant areas, they are said to form a *rift cluster*. The two best-known active rift clusters in the world are the Basin-and-Range extensional area in North America and the Aegean Sea and the surrounding regions (see Figure 5).

g5 – Rift nets: Rift nets constitute a rare pattern, which comes about when rifts form a roughly checkered pattern as in the Proterozoic basement of the East European platform or in the late Mesozoic in central North Africa (cf. Şengör and Natal'in, 2001). They resemble



Continental Rifts, Figure 8 The kinematic classification of rifts and taphrogens. (After Şengör, 1995.)

chocolate-bar boudinage, as seen in the Proterozoic basement of eastern Europe (Figure 5), and may have a similar origin, but more commonly rift nets form in complex and rapidly shifting stress environments in which dominant extension directions change fast. Many rift nets in fact may represent two superimposed rift clusters.

Kinematic classification of rifts

Because rifts are ubiquitous in all stages of the Wilson Cycle of ocean opening and closing, the kinematic characteristics of the plate boundaries have been taken as a basis for classifying them according to the environment of the overall displacement and strain in which they form (see Figure 8). There are three types of plate boundaries plus the plate interiors, to which four types of rift families correspond. In addition, incompatibilities arise around some unstable intracontinental triple junctions leading to complex rifting that should be treated separately from the other four classes, thus creating a fifth kinematic class, called "triple-junction rifts."

k1 – Intraplate rifts: Rifts surrounded entirely by undeformed lithosphere occupy this category. Such rifts are usually solitary, small, and rare (the difficulty in forming them is analogous to that forming a solitary fold or a nappe surrounded by entirely undeformed terrain), and are not easy to identify in the geological history. The Lake George and Lake Champlain rifts in the northeastern USA are active examples (see *Seismicity, Intraplate*).

k2 – Rifts associated with divergent plate boundaries: These rifts result from plate separation along nascent extensional boundaries. All the Cainozoic rifts in east Africa belong here. This category of rifts may be further subdivided into two classes as follows:

k21 – Rifts that form following an episode of doming: the divergent boundary along which rifts form is in this case preceded by an episode of lithospheric doming. The East African Rift Valleys are the best-known examples of such rifting (see *Isostasy, Thermal*).

k22 – Rifts that form with no pre-rift doming: in this case, rifts form without a prelude of uplift, as is the case in the Salton Trough and the Gulf of California.

A good fossil example is the rifting of the Alpine Neo-Tethys in the earlier Mesozoic.

k3 – Rifts that form in association with conservative plate boundaries: conservative, i.e., transform fault, boundaries are those along which neither extension nor shortening is required by the regional slip vectors. However, various reasons conspire to induce both extension and shortening to occur along considerable stretches of these boundaries. Rifts along conservative plate boundaries form in three different settings:

k31 – Transtensional conservative boundaries: if a conservative boundary is opening up all along its length because of a component of extension, it is called *transtensional*. Many active rifts have a transtensional component, and fossil examples of such rifts may be recognized largely through the structures they contain as shown by Olsen and Schlische (1990). Dewey (2002) gave an exhaustive analysis of the strain that develops in such rifts.

k32 – Pull-apart basins along conservative boundaries: major strike-slip faults commonly have bends along them that either facilitate ("releasing bends") or obstruct ("restraining bends") slip along them. Extensional basins form along the releasing bends, in which the magnitude of extension equals the magnitude of cumulative strike-slip offset along the strike-slip fault since the formation of the releasing bend. Such basins are called "pull-apart basins." Crowell's (1974) fault-wedge basins are nothing more than special cases of pull-apart basins.

k33 – Sphenochasms: not all basins created by secondary extension associated with strike-slip faults are pull-apart basins. Some represent tears caused by either an asperity or differential drag along the strike-slip fault in one of the fault walls, in which the amount of extension changes from a maximum along the fault to zero at the pole of opening of the tear-basin. S. W. Carey called such wedge-shaped rifts that open towards a major strike-slip fault *sphenochasms*.

k4 – Rifts that form in association with convergent plate boundaries: a large family of rifts forms in association with convergent plate boundaries. In this group, a first-order subdivision is between rifts associated with subduction zones and rifts associated with continental collision, although this may artificially split some genetic groups, such as those rifts that presumably form because of the tension generated by excessive crustal thickening. The usefulness of the present grouping is that it enables a rapid overview of the presently active rift environments and comparison with ancient ones.

k41 – Rifts associated with subduction zones: environments of rifting associated with subduction zones correspond to three different types of arc behavior, namely, extensional, neutral, and compressional arcs.

k411 – Rifts associated with extensional arcs: an extensional arc generally splits along the magmatic axis (if such an axis is already in existence) forming a small rift chain. Such a situation is today known from both the Okinawa rift and the Izu-Bonin arc system. Such rifts commonly do not get preserved intact, both because of the complications of the tectonic evolution of arcs involving common changes of behavior and because of later collisions with other arcs or continents.

In extensional arcs, rifts also develop orthogonal to arc trend owing to the extension of the arc as it bows out in front of an expanding marginal basin (as, for instance, in Crete).

k412 – Rifts associated with neutral arcs: neutral arcs have neither shortening nor extension across them. Therefore, the only rifts that may form in neutral arcs are those associated with arc-parallel strike-slip faults, which may be classified in the same way as the rifts that form along conservative plate boundaries. More complex rift basins may originate along such arc-parallel strike-slip faults if the sliver plate in the forearc area and its various pieces rotate about vertical axes.

Pull-apart basins in arcs are difficult to recognize, but the Sumatra Fault has several well-developed examples along it.

Sphenochasms along strike-slip faults in arcs are rarer still. Davis et al. (1978) have discussed two possible examples: the more recent of which may have created the "Columbia Embayment" by motion along the Straight Creek fault in the latest Cretaceous and the earliest Cainozoic.

k413 – Rifts associated with compressional arcs: in compressional arcs crust commonly thickens and lithosphere thins, both by heating and by eventual delamination. The arc becomes shortened across and elongated along its trend. This elongation commonly generates rifts at high angles to the trend of the arc. Rifts on the Altiplano in the Andes are examples of such high-angle rifts.

k42 – Rifts associated with zones of continental collision: three different environments of rifting form associated with the collision of continents: (1) *Lines of extension* that radiate from points at which collision commences, (2) *Regions of extension* abutting against sutures, and (3) *Nodes of extension* in areas of complex deformation in fore- and hinterlands shattered by collisions. Impactogens (k421), rifts forming in intracontinental convergence belts (k422), and pack-ice-type rifts (k423) correspond with these three environments, respectively.

k5 – Triple-junction rifts: Triple-junction rifts form at or near unstable intracontinental triple junctions, at which plate evolution dictates the generation of "holes" because continental lithosphere cannot be continuously subducted.

Dynamic (genetic) classification of rifts

Rifts are also classified according to the origin of forces (see *Geodynamics*) that lead to rifting (see Figure 6).

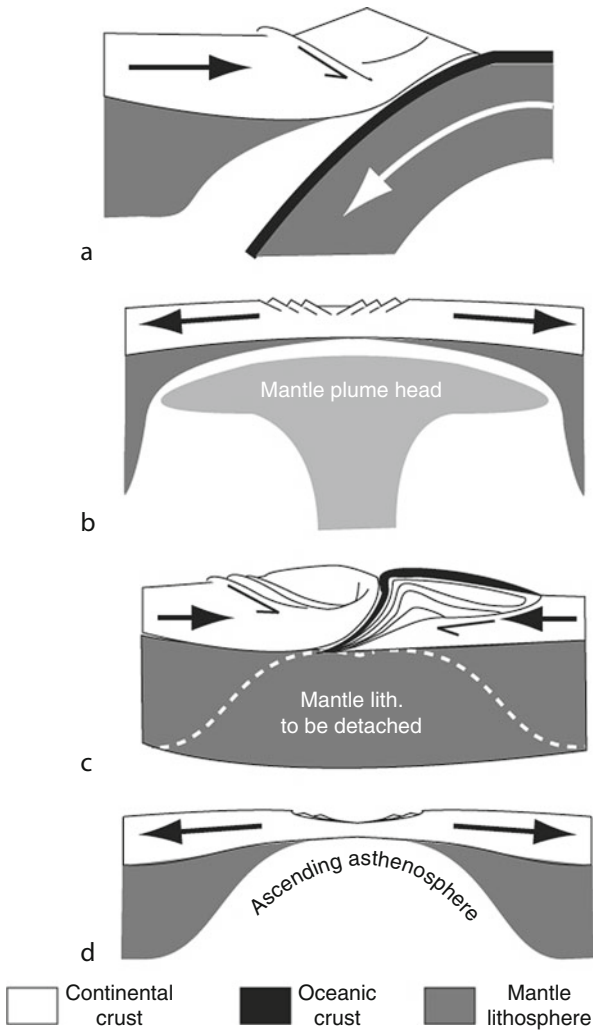
Şengör and Burke (1978) proposed that stresses which cause rifting may be imposed on the lithosphere directly by the mantle beneath it (cf. Şengör, 2001) or they may result from two-dimensional plate evolution. Accordingly, they termed these two modes of rifting "active" and "passive." Gans (1987) tried to replace these terms with "open-system' and "closed-system" rifting, respectively, which, however, did not find general acceptance.

d1 – Active rifting: "Active rifting" is rifting caused by mantle upwelling (see *Earth, Density Distribution*; *Mantle Convection*) associated with plumes in the mantle (see *Mantle Plumes*). Two views have been advanced to explain the origin of the extension in domes rising above hot-spot jets: one ascribes the rifting to basal shear stresses induced by a spreading plume head beneath a dome. The other holds the potential energy of the rising dome responsible for driving the rifting. All of these factors probably do contribute to maintaining the active rifting process at its habitually slow pace of considerably less than 1 cm/a (see *Geoid*).

Plume-caused taprogens may be also termed deeply rooted rifts and would be the extensional counterparts of subduction-related orogens (Figure 9a, b). These can be contrasted to collisional orogens that have lost their subductive "anchors" and the passive rifts with no deep mantle connections (Figure 9c, d).

d2 – Passive rifting: in the passive rifting mode, extension is caused by the two-dimensional motions of the lithospheric plates and not by an autonomous interference from the mantle (Figure 9d). In this mode of rifting, there is no pre-rifting doming associated with a hot-spot (Şengör and Burke, 1978). Kinematic mechanisms reviewed above under the headings k22, k31, k32, k33, k411, k412, k413, k421, k422, k423, and k5 all may form rifts in a "passive rifting mode."

There is only one kind of rift this classification does not consider: rifts that form by propagating from an already existing rift. Since propagation may take many forms, it might be sufficient to indicate such rifts with the notation d2 to indicate their passive mode of opening. The regional geologist may use Figure 8 as a "flow chart" to follow the evolutionary histories of the various kinds of rift basins he encounters.



Continental Rifts, Figure 9 Deeply rooted megastructures. (**a**) Subduction-controlled orogens; (**b**) mantle-plume controlled, i.e., active rifts and rootless megastructures; (**c**) collisional orogens; (**d**) plate motion-controlled, i.e., passive rifts.

Conclusions

Although they constitute one of the three great continental structure types and have serious relevance to human well-being, rifts remain poorly known. This is largely because there are still important technological difficulties in studying them directly because of the large sediment thicknesses they contain and because their diversity is little appreciated. They are so ubiquitous in all tectonic environments that they tend to be overlooked in favor of other, rarer, structures that may appear more prominent. It is commonly not recognized that all kinds of structures, such as magmatic arcs, collisional orogens, keirogens, intracratonic basins all have associated rifts and, consequently, people wishing to know about rifts tend not to concern themselves with them. A stereotypic rift that commonly bedevils textbooks is one that disrupts a craton and has alkalic or peralkalic vulcanism with a thick, mainly nonmarine sedimentary fill, although there are many more rifts in the world than those with such characteristics. What is now needed in rift studies is a comprehensive synthesis that takes into account this diversity.

Geodynamo

Definition

Dynamo. Process for generating electrical current and magnetic field by electromagnetic induction in a moving conducting medium.
Geodynamo. Dynamo process in the fluid outer core that generates Earth's main magnetic field.

Introduction

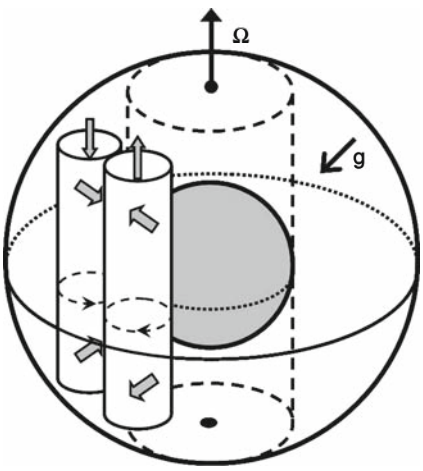
It has been firmly established that the geomagnetic field must be generated by a magnetohydrodynamic dynamo operating in the Earth's outer core. Thermal and compositional buoyancy forces drive a convective circulation of the liquid iron alloy. Assuming that a magnetic field is present, electrical currents are induced in the moving fluid. When the magnetic field associated with these currents has the strength and geometry that is suitable for the induction process and no external source for the field is required, this is called a self-sustained dynamo. The first approximation of the Earth's core is a sphere with uniform electrical conductivity, in contrast to technical dynamos, where the currents are guided by a highly inhomogeneous distribution of electrical conductors. In the former case, we speak of a homogeneous dynamo. From a theoretical point of view, homogeneous dynamos are more difficult to understand.

Simple motions, such as differential rotation (as in an electrical generator), are unable to drive a homogeneous dynamo, and flow patterns of a certain complexity are required. Until late into the twentieth century, dynamo theory has been concerned mainly with the conceptual understanding of how, in principle, a magnetic field can be generated in such an environment. Starting with models by Glatzmaier and Roberts (1995), Kageyama and Sato (1995) and Kuang and Bloxham (1997), realistic self-consistent numerical simulations of the geodynamo became available and have been successful in reproducing many of the observed properties of the geomagnetic field. The more fundamental aspects of the geodynamo are discussed elsewhere (see *Geomagnetic Field, Theory*). Here, the progress in understanding the geodynamo based on numerical modeling and comparing its results with specific properties of the geomagnetic field is addressed.

Dynamo model concept and equations

Model setup

In contrast to earlier kinematic dynamo models, where the flow is prescribed, modern geodynamo models aim at a fully self-consistent treatment of fluid flow and magnetic field generation in the Earth's outer core. There are some basic requirements for a realistic model: (1) The mechanism for driving flow by thermal or compositional buoyancy must be part of the model. (2) Because an axisymmetric field cannot be generated by a dynamo (Cowling's theorem), the model must be fully three-dimensional. (3) The model must be rotating because Coriolis forces are important to generate a flow pattern that is conducive for the dynamo process. The basic setup of geodynamo models is that of a rotating spherical shell of outer radius r_o and inner radius r_i, filled with a fluid of uniform conductivity, which represents Earth's outer core (Figure 1). For this system, the coupled equations for convection-driven flow and electromagnetic induction are solved. A detailed account on fundamental aspects of convection in rotating spheres is given in Jones (2007), and modeling aspects and the commonly employed numerical schemes are discussed in Christensen and Wicht (2007).



Core Dynamo, Figure 1 Columnar convection in a rotating spherical shell. The inner core tangent cylinder is shown by broken lines. Under Earth's core conditions, the columns would be thinner and more numerous. (From Christensen, 2010b, Copyright: Cambridge University Press.)

Dynamo equations

The relevant magnetohydrodynamic equations are usually written in non-dimensional form. A possible scheme for scaling the equations is to use the shell thickness $D = r_o - r_i$ as length scale, the viscous diffusion time D^2/ν as timescale (ν is kinematic viscosity), $(\rho\Omega/\sigma)^{1/2}$ for the scale of the magnetic field $\mathbf{B}$ and the imposed temperature contrast ΔT between inner and outer boundary for temperature T (ρ is density, σ electrical conductivity and Ω rotation rate). The Navier–Stokes equation for the velocity $\mathbf{u}$, augmented by rotational and electromagnetic forces, is

$$E\left(\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u}\cdot\nabla\mathbf{u}\right) + 2\hat{\mathbf{z}}\times\mathbf{u} + \nabla\Pi = E\nabla^2\mathbf{u} + \frac{Ra\,E}{Pr}\frac{\mathbf{r}}{r_o}T + \frac{1}{Pm}(\nabla\times\mathbf{B})\times\mathbf{B}. \quad (1)$$

The terms on the left-hand side describe in order the inertial force, the Coriolis force (with $\hat{\mathbf{z}}$ the unit vector parallel to the rotation axis) and the gradient of the non-hydrostatic pressure Π. The terms on the right-hand side stand for viscous friction, thermal buoyancy forces and the Lorentz force.

The magnetic induction equation, obtained from Maxwell's equations and Ohm's law for a moving incompressible conductor, is

$$\frac{\partial \mathbf{B}}{\partial t} + (\mathbf{u}\cdot\nabla)\mathbf{B} = (\mathbf{B}\cdot\nabla)\mathbf{u} + \frac{1}{Pm}\nabla^2\mathbf{B}, \quad (2)$$

where the second term on the LHS describes magnetic field advection and the terms on the RHS magnetic field generation and diffusion, respectively. Magnetic diffusion is a consequence of the ohmic resistance that damps the electrical currents associated with the magnetic field.

The advection–diffusion equation for temperature is

$$\frac{\partial T}{\partial t} + \mathbf{u}\cdot\nabla T = \frac{1}{Pr}\nabla^2 T + \varepsilon, \quad (3)$$

with a heat source term ε on the RHS. For compositional convection, an equivalent equation holds where the concentration of light components replaces temperature. The set of equations is completed by the condition of incompressibility, which seems to be justified for Earth's core where density differences are moderate, and the condition that $\mathbf{B}$ is solenoidal:

$$\nabla\cdot\mathbf{u} = 0, \quad \nabla\cdot\mathbf{B} = 0. \quad (4)$$

The equations are complemented by boundary conditions for the velocity, usually $\mathbf{u} = 0$, fixed temperature or fixed heat flux at r_o and r_i, and a continuity condition for the magnetic field at r_o that links the field in the dynamo with an external potential field that decays with radius. Simple models assume the inner core to be insulating, but in many cases it is taken as an electrical conductor with the same conductivity as in the outer core. It has been suggested that the finite conductivity of the inner core plays an important role for preventing frequent dipole reversals of the geodynamo, because a dipole reversal can only be completed successfully if the new polarity persists for the timescale of diffusive dipole decay in the inner core, $r_i^2/(\pi^2\lambda)$, which is several thousand years. However, this is contested by dynamo models that show little differences between simulations with a conducting or an insulating inner core.

Parameters

The four non-dimensional control parameters in these equations are defined in Table 1. In dynamo models, the values of most of these parameters fall short of their extreme values in the Earth's core. For practical reasons, it is not possible to resolve the very small spatial structures that occur at realistic parameter values. The *Rayleigh number Ra* describes the ratio between buoyancy driving convection and retarding effects. In the core, it is much larger than the critical value for the onset of convection, Ra_c, while models are more moderately supercritical (Table 1). The discrepancy is by ten orders of magnitude for the *Ekman number E*, the ratio of viscous forces to Coriolis forces. The very small core value of E indicates that viscous forces are negligible, except in very thin Ekman layers at the boundaries to the solid mantle and inner core. The *magnetic Prandtl number Pm*, the ratio of viscosity to magnetic diffusivity, is very small for liquid metals, but must be set to a value of order one to obtain a self-sustained dynamo in present models. Only the (hydrodynamic) *Prandtl number Pr*, the ratio of viscosity to thermal diffusivity, is of order one in the core and in dynamo models. In terms of physical parameters, the viscosity and the thermal diffusivity are far too large in the models and, in most cases, the rotation rate is too small.

Several dimensionless diagnostic numbers can be formed with the characteristic flow velocity U and magnetic field strength B in the dynamo (Table 1). The velocity in Earth's core can be estimated from the geomagnetic secular variation under the assumption that the magnetic flux at the core surface is approximately frozen into the moving fluid (Alfvén's theorem), which is the case when the diffusion term in Equation 2 can be neglected. In this case, the variation of the radial magnetic field component B_r at the core-mantle boundary can be written

$$\partial B_r/\partial t + \nabla_h \cdot (\mathbf{u} B_r) = 0. \tag{5}$$

where the suffix h indicates the horizontal part of the divergence operator. Additional assumptions are needed to infer the velocity at the top of the core (below the Ekman layer) from the observed B_r and its time derivative, but the flow pattern obtained from these inversions are broadly similar and the characteristic velocity is approximately 0.5 mm/s (Holme, 2007). The characteristic field strength inside Earth's core is probably in the range 1–4 mT, as will be discussed further below.

The most important diagnostic number is the *magnetic Reynolds number Rm*, which describes the ratio of magnetic advection and induction to magnetic diffusion. In order for induction effects in a dynamo to overcome the diffusive dissipation of magnetic field, it is expected that *Rm* must be larger than one. Practically, it turns out that self-sustained magnetic field generation occurs in geodynamo models when *Rm* exceeds approximately 40. Using $U \approx 0.5$ mm/s, the magnetic Reynolds number is of order 1,000, safely above the critical limit. Also, $Rm \gg 1$ is a condition for Equation 5 to apply. Still, the value of *Rm* in the Earth's core is moderate and can be handled in direct numerical simulations. This contrasts with the much larger values of *Rm* in other cosmic dynamos, which requires that magnetic induction and diffusion

effects at small unresolved scales are parameterized by applying concepts of the mean-field dynamo theory. The ability to solve for magnetic induction and diffusion in Earth's core directly without parameterizations is probably the main reason for the success of geodynamo models.

The (hydrodynamic) *Reynolds number Re* is much smaller in the models than it is in the core where it is of the order 10^9, indicating a highly turbulent regime. Consequently, dynamo models miss the small eddies that are expected to exist in the core. Viscosity kicks in only at length scales of some meters to suppress even smaller structures in the flow. However, the small eddies are unimportant for the magnetic induction process, because the magnetic diffusivity, which is $Pm^{-1} = 10^6$ times larger than the kinematic viscosity, homogenizes the magnetic field at scales of less than several tens of kilometers.

The *Elsasser number* Λ describes the ratio of Lorentz forces to Coriolis forces. In the Earth's core, both forces are assumed to be of leading order. A balance in Equation 1 that is dominated by these two forces (plus the pressure gradient force) is called a magnetostrophic balance. The magnetostrophic state is often associated with an Elsasser number of order one. Many present dynamo models match this value of Λ.

The *Rossby number Ro* describes the ratio of inertial forces to the Coriolis force and is very small in the core. In models, it is less than one, although larger than the core value. Instead of forming the Rossby number with the global length scale D, a more appropriate measure for the ratio of the two forces is obtained by using the characteristic length scale ℓ of the flow (local Rossby number Ro_ℓ). The value of Ro_ℓ is difficult to estimate for the core, but model values and the Earth value may be in better agreement than they are for *Ro*.

Energetics of the geodynamo

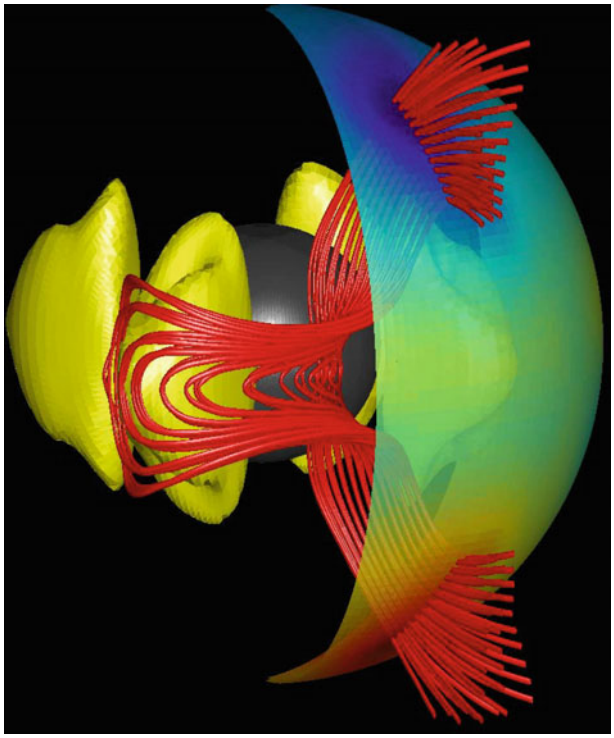
Although the decay of radioactive isotopes in the core may contribute to some degree to the core heat flux, most of the buoyancy that drives convection in the outer core is associated with secular cooling. The sluggish convection in the mantle controls the heat flux through the core-mantle boundary in terms of its magnitude and its spatial distribution, which is expected to be rather heterogeneous. Recent estimates put the heat flow at the core-mantle boundary into the range of 5–15 TW (Lay et al., 2008). For thermal convection to occur, the temperature gradient must reach or exceed the adiabatic gradient. Because iron is a comparatively good conductor, 3–8 TW can be transported by thermal conduction along an adiabatic gradient. This fraction of the heat flux is lost for driving the dynamo. For values of the heat flux near the low end of estimates and of the potential conductive flux near the upper end, a stable thermal stratification at the top of the core could exist. A consequence of core cooling is the slow growth of the solid inner core by freezing iron on its outer boundary. The associated latent heat release balances roughly one half of the heat loss from the core and renders the deep fluid core thermally unstable even if the top layer is not. The relative depletion of light alloying elements in the solid core is balanced by an enrichment in the residual fluid above the growing inner core, which drives compositional convection. Estimates for the work done by thermal and compositional buoyancy forces are of the order $W \approx 1$ TW (Nimmo, 2007). Compositional buoyancy contributes roughly two thirds to it. This energy flux is available to generate magnetic field and balance the associated ohmic dissipation. Viscous dissipation is usually assumed to play a minor role in the core.

Flow pattern and dynamo mechanism

The pattern of flow is strongly controlled by the Coriolis force. It is different for the regions inside and outside the *inner core tangent cylinder*. This is an imaginary cylinder aligned with the rotation axis and touching the inner core at the equator, which is shown by broken lines in Figure 1.

Flow outside tangent cylinder

Outside the tangent cylinder, the flow is organized in convection columns aligned with the vector of rotation, with the flow encircling the column axis (Figure 1). Superimposed is a circulation along the column axis that is directed towards the equatorial plane in columns with a cyclonic sense of rotation and away from the equator in anticyclonic columns. This results in helical flow, in which particles move on corkscrew-like trajectories. The helicity, $H = \mathbf{u} \cdot (\nabla \times \mathbf{u})$, is coherently negative in the northern hemisphere and positive in the southern hemisphere. Such helical flow is the basis for the α-effect, which can convert an axisymmetric toroidal field into an axisymmetric poloidal field, or vice versa, through intermediate steps involving non-axisymmetric small-scale fields (Moffatt, 1978). Because purely axisymmetric fields cannot be maintained by a dynamo, this mechanism plays an important role in the understanding of the dynamo process. The α-effect has been introduced in the context of mean-field dynamo theory, where it describes the induction effects of small unresolved flow scales. In geodynamo models and probably to some extent in the Earth's core, it is due to fairly large-scale convection columns (Busse, 1975). The models suggest that the axisymmetric toroidal field in the Earth's core (which is invisible from the outside) consists of a torus of westward-directed field north of the equatorial plane and eastward field south of the equatorial plane. The helical columnar flow converts this to a dipolar poloidal field whose field lines can leave the core (Figure 2). In some dynamo models, the toroidal magnetic field is regenerated by the same 'macroscopic α-effect from the poloidal magnetic field (α^2 dynamo, Olson et al., 1999). In other geodynamo models, the shearing of poloidal field lines by differential rotation, the Ω-effect, has been found to play an important role for toroidal field generation ($\alpha\Omega$-dynamo), but essentially all models confirm that the helical columnar convection produces the dipolar poloidal field component.



Core Dynamo, Figure 2 Bundle of magnetic field lines in a simple geodynamo model ($E = 10^{-3}$, Ra/Ra_c=1.8, Pm = 5, Pr = 1). The yellow blobs are anticyclonic vortices. Strong inward magnetic flux is shown in blue on the outer core boundary and outward flux in red. The NS-running part of the field lines represents poloidal magnetic field, and the EW-directed segments form the axisymmetric toroidal magnetic field, which consists of two bundles of opposite directions in the two hemispheres. The same field structure repeats periodically in longitude. (Courtesy of Julien Aubert.)

Although at low Ekman number and high Rayleigh number the simple columns give way to a more complex and turbulent pattern, the vortices are still elongated in the direction of the rotation axis and retain a coherent helicity in each hemisphere.

Strong concentrations of magnetic flux in the present geomagnetic field centered below North America and Sibera, which have counterparts at the same longitudes in the southern hemisphere, are interpreted as evidence for the presence of convection columns in the fluid core (Gubbins and Bloxham, 1987) (Figure 3a). The convergence at the core-mantle boundary associated with the equatorward flow in the axis of cyclonic columns (Figure 1) concentrates the poloidal magnetic field lines into these flux lobes, assuming that the frozen-flux assumption is approximately valid. In simple models, such as that in Figure 2, the fluxes lobes are associated with a single columnar vortex. Dynamo models at lower Ekman number and strongly supercritical Rayleigh number show similar high-latitude flux lobes in their magnetic fields when they are low-pass filtered to the resolution of the geomagnetic core field, roughly up to spherical harmonic degree 13 (e.g., Figure 3b). In this case, and probably in the Earth's core, the large-scale magnetic flux concentrations are due to the superposition of strong but complex and smaller-scale magnetic field structures, each associated with a separate convection column.

Flow inside tangent cylinder

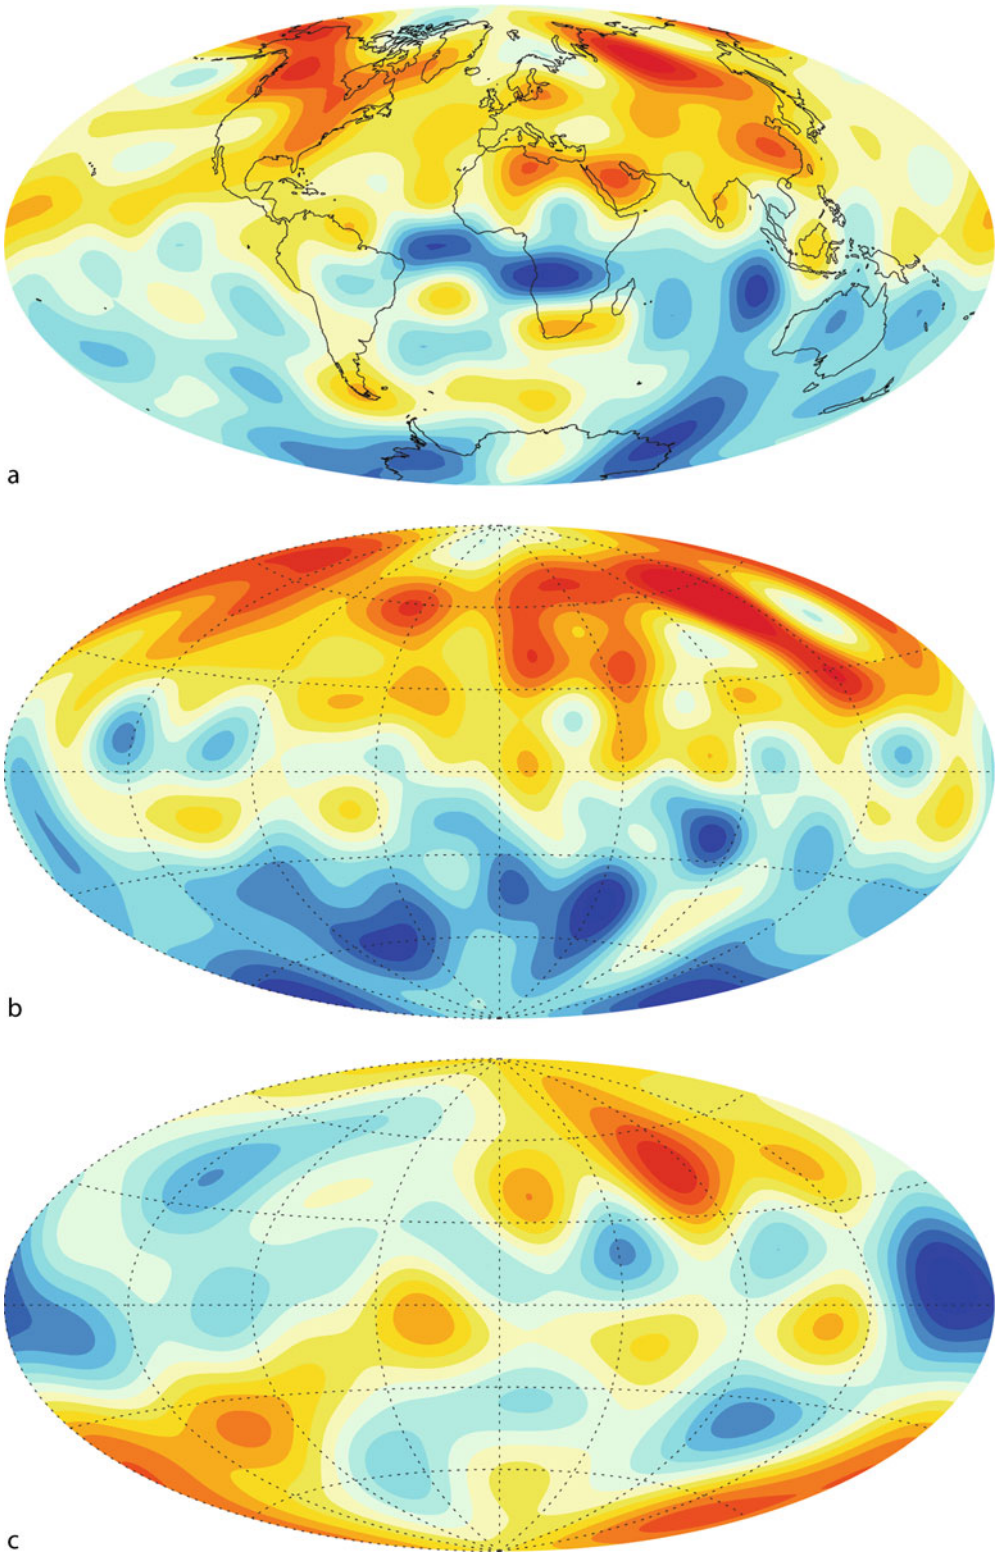
In the polar regions inside the tangent cylinder, many dynamo models show an upwelling plume at or near the rotation axis. Because of the action of Coriolis forces, the plume is associated with an eastward vortex motion near the inner core and by a westward vortex motion near the core-mantle boundary, which is called a thermal wind circulation. A westward vortex motion in the polar cap region at the top of the core has also been inferred from the observed geomagnetic secular variation (Hulot et al., 2002). A polar plume is associated with flow that diverges away from the rotation axis below the core surface, which disperses poloidal magnetic field lines. This is seen in many geodynamo models (e.g., Figure 3b) and can explain the weak magnetic flux in the north polar region of the core (Figure 3a). It has been suggested that the solid inner core couples electromagnetically to the eastward vortex motion of the overlying fluid, which leads to a superrotation of the inner core with respect to the mantle and crust. While perfect coupling to the outer core flow would lead to superrotation rates in excess of a degree per year (Glatzmaier and Roberts, 1996), gravitational coupling between the inner core and the mantle can slow down the rate. Seismological evidence indicates a superrotation at a fraction of a degree per year.

Field properties

Field strength inside the core

How strong is the magnetic field inside Earth's core? Observations allow to constrain the strength of the poloidal field at the core-mantle boundary, which is presently 0.26 mT for the dipole field alone and 0.39 mT in spherical harmonic degrees from 1 to 13. It is not known how much the small unresolved length scale add to the field at the top of the core, but possibly they double this value. Inside the Earth's core, the poloidal field is expected to be stronger than at the outer boundary, and the toroidal component also contributes. Suggestions that the toroidal field, if generated by an intense Ω-effect, could be much stronger than the poloidal field are not supported by geodynamo simulations. In most of them, the magnetic energy is equipartitioned between the two field components. The dynamo models suggest that the characteristic field strength inside the dynamo is around 5–15 times the dipole field strength on the outer boundary, which puts it into the range of 1–4 mT.

The field strength inside Earth's core can be probed directly by the observation of torsional waves and oscillations. To the extent that viscous and inertial forces are negligible, the azimuthal Lorentz force integrated over the



Core Dynamo, Figure 3 Radial magnetic field at the core-mantle boundary, *red* (*full lines*) inward and *blue* (*broken lines*) outward. (**a**) Geomagnetic field in 2010. (**b**) Dynamo model with dominant dipole contribution ($E = 10^{-5}$, $Pm = 0.8$, $Pr = 1$, $Ra/Ra_c = 114$). (**c**) Multipolar dynamo model ($E = 10^{-5}$, $Pm = 0.5$, $Pr = 1$, $Ra/Ra_c = 161$). The model magnetic fields are low-pass filtered to the resolution of the geomagnetic field.

surface of cylinders that are aligned with the rotation axis (geostrophic cylinders) must vanish in the so-called Taylor state. Perturbations of the Taylor state will results in torsional oscillations or torsional waves, consisting of an oscillatory differential rotation between the geostrophic cylinders. Magnetic field lines that permeate adjacent cylinders act like elastic strings and provide a restoring force when the cylinders are displaced relative to each other. The frequency of torsional eigenmodes and the wavespeed of traveling waves is directly related to the *rms* strength of the field component B_s in the cylindrically radial direction. The identification of torsional modes and waves in the secular variation data set is somewhat tentative, but is supported by a correlation between the inferred large-scale motion in the core and changes in the rotation rate of the solid part of the Earth (length-of-day changes) caused by angular momentum exchange between core and mantle (e.g., Holme, 2007). Torsional waves have led to estimates for the characteristic B_s-value ranging from 0.2 to 2 mT. Values near the upper end of this range for B_s agree with the dynamo model estimates for the total field assuming that the core field is statistically isotropic.

Scaling laws

An important question is what controls the magnetic field strength of the geodynamo and of planetary dynamos in general. It has been suggested that the magnitude of the internal core field is determined by a magnetostrophic force balance, meaning that the magnetic field inside Earth's core is driven towards a value that makes the Elsasser number (Table 1) to be of order one, i.e.,

$$B \propto (2\rho\Omega/\sigma)^{1/2}. \tag{6}$$

This results in $B \approx 2$ mT in good agreement with the above estimates. A different line of argument is based on the power available to balance ohmic dissipation. With some assumptions on how the length scale of the magnetic field in the core depends on the vigor of convection, this leads to

$$B \propto \mu_o^{1/2}\, \rho^{1/6}\, P^{1/3}, \tag{7}$$

where $P = W/(4\pi r_o^2)$ stands for the power per unit area of the core surface. With the current estimates for W Equation 7 results in a similar value of the field strength as the Elsasser number rule. However, the two scaling rules are radically different; in Equation 6, the field strength is independent of the energy flux, and in Equation 7, it does not depend on rotation rate or electrical conductivity. Sets of dynamo simulations that cover a substantial range in these properties, or their counterparts in terms of the non-dimensional control parameters, support the power-based scaling law (Equation 7). Furthermore, they show no significant dependence of the field strength on the viscosity. This may indicate that although current dynamo simulations are far too viscous (too high Ekman number), the viscosity is sufficiently low to not play a dominant role. However, testing this by further lowering the viscosity is desirable. The validity of the power-based scaling rule is also supported by the finding that it gives the right order of magnitude of the field strength for various convection-driven dynamos in rapidly rotating cosmic objects including Earth, Jupiter, and low-mass stars. A detailed discussion of dynamo scaling laws is given in Christensen (2010a).

Magnetic field geometry

While the rotation rate seems to have little influence on the field strength inside dynamo models, it probably controls the magnetic field morphology. In some geodynamo models, the magnetic field on the outer boundary resembles the Earth's field at the core-mantle boundary (Figure 3a and b) in terms of a dominant axial dipole and also of structures associated with multipole contributions. In other dynamo models, the dipole contribution is weak. In some cases, the field is dominated by the axial quadrupole or is restricted to one hemisphere, but in most cases it is irregular with contributions from a broad spectrum of multipole components without a pronounced dominance of a particular mode (Figure 3c). The selection of the field geometry was found to depend on the (local) Rossby number. At low values (rapid rotation and moderate flow velocities), dynamos are dipolar, whereas for high values (slower rotation and fast flow), they tend to be multipolar. In addition, boundary conditions and the mode of driving convection, i.e., either by secular cooling of the fluid core or by the latent heat and light element flux from the growing solid inner core, can play a role. The driving mode has changed over geological time. Before the Earth's inner core nucleated, which is estimated to have occurred about 0.5–1.5 Gyr ago (Nimmo, 2007), the dynamo has been driven by secular cooling alone, whereas thereafter the buoyancy source is mainly located at the inner core boundary. However, dynamo simulations for the different scenarios (Aubert et al., 2009) suggest that neither the geometry of the magnetic field nor its strength has changed very strongly. This is in accord with the lack of paleomagnetic evidence for drastic changes in the geomagnetic field since the Archean.

Secular variation

Timescales

The characteristic timescale of secular variation can be defined by the square root of the power of the magnetic field over the power in the time derivative of the field. This can be done separately for each harmonic degree n. The timescales decrease with increasing n. Aside from this scale dependence, the secular variation time has been found in dynamo models to vary with the inverse of the magnetic Reynolds number Rm, as would be expected if most of the secular variation is caused by the frozen-flux advection of magnetic field. Using the observed secular variation timescales to estimate the magnetic Reynolds number (or flow velocity) in the core gives essentially the same result, $Rm \approx 1,000$, as the more complex inversion of the secular variation for the core flow.

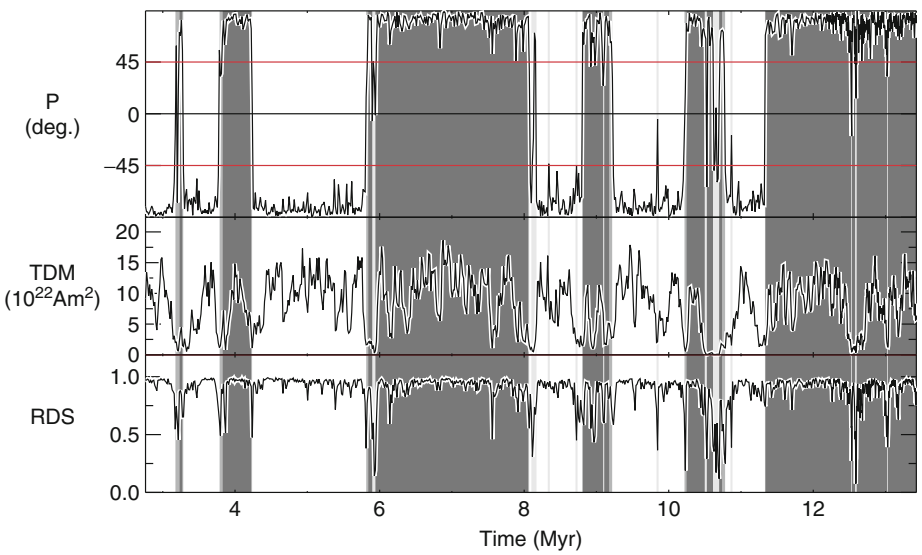
Advection versus diffusion of field

The westward drift of magnetic field structures is a long-standing issue. Some dynamo models show a persistent and global westward drift, whereas others do not. Over the past 400 years, magnetic field structures have systematically migrated westward in the Atlantic hemisphere, but not in the Pacific hemisphere, where the amplitude of secular variation is generally weaker. Dynamo models support the notion that such hemispherical dichotomy can be caused by coupling between the mantle and the core, in particular by the heterogeneity of the core heat flow caused by lower mantle thermal structure.

While much of the geomagnetic secular variation can be attributed to frozen-flux advection in a large-scale circulation, magnetic diffusion must play some role, in particular diffusion in the radial direction. It has been suggested that intense flux spots of both polarities, which are found in the geomagnetic field at low latitudes under Africa and the Atlantic (Figure 3a), have been formed by the expulsion of toroidal magnetic flux bundles through the core surface Bloxham (1986), somewhat analogous to the formation of sunspots. Because the toroidal field is confined to the core, the emergence of such spots necessarily involves diffusion, whereas their migration can be caused by frozen-flux advection. Some geodynamo simulations support such origin of equatorial flux spots. In these simulations, the columnar convection acts on a pair of toroidal flux bundles with opposite polarities and produces (anti) symmetric pairs of spots north and south of the equator. However, the geomagnetic low-latitude field pattern conforms at best marginally with this picture. An alternative explanation to the concept of field expulsion by convective columns and migration due to a large-scale westward flow is that, propagating hydromagnetic waves in the core create a periodic pattern of upwelling and downwelling that produces the belt of wave-train-like magnetic field structures in the low-latitude Atlantic hemisphere.

Magnetic field reversals

Several dynamo simulations show stochastic dipole reversals. Often the details resemble remarkably well what is known from the paleomagnetic record about geomagnetic reversals (e.g., Wicht et al., 2009). They are rather short events that interrupt long periods of stable polarity; both complete reversals and aborted reversals (excursions) occur; during a reversal the magnetic field is weak and not dipole dominated (Figure 4). Most model studies of reversal behavior have been performed with simple dynamo models at rather high values of the Ekman number, because long simulation times are needed to capture a fair number of these events. Reversing dipolar dynamos are typically found in a parameter regime between that of stable dipolar dynamos and of multipolar dynamos. Driving convection more strongly for otherwise identical conditions leads to very frequent and erratic dipole reversals that have little significance because the dipole is hardly ever dominating the magnetic field. Lowering the Prandtl number has the same effect, suggesting that strengthening the nonlinear inertial forces relative to the Coriolis force favors non-dipolar dynamo. Reducing the convective driving or increasing the Prandtl number results in strong dipolar fields that rarely or never reverse. In addition, boundary conditions



Core Dynamo, Figure 4 Time series of dipole tilt, true dipole moment (TRM) and relative dipole strength (RDS) from a numerical dynamo simulation. (Wicht, 2005, Copyright Blackwell.)

affect the reversal frequency. In particular, it has been shown that the pattern of heat flux at the core-mantle boundary, which is controlled by the thermal state of the lowermost mantle and varies on the long timescale of mantle convection, has a strong influence on the occurrence of reversals. This supports the assumption that the drastic secular change in the reversal rate over the past 200 Myr, which is observed in the paleomagnetic record, is caused by changes in the amplitude and pattern of core heat flow associated with a reorganization of mantle convection, such as formation and fading of superplumes. Although model studies have led to a number of suggestions concerning the cause for individual reversals, for example by the formation of strong new plumes in the core, so far no generally accepted concept for the reversal mechanism has emerged.

Summary

Helical convection columns outside the inner core tangent cylinder region play an essential role for our present understanding of the geodynamo. Theory and numerical simulations suggest that they are a fundamental element of the circulation in the outer core, and that they play a key role for the generation the Earth's dipole-dominated magnetic field. Certain details of the magnetic field structure at the core-mantle boundary are explained by such columns. Somewhat less certain, but supported by several lines of evidence, is the notion of rising plumes in the tangent cylinder near the rotation axis that are associated with weak magnetic field and westward vortex flow in the polar regions at the core-mantle boundary. However, much of our current understanding is based on numerical dynamo models that are far too viscous compared to the core. Although there is some evidence suggesting that this does not affect basic properties of the magnetic field, lowering the viscosity in dynamo models is important to test the robustness of our present results, even if models that use actual core values of the viscosity are out of reach. Modeling supports the notion that the magnetic field strength is controlled by the available power that drives the dynamo, not necessarily by a balance of Lorentz and Coriolis forces, as has been often assumed. Several dynamo models show dipole reversals that resemble, in many respects, geomagnetic reversals, but a full understanding of what causes reversals or controls the frequency of geomagnetic reversals is missing.

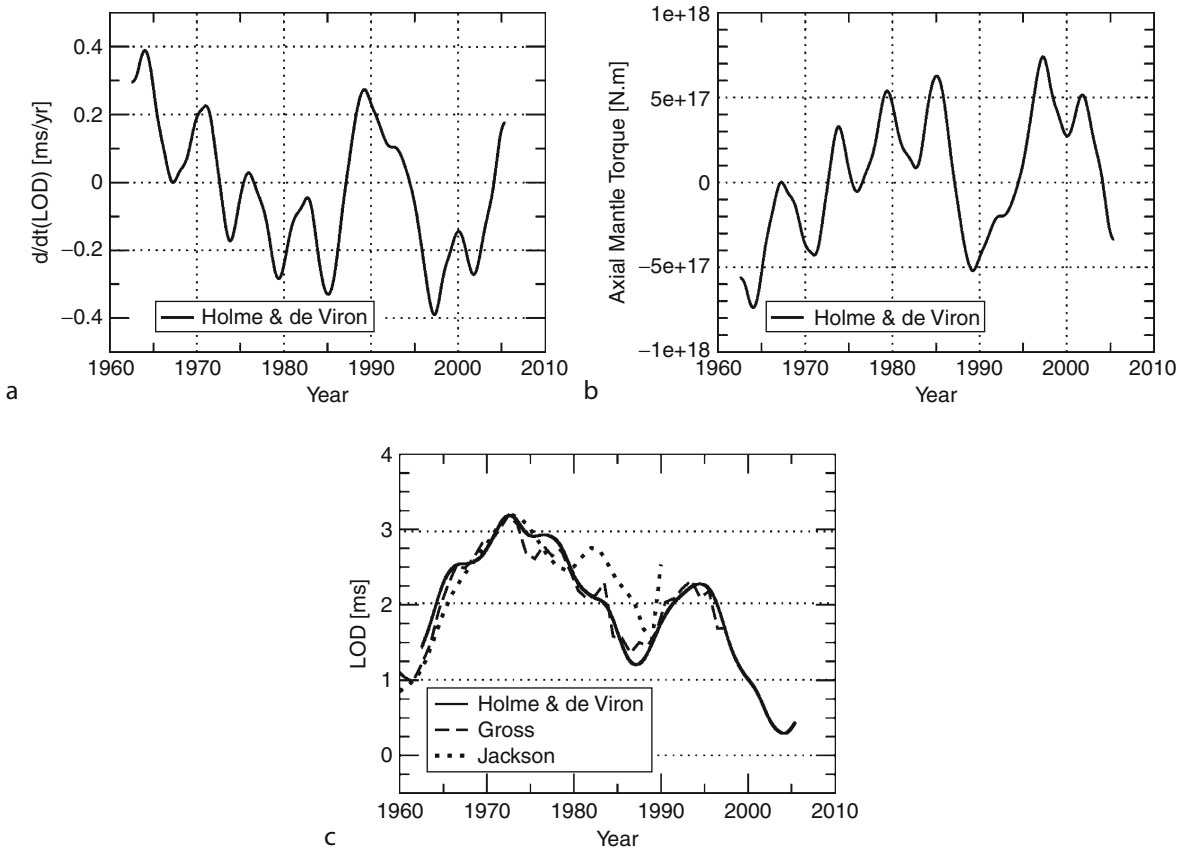
Definition, scope, and aims

The Earth is not a perfect timekeeper, and the spectrum of the variations in the mantle's angular velocity $\widehat{\mathbf{\Omega}}$ spans a wide range of frequencies. Of particular interest here are the comparatively large amplitude decadal and semi-decadal variations in which changes in length of day, P, of up to 2 ms occur. These would not be explained even if the global circulations of the atmosphere and oceans could be reversed. This is confirmed by a more detailed argument given in our recent review (Roberts and Aurnou, 2012), which will be referred to here as "RA12."

The origin of these length of day (LOD) variations must be sought in the Earth's core, and Figure 1 suggests that the task is not an easy one. Figure 1b shows dP/dt, derived by differentiating smoothed LOD data from the last half century, with atmospheric, oceanic, and tidal signals removed; semi-decadal time variations are clearly seen with a period τ_{LOD} of about 6 years (e.g., Abarca del Rio et al., 2000). Figure 1c shows the implied $\widehat{\Gamma}_z$ as a function of time t, where $\widehat{\Gamma}_z$ is the component parallel to the polar axis O_z of the torque $\widehat{\mathbf{\Gamma}}$ exerted by the core on the mantle. This shows that $\widehat{\Gamma}_z$ of nearly 10^{18} Nm is generated. We shall call this the "target torque" and seek its origin.

In addition, to the semi-decadal oscillations, larger variations seem to exist having longer periods, one of which is estimated to have a roughly 60 year period (e.g., Roberts et al., 2007). This time scale is reminiscent of the geomagnetic secular variation, and it is natural to seek



Core-Mantle Coupling, Figure 1 (**a**) LOD time series data from Holme and de Viron (2005) and Gross (2001) compared with LOD model from the "smooth" core flow inversion of Jackson (1997). The time series include the variation due to lunar tidal drag. (**b**) Temporal derivative, dP/dt, of the smoothed time series data of Holme and de Viron (2005), where P is the length of day. (**c**) The implied axial torque, $\widehat{\Gamma}_z = -(2\pi\widehat{C}/P^2)\mathrm{d}P/\mathrm{d}t$, on the mantle, where $\widehat{C}$ is the axial moment of inertia of the mantle. The LOD in panel (**a**) is arbitrary to within an additive constant, chosen here to obtain agreement at 1972.5 with Gross (2001).

a connection between them (e.g., Braginsky, 1970; Gillet et al., 2010). Figure 1c supports this quest. It shows the LOD data (Gross, 2001; Holme and de Viron, 2005) plotted against the estimated LOD variations inferred from the core flow models of Jackson (1997) that are based on inversion of geomagnetic secular variation data. The qualitative agreement implies that the variations in LOD are due to core-mantle angular momentum exchange associated with magnetohydrodynamic (MHD) processes in the core.

This review will focus on variations in LOD, i.e., changes in $\Omega_z(\approx \Omega)$. Precession and nutation of the Earth's axis, which describe variations in Ω_x and Ω_y, are also phenomena that cannot be satisfactorily explained without invoking core-mantle torques, but they are beyond the scope of this review. It will become clear that torques on the Solid Inner Core (SIC) are also of interest. Variables in the SIC will be distinguished by a tilde ($\widetilde{\ }$) and those in the mantle by a hat ($\widehat{\ }$). Except when making general statements, unadorned letters will refer to variables in the Fluid Outer Core (FOC).

The four coupling processes

The torque on the mantle about the geocenter O is

$$\widehat{\mathbf{\Gamma}} = \oint_{\widehat{\mathrm{S}}} \mathbf{r} \times \widehat{\mathbf{T}}\, \mathrm{dA}, \quad \text{where} \quad \widehat{T}_i = -\widehat{S}_{ij} n_j, \tag{1a,b}$$

sometimes called the "surface traction," is the stress associated with the normal and $\widehat{S}_{ij}$ is the total stress tensor; $\mathbf{r} = r\mathbf{1}_r$ is the radius vector from O, $r = |\mathbf{r}|$. The minus sign in Equation 1b arises because our unit normal, $\mathbf{n}$, to $\widehat{\mathrm{S}}$, the Core Mantle Boundary (CMB), points into the mantle. The axial torque, i.e., the component of $\widehat{\mathbf{\Gamma}}$ along the rotation axis Oz, is

$$\widehat{\Gamma}_z = -\oint_{\widehat{\mathrm{S}}} s\widehat{S}_{\phi n}\, \mathrm{dA}, \tag{1c}$$

where s is distance from the z-axis. For the torque on the SIC, we have similarly

$$\widetilde{\mathbf{\Gamma}} = \oint_{\widetilde{\mathrm{S}}} \mathbf{r} \times \widetilde{\mathbf{T}}\, \mathrm{dA}, \qquad \widetilde{T}_i = \widetilde{S}_{ij} n_j,$$
$$\widetilde{\Gamma}_z = \oint_{\widetilde{\mathrm{S}}} s\widetilde{S}_{\phi n}\, \mathrm{dA}; \tag{1d,e,f}$$

there is no minus sign in Equations 1e, f because our unit normal, $\mathbf{n}$, to the Inner Core Boundary (ICB) points out of the SIC.

Equation 1a tacitly assumes that the core alone exerts a torque on the mantle; sources of torque from outside the Earth are ignored, and therefore

$$\mathbf{\Gamma} + \widehat{\mathbf{\Gamma}} + \widetilde{\mathbf{\Gamma}} = \mathbf{0},$$
$$\mathbf{M} + \widehat{\mathbf{M}} + \widetilde{\mathbf{M}} = \text{constant}, \tag{1g,h}$$

where $\mathbf{\Gamma}$ is the torque on the FOC; $\mathbf{M}$, $\widehat{\mathbf{M}}$ and $\widetilde{\mathbf{M}}$ are the corresponding angular momenta. Equation 1g implies that, if one of the three torques changes, so do one or two of the others, in the opposite sense. The system is, in this respect, self-regulating. We shall treat the mantle and SIC as rigid bodies below.

Stress is exerted on the CMB in four ways: through viscosity, topography, gravity, and magnetic field, and there are correspondingly four parts to each of S_{ij}, $\mathbf{T}$ and $\mathbf{\Gamma}$, e.g., $\widehat{\mathbf{\Gamma}} = \widehat{\mathbf{\Gamma}}^V + \widehat{\mathbf{\Gamma}}^T + \widehat{\mathbf{\Gamma}}^G + \widehat{\mathbf{\Gamma}}^M$. The topographic and gravitational torques depend on the non-sphericity of $\widehat{\mathrm{S}}$ and $\widetilde{\mathrm{S}}$. For the others, negligible error is made by replacing the CMB and ICB by spheres, $\widehat{\mathrm{S}}_\bullet$ and $\widetilde{\mathrm{S}}_\bullet$, of radii r_o and r_i. The torques will be estimated below.

The viscous torque

Assuming uniform fluid density, ρ, and kinematic viscosity, ν, the part of the viscous stress tensor, $\widehat{S}^V_{ij}$, responsible for $\widehat{T}^V_i$ is $\rho\nu\nabla_j V_i$, i.e., $\widehat{\mathbf{T}}^V = -\rho\nu(\mathbf{n}\cdot\nabla)\mathbf{V} \approx -\rho\nu\partial_r\mathbf{V}$ so that, by Equations 1a, c,

$$\widehat{\mathbf{\Gamma}}^V = -\rho\nu \oint_{\widehat{\mathrm{S}}} \mathbf{r} \times \partial_r \mathbf{V}\, \mathrm{dA},$$
$$\widehat{\Gamma}^V_z = -\rho\nu \oint_{\widehat{\mathrm{S}}} s\partial_r V_\phi\, \mathrm{dA}. \tag{2a,b}$$

These torques involve only the radial gradient of the fluid velocity, $\mathbf{V}$. This tends to drag the mantle in the direction of the subsurface flow.

The viscosity of core fluid is hard to estimate. First principles calculations (de Wijs et al., 1998; Dobson et al., 2000; Vočadlo et al., 2000) suggest that ν at the CMB is within a factor of 3 of 10^{-6} m^2 s^{-1}. Suppose the viscous stress transfers momentum between the core and mantle over a length scale $d_\nu = E^{1/2} r_o \sim 0.2$ m, which is the thickness of the laminar Ekman boundary layer. Here

$$E = \nu/\Omega\mathcal{L}^2 \tag{2c}$$

is the Ekman number ($\approx 3 \times 10^{-15}$), which quantifies the ratio of the viscous and Coriolis forces; $\mathcal{L}$ is a characteristic scale of motion outside the boundary layer, for which we take $\mathcal{L} = r_o$. Assuming velocities of order $\mathcal{V} \approx 10^{-4}$ m s^{-1} (e.g., Jackson, 1997), the surface traction, $\widehat{T}^V \approx \rho\nu\mathcal{V}/d_\nu$, is about 10^{-5} N m^{-2}, implying that $\widehat{\Gamma}^V \approx 5 \times 10^{14}$ Nm.

In a highly turbulent medium such as the FOC, small scale motions transport macroscale quantities, such as angular momentum, far more effectively than molecular diffusion. When these scales are too small to be resolved by numerical computations, they are termed "sub-grid scales." Their effect must then be included in some other way. Appeal is often made to an analogy with molecular diffusion. Molecular transport depends on the molecular mean-free-path, ℓ, and the rms molecular speed, u. Simple

dynamical arguments show that the molecular diffusivity, ν, for momentum is of order $u\ell$. The analogy pictures small scale eddies replacing molecules as the transporters of macroscale momentum. The correlation length, $l_{\rm cor}$, of the turbulence replaces ℓ and the rms turbulent velocity, υ, replaces u. The transport of macroscale momentum is then governed by a kinematic "turbulent viscosity" $\nu_T \approx \upsilon l_{\rm cor}$, which greatly exceeds ν. We use $\upsilon = 10^{-4}$ m s^{-1} for the velocity scale. The length scale is harder to estimate. Here we take $l_{\rm cor} \sim E^{1/3} r_o \approx 100$ m, which is based upon the characteristic length scale for finite amplitude rapidly rotating convection (e.g., Stellmach and Hansen, 2004; Sprague et al., 2006). This gives $\nu_T \approx 10^{-2}$ m^2 s^{-1}. Though it is strictly inconsistent to use υ and $l_{\rm cor}$ when estimating the shear on the resolved scales, an upper bound on the turbulent traction follows from doing so: $\widehat{T}^V \approx \rho \nu_T \upsilon / l_{\rm cor} \approx \rho(\upsilon l_{\rm cor})\upsilon / l_{\rm cor} \approx 10^{-4}$ N m^{-2}, implying $\widehat{\Gamma}^V_z \lessapprox 5 \times 10^{15}$ Nm.

This may overestimate $\widehat{\Gamma}^V_z$. A stable layer may exist at the top of the FOC; see, e.g., Loper (2007), Buffett (2010). Braginsky (1999) pointed out that the light material released during the freezing of the SIC may preferentially congregate near the ICB, and that this may answer unresolved questions about the geomagnetic secular variation (Braginsky, 1984). Turbulent motions in a buoyantly stable layer tend to be damped preferentially in the direction of stratification, and this reduces the macroscale momentum transport across the layer (e.g., Gargett, 1984; Davidson, 2004). Waves in such a layer may increase what ν alone can do in transporting macroscale momentum (e.g., Rogers and Glatzmaier, 2006). But it is doubtful if they can transport it as effectively as ν_T for fully convective turbulence far from boundaries.

Though these and similar arguments lack rigor, the above estimates of $\widehat{\Gamma}^V$ are less than the target torque, but not vastly so (cf. Kuang and Bloxham, 1997; Brito et al., 2004; Deleplace and Cardin, 2006; Buffett and Christensen, 2007).

The topographic torque

The likelihood that there are inverted mountains and valleys on the CMB, and that these might create topographic torques large enough to explain the observed changes in LOD, was first suggested by Hide (1969). These irregularities are often collectively called "bumps," and their study was jokingly christened "geophrenology" by the late Keith Runcorn. Hide's idea generated much interest and literature, e.g., Anufriev and Braginsky (1975; 1977a; b), Jault and Le Mouël (1989), Kuang and Bloxham (1993, 1997), Buffett (1998) and Kuang and Chao (2001). Seismic studies infer the bump height, $\mathcal{H}$, is of order 1 km (e.g., Tanaka, 2010). See *Earth's Structure, Lower Mantle*.

Topographic coupling between the FOC and its boundaries depends on deviations from sphericity in the shapes of the CMB and ICB. The fluid pressure, p, creates surface tractions, $\widehat{\mathbf{T}}^T = p\mathbf{n}$ and $\widetilde{\mathbf{T}}^T = -p\mathbf{n}$, that are not purely radial. The resulting topographic torques on the CMB and ICB are

$$\widehat{\mathbf{\Gamma}}^T = \oint_{\widehat{\rm S}} p\mathbf{r} \times \mathbf{n}\, {\rm dA}, \qquad \widetilde{\mathbf{\Gamma}}^T = -\oint_{\widetilde{\rm S}} p\mathbf{r} \times \mathbf{n}\, {\rm dA}. \tag{3a,b}$$

Equal but opposite torques act on the FOC, so that (cf. Equation 1g)

$$\mathbf{\Gamma}^T = -\widehat{\mathbf{\Gamma}}^T - \widetilde{\mathbf{\Gamma}}^T = -\int_{\rm V} \mathbf{r} \times \boldsymbol{\nabla} p\, {\rm dV}. \tag{3c}$$

We define the CMB and ICB by

$$r = r_o + \widehat{h}(\theta, \phi), \quad r = r_i + \widetilde{h}(\theta, \phi), \tag{4a,b}$$

where $(r,\ \theta,\ \phi)$ are spherical coordinates. Equations 3a, b can be simplified if it is assumed that $\left|\widehat{h}\right|/r_o \ll 1$, $\left|\widetilde{h}\right|/r_i \ll 1$, $\left|\boldsymbol{\nabla}\widehat{h}\right| \ll 1$ and $\left|\boldsymbol{\nabla}\widetilde{h}\right| \ll 1$; see RA12. The projection of Equations 3a, b onto the spheres $\widehat{\rm S}_\bullet$ and $\widetilde{\rm S}_\bullet$ are then

$$\widehat{\mathbf{\Gamma}}^T = \oint_{\widehat{\rm S}_\bullet} \widehat{h}\mathbf{r} \times \boldsymbol{\nabla} p\, {\rm dA}_\bullet, \qquad \widetilde{\mathbf{\Gamma}}^T = -\oint_{\widetilde{\rm S}_\bullet} \widetilde{h}\mathbf{r} \times \boldsymbol{\nabla} p\, {\rm dA}_\bullet. \tag{4c,d}$$

The torques $\widehat{\mathbf{\Gamma}}^T$ and $\widetilde{\mathbf{\Gamma}}^T$ obviously depend on variations in p in the FOC, and we consider next the causes and magnitudes of these. This necessitates a considerable digression. The first step is to develop a reference state.

Convection mixes the FOC so well that, except in thin boundary layers at the CMB and ICB, it is chemically and thermodynamically homogeneous. It is therefore isentropic, i.e., its specific entropy, S, is uniform. The core is an unknown mixture of all elements, but the basics can be understood by assuming that it is a binary alloy of Fe and a lighter element, X, whose mass fraction is X. It is usually supposed that X is mostly Si or S, but it is unnecessary to be specific here. Except in boundary layers,

$$S = S_a = \text{Constant}, \qquad X = X_a = \text{Constant, in the FOC}, \tag{5a,b}$$

where the suffix $_a$ stands for "adiabatic".

Although fast enough to mix the core thoroughly, core flows are slow compared with the speed of sound, u_s ($\approx 10^4$ m s^{-1}). The primary dynamical balance is therefore hydrostatic and, allowing for centrifugal forces, it is governed by

$$\boldsymbol{\nabla} p_a = \rho_a(\mathbf{g}_a - \mathbf{\Omega} \times (\mathbf{\Omega} \times \mathbf{r})) = \rho_a\left(\mathbf{g}_a + \frac{1}{2}\nabla(\mathbf{\Omega} \times \mathbf{r})^2\right), \tag{5c}$$

where $\mathbf{\Omega} = \Omega \mathbf{1}_z$ is the angular velocity of the Earth and $\mathbf{g}$ is the gravitational acceleration. Newtonian gravitation theory requires that

$$\boldsymbol{\nabla} \times \mathbf{g} = \mathbf{0}, \quad \boldsymbol{\nabla} \cdot \mathbf{g} = -4\pi G\rho, \tag{5d,e}$$

where G is the constant of gravitation. It follows that

$$\boldsymbol{\nabla} p_a = \rho_a \mathbf{g}_e = -\rho_a \boldsymbol{\nabla} \Phi_e, \quad \text{where} \quad \mathbf{g}_e = -\boldsymbol{\nabla}\Phi_e \tag{5f,g}$$

is the effective gravitational field and $\Phi_e = \Phi_a - \frac{1}{2}(\mathbf{\Omega} \times \mathbf{r})^2$ is the "effective gravitational potential." Equation 5d shows that p_a, ρ_a, ... are constant on equipotential surfaces:

$$p_a = p(\Phi_e, S_a, X_a),$$
$$\rho_a = \rho(\Phi_e, S_a, X_a) = -\partial p(\Phi_e, S_a, X_a)/\partial \Phi_e, \ldots \tag{5h,i}$$

The effect of the centrifugal forces is quantified by $\varepsilon_\Omega = \Omega^2 r/g$. This is small, varying from 1.7×10^{-3} at the CMB to 1.5×10^{-3} at the ICB. The deviation of the equipotential surfaces from spheres is therefore small, as are deviations caused by the gravitational field produced by density anomalies in the mantle and SIC, quantified below. It is therefore helpful to refer to departures from a "reference state" that is spherically symmetric: $\Phi = \Phi^s(r)$, $p = p^s(r)$, $\rho = p^s(r)$, $T = T^s(r)$, etc., where T is temperature. There are large departures from adiabaticity in boundary layers and smaller departures throughout the FOC that are of two main types:

(a) *Deviations from Φ^s due to rotation and density anomalies in the mantle and SIC.* These will be denoted by a prime, e.g., $p'_a = p_a - p^s$. Rotation produces the larger deviation but, as will be seen below, this is less relevant to LOD variations than the anomaly created by the mantle, which in the FOC is dominantly

$$\Phi'_a = A'(r/r_o)^2 \sin^2\theta \cos\ 2\phi, \quad (A' > 0) \tag{6}$$

Wahr and deVries (1989), Forte et al. (1994). The value of the constant A' is about 1,300 $m^2\ s^{-2}$, according to Defraigne et al. (1996) and about 2,300 $m^2\ s^{-2}$ according to Forte et al. (1994); our compromise will be A' =1,800 $m^2\ s^{-2}$. By Equation 5i, $p'_a \approx -\rho^s_a \Phi'_a$. Therefore $\varepsilon_a = p'_a/p^s_a$ is 10^{-4} on the CMB equator and 10^{-5} at the ICB equator.

(b) *Deviations created by convection.* We use the notation

$$\rho = \rho_a + \rho_c, \tag{7a}$$

and similarly for other variables. The Earth radiates energy into space at a rate estimated to exceed 43 TW (e.g., §4.1.5 of Schubert et al., 2001). We take an extreme position by supposing the entire 43 TW emerges from the core. The outward heat flux in the FOC is the sum of the convective heat flux q_c and the adiabatic heat flux $q_a = -KdT^s/dr$, where K is thermal conductivity. Though the latter may be as much as 5 TW, we ignore it. Then q_c = 0.28 W m^{-2} at the CMB. We take

$$q_c = \rho c_p \overline{T_c V_r}, \tag{7b}$$

where c_p (≈800 J kg^{-1} K^{-1}) is the specific heat at constant pressure, p. The overline denotes a horizontal average over the flow, which is undoubtedly highly turbulent. For $V_r = 10^{-4}$ m s^{-1}, it follows that $T_c = 3.5 \times 10^{-4}$ K. As $T_a \approx 4,000$ K (e.g., Kawai and Tsuchiya, 2009), $\varepsilon_c = T_c/T_a$ is less than 10^{-7}, which is 3–4 orders of magnitude smaller than ε_a. Even this is an overestimate; it has never been suggested that Q_c is larger than 15 TW. The smallness of ε_Ω, ε_a, and ε_c means that all these effects can be treated as perturbations of the reference state.

As $p'_a(r,\ \theta,\ \phi) \gg p_c(r,\ \theta,\ \phi)$, it is sensible to consider first the effect of p'_a by introducing the "adiabatic topographic torques" on the mantle, ICB, and FOC:

$$\widehat{\mathbf{\Gamma}}^T_a = \oint_{\widehat{S}} p_a\, \mathbf{r} \times \mathbf{n}\, dA,$$
$$\widetilde{\mathbf{\Gamma}}^T_a = -\oint_{\widetilde{S}} p_a\, \mathbf{r} \times \mathbf{n}\, dA, \tag{8a,b,c}$$
$$\mathbf{\Gamma}^T_a = -\int_V \mathbf{r} \times \boldsymbol{\nabla} p_a\, dV.$$

If the CMB (ICB) were an equipotential or if it were spherical, $\widehat{\mathbf{\Gamma}}^T_a \left(\widetilde{\mathbf{\Gamma}}^T_a\right)$ would vanish according to Equation 8a, b, but generally these torques are nonzero. They can be evaluated only if $\widehat{p}$ ($\widetilde{p}$) is known on the CMB (ICB). It will be shown in the next section that $\widehat{\mathbf{\Gamma}}^T_a$ and $\widetilde{\mathbf{\Gamma}}^T_a$ are intimately related to what we shall call "adiabatic gravitational torques." We therefore postpone further discussion and estimation of adiabatic topographic torques.

Consider the torque $\widehat{\mathbf{\Gamma}}^T_c$ associated with the convective motions in the FOC:

$$\widehat{\mathbf{\Gamma}}^T_c = \oint_{\widehat{S}_\bullet} \widehat{h}\mathbf{r} \times \boldsymbol{\nabla} p_c\, dA_\bullet,$$
$$\widehat{\Gamma}^T_{c,z} = \oint_{\widehat{S}_\bullet} \widehat{h} \partial_\phi p_c\, dA_\bullet. \tag{9a,b}$$

Reasons will be given in the section on the "Magnetic Torque" why core flow may be well described by the magnetostrophic approximation Equation 20a, and why, deep in the core, Coriolis and Lorentz forces are comparable, implying a magnetic field strength $\mathcal{B}$ there of about 2 mT, or about four times greater than the typical field strength $\mathcal{B}_o$ on the CMB. The Lorentz force is therefore 16 times less on the CMB than in the bulk of the core. Also, as g_ϕ, is small, $\partial_\phi p_c \approx -2\Omega\rho_0 r_o V_\theta \cos\theta \sin\theta$ should be a good approximation to the ϕ-component of Equation 20a on the CMB. Therefore (Hide et al., 1993)

$$\widehat{\Gamma}^T_{c,z} = -2\Omega\rho_0 r_o \oint_{\widehat{S}_\bullet} \widehat{h}(\theta,\phi) V_\theta(r_o,\theta,\phi)\cos\theta\sin\theta\,\mathrm{dA}_\bullet. \tag{9c}$$

In principle, $\widehat{\Gamma}^T_{c,z}$ can be estimated by extracting $\widehat{h}$ from seismological analysis, and by using the V_θ (r_o, θ, ϕ) inferred from the core surface motion. In practice, this is difficult and has generated controversy. Equation 9c suggests that

$$\widehat{\Gamma}^T_{c,z} = \mathrm{O}\left(2\Omega\rho\mathcal{V}\mathcal{H}r_o^3\right), \tag{9d}$$

which is 10^{18} Nm for a bump height of $\mathcal{H}$ = 100 m. Such a bump height is well within the bounds set by recent seismic investigations (e.g., Tanaka, 2010). Equation 9b indicates, however, that Equation 9d may be a serious overestimate because p_c is a single-valued function and $\partial_\phi p_c$ is as often positive as negative in the integrand of Equation 9b. Though $\pm 2\Omega\rho\mathcal{V}r_o$ is a reasonable estimate of $\partial_\phi p_c$ at most points on the CMB, considerable cancellation is likely when evaluating the integral in Equation 9b. There is even an outside chance that the cancellation might be complete; see Anufriev and Braginsky (1978b).

Reliable estimation of the convective topographic torque must probably await careful experiments and allied theory. No argument has so far convincingly demonstrated that topography can create torques of the target magnitude of 10^{18} Nm but, equally, none have shown that it cannot.

The gravitational torque

The gravitational torque on a body V of density $\rho(\mathbf{x})$ in a gravitational field $\mathbf{g}(\mathbf{x})$ is

$$\mathbf{\Gamma}^G = \int_V \rho\,\mathbf{r}\times\mathbf{g}\,\mathrm{dV}. \tag{10a}$$

This volume integral can be usefully transformed into a surface integral by drawing on the analogy between the theories governing Newtonian gravitation and electrostatics, the only difference between these theories being one of sign: like charges repel but all bodies attract gravitationally. It can be shown that

$$\rho g_i = \nabla_j S^G_{ij}, \quad \text{where} \quad S^G_{ij} = -\frac{1}{4\pi G}\left(g_i g_j - \frac{1}{2}g^2\delta_{ij}\right) \tag{10b,c}$$

is the gravitational stress tensor, the gravitational pressure $-g^2/8\pi G$ being also the gravitational energy density. Equations 10b, c enable Equation 10a to be written as a surface integral:

$$\mathbf{\Gamma}^G = -\frac{1}{4\pi G}\oint_S \mathbf{r}\times\left[(\mathbf{n}\cdot\mathbf{g})\mathbf{g} - \frac{1}{2}g^2\mathbf{n}\right]\mathrm{dA}, \tag{10d}$$

where $\mathbf{n}$ points out of V. See RA12 and Appendix B of Braginsky and Roberts (1995) for derivations of these results. When they are applied below, $\mathbf{n}$ on the CMB and SIC will, as previously defined, be oriented approximately parallel to $\mathbf{r}$.

By Equation 10a, the gravitational torque on the FOC due to the mantle and SIC is

$$\mathbf{\Gamma}^G = \int_V (\rho_a+\rho_c)\mathbf{r}\times(\mathbf{g}_a+\mathbf{g}_c)\mathrm{dV} = \mathbf{\Gamma}^G_a + \mathbf{\Gamma}^G_c, \tag{11a}$$

where $\mathbf{\Gamma}^G_a$ and $\mathbf{\Gamma}^G_c$ are the adiabatic and convective parts of $\mathbf{\Gamma}^G$:

$$\mathbf{\Gamma}^G_a = \int_V \rho_a\mathbf{r}\times\mathbf{g}_a\,\mathrm{dV}, \qquad \mathbf{\Gamma}^G_c = \int_V \mathbf{r}\times(\rho_c\mathbf{g}_a + \rho_a\mathbf{g}_c + \rho_c\mathbf{g}_c)\mathrm{dV}. \tag{11b,c}$$

It was pointed out earlier that $\rho_c = \mathrm{O}(10^{-4}\rho'_a)$, $g_c = \mathrm{O}(10^{-4}g'_a)$, etc. Apparently therefore $\Gamma^G_c = \mathrm{O}(10^{-4}\Gamma^G_a)$, making it sensible to focus first on the adiabatic torque.

Consistent with hydrostatic balance in the FOC (see Equation 5f), Equations 8c and 11b, give

$$\mathbf{\Gamma}^{G+T}_a = \mathbf{\Gamma}^G_a + \mathbf{\Gamma}^T_a = \int_V \mathbf{r}\times(\rho_a g_a - \boldsymbol{\nabla}p_a)\mathrm{dV} = \mathbf{0}. \tag{12a}$$

By Equations 8a, b and 10d and the continuity of $\mathbf{g}$ and p, we also have

$$\widehat{\mathbf{\Gamma}}^{G+T}_a = \oint_{\widehat{S}} \mathbf{r}\times\left\{p_a\mathbf{n} + (4\pi G)^{-1}\left[(\mathbf{n}\cdot\mathbf{g}_a)g_a - \frac{1}{2}g_a^2\mathbf{n}\right]\right\}\mathrm{dA}, \tag{12b}$$

$$\widetilde{\mathbf{\Gamma}}^{G+T}_a = -\oint_{\widetilde{S}} \mathbf{r}\times\left\{p_a\mathbf{n} + (4\pi G)^{-1}\left[(\mathbf{n}\cdot\mathbf{g}_a)g_a - \frac{1}{2}g_a^2\mathbf{n}\right]\right\}\mathrm{dA}, \tag{12c}$$

from which, in agreement with Equation 12a,

$$\widehat{\mathbf{\Gamma}}^{G+T}_a + \widetilde{\mathbf{\Gamma}}^{G+T}_a = \mathbf{0}. \tag{12d}$$

If the torques $\widehat{\mathbf{\Gamma}}^{G+T}_a$ and $\widetilde{\mathbf{\Gamma}}^{G+T}_a$ are nonzero, $\widehat{\mathbf{\Omega}}$ and $\widetilde{\mathbf{\Omega}}$ evolve. The consequent change in the relative orientation of the mantle and SIC modifies $\mathbf{g}_a$ and p_a in Equation 12b, c so that the system evolves toward a configuration of minimum energy E. In this configuration

$$\widehat{\mathbf{\Gamma}}^{G+T}_a = \mathbf{0}, \qquad \widetilde{\mathbf{\Gamma}}^{G+T}_a = \mathbf{0}. \tag{13a,b}$$

If this minimum energy, torque-free state is perturbed, the restoring GT-torques (as we shall call them) set up a "gravitational oscillation" of the SIC relative to the mantle.

To give a simple example, suppose that the gravitational anomaly defined by Equation 6 is created by sources entirely within the mantle, the CMB having no

bumps, so that $\widehat{\Gamma}^{G+T}_{a,z} = \widehat{\Gamma}^{G}_{a,z}$. Similarly, suppose the SIC is spherical but has internal sources that above the ICB produce the gravitational anomaly

$$\Phi''_a = A''(r_i/r)^3 \sin^2\theta \cos 2(\phi - \varphi), \quad (A'' > 0), \tag{14a}$$

where φ is the angular displacement of the system from the stable state, $\varphi = 0$, in which Equations 13a, b hold. Equations 12b, c show that

$$\widehat{\Gamma}^{G}_{a,z} = -\widetilde{\Gamma}^{G}_{a,z} = \Gamma^{G}_{0} \sin 2\varphi, \quad \text{where} \quad \Gamma^{G}_{0} = 8A'A''r_i^3/3Gr_o^2 (> 0). \tag{14b,c}$$

These torques vanish for the stable minimum energy states $\varphi = 0, \pi$ (and also for the unstable $\varphi = \pm\frac{1}{2}\pi$). Small departures from a stable state satisfy

$$\widehat{C} d_t^2 \widehat{\varphi} = 2\Gamma^{G}_{0}(\widetilde{\varphi} - \widehat{\varphi}), \quad \widetilde{C} d_t^2 \widetilde{\varphi} = 2\Gamma^{G}_{0}(\widetilde{\varphi} - \widehat{\varphi}), \tag{14d,e}$$

where $\widehat{C}$ (= 7.12×10^{37} kg m^2) and $\widetilde{C}$(= 5.86×10^{34} kg m^2) are the polar moments of inertia of mantle and SIC, respectively. The frequency, ω^G, of the oscillation is

$$\omega^G = [2(\widehat{C} + \widetilde{C})\Gamma^{G}_{0}/\widehat{C}\widetilde{C}]^{1/2} \approx [2\Gamma^{G}_{0}/\widetilde{C}]^{1/2}. \tag{14f}$$

Although an anomaly of the form of Equation 14a could be produced by density variations within the SIC, it is more plausibly created by SIC topography for the following reasons. It is generally believed that the SIC is the result of freezing of the FOC, an ongoing process even today (Jacobs, 1953). An alloy generally changes its composition when it changes phase. The rather large density jump at the ICB, $\widetilde{\Delta} = \widetilde{\rho}(r_i) - \rho(r_i) \approx 600$ kg m^{-3}, is hard to attribute to contraction on freezing but can be readily explained as a small reduction in X on freezing. Phase equilibrium at the ICB implies $T^s_a(\Phi_a, S_a, X_a) = T_m(p_a, X_a)$, where T_m is the melting temperature. This implies that the ICB is an equipotential surface. Since $\Phi = \Phi^s_a(r) + \Phi'_a(r,\theta,\phi)$ where $|\Phi'_a/\Phi^s_a| \ll 1$, Taylor expansion, using Equation 4b, shows that $\Phi^s_a(r_i) + \widetilde{g}\widetilde{h}(\theta,\phi) + \Phi'_a(r_i,\theta,\phi)$ is approximately constant, where $\widetilde{g} = -g^s_{a,r}(r_i) = \partial_r \Phi^s_a(r_i) (> 0)$ is gravity at the ICB. It follows that

$$\widetilde{h} = -\Phi'_a(r_i,\theta,\phi)/\widetilde{g} = \widetilde{\varepsilon} \sin^2\theta \cos 2\phi, \quad \widetilde{\varepsilon} = -A'(r_i/r_o)^2/\widetilde{g}. \tag{14g,h}$$

This shows how the gravitational anomaly in the mantle imposes its $n = m = 2$ preference on the SIC. It makes the otherwise ad hoc assumption of Equation 14a seem perfectly reasonable. The condition that $\widetilde{h}$ creates Equation 14a, for $\varphi = 0$ and $r - r_i \ll \widetilde{h}$ is

$$A''/A' = 4\pi G r_i^3 \widetilde{\Delta}/5r_o^2\widetilde{g} \approx 0.0034. \tag{14i}$$

The maximum bump height on the ICB is $|\widetilde{\varepsilon}| \approx 50$ m. Nonzero φ corresponds to a rotated SIC. Such a rotation is to be expected; core turbulence continually subjects the SIC to (topographic) torques that continuously change its orientation. Two relaxation processes act to restore the ICB to its equipotential: (i) flow within the SIC, (ii) new freezing/melting on the ICB. If either were instantaneous, there would be no torque between the mantle and SIC, but both appear to act on much longer time scales than core turbulence, so that SIC topography is almost "frozen" to the SIC as it turns.

Concerning (i), the viscosity of the SIC is plausibly much less than the viscosity of the mantle. According to Schubert et al. (2001) $\widehat{\nu} \approx 5 \times 10^{19}$m^2 s^{-1} in the deep mantle but, according to Mound and Buffett (2006), $\widetilde{\nu} \gtrsim 10^{13}$m^2 s^{-1}. Whereas mantle anomalies are essentially "frozen in," slow motions within the SIC created by stresses exerted by the FOC on the ICB can gradually restore equilibrium (Yoshida et al., 1996; Buffett, 1997). Concerning (ii), the thermodynamic disequilibrium created by the misalignment of the ICB from its equipotential surface is slowly removed by new freezing of the FOC or new melting of the SIC. This processes has not been fully explored (but see Fearn et al., 1981; Morse, 1986). The possible significance of melting/freezing processes on SIC structure has been recently investigated by Alboussière et al. (2010) and Monnereau et al. (2010).

Interest in gravitational torques and oscillations was sparked by Buffett (1996). We follow him but by a different method, making use of Equations 14c, i:

$$\Gamma^{G}_{0} = 32\pi r_i^6 \widetilde{\Delta} A'^2/15 r_o^4 \widetilde{g} \approx 6.7 \times 10^{19}\,\text{Nm} \tag{15a}$$

By Equation 14f, the frequency of the oscillation is $\omega^G \approx 4.8 \times 10^{-8}$ s^{-1}, with a period of

$$\tau^G = 2\pi/\omega^G \approx 4.1 \text{ years}. \tag{15b}$$

According to Buffett et al. (2009), gravitational oscillations are mainly responsible for the LOD variations shown in Figure 1. Mound and Buffett (2006) obtain $\Gamma^{G}_{0} \approx 1.5 \times 10^{20}$ Nm.

Equations 14d, e imply, for some t_0,

$$\widehat{\Omega} = \widehat{\Omega}_0 + d_t\widehat{\phi} = \widehat{\Omega}_0 + (2\Gamma^{G}_{0}/\widehat{C}\omega^G)(\widetilde{\phi} - \widehat{\phi})_{\max} \sin\omega^G(t - t_0). \tag{15c}$$

The amplitude of the gravitational oscillation is therefore related to that of the variation, ΔP, in LOD by

$$\left(\widetilde{\phi} - \widehat{\phi}\right)_{\max} = \pi\widehat{C}\omega^G \Delta P/\Gamma^{G}_{0} P_0^2 \approx 1.2^\circ, \tag{15d}$$

for $\Delta P = 1$ ms. This gives a maximum angular velocity difference $\omega^G\left(\widetilde{\phi} - \widehat{\phi}\right)_{\max} \approx 2^\circ$ year^{-1}. Furthermore the peak-to-peak variation in the radial gravitational acceleration at the Earth's surface, $r = r_E$, is

$$\Delta g_r''(r_E) = \frac{12A''}{r_i}\left(\frac{r_i}{r_E}\right)^4 (\widehat{\phi} - \widetilde{\phi})^2_{\max} \simeq 4\,\text{nGal}. \quad (15e)$$

This value is too small by roughly a factor of 5 to be detectable by the GRACE satellite system (e.g., Wahr et al., 2006).

One limitation of this analysis is the neglect of electromagnetic stresses at the boundaries when they are in motion relative to the core fluid. It has been implicitly assumed that the SIC is completely decoupled from the fluid within the tangent cylinder (TC), the imaginary cylinder that touches the ICB at its equator. This is particularly significant because the fluid dynamics inside and outside the TC are quite dissimilar. See Hide and James (1983), Heimpel and Aurnou (2007), and the next section. Because the SIC is as good an electrical conductor as the FOC (or better), it may be tightly coupled magnetically to $\mathcal{C}^N$ and $\mathcal{C}^S$, as suggested by Braginsky (1970); see the next section. To examine the effect of this coupling, we make the extreme assumption that all the fluid in the TC is completely locked to the SIC. Because the mantle is a poor electrical conductor, this fluid is not well coupled to the mantle, so that the entire fluid column within the TC can co-rotate about O_z almost freely with the SIC. This suggests that, instead of Equations 1g, h, a more useful division of the total angular momentum of the Earth might be based on

$$\widehat{\mathbf{\Gamma}} + \mathbf{\Gamma}^{\text{TC}} + \mathbf{\Gamma}^{\text{XTC}} = \mathbf{0}, \qquad \widehat{\mathbf{M}} + \mathbf{M}^{\text{TC}} + \mathbf{M}^{\text{XTC}} = \text{constant}, \quad (16a,b)$$

where $^{\text{TC}}$ refers to the TC and SIC locked together, and $^{\text{XTC}}$ refers to the part of the FOC exterior to the TC. The moment of inertia of the fluid within the TC is 2.12×10^{35} kg m^2 which, when added to $\widetilde{C}$, gives $C^{\text{TC}} = 2.71 \times 10^{35}$ kg m^2. Using this instead of $\widetilde{C}$ in Equation 14f, τ^{G} is lengthened from 4.1 years to

$$\tau^G_{\text{TC}} = 2\pi/\omega^G_{\text{TC}} \approx 8.9 \text{ years}, \quad \text{where } \omega^G_{\text{TC}} = [2(\widehat{C} + C^{\text{TC}})\Gamma^G_0/\widehat{C}C^{\text{TC}}]^{1/2}. \quad (16c,d)$$

See also Mound and Buffett (2006).

Even though ρ_c/ρ_a, p_c/p_a, etc., are of order 10^{-4}, this does not mean that $\Gamma_c^{G+T}/\Gamma_a^{G+T}$ is as small as that. In fact, Equation 13a shows that $\mathbf{\Gamma}_a^{G+T} = \mathbf{0}$ in the minimum energy state. The adiabatic GT-torques dominate the convective torques only if φ is sufficiently large. Stated another way, a convective torque can be nullified by a small departure from the minimum energy state. Earlier, the torque on the SIC created by core turbulence was held responsible for causing φ to deviate from zero. This torque is essentially (magneto-)convective, and is nullified by the GT-torque for a tiny change in φ. Another way of estimating how tiny this φ is equates the magnitudes of the GT-torque, taken as $1.3 \times 10^{20}\,\varphi$ Nm (see Equations 14b, c and 15d), and the convective torque, taken to have its target value of 10^{18} Nm. This gives $\varphi \approx 0.5°$. Within this angle, the mantle and SIC are gravitationally locked together, over short time scales compared with those of the relaxation processes in the SIC described above. See Buffett and Glatzmaier (2000).

The magnetic torque

This section assumes that readers are familiar with pre-Maxwell EM theory and the fundamentals of MHD, including the frozen flux theorem and Alfvén waves. Davidson (2001) contains the necessary background.

It may be useful to remind readers that the magnetic torque about O on a body V carrying a current of density $\mathbf{J}$ is the integrated moment of the Lorentz force, $\mathbf{J} \times \mathbf{B}$:

$$\mathbf{\Gamma}^M = \int_V \mathbf{r} \times (\mathbf{J} \times \mathbf{B})\,\text{dV} = \int_V r[B_r\mathbf{J} - J_r\mathbf{B}]\,\text{dV}. \quad (17a)$$

The Lorentz force can be expressed as a divergence:

$$(\mathbf{J} \times \mathbf{B})_i = \nabla_j S^M_{ij}, \quad \text{where } S^M_{ij} = \mu_0^{-1}\left(B_iB_j - \frac{1}{2}B^2\delta_{ij}\right) \quad (17b,c)$$

is the magnetic stress tensor. An alternative form of Equation 17a is therefore

$$\mathbf{\Gamma}^M = \mu_0^{-1}\oint_S \mathbf{r} \times \left[(\mathbf{n}\cdot\mathbf{B})\mathbf{B} - \frac{1}{2}B^2\mathbf{n}\right]\text{dA}, \quad (17d)$$

where the unit normal $\mathbf{n}$ to S points out of V. Therefore

$$\widehat{\Gamma}^M_z = -\mu_0^{-1}\oint_{\widehat{S}} s\widehat{B}_r\widehat{B}_\phi\,\text{dA}, \quad \widetilde{\Gamma}^M_z = \mu_0^{-1}\oint_{\widehat{S}} s\widetilde{B}_r\widetilde{B}_\phi\,\text{dA}. \quad (17e,f)$$

These results can be used as they stand to assess the magnetic coupling between the inferred core surface flow and the mantle. See Stix and Roberts (1984), Love and Bloxham (1994), Holme (1998). Here, however, we are more interested in forging a link between the observed changes in LOD and torsional waves. To explain what the latter are, it is necessary to consider some dynamical issues.

Most studies of core MHD are based on the Boussinesq approximation; see, e.g., Braginsky and Roberts (2007). This assumes constant density, $\rho_0 (\approx 10^4 \text{kg m}^{-3})$, and expresses conservation of mass and momentum as

$$\nabla\cdot\mathbf{V} = 0, \quad \partial_t\mathbf{V} + \mathbf{V}\cdot\nabla\mathbf{V} + 2\Omega\times\mathbf{V} = -\nabla(p_c/\rho_0) + \mathcal{C}\mathbf{g}_e + \mathbf{J}\times\mathbf{B}/\rho_0 + \nu_T\nabla^2\mathbf{V}. \quad (18a,b)$$

The accelerations in Equation 18b are from inertia ($\partial_t\mathbf{V}$ and $\mathbf{V}\cdot\nabla\mathbf{V}$), rotation ($2\mathbf{\Omega}\times\mathbf{V}$), pressure ($p_c$), buoyancy ($C\mathbf{g}_e$), magnetic field ($\mathbf{J}\times\mathbf{B}/\rho_0$), and viscosity ($\nu_T\nabla^2\mathbf{V}$). Thermal and compositional buoyancy, combined in the

codensity C (Braginsky and Roberts, 1995), maintains the flow and the magnetic field; see *Core Dynamo*.

The Coriolis force is generally more significant than the inertial and viscous forces. This is indicated by the smallness of the Ekman and Rossby numbers:

$$Ro = \mathcal{V}/\Omega\mathcal{L}. \tag{19}$$

See Equation 2c for the definition of E. From $\mathcal{V} = 10^{-4}$ m s^{-1}, $\mathcal{L} = r_o$ and $\nu_T = 10^{-2}$ m^2 s^{-1} follow $Ro \approx 10^{-6}$ and $E \approx 10^{-11}$. This suggests that the inertial and viscous terms can be safely omitted from Equation 18b, except on small length scales.

If the inertial and viscous forces are ejected from Equation 18b, it becomes

$$2\rho_0\mathbf{\Omega} \times \mathbf{V}^{\mathrm{N}} = -\nabla p_c + \rho_0 \mathcal{C}\mathbf{g}_{\mathrm{e}} + \mathbf{J} \times \mathbf{B}, \tag{20a}$$

where $^{\mathrm{N}}$ stands for "non-geostrophic," and "geostrophic" is defined below. Equations 18a and 20a define the "magnetostrophic approximation," often used to describe the quasi-steady macroscales of core MHD. As the viscous term has been ejected, the only boundary condition that $\mathbf{V}^{\mathrm{N}}$ must obey is

$$\mathbf{n} \cdot \mathbf{V}^{\mathrm{N}} = 0, \quad \text{on the CMB and ICB.} \tag{20b}$$

The full boundary conditions of continuous $\mathbf{B}$ and $\mathbf{n} \times \mathbf{E}$ still apply. Because $\partial_t \mathbf{V}$ has been ejected from Equation 20a, there are no Alfvén waves. Instead, the system evolves on the much longer ageostrophic time scale,

$$\tau^{\mathrm{N}} = 2\Omega\mathcal{L}^2/V_{\mathrm{A}}^2 = \tau_\eta/\Lambda, \quad \text{where } \tau_\eta = \mathcal{L}^2/\eta \approx 10^5 \text{ years} \tag{20c,d}$$

is the free decay time for magnetic fields of scale $\mathcal{L}$, and Λ is the "Elsasser number":

$$\Lambda = V_{\mathrm{A}}^2/2\Omega\eta, \quad \text{where} \quad V_{\mathrm{A}} = \mathcal{B}/\sqrt{(\mu_0\rho_0)} \tag{20e,f}$$

is the Alfvén velocity. Elsasser (1946) suggested that $\mathcal{B}$ is determined by a balance of Lorentz and Coriolis forces. Taking $\mathcal{J} \approx \sigma\mathcal{V}\mathcal{B}$, this implies $\Lambda = 1$, $\mathcal{B} \approx 2$ mT, and $V_{\mathrm{A}} \approx 2$ cm s^{-1}. It also gives $\tau^{\mathrm{N}} \approx \tau_\eta \approx 2 \times 10^5$ years for $\mathcal{L} = r_o$.

In cylindrical coordinates (s, ϕ, z), the ϕ-component of Equation 20a is

$$2\Omega\rho_0 V_s^{\mathrm{N}} = -\partial_\phi p_c + (\mathbf{J} \times \mathbf{B})_\phi. \tag{21a}$$

Integrate this over the surface, $\mathcal{C}(s)$, of the circular cylinder of radius s ($> r_i$) coaxial with Oz. The left-hand-side vanishes by mass conservation, as can be verified by integrating Equation 18a over the interior, $\mathcal{I}(s)$, of $\mathcal{C}(s)$ and applying Equation 20b to $\mathcal{N}(s)$ and $\mathcal{S}(s)$, the spherical caps of $\mathcal{C}(s)$ on the CMB that complete the boundary of $\mathcal{I}(s)$. It follows that

$$\int_{\mathcal{C}(s)} (\mathbf{J} \times \mathbf{B})_\phi \, \mathrm{dA} = 0. \tag{21b}$$

If $s < r_i$, there are two cylinders, $\mathcal{C}^N(s)$ and $\mathcal{C}^S(s)$, of radius s to the north and south of the SIC for which

$$\int_{\mathcal{C}^N(s)} (\mathbf{J} \times \mathbf{B})_\phi \, \mathrm{dA} = 0, \quad \int_{\mathcal{C}^S(s)} (\mathbf{J} \times \mathbf{B})_\phi \, \mathrm{dA} = 0. \tag{21c,d}$$

Equations 20b–d are examples of "Taylor's constraint" (Taylor, 1963). The cylinders $\mathcal{C}(s)$ are termed "Taylor cylinders." Of these, $\mathcal{C}(r_i)$ is the tangent cylinder (TC).

It is obviously possible to assign a $\mathbf{J}$ which creates a $\mathbf{B}$ that contradicts Equations 21b–d, at least initially. This shows that Equation 20a is an oversimplification. That approximation rested on discarding the inertial force in comparison with the Coriolis force. Consider however the class of "geostrophic flows":

$$\mathbf{v} = \upsilon(s,\ t)\, \mathbf{1}_\phi. \tag{22a}$$

The corresponding Coriolis acceleration is

$$2\rho_0\mathbf{\Omega} \times \mathbf{v} = -\nabla\mathcal{X}, \quad \text{where} \quad \mathcal{X} = 2\Omega\rho_0 \int \upsilon(s,t)\, \mathrm{d}s \tag{22b,c}$$

can be absorbed into p_c. Coriolis forces are therefore totally ineffective when they act on geostrophic flows. Other forces previously abandoned in comparison with Coriolis forces become influential, especially the inertial forces, which must be restored when analyzing the geostrophic part of core flow. This recovers the Alfvén wave, or something very like it, called the "torsional wave." They share a common time scale:

$$\tau_{\mathrm{A}} = r_o/V_{\mathrm{A}} \approx 6 \text{ years}. \tag{22d}$$

That this is also the time scale $\mathrm{t_{LOD}}$ of the semi-decadal variations of in Figures 1a, b may not be a coincidence, as argued by Gillet et al. (2010).

The geostrophic part $\mathbf{v}$ of $\mathbf{V}$ can be extracted from $\mathbf{V}$ by taking the "geostrophic average," $\langle V_\phi \rangle$, of V_ϕ: for $s > r_i$, this average is defined by

$$\upsilon = \langle V_\phi \rangle \equiv \frac{1}{\widehat{A}(s)} \int_{\mathcal{C}(s)} V_\phi \, \mathrm{dA}, \quad \text{so that} \quad \mathbf{V}^{\mathrm{N}} = \mathbf{V} - \upsilon\mathbf{1}_\phi, \tag{22e}$$

where $\widehat{A}(s) = 4\pi s z_1$ is the area of $\mathcal{C}(s)$, and $z_1(s) = \sqrt{(r_o^2 - s^2)}$ is the semi-length of its sides. The axial angular momentum of the FOC is carried by υ. Therefore, insofar as the rotation of the SIC is locked to that of the fluid in the TC, the angular momentum, $M_z + \widetilde{M}_z$, of the entire core can be derived from the zonal part of the inferred core surface flow. The LOD record provides $\widetilde{M}_z$. Therefore Equation 1h can be tested: $\widehat{M}_z = -(M_z + \widetilde{M}_z)$, Results have been gratifying; see Jault et al. (1988), Jackson (1997) and Figure 1c above. The previous section indicates however that the mantle and SIC are not locked together but take part in

a gravitational oscillation having a period (4–9 years) similar to the torsional wave period $\tau_A \approx 6$ years. The implied convolvement of gravitational and magnetic coupling complicates the task of extracting information about either; see Buffett et al. (2009).

In a torsional wave, the geostrophic cylinders are in relative angular motion about their common (polar) axis; see Figure 2a. The response **b** of **B** to the motion **v** can, as for an Alfvén wave, be visualized using the frozen flux theorem, the field lines behaving like elastic strings threading the cylinders together and opposing their relative motion; see Figure 2b. The resulting torque on a cylinder supplies the restoring force for a wave, the mass of the cylinders providing the inertia. Whenever **J** and **B** contradict Equations 21b–d, a torsional wave is launched that travels in the $\pm s$-indirections.

The canonical torsional wave equation is

$$\frac{\partial^2 \zeta}{\partial t^2} = \frac{1}{s^2 \widehat{A}(s)} \frac{\partial}{\partial s}\left[s^2 \widehat{A}(s) V_A^2(s) \frac{\partial \zeta}{\partial s}\right], \tag{23}$$

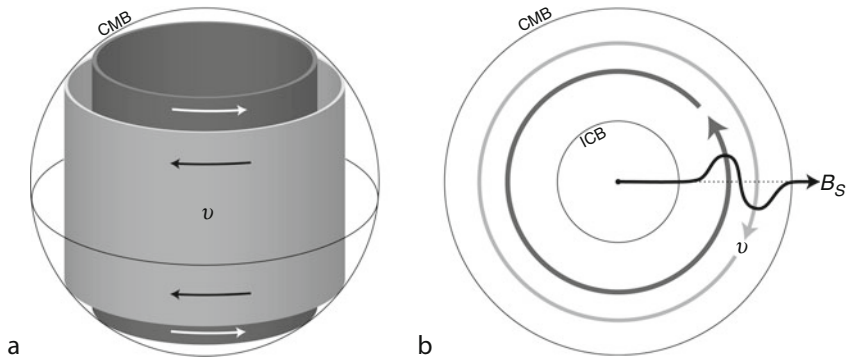
where $\zeta(s, t) = \upsilon/s$ is the angular velocity of $\mathcal{C}(s)$ and $V_A(s) = \mathcal{B}_s(s)/(\mu_0 \rho_0)^{1/2}$ is the Alfvén velocity based on the mean $\left(B_s^N\right)^2$ over $\mathcal{C}(s)$: $\mathcal{B}_s^2(s) = \left\langle \left(B_s^N\right)^2 \right\rangle$. Equation 23 is called canonical because it displays the essential nature of torsional waves clearly. It is however not only incomplete but also ignores magnetic coupling to the mantle and SIC. Equation 23 presupposes that the field, $\mathbf{B}^N$, on which the waves ride is axisymmetric. In this case, Equation 23 has a severe singularity at $s = 0$ which excludes physically acceptable solutions. This difficulty can be evaded by supposing that the TC rotates as a solid body, as suggested by Braginsky (1970), and by applying Equation 23 only in XTC. For general, non-axisymmetric $\mathbf{B}^N$, the regular singularity at $s = 0$ is harmless, but unfortunately Equation 23 is then incomplete. The terms missing from Equation 23 represent the transmission of torque from one Taylor cylinder to another by the potential field outside the core. As the terms are troublesome if retained, they are usually abandoned, with an unsubstantiated claim that they are too small to be worth keeping. Whether they are retained or abandoned, the wave equation admits normal mode solutions, i.e., solutions in which ζ is proportional to $\exp(-\imath\omega t)$, where every ω is real, as shown in RA12. When magnetic coupling to the mantle is included, ω acquires a negative imaginary part, representing the ohmic losses in the mantle. The inclusion of magnetic coupling is highly relevant to our focus here, but it clearly adds another layer of complexity.

In view of these theoretical obstacles, the reader may wonder whether computer simulation would not provide a simpler approach. It is however difficult to extract evidence of torsional waves from geodynamo simulations. This is because it is not yet possible to attain geophysically realistic magnetic Prandtl numbers, Pm, in numerical integrations. The importance of viscous damping of torsional waves can be assessed by the ratio of the torsional wave time scale, $\tau_A = r_o/V_A$, to the spin-up time scale, $\tau_{SU} = \sqrt{\left(r_o^2/2\Omega\nu\right)}$, which is their viscous decay time; see Roberts and Soward (1972). This ratio,

$$\tau_A/\tau_{SU} = (2\Omega\nu)^{1/2}/V_A = \sqrt{(Pm/\Lambda)}, \tag{24}$$

is small for the Earth ($\sim 10^{-3}$) but inconveniently large in simulations ($\gtrsim 0.1$). See Wicht and Christensen (2010) for recent simulations of torsional waves.

Space limitations do not permit the mathematical theory of torsional waves to be presented here; see Braginsky (1970), Roberts and Soward (1972), Jault (2003), Dumberry (2007) and RA12. The principal aim in what follows is to outline the underlying physics, that has been employed in theoretical studies, and that will have to be incorporated in numerical models in the future, when computer technology has advanced far enough to permit core MHD to be modeled more faithfully. Our discussion here sidesteps interesting and as yet incompletely answered questions, the first of which is whether torsional waves are involved in any essential way with the semi-



Core-Mantle Coupling, Figure 2 Schematics showing (**a**) geostrophic flows in the core, V^g, and (**b**) plan view of an initially cylindrical magnetic field (*dashed line*) distorted by *v*. The restoring Lorentz torques on the distorted magnetic field, B_s (*solid line*), lead to the cylindrical propagation of torsional waves (Adapted from Dumberry, 2007).

decadal LOD periodicity; might not the gravitational oscillation described in the last section be mainly responsible? The answer is unclear but core field strengths of 2 mT suggest that torsional waves very effectively link together geostrophic motions throughout the core, and that torsional waves therefore necessarily accompany gravitational oscillations. This obviously does not imply that torsional waves couple well to the mantle; if the mantle were an electrical insulator, there would be no magnetic coupling of core and mantle at all. The waves would then be detectable only through the inferred core surface motion. Strong magnetic coupling of the waves to the mantle raises difficult questions about both the excitation and dissipation of the waves. As shown below, the waves are mainly and heavily damped by ohmic dissipation in the mantle. What maintains the waves against this energy loss? No definitive answer has been given to this very significant question. Core turbulence may be directly responsible, or indirectly through the Reynolds magneto-stresses it exerts on the SIC or on the TC. Buffett et al. (2009) find evidence for wave generation at the TC. Core turbulence would presumably excite many damped normal modes. This might help to explain some of the recently discovered short time scales of core surface motions (Olsen and Mandea, 2008; Finlay et al., 2010). It has not been established unequivocally that the 6 year period is the fundamental mode. Though often questioned, evidence of a 60 periodicity exists, This longer period signal might be representative of the fundamental mode but would require current estimates of $\mathcal{B}_s(s)$ to be revised downward.

These matters are beyond the scope of this review. We shall merely sketch, mostly in a qualitative way, the approximate theory that is currently the most complete. We also aim to expose its strengths and weaknesses.

Underlying the entire theory is the idea that core flow can be neatly separated into geostrophic motions of short time scale, τ_A, and non-geostrophic motions of long time scale τ^{N}obeying Equation 20a. In other words, the theory focusses on the large length scales of core flow, in the belief that this includes the fundamental torsional wave mode of greatest interest. The torsional wave therefore rides on a flow satisfying Taylor's constraints Equations 21a–c. Because the Lehnert number, $\lambda = \tau_A/\tau^{\mathrm{N}} = V_A/2\Omega r_o = \omega_A/2\Omega \approx 3 \times 10^{-5}$, is small, the time dependence of $\mathbf{B}^{\mathrm{N}}$ can be ignored in torsional wave theory.

It was pointed out earlier that torsional waves are geostrophic motions in which the inertial force is crucial. The first step in deriving the torsional wave equation is therefore to restore the time-dependent inertial force to Equation 21a, obtaining

$$\rho_0 s\partial_t V_\phi + 2\Omega\rho_0 s V_s = -\partial_\phi p_c + s(\mathbf{J}\times\mathbf{B})_\phi, \qquad (25a)$$

from which $\partial_t\zeta$ is extracted, by taking the geostrophic average; see Equation 22e.

The evaluation of $\langle \mathbf{J}\times\mathbf{B}\rangle_\phi$ is simplified because E is small and the Lundquist number, $Lu = \tau_\eta/\tau_{\mathrm{A}} = V_{\mathrm{A}} r_o/\eta \approx 3\times 10^4$, of the waves is large. In a first approximation, $E = Lu^{-1} = 0$. Then viscous and ohmic diffusion and the associated boundary conditions are discarded. In particular, the electric field created in the FOC by the waves simplifies to

$$\mathbf{e} = -\mathbf{v}\times\mathbf{B}^{\mathrm{N}} - \mathbf{V}^{\mathrm{N}}\times\mathbf{b} - \mathbf{v}\times\mathbf{b}, \qquad (25b)$$

where $\mathbf{b}$ is the magnetic field of the waves. The term $-\mathbf{V}^{\mathrm{N}}\times\mathbf{B}^{\mathrm{N}}$ does not appear because it already acts on the Taylor state. The last term in Equation 25b is also ignored because the wave amplitude is assumed to be small. The ratio of $-\mathbf{V}^{\mathrm{N}}\times\mathbf{b}$ to $-\mathbf{v}\times\mathbf{B}^{\mathrm{N}}$ is of order $A^{\mathrm{N}}[b/\upsilon\sqrt{(\mu_0\rho_0)}]^{-1}$, where $A = V/V_{\mathrm{A}}$ is the Alfvén number, which for the non-geostrophic flow is about 0.1 (see above). As in an Alfvén wave, $\upsilon = \mathrm{O}[b/\sqrt{(\mu_0\rho_0)}]$, so that $|\mathbf{V}^{\mathrm{N}}\times\mathbf{b}| \approx 0.1|\mathbf{v}\times\mathbf{B}^{\mathrm{N}}|$. This, combined with the fact that the inclusion of $-\mathbf{V}^{\mathrm{N}}\times\mathbf{b}$ in $\mathbf{e}$ adds severe complications, encourages the neglect of $-\mathbf{V}^{\mathrm{N}}\times\mathbf{b}$ in Equation 25b, leaving

$$\mathbf{e} = -\mathbf{v}\times\mathbf{B}^{\mathrm{N}}. \qquad (25c)$$

The mantle and core are linked across a boundary layer of Ekman-Hartmann type; e.g., see Dormy et al. (2007). Because $Pm \ll 1$, this has a double structure. Viscosity acts only in an Ekman layer of thickness $d_\nu = \sqrt{(\nu/2\Omega)} \approx 0.1$ m; magnetic diffusion acts in a layer whose thickness is comparable with the EM skin depth, $d_\eta = \left(\frac{1}{2}|\omega|\mu_0\sigma\right)^{-1/2} \approx 10\,\mathrm{km}$. We therefore call this a "magnetic diffusion layer" (MDL), even though Coriolis and Lorentz forces affect its structure too. In the MDL, Equation 25c is replaced by

$$\mathbf{e} = -\mathbf{v}\times\mathbf{B}^{\mathrm{N}} - \eta\boldsymbol{\nabla}\times\mathbf{b} \approx -\mathbf{v}\times\mathbf{B}^{\mathrm{N}} - \eta\mathbf{1}_r\times\partial_r\mathbf{b}. \qquad (26)$$

As $d_\eta/d_\nu \gg 1$, the Ekman layer is only a tiny part of the MDL. Ekman-Hartmann theory simplifies by discarding the Ekman part, setting $\nu = 0$ and abandoning the no-slip boundary conditions. The structure of the MDL still depends on rotation, and on the Elsasser number, Λ, defined in Equation 20e.

The boundary layers play a vital role in linking ζ in the main bulk of the FOC to $\widehat{\mathbf{b}}$ on the CMB and $\widetilde{\mathbf{b}}$ on the ICB. They are therefore essential in determining $\widehat{\mathbf{\Gamma}}^M$ and $\widetilde{\mathbf{\Gamma}}^M$. At the CMB, $\mathcal{B} \approx 0.5$ mT and $\Lambda \approx 0.07$. The prevailing magnetic field, $\mathbf{B}^{\mathrm{N}}$, therefore has very little effect on the boundary layer, which is controlled almost entirely by Coriolis forces and magnetic diffusion. At the ICB, where $\mathcal{B}$ may be even an order of magnitude greater than at the CMB, $\Lambda > 1$, and Lorentz forces are too significant to ignore in the boundary layer. Further details are given in RA12.

The torque exerted by the waves on the mantle is proportional to the electrical conductivity, $\widehat{\sigma}(v, \theta, \phi)$, of the mantle, which we assume is nonzero only in the layer

$r_o < r < r_1 = r_o + d$ at the base of the mantle. The conductance of this layer is

$$\widehat{\Sigma}(\theta,\phi) = \int_{r_o}^{r_1} \widehat{\sigma}\ (r,\theta,\phi)\, dr. \tag{27a}$$

It is commonly assumed that $10^7 S < \widehat{\Sigma} < 10^9$S; we take $\widehat{\Sigma} = 10^8$S below.

Electric currents, $\widehat{\mathbf{j}}$, flow in the mantle, $\widehat{\mathrm{V}}$, either by leaking from the core or by electromagnetic induction, through the time dependence of the EM field on the CMB. We shall be interested in the penetration of the fields **b** and **e** of the waves, at frequencies ω of order 5×10^{-8} s^{-1}. The resulting magnetic and electric fields, $\widehat{\mathbf{b}}$ and $\widehat{\mathbf{e}}$, in the mantle depend on ω and on L, the horizontal length scale imposed by **b** and **e** on the CMB. Associated with ω is the skin depth of the mantle:

$$\widehat{d}_\eta = \left(\frac{1}{2}|\omega|\mu_0\widehat{\sigma}_o\right)^{-1/2}. \tag{27b}$$

Starting with Glatzmaier and Roberts (1995), theoreticians have usually simplified EM theory in the mantle by adopting the "thin-layer approximation" (TLA). This originated from the modeling of laboratory MHD experiments (see, e.g., Müller and Bühler, 2001). It is easily applied and therefore popular, although the conditions for its validity are seldom mentioned or questioned. The TLA demands that $d \ll \widehat{d}_\eta\ (\ll L)$. The horizontal part, $\widehat{\mathbf{e}}_\mathrm{H}$, of the electric field $\widehat{\mathbf{e}}$ is then independent of r, so that

$$\widehat{\mathbf{j}}_\mathrm{H} = \widehat{\sigma}\,\widehat{\mathbf{e}}_\mathrm{H}, \quad \text{and} \quad \widehat{\mathcal{J}} = \widehat{\Sigma}\,\widehat{\mathbf{e}}_\mathrm{H}, \tag{27c,d}$$

where $\widehat{\mathcal{J}}$ is the total horizontal current carried by the layer.

It may be helpful to visualize the TLA as a mathematical limit, $d \to 0$, $\widehat{\sigma} \to \infty$ with $\widehat{\Sigma}$ held fixed. Then $\widehat{\mathcal{J}}$ is a surface current responsible for a discontinuity in the magnetic field. If $\check{\mathbf{b}}(= -\boldsymbol{\nabla}\check{\mathrm{w}})$ is the potential field above the conducting layer,

$$\begin{aligned}\check{\mathbf{b}}(r_o,\theta,\phi) - \widehat{\mathbf{b}}(r_o,\theta,\phi) &= \mu_0\widehat{\mathcal{J}}(\theta,\phi)\times\mathbf{1}_r \\ &= \mu_0\widehat{\Sigma}(\theta,\phi)\widehat{\mathbf{e}}_\mathrm{H}(r_o,\theta,\phi)\times\mathbf{1}_r.\end{aligned} \tag{27e}$$

The potential field does not affect the torque, $\boldsymbol{\Gamma}^M$, on the mantle, although it does contribute to the torque that each Taylor cylinder exerts on the others.

We contrast two proposed conductivity distributions. Buffett et al. (2002) inferred from their studies of nutational resonances that d is only 200 m and that $\widehat{\sigma} = 3 \times 10^5$ S m^{-1}, which is comparable to the core conductivity σ, and gives $\widehat{d}_\eta = 10$ km. The TLA should therefore be excellent in most applications. In contrast, the laboratory experiments of Ohta et al. (2008) suggest $\widehat{\sigma} = 100$ S m^{-1} and $d = 3 \times 10^5$ m; see also Yoshino (2010). This gives $\widehat{d}_\eta = 2 \times 10^6$ m, so it is doubtful if the TLA can be validly applied. The similar conductances of the models ($\widehat{\Sigma} = 3/6 \times 10^7$ S) are insufficient to justify the use of the TLA.

This completes our critique of the basics of torsional wave coupling to the mantle. Some of its consequences are unexpected; but most are not. Even dimensional reasoning leads to

$$\begin{aligned}&\widehat{\Gamma}_z^M = \widehat{\Gamma}_0^M(\overline{\zeta} - \widehat{\zeta}), \\ &\text{where } \widehat{\Gamma}_0^M = O\left(r_o^4\widehat{\Sigma}\mathcal{B}_o^2\right) \approx 4 \times 10^{27}\,\mathrm{Nms},\end{aligned} \tag{28a,b}$$

for $\mathcal{B} = 0.5$mT . Here $\mathcal{B}_o^2$ is an average of $\left(B_r^N\right)^2$ over the CMB, and $\overline{\zeta}$ is defined by:

$$\overline{\zeta}(t) = \frac{1}{s^2\widehat{A}(s)}\int_0^{r_o} s^2\widehat{A}(s)\zeta(s,t)\mathrm{d}s \tag{28c}$$

Perhaps unexpectedly, the boundary layer on the CMB described above reduces $\widehat{\Gamma}_0^M$ by a factor of $\Sigma/(\Sigma + \widehat{\Sigma})$, where Σ is the conductance of the boundary layer, defined by

$$\Sigma = \frac{1}{2}(1 + \imath\varsigma)\sigma d_\eta = (1 + \imath\varsigma)(\sigma/2\mu_0|\omega|)^{1/2}, \tag{28d}$$

and $\varsigma = \mathrm{sgn}(\omega)$. This gives $|\Sigma| \approx 3 \times 10^9$ S, which is comparable with $\widehat{\Sigma}$. Ignoring this factor, the magnetic interaction of mantle and FOC is governed by

$$\widehat{C}d_t\widehat{\zeta} = \widehat{\Gamma}_0^M(\overline{\zeta} - \widehat{\zeta}), \qquad Cd_t\overline{\zeta} = -\widehat{\Gamma}_0^M\left(\overline{\zeta} - \widehat{\zeta}\right), \tag{28e,f}$$

where $C = 9.08 \times 10^{36}$ kg m^2 is the polar moment of inertia of the solidly rotating FOC. These equations provide an estimate of the e-folding time, $\widehat{\tau}_\eta$, taken by mantle conduction to kill ζ and $\widehat{\zeta}$: $\widehat{\tau}_\eta = C\widehat{C}/(C + \widehat{C})\widehat{\Gamma}_0^M \approx 64$ years. This is greater than the time taken by the waves to cross the core, which is $\tau_\mathrm{A} = r_o/V_\mathrm{A} \approx 5.6$ years, for $\mathcal{B} = 2$mT.

If we take $\delta\widehat{\zeta} \approx 3 \times 10^{-12}$s^{-1}, as indicated by the LOD data of the first section above, Equations 28e, f suggest that $\overline{\zeta} - \widehat{\zeta} \approx (\widehat{C} + C)\widehat{\zeta}/C$ is about 2×10^{-11} s^{-1}, so that $r_o(\overline{\zeta} - \widehat{\zeta}) \approx 7 \times 10^{-5}$ m s^{-1}, which is less than, but comparable with, the inferred core surface flow. It also gives $\widehat{\Gamma}_z^M \approx 8 \times 10^{16}$ Nm. This increases to the target torque if we take $\widehat{\Sigma} = 1.2 \times 10^9$ S, but that reduces $\widehat{\tau}_\eta$ to 5.3 years, which is less than τ_A.

This highlights a difficulty that might be called the "magnetic coupling paradox," and quantified by a quality factor:

$$\Pi = \widehat{\tau}_\eta/\tau_\mathrm{A} = (\mathcal{B}/\mathcal{B}_o)^2\left(\mu_0\widehat{\Sigma}V_\mathrm{A}\right)^{-1}. \tag{29}$$

There is a window for $\widehat{\Sigma}$, that may be narrow or nonexistent, in which $\widehat{\Gamma}_z^M$ is large enough to explain variations in LOD by torsional waves, but simultaneously is small enough to ensure that $\Pi > 1$ so that the waves are not over

damped by mantle conduction. According to the admittedly imprecise, order of magnitude estimates made here, the window is nonexistent. For the target torque to be reached or exceeded, $\widehat{\Gamma} \gtrsim 1.2 \times 10^9$ S, but $\Pi > 1$ requires $\widehat{\Gamma} \lesssim 1.1 \times 10^9$ S. See also Dumberry and Mound (2008).

So far the existence of the SIC has been ignored, almost totally. We have however recognized that, for $s < r_i$, two Taylor cylinders exist, $\mathcal{C}^N(s)$ and $\mathcal{C}^S(s)$, in which $\zeta^N(s)$ and $\zeta^S(s)$ may be expected to differ. For simplicity, we assume here that they are equal. To evaluate $\widetilde{\Gamma}_z$, it is necessary to link $\mathbf{b}$ to $\widetilde{\mathbf{b}}$ across a boundary layer strongly influenced by Λ. An analysis of the boundary layer leads to (see RA12)

$$\widetilde{b}_\phi = \mu_0 \widetilde{\sigma} \widetilde{d}_\eta s B_r^N (\overline{\zeta} - \widetilde{\zeta}) \quad \text{on} \quad r = r_i, \tag{30a}$$

where $\widetilde{\zeta}$ is the angular velocity of the SIC, and $\widetilde{d}_\eta = \left(\frac{1}{2}|\omega|\mu_0 \widetilde{\sigma}_i\right)^{-1/2} \approx d_\eta \approx 10$ km. This leads to an expression for $\widetilde{\Gamma}_z^M$, in which the main part that couples to the TC is

$$\widetilde{\Gamma}_z^M = \widetilde{\Gamma}_0^M (\overline{\zeta} - \widehat{\zeta}), \quad \text{where} \quad \widetilde{\Gamma}_0^M = \mathrm{O}\left(r_i^4 \widetilde{\sigma} \widetilde{d}_\eta \mathcal{B}_i^2\right); \tag{30b,c}$$

cf. Equations 28a, b. For $\mathcal{B}_i = 5$ mT, $\widetilde{\Gamma}_0^M \approx 2 \times 10^{29}$ Nms. This large torque acts on the SIC whose moment of inertia is less than $10^{-3}\widehat{C}$. The coupling time, $\widetilde{\tau}_\eta$, is therefore very much less than $\widehat{\tau}_\eta$. Equations analogous to Equation 28a, b give (for $\widetilde{\sigma} = \sigma$)

$$\widetilde{\tau}_\eta \approx \widetilde{C}/|\widetilde{\Gamma}_0^M| \approx 4 \text{ days}. \tag{30d}$$

This is the time taken for a mismatch between ζ and $\widetilde{\zeta}$ to be wiped out by magnetic torques. Clearly the coupling between TC and SIC is substantial at frequencies of order ω_A. This supports the opinion, advanced several times in this review, that on semi-decadal time scales, the TC is effectively locked to the SIC in its rotation about Oz.

Synthesis

In this review we have analyzed the various ways in which Earth's core is coupled to the mantle and have presented estimates of the amplitudes of these couplings in order to show which may plausibly explain the available LOD data. In our first section, we provide observational evidence for core-mantle coupling. We show that Earth's rotation rate has a roughly semi-decadal time variability, such that the LOD fluctuates at the ms level. To explain these LOD fluctuations, an internal coupling must exist between the mantle and the core that provides torques of order 10^{18} Nm, which we named "the target torque."

In the later text, we develop estimates of the strength of the viscous, topographic, gravitational, and electromagnetic torques. Only the viscous torque, Γ_z^V, appears to be too weak to explain the LOD signal. This is true even when we allow for the enhanced coupling that turbulence can provide.

The topographic torque on the mantle, $\widehat{\Gamma}_z^T$, is created by core flow interacting with bumps on the CMB. In analyzing $\widehat{\Gamma}_z^T$, it became clear that exchange of angular momentum with the SIC is significant. Order of magnitude arguments showed that potentially the largest part of $\widehat{\Gamma}_z^T$ is $\widehat{\Gamma}_{a,z}^T$, which is produced by the gravitational field of density anomalies in the mantle and possibly SIC, including bumps on their surfaces. This part of $\widehat{\Gamma}_z^T$ is therefore intimately related to the gravitational torque $\widehat{\Gamma}_z^G$. When the two are treated together as $\widehat{\Gamma}_{a,z}^{G+T}$, there is an equal but opposite torque, $\widetilde{\Gamma}_{a,z}^{G+T}$ on the SIC. Gravitational oscillations (Buffett, 1996) occur when the system is perturbed from a state of minimum gravitational energy in which $\widehat{\Gamma}_{a,z}^{G+T} = \widetilde{\Gamma}_{a,z}^{G+T} = 0$. An oscillation period of $\tau^{\mathrm{G}} = 4.1$ years was derived. If, as seems likely, strong magnetic coupling exists between the tangent cylinder (TC) and the SIC, the gravitational oscillation period increases to $\tau_{\mathrm{TC}}^G = 8.9$ years.

The remaining part of $\widehat{\Gamma}_z^T$ is $\widehat{\Gamma}_{c,z}^T$, and is produced by core convection. Its importance is uncertain. From what is known today, $\Gamma_{c,z}^T$ may be 0 Nm or may exceed the target torque (cf. Kuang and Bloxham, 1997; Hide, 1998; Jault and Le Mouël, 1999; Kuang and Chao, 2001).

A simple model of torsional waves traversing FOC can explain oscillations of period, $\tau \approx 6$ years, but there is a paradox: The target torque cannot be attained by magnetic coupling between the waves and the mantle unless a dimensionless "paradox parameter," Π, defined in Equation 29, is large enough. If this parameter is too large, however, the waves are damped out before they can cross the core. Whether the core can evade the paradox seems uncertain.

The topographic, gravitational and magnetic torques all have significant uncertainties in their amplitudes, but the target torque falls within these uncertainties, i.e., conceivable any of them could explain the semi-decadal LOD signals. The coupling processes may be convolved. The recent model of Buffett et al. (2009) allows for this, but argues that the gravitational torque dominates. In contrast, Gillet et al. (2010) infer that torsional oscillations in the FOC can explain the LOD observations without strong gravitational coupling. Improvements in data and modeling of Earth's rotation (e.g., Gross, 2009), the geomagnetic field (e.g., Hulot et al., 2002; Jackson, 2003), core seismology (e.g., Dai and Song, 2008), and the time-variations in the gravity field (e.g., Velicogna and Wahr, 2006; Dumberry, 2010) will all prove important in testing these core-mantle coupling arguments.

This review has focussed on explaining variations in LOD owing to internal coupling between the mantle and core. This coupling produces changes primarily in the axial angular rotation rate, Ω_z, on semi-decadal time scales. Detailed measurements now exist of variations in Earth's full rotation vector on many time scales (e.g., Gross, 2007), with the different directional components

providing information on different geophysical phenomena (e.g., Mathews et al., 2002). Furthermore, rotation vector and magnetic field measurements now exist for other planets (e.g., Margot et al., 2007; Uno et al., 2009), and will improve in quality in the coming decades. Such measurements will allow the development of models of deep interior structure and dynamics in planetary bodies throughout the solar system (e.g., Tyler, 2008; Noir et al., 2009; Goldreich and Mitchell, 2010).

Acknowledgments

We thank Richard Gross, Richard Holme, and Andrew Jackson for sharing their insights and their data. We are also grateful to Bruce Buffett and the referee (Mathieu Dumberry) for giving helpful advice.

CRUSTAL REFLECTIVITY (OCEANIC) AND MAGMA CHAMBER

Satish C. Singh
Laboratoire de Géoscience Marines, Institut de Physique du Globe de Paris, Paris, France

Synonyms

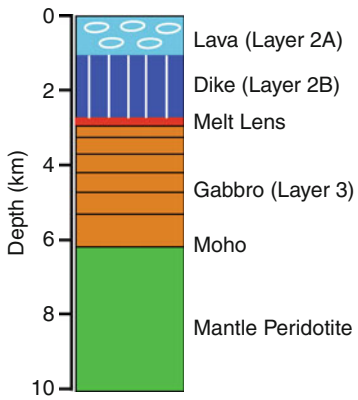
Melt lens; Spreading center and ridge

Definition

Axial magma chamber (*Melt lens*) is a thin melt lens observed at ocean spreading centers.
Layer 2A or *Lava* is the top layer of oceanic igneous crust.
Layer 2B is a dike sequence and lies above the axial melt lens.
Layer 3 (*gabbro*) forms the lower oceanic crust.
Moho is a boundary between the crust and mantle.
Pg is a seismic ray that travels through the crust.
PmP is a reflection from the crust–mantle boundary.
Pn is a ray that travels in the upper mantle.
Tomography is a technique to image the velocity structure of the earth.

Introduction

Over 70% of the earth's crust is formed by the cooling and crystallization of melt at ocean spreading centers, which represent over 55,000 km of chains of volcanoes in the middle of the oceans, called mid-ocean ridges. At ocean spreading centers, the oceanic plate separates causing the mantle to move upward, reducing the pressure and causing the melting of the mantle. Since the newly formed melt is lighter than the surrounding mantle material, it moves upward toward the surface of the earth. Part of the melt is erupted on the seafloor as lava, which cools very rapidly forming a cap of solid extrusive layer, also known as Layer 2A (Figure 1). As there is a significant amount of water present at mid-ocean ridges, the water circulates deep in the crust. Therefore, the melt stays mainly in the middle of the crust and erupts along thin dikes. When these dikes are cooled and crystallized, they form a thick intrusive layer or Layer 2B. Below the dikes, the melt could reside for a long period, forming a steady state melt lens, called axial melt lens or axial magma chamber (AMC). The magma cools and crystallizes in this melt lens, forming a crystalline lower crust. The melt lens forms the lower limit for further penetration of water, and therefore, partial melt is generally present beneath the melt lens down to the crust–mantle boundary. Sometimes hot melt ascending from the mantle may get injected in this partially molten region. Based on this basic process, the oceanic crust is divided into three layers, lava (extrusive), dikes (intrusive), and gabbroic crust. The relative



Crustal Reflectivity (Oceanic) and Magma Chamber, Figure 1 Classical model of the oceanic crust. Layers 2A and 2B form the upper crust whereas the gabbro layer corresponds to the lower crust.

thicknesses of these layers depend on the spreading rate, which can vary from a few millimeters up to 200 mm per year.

Based on the spreading rate, mid-ocean ridges are divided into four groups: fast, intermediate, slow, and ultraslow. East Pacific Rise (EPR) is a fast spreading center, where the spreading rate varies from 70 to 180 mm per year (Figure 2). Juan de Fuca Ridge and Valu Fa Ridge are intermediate spreading centers, where the spreading rate varies from 55 to 70 mm per year. Mid-Atlantic Ridge and Central Indian Ridge are slow spreading centers with spreading rates of 20–55 mm per year. South-West Indian Ridge and Gakkel Ridge are ultraslow spreading centers with spreading rates of less than 20 mm per year. The melt production depends on the spreading rate and, therefore, the crustal thickness also varies from 3.5 to 8 km, with an average thickness of 6 km.

Methods

There are two main methods to study the oceanic crustal structures: seismic refraction or tomography and reflection methods. In seismic refraction method, a set of ocean bottom seismometers (OBS) are placed on the seafloor and an array of air guns is used to generate acoustic energy that travels through water column into the crust and mantle and is recorded on OBS (Figure 3). There are three types of waves that arrive on an OBS: waves that travel in the crust (Pg) and the mantle (Pn) and waves reflected from the crust–mantle boundary, Moho (PmP). The travel times of arrivals of energy on these OBS are used to determine the velocity structure of the crust and upper mantle. Since OBS are small in numbers, they are placed 5–20 km apart on the seafloor, and hence provide a very large-scale (5–10 km) velocity structure of the crust. Since the compressional (P) waves travel fast, they arrive first on OBS, and hence mainly P-wave velocities are estimated using OBS data. However, sometimes secondary (S) arrivals, converted phases Ps, are recorded on these OBS and provide information on S-wave velocity.

Seismic reflection method is most commonly used to obtain crustal reflectivity. A streamer containing pressure sensors (hydrophones) is towed behind a vessel recording seismic energy generated by an array of air guns as the vessel moves at 4.5–5 knots (Figure 3). The length of the streamer varies from a few hundred meters up to 15 km (Singh et al., 2009), and hydrophones are generally spaced at 12.5 m. For crustal imaging the air gun shot spacing is ~50 m. Depending upon the target depth, the recording length varies from 10 to 20 s (20–60 km depth). This technique is routinely used for oil and gas exploration,

OBS – ocean bottom seismometers; Pg – crustal arrival; Pn – mantle arrival; and PmP – reflection from the crust–mantle boundary. *Red ellipse* indicates melt lens.

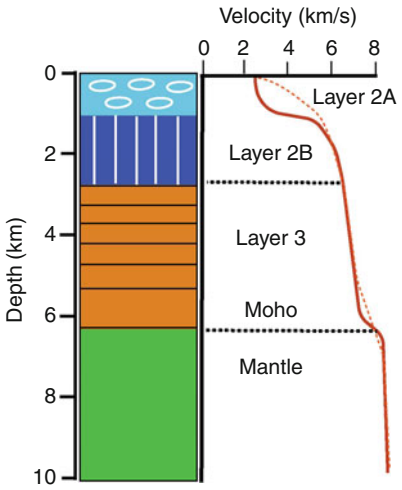
and has become a standard technique for crustal studies. There are standard tools to analyze these data. Since the source receiver distance is small as compared to the depth of the target, the data are initially presented as a function of time, and then are depth-converted using velocities obtained from the OBS study or from other sources.

Crustal structure at fast spreading centers

Based on seismic refraction and reflection studies at fast spreading centers and on ophiolites from Oman, the crust at fast spreading centers is considered as a layer cake and is divided into three distinct layers: Layer 2A (pillow lava), Layer 2B (dike sequence), and Layer 3 (gabbro) (Figure 4). The velocity in Layer 2A varies from 2.5 to 4.5 km/s, that in Layer 2B from 4.5 to 6 km/s, and in gabbro from 6 to 7 km/s. On the ridge axis, a magma chamber is generally present between the dike and the gabbro layer.

The structure of Layer 2A is inferred either using the velocity from OBS study or from the reflection method. The boundary between Layer 2A and 2B is not sharp but there is a high velocity gradient where the velocity increases from 2.5 to 4–4.5 km/s in a thin transition zone, which leads to three arrivals (triplication) from Layer 2A (Figure 5). However, since the first arrival tomography is performed on OBS data, spaced at 5–10 km distance, one can only get a smooth velocity of the crust. Therefore, a velocity contour of 4.5 km/s is generally used at the base of Layer 2A (Figure 4, *dashed curve*).

In seismic reflection data, the triplication from the Layer 2A/2B boundary lies in a narrow offset range at intermediate offsets, depending on the water depth and the thickness of Layer 2A (Figure 5) (Harding et al., 1993; Seher et al., 2010a). Since the cusp of triplication has strong amplitude, it can be used to image the base of Layer 2A, and leads to a very nice image of Layer 2A. Since the energy lies in a limited offset range, the two-way travel time for these images varies depending on the

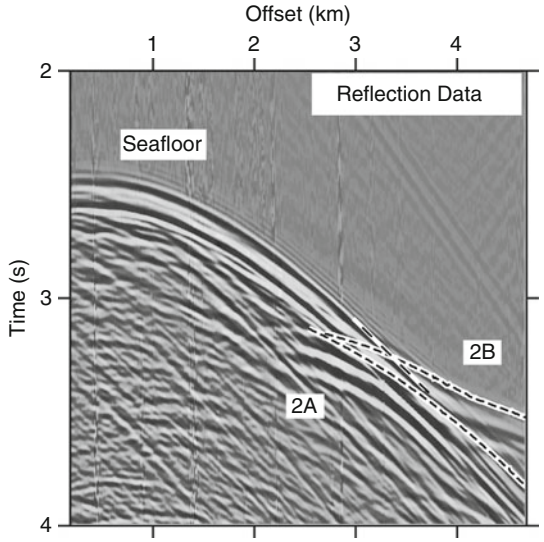


Crustal Reflectivity (Oceanic) and Magma Chamber, Figure 4 Average one-dimensional velocity of oceanic crustal layers and mantle (*solid brown line*). *Thin dashed line* indicates velocity determined using tomographic type techniques.

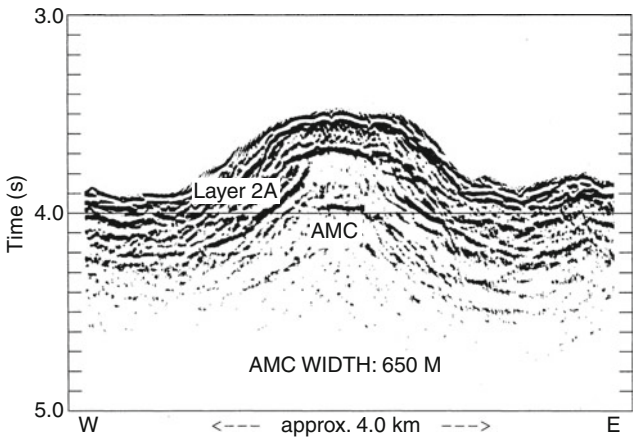
velocity used for stacking. This becomes particularly important when the thickness map needs to be prepared from 3D seismic reflection data or compared along long profiles. In order to objectively compare Layer 2A thickness, a constant velocity that provides the best image of Layer 2A is used to stack Layer 2A arrival and the two-way travel time is converted into depth using the tomographic velocity obtained using either OBS data or streamer tomography (Seher et al., 2010a).

Plot triplication

Figure 6 shows the image of Layer 2A obtained along the southern East Pacific Rise (Kent et al., 1994). The thickness of the layer varies from ~200 m on the ridge axis



Crustal Reflectivity (Oceanic) and Magma Chamber, Figure 5 Seismic reflection from the Lucky Strike Segment of Mid-Atlantic Ridge showing triplication (*dashed curve*) from Layer 2A/2B boundary (modified from Seher et al., 2010a).



Crustal Reflectivity (Oceanic) and Magma Chamber, Figure 6 Seismic reflection image of Layer 2A and axial magma chamber at 14° S East Pacific Rise (Position 3 in Figure 2) (from Kent et al., 1994). The Layer 2A thickness varies from 200 m on the ridge axis to 400 m off-axis.

and increases to 600 m off-axis (Kent et al., 1994; Harding et al., 1993). The thickening of Layer 2A off-axis could be associated with the accumulation of lavas away from the ridge axis. On slow spreading ridges, Layer 2A could be up to 1 km thick (Singh et al., 2006a; Seher et al., 2010a). Instead of thickening of Layer 2A away from the spreading center, its thickness decreases, which could be due to thinning by stretching (faulting) of the crust (Figure 7). In fact, the thinnest (300 m) Layer 2A at the Lucky Strike segment is observed near the Median bounding faults (Seher et al., 2010a).

There is still debate about the causes of Layer 2A reflection: it could be due to pillow lava and dike boundary as shown in Figure 4 or due to alteration front associated with hydrothermal circulation or pressure collapse boundary (Christeson et al., 2007).

Below Layer 2A, the velocity increases from 4.5 up to 6 km/s, corresponding to dike sequence, below which a magma chamber reflection might be present. The thickness of the dike sequence is ~1.5 km on a fast spreading center (Vera et al., 1990) and up to 2 km on a slow spreading center (Seher et al., 2010b).

Axial magma chamber (melt lens)

On a fast spreading center, the axial magma chamber (AMC) reflector marks the boundary between the upper crust (lava and dikes) and the lower crust (gabbro). It is observed along a significant part of the fast spreading axis at 1.5–2 km below the seafloor. The width of the AMC varies from a few hundred meters to 4.5 km (Kent et al., 1993). The largest melt lens is observed beneath 9° N overlapping spreading center at the East Pacific Rise (Kent et al., 2000; Singh et al., 2006a) (Figure 8). Recently, Canales et al. (2009) have imaged an off-axis melt lens. A 3D seismic reflection study of the 9° N EPR suggests that there might be an extensive presence of melt sills off-axis (Carton et al., 2009).

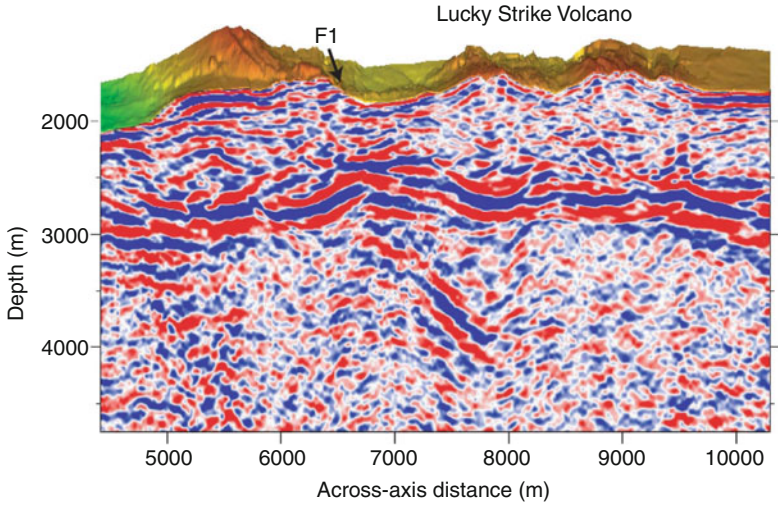
The AMC have also been observed beneath intermediate spreading centers such as Juan de Fuca Ridge (Canales et al., 2006) and Valu Fa Ridge (Collier and Sinha, 1990). They are generally observed about 3 km below the seafloor. It has been difficult to image AMC reflection on slow spreading ridges, which has been due to strong scattering on the seafloor and complex 3D bathymetry. Using 3D seismic reflection technique, Singh et al. (2006b) discovered AMC beneath the Lucky Strike segment of the Mid-Atlantic Ridge (Figure 9). The AMC is about 3 km wide and 7 km long at ~3 km below the seafloor.

The thickness of the melt lens is difficult to determine. Forward modeling of seismic reflection data from 9° N at EPR suggests that it could be 50–100 m thick (Kent et al., 1993). Seismic full waveform inversion of data from two locations at the EPR suggests that it should be 50–60 m thick (Collier and Singh, 1997; Singh et al., 1998, 1999). Using full waveform of seismic reflection data from 14° S at EPR, Singh et al. (1999) found that a 60 m thick melt lens is overlain by a 60 m thick solid roof and underlain by a 200 m thick solid floor. Above the roof layer, they find a 200 km thick low velocity layer, which they associate with the presence of hydrothermal circulation (Singh et al., 1999) (Figure 10). The roof layer could be the transition zone between the hot melt (1,200°C) below and the hydrothermal layer (400°C) above.

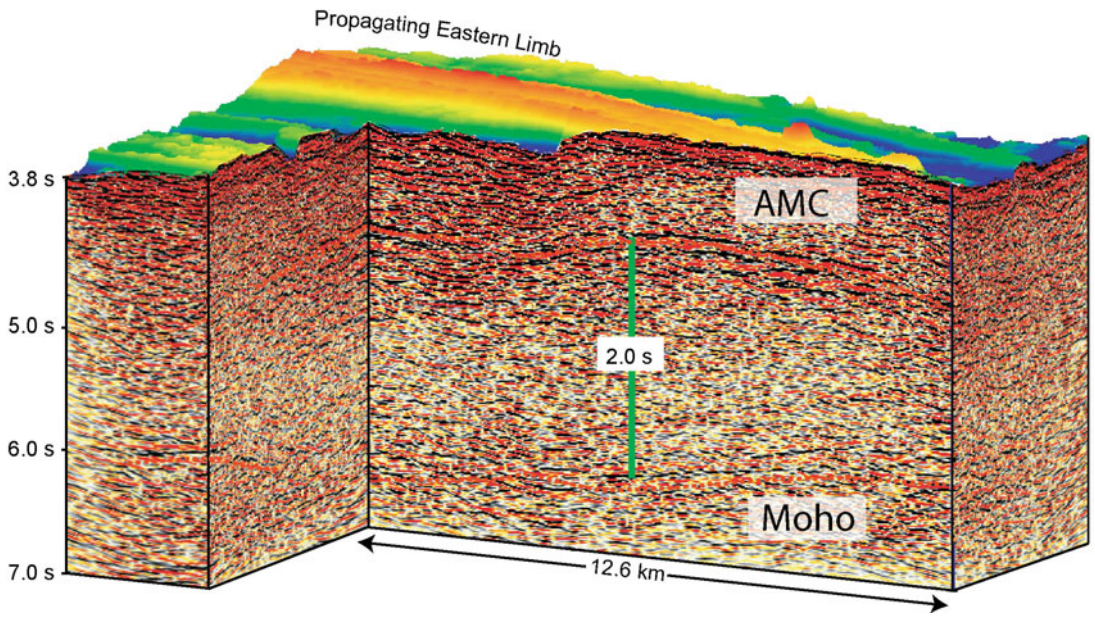
The presence of a solid floor suggests that magma cools and crystallizes in the melt lens and forms the solid floor. Using 3D seismic reflection data, we can image the base of the melt lens. Here the melt lens is about 4.5 km wide and could be up to 250 m thick (as compared to

50–100 m observed elsewhere). This could be due to its very large size (4.5 km) and the presence of low velocity underneath it (Bazin et al., 2003). Singh et al. (2006a) suggest that up to 40% melt could be present between 1.5 and 6 km depth, making it the largest observed melt lens in the crust observed on the earth so far (Figure 11).

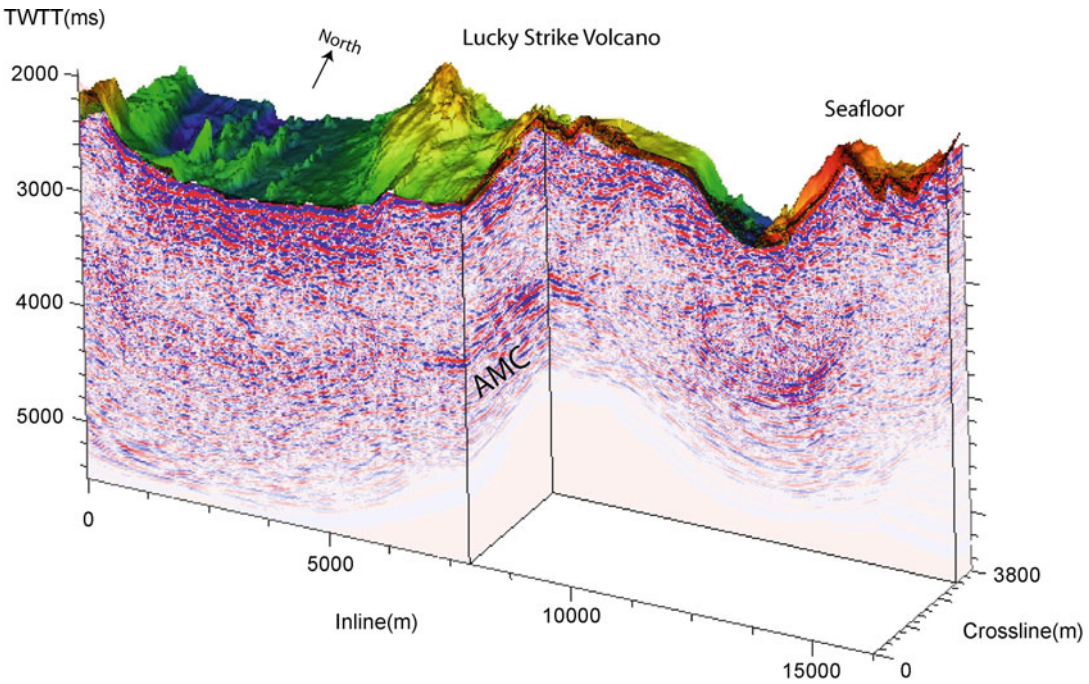
Using full waveform and partial stacking technique of seismic reflection data, Singh et al. (1998) show that the melt along 14° S EPR consists of 2–4 km long pure melt zones at 15–20 km interval along the ridge axis (Figure 10). They associate pure melt region where the shear wave velocity is nearly zero and partial melt zone where the shear wave velocity is nonzero (Taylor and Singh, 2002). They suggest that a pure melt region corresponds to fresh supply of magma from the mantle and a partial melt region corresponds to cooled and crystal-



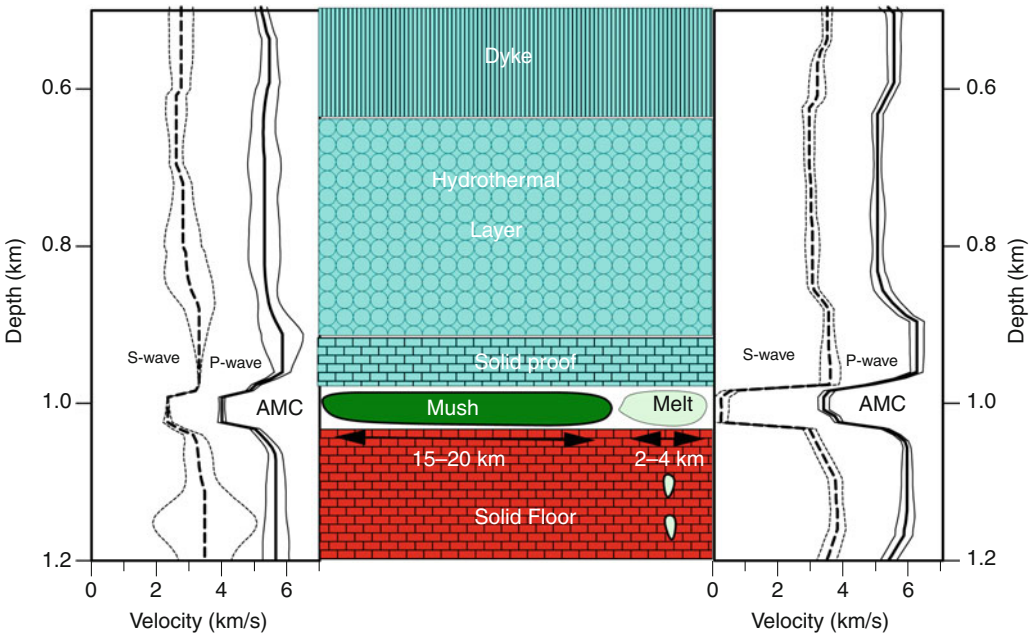
Crustal Reflectivity (Oceanic) and Magma Chamber, Figure 7 Seismic reflection of Layer 2A beneath the Lucky Strike volcano at slow spreading Mid-Atlantic Ridge (Position 1 in Figure 2). F1 indicates an active fault. Layer 2A is thick beneath the ridges and thin beneath the fault.



Crustal Reflectivity (Oceanic) and Magma Chamber, Figure 8 Seismic reflection image of axial magma chamber (AMC) and Moho reflection at 9° N overlapping spreading center at the East Pacific Rise (Position 2 in Figure 2) (modified from Singh et al., 2006a).



Crustal Reflectivity (Oceanic) and Magma Chamber, Figure 9 Axial magma chamber reflection image from the Lucky Strike Segment of the Mid-Atlantic Ridge (Position 1 in Figure 2).



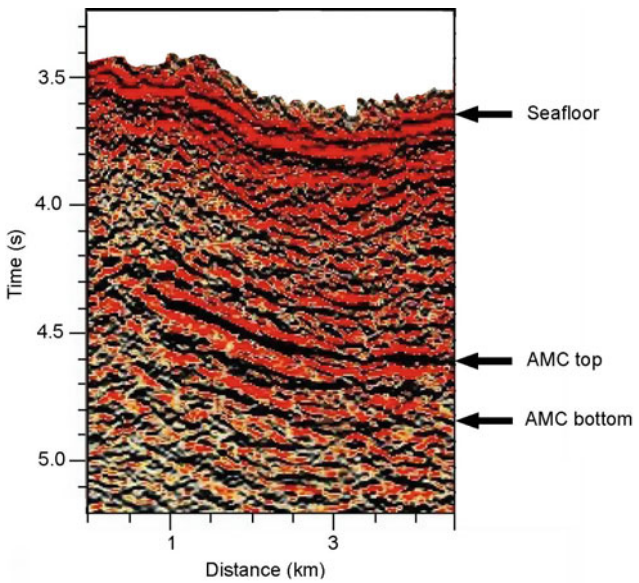
Crustal Reflectivity (Oceanic) and Magma Chamber, Figure 10 Full waveform inversion results at two different locations along the 14° S EPR (Position 3 in Figure 2). Inversion results show the presence of 60 m AMC, 60 m thick roof, and 200 m thick floor of the AMC. It also shows a hydrothermal layer above the roof of the AMC. The result on the *left panel* corresponds to a partial melt region (less than 50% of liquid melt) whereas that on the *right* corresponds to a pure melt (more than 80% of liquid) region. The depth is from the seafloor (modified from Singh et al., 1999).

lized state of melt lens. They also find that a pure melt region is associated with hydrothermal activities on the seafloor, linking the supply of magma from the mantle with hydrothermal circulation on the seafloor. In order for the melt lens to be in steady state, it would require a supply of magma from the mantle every 30 years as it will take 50 years to completely solidify a 50 m thick melt lens (Singh et al., 1999).

Lower crust

So far, no other crustal melt lenses have been observed beneath the axial melt lens. Therefore, only tomographic methods using OBS data are used to determine the velocity structure of the lower crust. Using two-ship expanding spread profile, Vera et al. (1990) and Harding et al. (1989) found that the velocity in the lower crust (5.5–6 km/s) on-axis was lower than that off-axis (6.8–7 km/s), which suggested the presence of partial melt in the lower crust. Using 3D tomography technique, Toomey et al. (1990) and Dunn et al. (2000) showed the presence of low velocity in the lower crust, suggesting the presence of partial melt. Singh et al. (2006b) found a large anomaly in two-way travel time between the Moho reflection and AMC and suggest that up to 40% of melt might be present in the lower crust (Figure 8). A low velocity anomaly has also been observed beneath the Lucky Strike segment of the Mid-Atlantic Ridge beneath the melt lens (Seher et al., 2010c; Singh et al., 2006b). These results suggest that partial melt is present in the lower crust beneath the melt lens (Figure 12).

Based on the study of Oman ophiolite, Kelemen et al. (1997) and Boudier et al. (1996) suggested that the lower crust is formed by injection of melt sills in the lower crust instead of cooling and crystallization of magma in the upper crustal melt sill. However, no melt lenses have been imaged in the lower crust so far, even using 3D seismic reflection technique (Singh et al., 2006a), which suggest that the melt in the lower crust must be in small pockets, not in large melt sills.



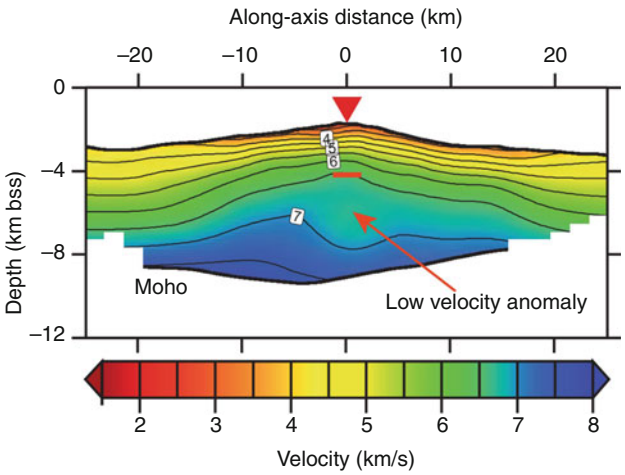
Crustal Reflectivity (Oceanic) and Magma Chamber, Figure 11 Seismic reflection image showing the top and bottom of the axial magma chamber at 9° N EPR (Position 2 in Figure 2).

Oceanic Moho

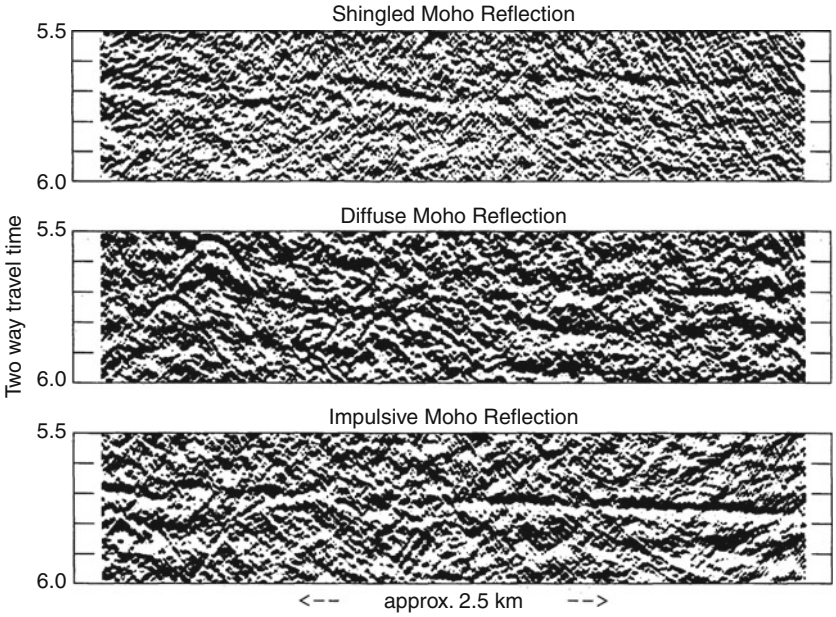
The Moho is a boundary between the crust and mantle, where the velocity changes from 6.8–7.0 km/s to 7.8–8.1 km/s. For a sharp boundary, a clear Moho reflection is observed. However, the Moho is not just a simple boundary. Kent et al. (1994) identified three types of Moho reflection: (1) Impulsive Moho where a clear single reflection is observed (Figure 13), (2) Diffuse Moho where reflection from Moho is patchy, and (3) Shingled Moho where reflection is shingled.

Moho reflections are generally observed away from the spreading center, not beneath the melt lens. This is because the upper crustal melt lens and associated lower crustal melt would attenuate seismic energy and hence, it would be difficult to image Moho using conventional seismic reflection techniques. Secondly, it was accepted that Moho is formed away from the ridge axis. However, using 3D seismic reflection technique, Singh et al. (2006a) have imaged Moho beneath the wide axial melt lens (Figure 14), suggesting the Moho is formed at zero age.

Moho reflections are observed ~2 s two-way travel time below the seafloor. The average crustal velocity is about 6 km/s, and hence the average crustal thickness is about 6 km. However, Singh et al. (2011) have observed Moho reflection 1.3 s below the seafloor offshore NW



Crustal Reflectivity (Oceanic) and Magma Chamber, Figure 12 Tomographic results from the Lucky Strike Segment of the Mid-Atlantic Ridge (Position 1 in Figure 2) showing melt lens (*red line*), low velocity in the lower crust, and Moho across the ridge axis. The inverse triangle is the center of the ridge axis (modified from Seher et al., 2010c).



Crustal Reflectivity (Oceanic) and Magma Chamber, Figure 13 Different types of reflection for Moho boundary observed at Southern East Pacific Rise (Position 3 in Figure 2) (Kent et al., 1994). *Top*: Shingled Moho, *Middle*: Diffuse Moho, *Bottom*: Impulsive Moho.

Sumatra, where the crust was formed at the fast spreading Wharton ridge about 55 Ma ago. If we assume an average velocity of 6.0 km/s, which means at the crust there is only 3.5 km thick, it would be the thinnest crust ever observed in a fast spreading environment (Figure 15).

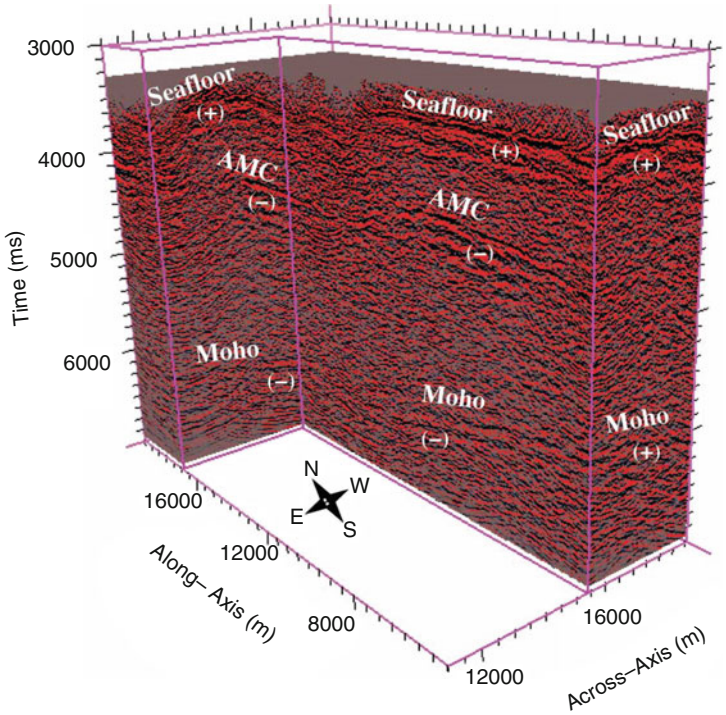
Since there is a positive velocity contrast at the crust–mantle boundary, large amplitude critical angle reflections (PmP) are generated that arrive at large offsets (15–30 km), and are recorded on OBS. These data are then used to map the Moho structure. However, there are two problems in using arrival times of PmP arrivals. The velocity gradient in the lower crust is very small or close to zero, and therefore rays that sample the lower crust do not turn in the lower crust making it difficult to estimate velocity in this zone. Since the arrival time of PmP arrival depends on the velocity in the crust, particularly the lower 3 km of the crust, it is difficult to estimate both the velocity in the lower crust and the Moho structure. Since the velocity in the lower crust can be approximated to a large extent ~6.8 km/s, these data provide a reasonable constrain on the Moho structure, and are routinely used. Secondly, the OBS spacing is generally 5–20 km and the lateral resolution of the Moho structure is very poor.

Crustal thickness

Once we determine the velocity in the crust and Moho structure, we can estimate the crustal thickness. So far, most of the crustal thickness estimations are based on wide-angle seismic studies, and there are significant uncertainties in crustal thickness estimations for the reason explained above. However, combined analyses of seismic reflection, refraction, and gravity data suggest that wide-angle estimation of the crustal thickness can be very reliable.

The crust formed at fast spreading centers is generally uniform and 6 km thick (White et al., 1992; Eittreim et al., 1994) but some variations (5–8 km) have been observed recently (Canales et al., 2003; Singh et al., 2006a; Barth and Mutter, 1996). There is no significant crustal thickness variation across the fracture zone in a fast spreading environment, where it is also 5.5–6 km thick (van Avendonk et al., 2001). The crust formed at slow spreading centers is generally thick at the center of the segment (6–7 km) and thin at segment ends (4–5 km) (Barclay et al., 1998; Seher et al., 2010b). The crust beneath fracture zones in a slow spreading environment is generally thin (3–4.5 km) (Detrick et al., 1993). The thinnest crust (3.5–4.5 km) is formed at ultraslow spreading centers (Jokat and Schmidt-Aursch, 2007). These observations suggest that the thickness of the crust depends on the spreading rate and melt distribution in the crust. On the other hand, thicker crusts are found beneath large igneous provinces, across hotspot tracks or at the interaction of plume and ridges, which are believed to be formed by higher mantle temperatures due to the presence of a plume (e.g., Parkin and White, 2008; Watts et al., 1985; Charvis et al., 1999; Grevemeyer et al., 2001). For example, the crust beneath Iceland could be up to 30 km thick, and beneath La Reunion Island it is 13 km (Charvis et al., 1999).

However, anomalously thin crust has been reported. A 5 km thick crust is observed near the South American



Crustal Reflectivity (Oceanic) and Magma Chamber, Figure 14 Seismic reflection image of Moho beneath the melt lens at the 9° N East Pacific Rise (Position 2 in Figure 2).

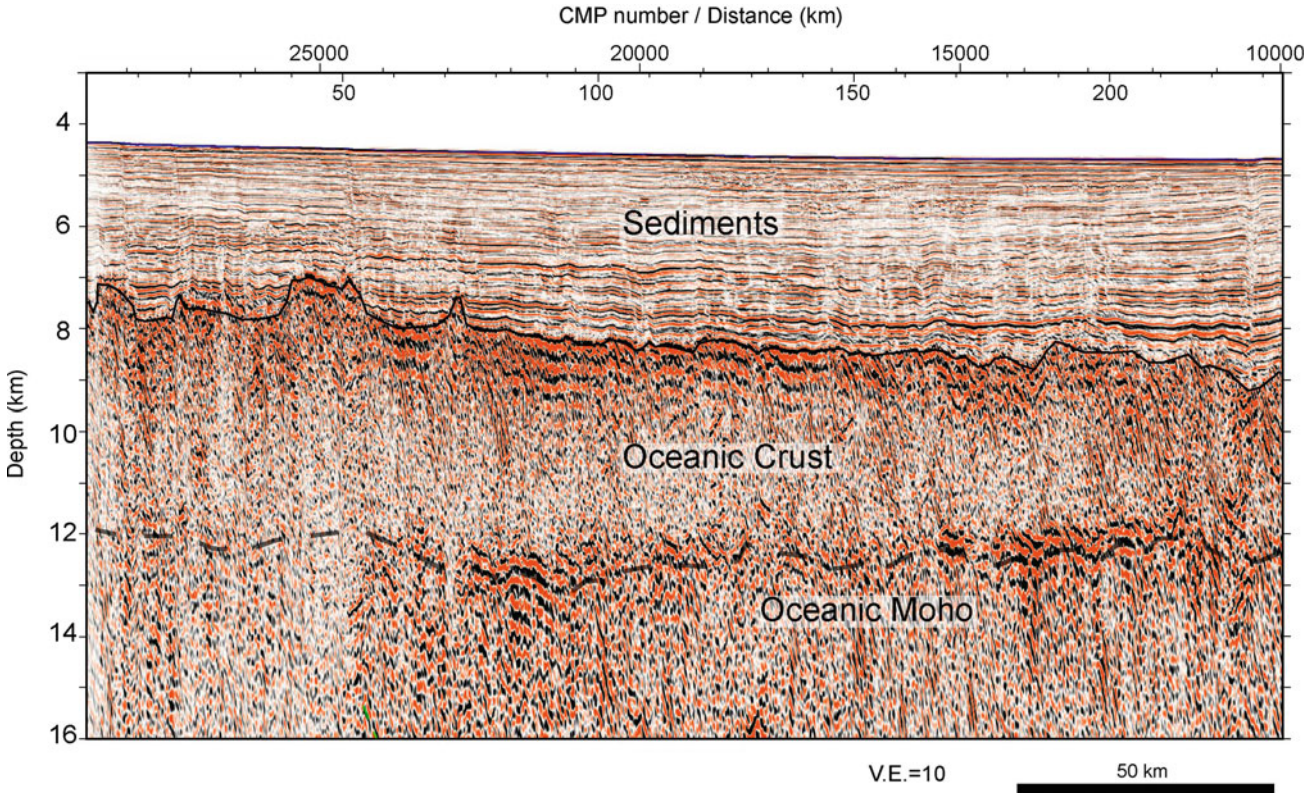
trench (Grevemeyer et al., 2007) and in the area of IODP Hole 1256 (Hallenborg et al., 2003) for crusts formed at the EPR about 20 Ma. Rodger et al. (2006) found an ultrathin crust (4 km) that was formed near the central MAR about 85 Ma ago, which they associate to be due to a reduction in the spreading rate from slow to ultraslow. The crustal study at ODP holes 504B also found thin crust (5 km), which Collins et al. (1989) associate to be due to depleted mantle. Singh et al. (2011) have observed ultrathin crust (3.5–4.5 km) in the Indian Ocean (Figure 15) that was formed at fast spreading Wharton center 55 Ma ago, which they associate to be due to the interaction of the Kerguelen plume with the Wharton Spreading center due to channeling of the cold lithosphere around a plume and its interaction with the spreading center.

Upper mantle

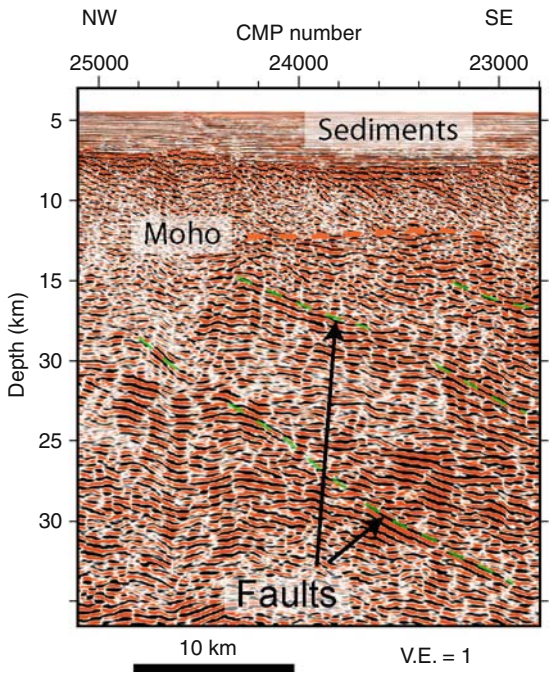
The velocity in the upper mantle is generally determined using rays that turn below the Moho, which are called Pn arrivals. The velocity in the mantle beneath ridge axis is ~7.6–7.8 km/s and is 8–8.1 km/s away from the ridge axis (Vera et al., 1990; Harding et al., 1989). An extensive 3D tomography and undershoot experiment were carried out at 9° N EPR. Using these data, Dunn et al. (2000, 2001) obtained a symmetric low velocity anomaly below the Moho in the mantle. Using the same data and some new data Toomey et al. (2007) found asymmetric low velocity anomaly at 10 km away from the ridge axis. There are serious problems with these results. First, the crustal thickness in this area varies from 6 to 8 km. Secondly, the velocity anomaly depends on the background velocity used during the inversion. Dunn et al. (2000) use a starting mantle velocity of 8.2 km/s whereas one year later Dunn et al. (2001) use 7.6 km/s. Although the crustal thickness is up to 8 km (Canales et al., 2003), Dunn et al. (2001) interpret velocity at 7 km below the seafloor; the part of the anomaly could be due to crustal variations. Toomey et al. (2007) show that the ray only penetrates down to 8 km below the seafloor but interpret the velocity at 9 km below the seafloor. These conflicting results and the inaccuracy in inversion led Singh and Macdonald (2009) to suggest that these results are not reliable. The only robust solution we have is that the velocity in the mantle is ~7.6–7.8 km/s below the ridge axis and 8–8.1 km/s away from the ridge axis (Vera et al., 1990; Harding et al., 1989). However, it is possible that melt sills get trapped in the mantle as shown by Nedimovic et al. (2005) and may lead to a low velocity anomaly in the mantle.

Faults in the oceanic crust and upper mantle

Along with magmatic process, tectonic processes also play an important role in shaping the oceanic crust. Singh et al. (2006b) have shown that median valley bounding faults could be imaged down to 3 km, close to the melt lens. They also found extensive faults above the melt lens. It is possible that some of these faults penetrate down to the crust–mantle boundary (Dusunur et al., 2009).



Crustal Reflectivity (Oceanic) and Magma Chamber, Figure 15 Seismic reflection image of extremely thin crust in the Indian Ocean (Position 4 in Figure 2) (modified from Singh et al., 2011).



Crustal Reflectivity (Oceanic) and Magma Chamber, Figure 16 Seismic reflection of deep penetrating faults in the mantle in the Indian Ocean (Position 4 in Figure 2).

In a subduction zone environment, there are two forces that act on the incoming oceanic plate: plate bending leading to normal faulting and compressive forces leading to thrust faulting. Water can enter into the mantle leading to serpentinization of the oceanic mantle. Normal faulting down to 5–8 km below the Moho, related to bending of the subducting plate and the associated serpentinization, has been reported for the Central American trench (Ranero et al., 2003). Faults have also been imaged in the mantle offshore Sumatra down to 35 km depths (Figure 16) suggesting that a significant part of the oceanic lithosphere is involved during oceanic earthquakes.

Summary

The reflectivity of the oceanic crust and axial magma chambers at ocean spreading centers are described in detail using real seismic images. The oceanic crust consists of three distinct layers: Layer A is 200–1,000 m thick and consists mainly of pillow lavas. Layer B is 1–2 km thick and consists mainly of cooled basalts in dikes. Layer 3 is 2–3 km thick and is formed by the cooling and crystallization of magma in the melt lens. Axial melt lens has been imaged on fast and intermediate spreading centers and recently on a slow spreading center (Singh et al., 2006b). Melt lenses are 50–60 m and have a roof and a floor. Between the melt and Moho, lower crust,

partial melt is generally present. The oceanic crust is about 6 km thick, which could vary from 3.5 to 8 km. The P-wave velocity in the mantle lie between 7.6 and 8.1 km/s, but the detailed nature of the oceanic mantle is poorly constrained and requires further investigations. Faults due to earthquakes have been observed down to 35 km depth.

CURIE TEMPERATURE

Vincenzo Pasquale
Dipartimento per lo Studio del Territorio e delle sue Risorse, Settore di Geofisica, Università degli Studi di Genova, Genova, Italy

Synonyms

Curie point

The critical temperature above which any material loses its permanent magnetism.

A rock containing magnetic minerals loses its permanent magnetism when heated up to reach a critical temperature. This is the Curie temperature or Curie point, ϑ_c, above which the rock is paramagnetic. On the atomic level, below ϑ_c, the magnetic moments are aligned in their respective domains and even a weak external field results in a net magnetization. As the temperature increases to ϑ_c and above, however, fluctuations due to the increase in thermal energy destroy that alignment.

Strongly magnetic minerals are all of ferrimagnetic type, in which neighboring magnetic moments are aligned antiparallel, as in antiferromagnetism, but unequal numbers or strengths give a net magnetization. Among them, magnetite, one of the members of the titanomagnetite solid-solution series, is the most important magnetic mineral to geophysical studies of crustal rocks (Stacey, 1992). There are many other magnetic minerals, but they are rare

(iron sulfide), unstable (maghemite) or having a weak spontaneous magnetization due to the canting of its nearly equal and opposite atomic moments (canted antiferromagnetism), as hematite occurring in sedimentary rocks often in solid solution with ilmenite.

Variation of Curie temperature of titanomagnetite, $Fe_{3-x}Ti_xO_4$, is approximately given by $\vartheta_c = 580\,(1-1.26\,x)$, where magnetite (with chemical composition $x = 0$) and ulvöspinel ($x = 1$) are end members. In pure magnetite, ϑ_c is 580°C, but titaniferous inclusions can reduce ϑ_c, which approximates room temperature for $x = 0.77$ (Hunt et al., 1995). Saturation magnetization is thus a function of temperature, and it disappears above ϑ_c; at room temperature it decreases from 92 A m^2 kg^{-1} for $x = 0$ to about zero for $x = 0.8$. ϑ_c increases with pressure, but the change is quite small. At the crust–mantle boundary, it should not be more than a few degrees of the experimental values at normal pressure.

The crustal rocks lose their magnetization when they are at a depth where the temperature is greater than ϑ_c and their ability to generate detectable magnetic anomalies disappears. A comparison of the crustal temperature with ϑ_c may give information on the depth of compositional change where magnetic rocks are replaced with nonmagnetic material. Transforming regional magnetic anomalies data sets into the Fourier domain and analyzing their spectra allow to obtain information about deep magnetic discontinuities (Blakely, 1996). An example of deep magnetic discontinuities and their relation with Moho depth, temperature, and surface heat flux in central and southern Europe is given by Chiozzi et al. (2005) (Table 1).

The depth of the magnetic layer bottom corresponds to the Moho in the Variscan units and the expected temperature is close to ϑ_c of magnetite. Beneath the Alpine units, this depth is within the crust and its average temperature of 550°C indicates the presence of Ti content. In the Ligurian basin and the Tuscany-Latium geothermal area, the deep magnetic discontinuity sometimes lies a few kilometers below the Moho. This may indicate that the uppermost mantle also contributes to the geomagnetic field. The observed maximum temperature of 650°C, decidedly larger than ϑ_c of magnetite, is due to the fact that the local thermal anomalies are not discernible by the spectral analysis, which is a kind of low-pass filter depending on the window size of the magnetic data investigated.

Curie Temperature, Table 1 Crustal magnetic discontinuities with corresponding parameters

Area	Magnetic layer bottom depth (km)	Moho depth (km)	Temperature at magnetic layer bottom (°C)	Surface heat flux (mW m^{-2})
Variscan units (central Europe, Corsica–Sardinia block)	29–33	29–33	540–580	60–70
Alpine units (Alps, Apennines, Molasse and Po basins)	22–28	25–50	500–600	50–80
Ligurian basin, Tuscany–Latium geothermal area	17–28	17–20	500–650	80–120

DEEP SCIENTIFIC DRILLING

Ulrich Harms[1], Harold J. Tobin[2]
[1]Scientific Drilling, GFZ German Research Centre for Geosciences, Potsdam, Germany
[2]Department of Geoscience, University of Wisconsin-Madison, Madison, WI, USA

Definition

Scientific drilling. Applying drilling methods developed in the hydrocarbon and mineral exploration industry to dig holes and retrieve samples of rock and fluid for scientific, not-for-profit purposes.

Deep scientific drilling. Drilling for scientific research goals beyond near-surface geological and shallow groundwater exploration to depths greater than several hundred meters subsurface, through land, sea ice, or below the sea/lake floor.

Introduction

Geoscientific insight into the deep Earth is mostly based on observations from the surface, indirect evidence through deep geophysical investigations or, increasingly, modeling. However, several critical Earth system processes and records of environmental and paleoclimate change are difficult to observe from ground level only. Hence, despite the great progress achieved in solid Earth science of the past decades, truly ground-truthed knowledge of the dynamics of Earth's crust is limited.

Today, direct access to the interior of the Earth's crust is still confined almost exclusively to sedimentary basins where hydrocarbon resources are recovered through deep industry-financed wells, if typically shallow exploration and mining for groundwater and minerals are neglected. Deep drilling for mainly scientific reasons has remained so far a relatively rare exception because the very high cost of drilling is a critical barrier in the design of research projects. Nevertheless, this threshold can be overcome if societal interests are pressing, if political and financial support is gained, and if international long-term cooperation is achieved. A small number of international Earth science programs devoted to scientific drilling have been established with widely agreed strategic scientific goals, international co-funding, and a necessary minimum of infrastructure and operational capabilities. While the overarching research goals are almost identical, the drilling programs are separated, based on largely technological grounds, into oceanic (Integrated Ocean Drilling Program; Scientific Planning Working Group, 2001) and continental (International Continental Scientific Drilling Program, Harms and Emmermann, 2007; Harms et al., 2007).

Goals of scientific drilling

The international programs for scientific drilling address topics of broad international interest, which can contribute significantly to solving important Earth science themes of high societal relevance (Figure 1). The research themes of these programs can be summarized in three overarching branches:

- The evolution and dynamics of the Earth's crust and lithosphere, especially in subduction zones and orogenic belts, with special emphasis on the physicochemical background of geological hazards such as earthquakes, volcanic eruptions, landslides, and meteorite impacts
- Environmental, climate, and paleoceanographic changes as recorded in geological archives of sediments in the oceans, in lakes, in ice shields, and in other depositional environments, including the resulting biological consequences, as well as the exploration of the widely unknown microbial biosphere living at depth
- Basic science of unconventional resources such as methane hydrates or geothermal energy, and of novel

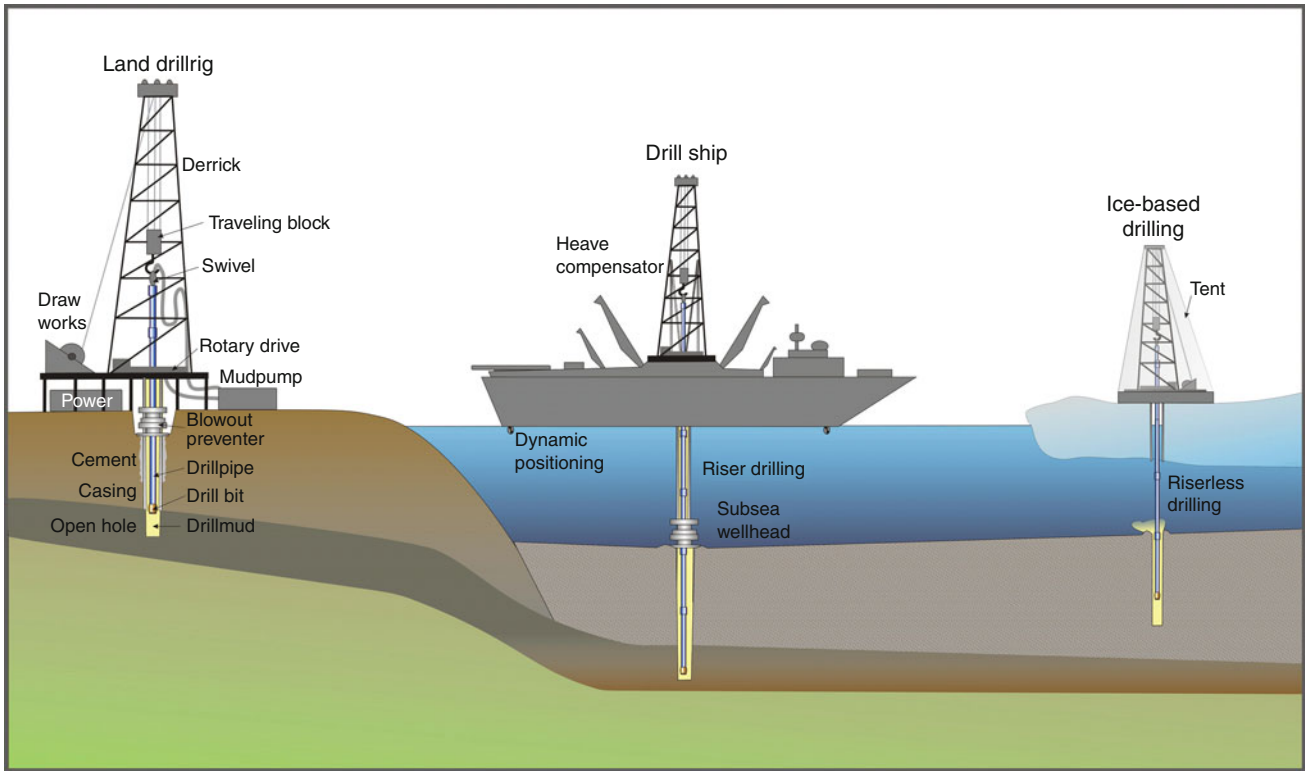
utilization of the deep underground environment such as CO_2-sequestration

This entry addresses mainly the first topic on lithospheric dynamics, hazards, and evolution of the Earth because most deep scientific drilling projects are dealing to a large extent with questions about internal forcing while climate, environmental, and subsurface biosphere research primarily employs shallow drilling techniques. Due to this limited depth extent, paleo-environmental scientific drilling projects are not included here.

Drilling, sampling, and monitoring techniques

A standard in most deep drilling operations (e.g., hydrocarbon exploration) is the rotary drilling technique. A cutting bit is lowered into the ground on a steel tube rotated through a rotary drive in a drilling derrick. The propelled drill string consists of connected pipe elements through which a drilling fluid is pumped down the well. The drill mud, usually water with clay minerals and other added solids to provide viscosity, cools the bit and flushes out chips of the destroyed volume of rock (drill cuttings) to the surface through the annulus between the borehole wall and the drill string. The weight-on-bit is controlled through variable lifting of the pipe, which is pulled down and kept in tension by heavyweight sections of drill pipe installed right above the drill bit. The drilling progress is supported by extending the string in the derrick with additional sections, or stands, of pipe. When drilling from a barge, ship or floating platform, the annulus extends only to the sea/lake floor, so mud and cuttings do not return to the drill rig. In this setting drilling can be performed with water in place of drilling mud, and cuttings spill out on sea or lake bottom around the well. However, if pressure control and mud return is required, an outer second pipe, a so-called "riser," is put in place so the mud and cuttings can be pumped back to the deck. Furthermore, in waves or swell, a heave compensation device is required to ensure constant weight-on-bit. Drilling through tidally lifted ice necessitates defrosting of the pipe in the ice section. Figure 2 summarizes basic drilling methods and important elements used in scientific drilling.

In normal rotary drilling technique, coring is performed with a hollow core bit that leaves a central column of rock that slides into the pipe while drilling progresses. After a few meters of coring, the whole assembly has to be pulled back out of the hole (called "pipe tripping") to get the core to surface. In scientific drilling projects, by contrast, continuous coring is often desirable. To avoid time-consuming pipe tripping runs, wireline coring techniques are applied. An inner core barrel is lowered through the drill string and latches above the core bit to retrieve the barrel with drilled-out rock column by a winch-drawn steel cable, obviating the need for a complete pipe trip with each core. The actual formation-cutting method varies depending on the type of rock or sediment present. Typically, thin-kerfed diamond core bits with high-rotation speed are used for hard rock drilling, roller cone abrasion bits are used for softer sedimentary rock, and nonrotating sharp edged hollow metal pistons of several meters length are hydraulically shot (forced) into soft sediments to collect cores and advance the borehole.



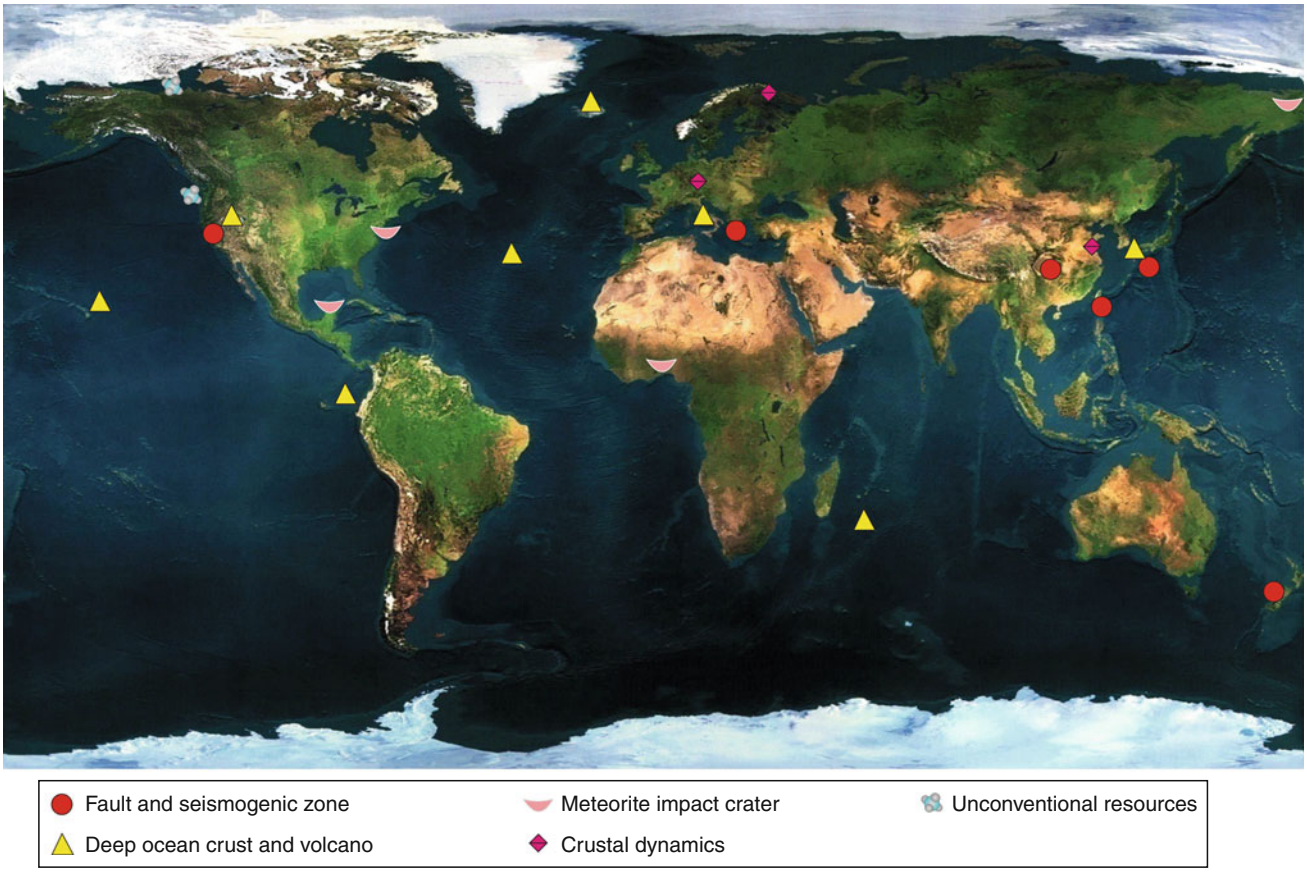
Deep Scientific Drilling, Figure 2 Principle technical components and styles of drilling operations in different environments.

After research wells are drilled, in situ measurements and monitoring of active processes in rocks and fluids allow for unprecedented data acquisition undisturbed by surface processes. A classic example is seismometer recordings in boreholes whose resolution and noise floor is improved by orders of magnitudes in comparison to surface measurements (Abercrombie, 1997). Sealed long-term borehole observatories have been installed in many places on land and at sea that are designed to record changes in temperature, pressure, strain, tilt, acceleration, and hydrologic parameters, and to sample fluids or microbiology (Fisher et al., 2008; Kastner et al., 2006; Prevedel and Kück, 2006).

Dynamics of continental crust

An unprecedented and still standing depth record in ultradeep scientific drilling was achieved in 1989 in the former Soviet Union when the Kola Superdeep Borehole reached 12,261 m after 25 years of drilling (Kozlovsky, 1987; Fuchs et al., 1990). Temperatures of less than 200°C, low tectonic stress, and special lightweight aluminum tools were key to this success. The well intersected Paleoproterozoic to Archean meta-volcano-sedimentary sequences and plutonic rocks in the Kola Peninsula of the northeastern Baltic Shield. The main scientific targets were the origin and extent of ore deposits as well as the principal structure and composition of the deeper crust. Important findings include – besides the falsification of a hypothesized basaltic layer in an onion-skin-like deep crust – the discovery of high-permeability and circulating fluids throughout the crust.

The German Continental Deep Drilling Program (KTB) aimed at principal physical and chemical processes and the geological evolution of the mid-European continental crust in an amalgamated collision zone (Emmermann and Lauterjung, 1997) (Figure 3). After 4 years of drilling through high-grade metamorphic rocks, a final depth of 9,101 m was reached in 1994 at formation temperatures of ~270°C. A truncated Paleozoic suture zone was strongly deformed by post-orogenic Mesozoic fault zones in an antiformal stack. Down to 9 km, faults contain saline, gas-rich free Ca-Na-Cl fluids, the geothermal gradient increases from about 21 to 28 K/km, and fluids percolate freely along fracture pathways. A detailed correlation of geophysical data with petrophysical properties at depth allowed for the calibration of surface geophysics to in situ conditions. Furthermore, for the first time, the state of stress and the rheological behavior of a deep crustal profile were analyzed in situ. Determinations of the minimal and maximum horizontal principal stress between 3 and 9 km depth yielded a uniform stress direction except for a major fault at 7 km depth (Zoback and Harjes, 1997). In conjunction with the deep main well, a 4,000-m-deep pilot hole just 200 m away allowed for the installation of a deep laboratory for fluid level (Schulze et al., 2000) and induced seismicity experiments (Baisch et al., 2002).



Deep Scientific Drilling, Figure 3 World map with important scientific deep drilling sites.

Ultrahigh pressure metamorphic (UHPM) rocks form the 1,000-km-long Qinling-Dabie-Sulu Belt in China, which was formed in a Triassic continental plate collision zone. From 2002 to 2005 a 5,158-m-deep corehole of the Chinese Continental Scientific Drilling project served to retrieve a vertical sample profile of the protracted multiphase deep (>150 km) subduction and rapid exhumation history of UHPM rocks (e.g., Liu et al., 2007; Zhang et al., 2006). The complex metamorphic path and its timing could be determined specifically in high-pressure minerals, which survived late-stage fluid-enhanced retrogression and overprint encased in zircons and other refractory accessories.

Volcanic systems

Volcanism is one of the most spectacular expressions of the dynamics of tectonic processes and the gigantic scale of recycling working in the Earth. The scientific investigation of volcanic processes is also crucial for societal security and thus an important mission for science. Since most of the history of volcanism is encapsulated in rocks that are overlain by sediments, younger lava flows or beneath the sea, drilling is in many cases a critical tool for the investigation of the different types of magmatism reaching surface.

Mid-ocean ridge magmatism

As defined by Conference Participants (1972), ophiolites represent a suite of oceanic crust plus upper mantle. Beneath a sediment cover, lava flows and pillow basalts overlay sheeted dike complexes, gabbroic rocks and, as part of the upper mantle, serpentinized peridotites and similar ultramafic rocks. Several holes drilled by the Deep Sea Drilling Program 1969 to 1985 and the Ocean Drilling Program 1985 to 1996 confirmed this structure but at the same time provided a much more complex picture. After several meters of lava flows were encountered in the early years of these programs, deeper parts of the oceanic plutonic rock succession were drilled in composite sections in tectonic windows and contributed much to the understanding of the ocean crust and mantle. Several drillholes in the Mid-Atlantic Ridge provided insight into slow-spreading modes with emplacement of ultramafic rocks. A 1,508-m-deep hole (735B) penetrated a long section of gabbroic rocks of the slow-spreading Southwest Indian Ridge off Madagascar (Dick et al., 2000).

The first lava-dike transition was drilled in 6 Ma age crust of the Nazca Plate off Ecuador (Hole 504B) down to 2,111 m below seafloor (Alt et al., 1996). And the first complete section of the upper oceanic crust was recovered by the Integrated Ocean Drilling Program at Site 1256 in

2005 and 2006 when the lava-sheeted dyke (1,061 m) and the sheeted dyke-gabbro (1,407 m depth) transitions of the Cocos Plate off Costa Rica were penetrated. The 15 Ma crust was formed in the East Pacific Rise by superfast spreading producing a thick succession (750 m) of lava flows, a relatively thin-sheeted dyke complex, and an upper gabbro section of still unknown extent (Alt et al., 2007). As the drilled fractionated gabbros (1,407–1,507 m) are not the residues of the overlying volcanics, the full sequence of plutonic ocean crust and the Moho transition to the upper mantle remains to be detected in future ocean drilling (Ildefonse et al., 2007).

Active volcano drilling and subduction-induced volcanism

The most common and typically most dangerous types of volcanoes on Earth are aligned along the subduction-related arc systems. They are typically fed by highly viscous andesitic to rhyolithic magmas whose degassing behavior is critical for their eruption mode, either effusive or explosive. While erosion and tectonics provide detailed insight into solidified and cooled volcanic structures, little is known about the physical and chemical conditions or permeability close to and in feeder fissures and magma conduits of active volcanoes. Despite challenging engineering and safety issues, some attempts have been made to drill into active volcanism. Still notable because of temperatures of above 1,400°C is the shallow drilling of the Kilauea Iki lava lake on Hawaii in the 1970s (Hardee et al., 1981). Furthermore, in Eastern California the recent, rhyolithic Inyo Lava Domes were sampled to understand degassing mechanisms (Eichelberger et al., 1986).

A series of devastating eruptions with frequently occurring pyroclastic flows and vulcanian explosions in early 1990 at Mount Unzen Volcano in southeastern Japan was accompanied by volcano-tectonic earthquakes and isolated tremor allowing for a geophysical pinpointing of the ascent path and surface appearance of magma. The identified conduit locale was within depth reachable by drilling, and justified drilling to sample in situ conditions after eruptions ended. Within the framework of the International Continental Scientific Drilling Program, the Unzen Volcano Drilling Project 2004 hit the conduit through an almost 2,000 m long but 1,500-m-deep well (Sakuma et al., 2008). Deviated drilling steered by downhole motors from the northern flank of Unzen was utilized to meet environmental and safety restrictions. Large-diameter casings were cemented in place to allow mud circulation for cooling of high temperatures, which were modeled to reach up to 600°C. However, maximum temperatures were as low as 160°C, and no gas kicks appeared due to enhanced permeability and 9 years of convection and groundwater circulation after the last eruptions. At 1,996 m depth, rocks were cored that could be identified as feeder dyke material (Nakada et al., 2005).

In the next stage of scientific drilling into volcanic features, calderas will be explored because they form through collapse during super-eruptions – the most explosive volcanism on Earth. An outstanding example of an actively inflating caldera is the Campi Flegrei volcanic field in Naples, Italy (Troise et al., 2007). A shallow crustal magma chamber, strong geothermal activity with enormous release of volcanic gases, and recent episodes of unrest call for drilling as a tool to investigate the driving mechanisms. Similar to the Unzen drilling, a deviated well is planned to be drilled from the land under the Bay of Naples toward the center of seismic unrest in the heart of the structure at 3.5 km depth.

Mantle plume volcanism

Hot spots truncate lithospheric oceanic and continental plates and build up giant volcanic edifices in Large Igneous Provinces (LIP) and Ocean Island Volcanoes. Their buildup requires vast melt extraction from the deep mantle and provides insight into mantle compositions, transport mechanisms, and the evolution of volcanic structures over space and time. Several boreholes of the Ocean Drilling Program opened windows into the Ontong-Java Plateau of the Western Pacific (Fitton et al., 2004) and the Kerguelen Plateau in the Southern Indian Ocean (Frey et al., 2000) to confirm their LIP origin.

In the Hawaii Scientific Drilling Project, the Mauna Kea volcano was cored with 95% recovery to a total depth of 3,520 m (3,508 m below sea level) to sample the evolution of plume melts over about 700,000 years as the volcanoes have drifted with the Pacific Plate over the Hawaii Plume (Stolper et al., 2009). The formation temperatures increase only from about 10°C to 50°C in the borehole (19°C km^{-1} gradient below 2,000 m) due to deep circulation of seawater in a complex hydrological regime including freshwater inflow as deep as 3,000 m. The circa 850 m subaerial and 2,440 m submarine layered lava and hyaloclastite accumulations represent almost 400 lithological units such as individual lava flows. They show geochemical and isotopic heterogeneity with tholeiitic versus alkaline magma transitions. This bimodal distribution of source components indicates a radial zoning within the melting region with a hot inner zone, which does not contain entrained mantle material and must be based in the lowermost mantle region (Bryce et al., 2005).

A further drilling target is supercritical fluids at 4–5 km depth in the Iceland Deep Drilling Project (Fridleifsson and Elders, 2007). Through coupled geothermal industry research and scientific investigation of in situ fluid-magma exchange, the first well at Krafla, Northern Iceland, hit rhyolithic magma at about 2,000 m depth before the well was cased for testing (Fridleifsson et al., 2010). In the late stages of planning is also drilling of the track of the Yellowstone plume in the Snake River Plain of southern Idaho (DePaolo and Weis, 2007).

Scientific drilling into volcanic rocks of the ocean crust provided the most important test and confirmation of the seafloor-spreading hypothesis. Samples retrieved from thickened ocean crust confirmed another type of seafloor

volcanism forming Large Iigneous Provinces, which contribute large magma volumes to the continental crust as well. These LIPs seem to represent transient plume heads while the plume tails persist in ocean island volcanoes. Hawaii served as pivotal example to drill deep into a single volcano to sample different parts of the plume and the volcanic history. Furthermore, recent penetrations into active volcanoes demonstrated the technical feasibility of such operations at very high temperatures. This access to deep volcanic processes is opening novel possibilities for monitoring.

Impact craters

Almost 180 craters on Earth are known currently that have been formed by astrophysical chance when celestial bodies collided with the Earth. The effects on life and the environmental consequences of the destructive forces as well as the input of extraterrestrial material, including organic compounds, is an overarching question in Earth systems history. Together with geophysical illumination, deep drilling into impact structures provides crucial data to study cratering, informing models of the impactor's size, impact angle, the resulting energy release through melting, evaporation, ejection and, most importantly, provides data for charting the aftermaths of such dramatic events. The best studied example to date is the Chicxulub crater (Dressler et al., 2003) in which the approximately 10-km-large impactor penetrated the whole crust and caused upper mantle rebound and an exemplary drastic biotic turnover 65.5 Ma ago (Schulte et al., 2010). The impact ejected a spherule-rich ash layer over the whole globe and released vast amounts of carbonate and sulfate gases previously bound in sedimentary rocks at the site of impact. The resulting darkness, cooling, geochemical cycle perturbations, and sudden change of environment interrupted the food chain and led to the major extinction event at that time.

In the past decade, four main impact crater studies including scientific drilling have been accomplished: the 200-km-wide Cretaceous-Paleogene Chicxulub Crater in Mexico (Hecht et al., 2004), the 1 Ma age 12-km-wide Bosumtwi Crater in Ghana (Ferrière et al., 2008), the late Eocene, 60 km Chesapeake Bay Crater in the Eastern USA (Gohn et al., 2008), and the 14 km Lake Elgygytgyn Crater in Chukotka, Siberia (Brigham-Grette and Melles, 2009). One of the important results is an improved understanding of the cratering process. Giant km-sized megablocks of target rocks were drilled in the lower sections of the huge Chesapeake and Chicxulub craters at 800–1,700 m depth. The blocks were shattered by shock waves into the transient crater and embedded in suevititic and lithic impact breccias by rapid mass transport in the crater within a few minutes. Unsorted marine debris flows driven by resurge and finally sorted airfall layers buried the blocks, which appear at a first glance as in situ target rocks. Furthermore, for large craters, a quasi-fluidization of target rocks and impactors leads to the formation of a central uplift by rebounded upper lithosphere, whereas in smaller craters such as Bosumtwi a central peak at about 500 m depth is formed by brittle deformation processes.

Active fault zones

Since the late 1990s, researchers have undertaken a wide range of ambitious projects aimed at drilling into active faults in a range of tectonic settings, both on land and at sea. These projects have been motivated by the recognition that fault zone processes are poorly understood from surface data, and that a combination of (a) samples of fault materials from "live" systems in the subsurface and (b) access through boreholes to in situ measurements and monitoring of ambient conditions in active faults, can provide key new observations for learning about these processes. Our understanding of the mechanics and dynamics of plate boundary faulting is severely limited by a lack of information on ambient conditions and mechanical properties of active faults at depth. A major goal in earthquake mechanics research is thus direct in situ sampling and instrumentation by drilling into the seismogenic zone of active faults, including both inter- and intra-plate fault systems in many tectonic settings.

Understanding of the complex physics of tectonic faulting, earthquakes, and the generation of tsunami in the Earth's crust is one of the grand challenges of the geosciences in general and seismology in particular (Lay, 2009). Because earthquakes take place deep below the Earth's surface, direct observation of processes acting in the faults themselves has generally not been possible; what we know about earthquake processes is derived from seismologic observations, geodetic deformation, and studies of exhumed rocks containing products of slip at depth long ago. Researchers have learned and inferred a great deal from these studies, but they are inherently limited. Much of fault zone drilling is aimed at understanding earthquake slip, but in fact fault physics encompasses a spectrum of slip and slip rates ranging from purely aseismic behavior, such as steady creep, through events such as slow earthquakes and episodic creep, to true seismicity. It is not yet clear how similar or distinct the physics of these modes of fault slip may be (Ide et al., 2007).

Hence, some of the key questions addressed through fault zone drilling projects include the following: What are the deformation mechanisms of fault slip in both aseismic and seismic conditions? Why is slip sometimes seismic, sometimes aseismic, and sometimes in an intermediate state, and what governs the transitions among these processes? How do earthquakes nucleate, and how does rupture grow and stop? Are there precursory phenomena in the fault or near field that indicate a preparatory phase to earthquake or slip nucleation? If so, can a prediction or early warning strategy based on borehole observation be developed? What are the processes governing tsunami-genic slip? What is the role of fluid content and fluid pressure in modulating faulting processes, especially during rapid seismic slip? How does

permeability of the fault zone evolve interseismically and coseismically? What is the stress tensor in and around a fault zone throughout the earthquake cycle or other slip? What controls localization of slip versus distributed strain in faulting?

Pursuing these questions, a number of major national and international efforts have been carried out or planned in recent years. These prominently include the San Andreas Fault Observatory at Depth (SAFOD), the Taiwan Chelungpu Fault Drilling Project (TCDP), and the Gulf of Corinth drilling on land, and the Nankai Trough Seismogenic Zone Experiment (NanTroSEIZE) at sea.

Fault zone drilling projects are different in many respects from most other scientific drilling efforts. Rather than the complete stratigraphic intervals or sampling of broader rock volumes targeted by most other deep drilling, fault zone targets include *discontinuities* and small anomalous intervals. The targets of interest are often the exact locations of poorest drilling conditions, such as a highly fractured damage and gouge zone with potential for excess pore pressure above hydrostatic condition, anomalous stress state, weak rock, and other drilling hazards. The scientific approach commonly focuses on obtaining very extensive downhole measurements, logs, cores, and seismic structure in and around these fault zone environments. Measurements at the time of drilling as well as long-term observations are emphasized.

Nojima fault projects, Japan

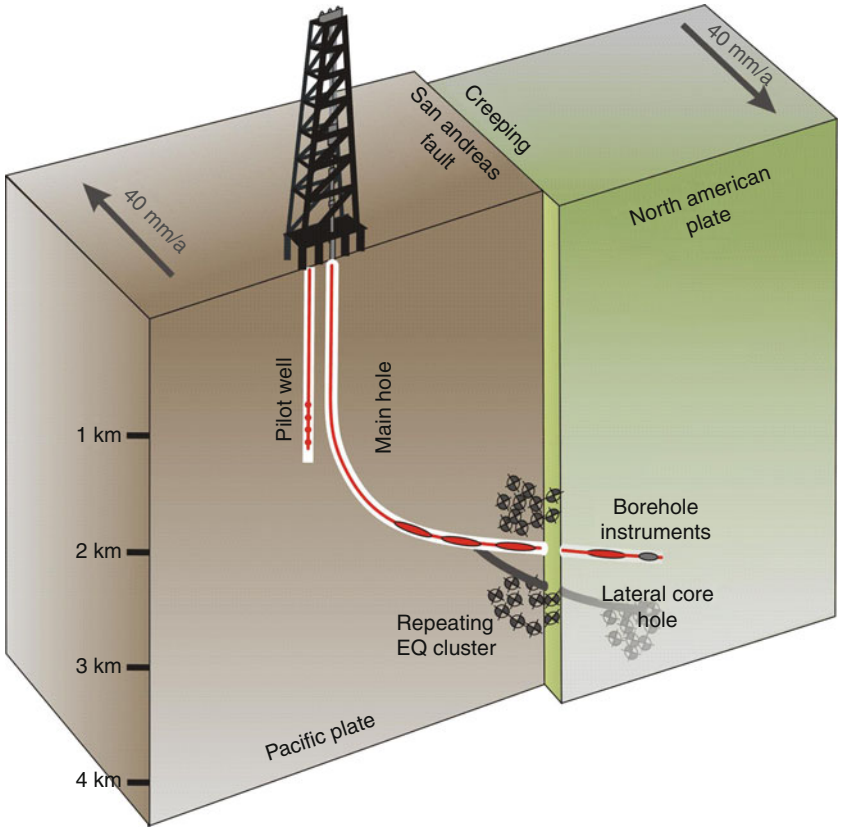
Soon after the Kobe earthquake in 1995 (M6.9), several research teams drilled multiple boreholes into and across the shallow portion of the Nojima fault (the locus of that event) from ~750 to ~1,800 m depth (Ito et al., 1999). Detailed compositional and structural analyses identified a narrow fault core of gouge and surrounding damage zone, with asymmetric structure in the footwall and hanging wall (Boullier et al., 2001; Fujimoto et al., 2001; Ito et al., 1999; Ohtani et al., 2001; Tanaka et al., 2001). Shear wave splitting studies of aftershocks showed a rapid evolution of fast direction after the earthquake, interpreted as evidence of fracture healing during a 12 month postseismic period (Tadokoro and Ando, 2002). From repeated injection tests, permeability change with time was observed (Tadokoro et al., 2000). The structural properties (fault zone width, shear wave velocity, and Qs) of the Nojima fault were studied using Love-wave-type fault zone trapped waves (LTWs) recorded at two borehole seismic stations.

SAFOD, California

The SAFOD borehole was drilled into the creeping section of the San Andreas Fault in central California close to the northern end of the locked Parkfield segment (Williams et al., 2010; Zoback et al., 2010). A vertical pilot hole was drilled in 2002 to circa 2 km depth (Hickman et al., 2004). The main hole was drilled in three phases from 2004 to 2007 to a depth of 4 km (3 km true vertical depth), the first 1,800 m vertical, then deviated toward the steeply dipping San Andreas Fault Zone, and finally crossing the fault at an angle of 55° (Figure 4; Hickman et al., 2007). High-resolution seismic observations in the well and at the surface allowed to steer the well directly into a zone of repeating micro-earthquakes. The initial main borehole was logged and cased; repeated casing diameter logs over time showed that two intervals of casing several meters wide were actively deforming. Together with drastically decreasing values of v_p, v_s, and resistivity, the deforming intervals were interpreted as a manifestation of creep in two discrete fault zones (Hickman et al., 2007). In 2007, the hole was reentered and sidetracks were drilled to obtain core samples (Williams et al., 2010). A core interval of approximately 40 m was obtained from one of the two identified major fault zones, and additional cores were collected from adjacent wall rock intervals. Borehole seismometers installed in the well detected target earthquakes as small as M ~ 2 within a few tens of meters of the source, allowing unprecedented high-frequency detection of source processes (Ellsworth et al., 2007). A notable result from SAFOD has been the absence of evidence for either a thermal anomaly from frictional heating around the fault core or an excess pore fluid pressure substantially above hydrostatic anywhere in or around the faults, as well as geochemical evidence that the fault zone is a permeability barrier to cross-fault flow (Hickman et al., 2007; Wiersberg et al., 2007), simultaneously adding evidence for absolute fault weakness in the San Andreas and opening new questions about the source of that weakness. The actively deforming zones consist of about 2 m wide foliated fault gouge showing dissolution–precipitation reactions, serpentinite porphyroclasts and smectite–illite coatings on minerals lubricating the fault in the creeping section. A permanent borehole monitoring package for seismic and tilt observations was installed in 2008. As this instrument set failed due to hostile fluid conditions, a new observatory system is in the design phase and will be installed for long-term measurements. The long-term observation of in situ physical parameters over several seismic cycles is the key goal of SAFOD.

Corinth rift laboratory, Greece

The Gulf of Corinth is a location of back-arc extension within the Hellenic Arc system and is among the most seismically active areas of Europe (Cornet, 2007). The Corinth Rift Laboratory (CRL) project drilled into the Aigion fault at 760 m depth and continued to 1,000 m, encountering cataclastic fault rocks in a karstic carbonate host-rock environment. The fault zone forms a strong hydrologic barrier with an associated pressure differential across it. Transients in pore pressure have been detected associated with remote earthquakes (Cornet et al., 2004). Since 2007, pore pressure measurements have been made in the borehole, but only in the hanging wall of the fault zone. Plans for upcoming activities at CRL include



Deep Scientific Drilling, Figure 4 Sketch of drilling design in the San Andreas Fault Zone Observatory at Depth (SAFOD).

near-term deployment of a string of high-frequency three-component geophones, packers, pressure transducers, tiltmeters, and thermistance meters across the fault penetration, and also a proposed 4.5-km-deep borehole to monitor pore pressure and other features of the seismogenic zone (Cornet, 2007).

Taiwan Chelungpu drilling project, Taiwan

The devastating 1999 M7.6 Chi-Chi earthquake in Taiwan was a thrust event in a collisional tectonic setting that exhibited very large slip (>10 m), including large surface displacements, on the Chelungpu fault. The principal objective of drilling was to sample the main slip surface or zone, if one could be identified, at a relatively short post-seismic interval. The fault zone was drilled in 2004 and 2005 in an area of high-velocity large slip during the main shock, and crossed the fault zone and several hundred meters of the footwall in two adjacent holes (Ma et al., 2006). The main slip zone and several subsidiary (or older) fault cores were identified in the borehole at ~1,100 m depth (Hung et al., 2007). Studies of the fault gouge particle size, thickness, and composition have yielded quantitative estimates for the work done in forming gouge and damage (fracture energy), contributing to the understanding of energy budgets during earthquakes (Ma et al., 2006). Borehole hydrologic tests, temperature logging, and sample-based frictional experiments contributed to a tight integration of borehole-derived information with seismological observations.

Wenchuan fault scientific drilling program, Sichuan, China

The devastating Wenchuan earthquake (M7.9) of May 12, 2008 caused at least 68,000 deaths. It occurred on a reverse fault in crystalline basement rocks, and slip propagated to the near surface. Only 178 days after the earthquake, the Wenchuan Fault drilling program was begun to access the coseismic slip zone for sampling and in situ observations, in up to four planned boreholes. The first borehole was completed in 2008, but results have not been reported internationally as of this writing.

Subduction zone fault drilling at sea

For over 20 years, drilling efforts have targeted active large-offset thrusts and décollement faults in subduction zone settings, but these have mostly been in areas shallower than the depth of seismogenic strain accumulation and release. Beginning in the 1980s with the Barbados Accretionary Wedge, at the Atlantic Caribbean plate boundary, drilling was aimed at understanding the faulting conditions, ambient pore fluid pressure, and mechanics in a very low angle (~2° dip) décollement thrust fault at the

base of an accretionary wedge (Moore, 1989). Drilling and logging measurements made while drilling (LWD) there demonstrated that the fault zone was a mechanically very weak interval with high excess pore fluid pressure and patchily distributed areas of anomalously high porosity (Moore et al., 1998). Installation of a borehole seal (CORK), downhole testing, and other studies at ODP Sites 948 and 949 have shown that the fault zone has effective permeability that is strongly pressure dependent and varies over ~4 orders of magnitude with fluid pressure (Fisher, 2005). Drilling at Costa Rica off the Nicoya peninsula also elucidated the structure of a shallow décollement zone. Structural studies and geochemical tracers of hydrological flow paths suggest that two strongly decoupled systems exist above and below the ~20-m-thick main fault zone, which acts simultaneously as a low-permeability barrier to cross-fault flow and a high-permeability channel for along-fault flow (Tobin et al., 2001). Installation of a sealed borehole monitoring system there documented an apparently weakly overpressured décollement zone that exhibits temporal pressure excursions tied to apparent aseismic transients recorded geodetically on land (Davis and Villinger, 2006). Similarly, instrumented boreholes at the Nankai Trough off Shikoku Island in Japan show pressure transients associated temporally and spatially with swarms of very low frequency earthquakes, suggesting a long-distance (tens of kilometers) poroelastic connection between the earthquake events and the boreholes (Davis et al., 2006). The same data show long-term pressure trends interpreted as a response to gradual interseismic strain accumulation.

Beginning in 2007, IODP embarked on its most ambitious fault zone drilling project to date, to drill a transect of boreholes, including two deeper than 1,500 m below the seafloor, spanning the up-dip transition from seismic to aseismic fault mechanics. The Nankai Trough Seismogenic Zone Experiment (NanTroSEIZE) project is the first attempt to drill, sample, and instrument the seismogenic portion of a plate boundary fault or megathrust within a subduction zone. The fundamental goal of NanTroSEIZE science plan (Tobin and Kinoshita, 2006) is to access, sample, and then instrument the faults in aseismic and seismogenic regions of the megathrust system. This is pinpointed in a region where recently discovered very low frequency (VLF) earthquakes have been shown to occur (Ito and Obara, 2006), as well as possible shallow low frequency tremor (Obana and Kodaira, 2009). NanTroSEIZE involves drilling of faults in the active plate boundary system at several locations off the Kii Peninsula of Honshu Island, Japan, from the very shallow onset of the plate interface at the trench to ~7 km depths where earthquake slip and locking takes place. At this location, the plate interface and active mega-splay faults implicated in causing tsunami are accessible to drilling within the region of coseismic rupture in the 1944 Tonankai (magnitude 8.1) great earthquake (Baba et al., 2006). In 2007, an initial transect of eight sites was drilled to depths from 400 to 1,400 m below the seafloor (Tobin et al., 2009a, b). Sampling of major large-offset thrust faults imaged in 3D seismic data (Moore et al., 2007) identified strongly localized fault slip zones even at positions just a few hundred meters below the surface where the host sediments are poorly consolidated. New evidence from detailed vitrinite reflectance measurements (Sakaguchi et al., 2009) suggests that frictional thermal heating may have affected even these presumed aseismic faults. In a second stage of drilling in 2009, the riser system was deployed for the first time to drill a cased observatory hole to 1,600 m (Saffer et al., 2009), and the incoming plate geology and fluids were sampled on the incoming plate beyond the subduction front (Underwood et al., 2009), to define a baseline and mass balance for material delivered to the subduction interface. Borehole observatories to monitor seismic activity, strain, tilt, temperature, and pore fluid pressure were planned for installation in late 2010. The main objective of NanTroSEIZE, however, is slated to take place in 2011 and 2012, with planned deep riser drilling to 7 km below the seafloor, across the full plate interface. The objective is to access and instrument the full Nankai plate interface within the seismogenic zone, sampling the fault and wall rocks and obtaining measurements for years to come as the interseismic period passes.

Unconventional resources

Among the unexplored, unconventional resources requiring drilling for basic scientific research are gas hydrates, in which methane and other gaseous hydrocarbons combine with water to form crystalline, ice-like structures. Their stability field varies only within a few MPa and °C but they can be stable even at temperatures above 0°C in deepwater or buried sediments. Two widespread environments of their occurrence have been known for a long time: in sediments of the continental slopes where they simulate bottom reflectors in seismic images, and below permafrost in polar regions (Kvenvolden, 1988; Buffett and Archer, 2004). Although estimates of the global abundance of gas hydrates vary widely, the total volume appears to be in the same order of magnitude as conventional hydrocarbon resources. At the same time, they bear a high potential of generating continental slope instabilities causing giant submarine landslides and contributing significantly to the atmospheric greenhouse effect when released into atmosphere (Dickens, 2003).

Little is known about the distribution of gas hydrates, and even less about the physical and chemical parameters that affect the formation and stability of gas hydrates. At sea, the best studied, drilled areas are in the Eastern Pacific off Vancouver Island and at Blake Ridge in the western Atlantic Ocean off Georgia (Tréhu et al., 2006). Continental gas hydrate accumulations were drilled in the Mackenzie River delta in northern Canada (Dallimore and Collett, 2005). Two observation wells and one central production well dug to 1,200 m depth were used for an

extensive field program including coring, downhole logging, cross-hole experiments, and production testing. All three wells show massive thermogenic methane gas hydrate accumulations between 890 and 1,100 m depth with the highest concentration at the base of the gas hydrate stability zone (Takahashi et al., 2005). Similarly, in marine sediments the hydrates are concentrated in coarse-grained, high-permeability layers. A series of controlled depressurization and thermal-stimulation experiments yielded important baseline data on phase equilibria as well as on petrophysical and hydraulic parameters. Warm drill mud caused dissociation of gas hydrate in a 13-m-thick hydrate concentration zone at about 920 m depth (80% pore saturation) and produced 50–350 m^3/day. Existing fluid pathways such as in faults appear to enhance the gas production. Concentrated gas flow along such pathways seems to be also critical for the gas hydrate formation, in sediments and especially on seafloor.

Summary

This paper summarizes the most significant, but not all deep scientific drilling projects that have been carried out in recent years by international research teams. Key goals of these projects encompass topics of high societal relevance such as a better understanding of the physics driving geological disasters and a wise utilization of resources. Various several kilometer deep drilling ventures allowed for unprecedented sampling and in situ monitoring of dynamic processes governing formation and restructuring of the Earth's crust such as collision events, volcanism, faulting, or impact cratering. Despite grand engineering challenges, deep Earth access techniques are now available for novel burgeoning scientific exploration. Scientific drilling promises to be an integral tool of research generating new observations for the time to come.

Definition

Multi-channel recording, along a measurement line, of seismic waves, artificially generated using large energy sources, after these have travelled deep through the earth's crust (and upper mantle).

Deep-reflection profiling is done using vibrators (on land) or air guns (in water) at near-vertical distances (8–12 km) to image the structure of the crust and upper mantle. Wide-angle reflection/refraction profiling uses large explosions and recording distances (200–300 km), primarily to obtain velocity information down to upper mantle.

Introduction

Vibrations caused by earthquakes are known to travel great distances, and provide valuable information about the internal structure of the earth. Explosions and other artificial sources could also be used to generate such waves. Man-made *earthquake* signals have several advantages of their own, e.g., their location – both in space and in time – is precisely known. Further, due to relatively shorter distances of observation, higher frequencies are better preserved, and allow a better resolution of the subsurface structure. Development of *marine seismics* has extended the coverage of this technique to offshore regions too.

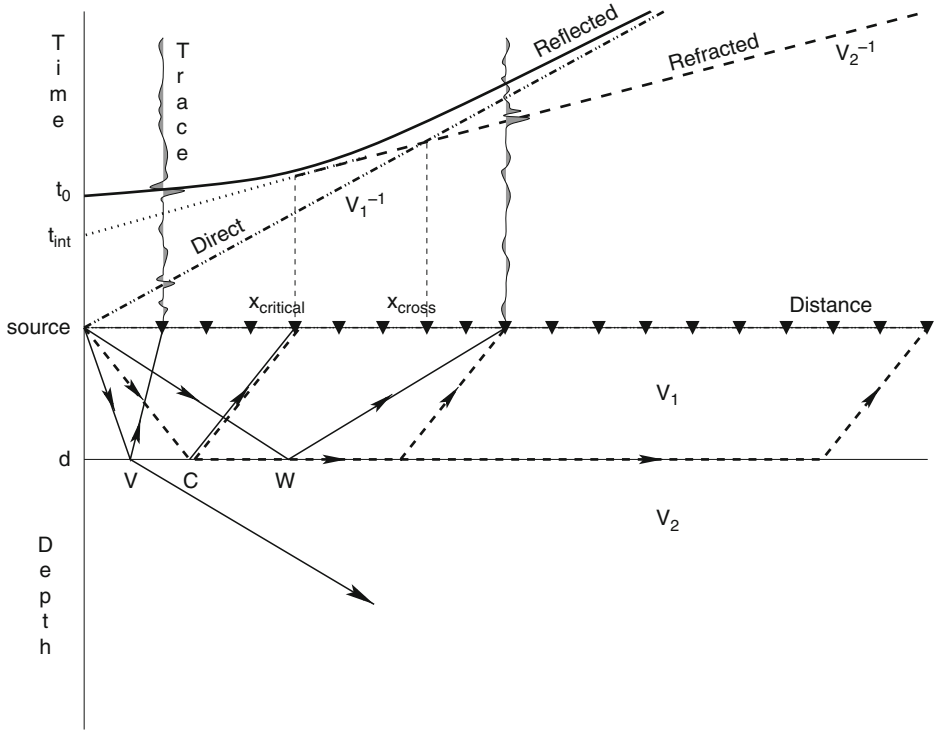
As a science, *Deep Seismics* is positioned between exploration seismics and seismological studies. The former uses man-made waves to investigate structures in the sedimentary basins (down to about 5 km) to locate likely occurrences of oil and gas, whereas the latter uses earthquake-generated waves to study earth's deep interior down to the core. With the shared theory of wave propagation in (visco)elastic media, similar instrumentation and computer-intensive processing/interpretation techniques (see *Seismic Data Acquisition and Processing* for a comparative table), there is considerable overlap between these two approaches. Improvements in data-acquisition and processing have extended the depth-range of exploration seismics – covering the entire continental crust down to *Moho* and the upper-mantle region immediately below it (50–100 km). Such studies are called by different names (deep seismic sounding, long-range reflection/refraction, wide-angle crustal-seismics, etc.) depending upon their focus and regional usage. Here, the term *DSRRP,* derived from the title, will be used to denote this developing branch of Earth Sciences, concerned with studying the (continental) crust and upper mantle of the earth, using man-made sources. The article will include studies of continental margins, but not those covering oceanic crust (See also *Earth's Structure, Continental Crust*).

There are several good resources about the general theory of wave propagation in elastic media (e.g., Aki and Richards, 2002) and exploration seismics (e.g., Sheriff and Geldart, 1995 and "*Seismic Data Acquisition and Processing*"), special issues pertaining to the latter in the context of DSRRP will be elaborated whenever needed. Below, all capitals will be used for acronyms and phrases within double quotes will refer to articles elsewhere in *this* volume.

Basic principles

Figure 1 illustrates the principle of the seismic experiment using a simplified earth model. Here, a horizontal boundary separates the top layer of velocity (actually wave-speed) v_1 and thickness d from a half-space of velocity v_2, with $v_1 < v_2$, mostly valid within the earth. After the generation of the vibration at the source, elastic energy travels through the media, and is recorded by many (usually hundreds) of receivers on the surface as *seismic traces,* the collection being a *seismic record*. Plot of such a record – amplitudes as a function of recording distance vs. travel-time – shows distinct spatio-temporal *alignments,* representing different wave-types (*phases*), three of which have been sketched in the figure. Depending upon their travel path, the phases show up in the record as *first,* or, later arrivals, and have information about the structure of the medium. In addition, the amplitudes of these arrivals – and their variation with the recording distance (*offset*) – yield information about the material properties of the medium, e.g., *density*, *elasticity*, etc.

The subject matter of this article forms an extension of exploration seismics, which is a broad field, with a substantial literature. Sheriff and Geldart (1995) and Liner (2004) provide good coverage of its various aspects, e.g., theory, data-acquisition, -processing, and -interpretation. Aki and Richards (2002) (theory of wave propagation), Vermeer (2002) (data-acquisition), and Yilmaz (2001) (data-processing) provide more focused treatments of individual topics. DSSRP-specific modifications/extensions to the standard field- and processing-procedures will be described later; see *Seismic Data*



Deep Seismic Reflection and Refraction Profiling, Figure 1 Schematics of a multi-channel seismic experiment to image the earth (layer of wave-speed v_1 overlying a half-space of wave-speed v_2). Energy travels from the source through the medium and is recorded by the receivers (filled triangles), planted in the ground, as *seismic traces*. Lines with different patterns represent typical travel paths (rays). Dash-dots indicate energy *directly* travelling from the source to the receivers along the surface, continuous lines show *reflections* from the layer boundary, and dashes represent energy *critically refracted* along the boundary. The upper-half uses the same patterns to show the *travel-times* of these three arrivals. The refracted phase is first recorded at the critical distance $x_{critical}$ and overtakes the direct wave as the first arrival from the crossover distance x_{cross} onward. Letters *v*, *c*, and *w* are points representing (near) vertical, critical, and wide-angle incidence of energy on the boundary, see text for further explanation.

Acquisition and Processing for a general introduction. Based on Figure 1, a brief overview of some key concepts from *seismics* – relevant to DSRRP – follows.

Linear arrivals represent the travel-times of both *direct* and *refracted* arrivals, if v_1 and v_2 are constant, the slopes (dt/dx) being inversely proportional to the corresponding velocities. Using these, and the *intercept time* (t_{int}, Figure 1) of the refracted arrival, the layer thickness d can be calculated.

Critical distance is the minimum recording distance for observing the refracted wave. According to Snell's law, only when the energy is incident on the boundary at the critical angle $\left(= \sin^{-1} \frac{v_1}{v_2}\right)$, will it be refracted *along* the boundary, will propagate with the velocity v_2 of the lower medium, and will keep sending energy back into the upper medium according to the Huygen's principle.

Crossover distance denotes the distance, beyond which the faster refracted phase overtakes the direct wave ($v_2 > v_1$) and becomes the first arrival; the latter can also be used to determine the thickness d. In a layered earth with velocities increasing with depth, refraction arrivals from deeper boundaries become the first arrival after their respective crossover distances. Note, that A. Mohorovicic used the overtaking of the direct P-phase by a faster (refracted) one, which he called P_n, to infer the thickness of the earth's crust and the presence of a higher velocity medium underneath.

Reflections represent that part of wave energy incident upon a layer boundary, say at the point "*V*" in Figure 1, which will be transmitted back into the upper medium, according to Snell's law. The *reflected* arrival is hyperbolic in shape, with its apex at time t_0, corresponding to the vertical two-way time ($= 2d/v_1$) from the source down to the boundary and back. Reflection amplitude is sensitive to the (contrast of) material properties across the boundary, and the incidence angle, and provides valuable additional information regarding the media. The importance of this phase for crustal imaging was realized following corresponding advances in exploration seismics.

Super-critical incidence occurs, as the recording distance increases, with the incidence angle changing in Figure 1 from (near) vertical (e.g., point "*V*") through the critical incidence (e.g., point "*C*") to super-critical (e.g., point "*W*"). Note, that the reflection hyperbola becomes asymptotic to the linear arrival belonging to the layer above,

but never crosses it. This relationship holds in a multi-layered situation, with increasing velocities, too.

Wide-angle incidence corresponds to large recording distances (compared to the target-depth), and sees a sharp increase of *reflection coefficient.* Reflections from crustal boundaries, even with small contrasts, may thus be observable in this *wide-angle* range. Also, the quantity $t_x - t_0$ associated with the reflection hyperbola (Figure 1), called normal moveout (NMO), can be measured well in this region and helps velocity estimation. The seismic signal window gets compressed though at this range due to the geometry (kinematics) of the travel-time curves; note the *squeezing* in Figure 1 (top) between the direct and the reflected branches with distance.

Modern DSRRP represents an integration of the *near-vertical* and *wide-angle* modes of seismic investigation. While near-vertical multi-channel reflection seismic (NMRS) provides powerful tools for structural imaging developed for the exploration industry, wide-angle reflection/refraction (WARR) is valuable for constraining the velocities of the crustal units and thus provides the geological framework.

Data acquisition

Seismic field measurements need three components, namely, man-made *source* to produce seismic energy (usually at the earth surface, or, within water), which then propagates within the earth, *receivers* (usually also at the surface) to pick up a part of this energy returning back after reflection/refraction/diffraction (scattering in general) from within, and *recorder* to store the received signals (nowadays after digitization), see *Seismic Data Acquisition and Processing* for details.

Sources used in DSRRP have to be much stronger than those typical in exploration, as the distances travelled by the seismic waves – both vertically, but especially horizontally – are much larger. Earlier, large explosions – several kilotons of TNT strong – were routinely set off for this purpose. Such explosions – sometimes under water – were recorded over long distances, sometimes across international boundaries (Steinhart and Meyer, 1961; György, 1972; Kaila et al., 1978). Sometimes quarry-blasts were used for crustal seismic studies, provided good arrangements could be made for the recording of the time of explosion. Calibrating and monitoring of nuclear explosions necessitated several long-distance (mostly) refraction profiles, with nuclear explosions as sources (see also *Seismic Monitoring of Nuclear Explosions*). Later, very long-range crustal seismic measurements were carried out in the Soviet Union using dedicated *peaceful nuclear explosions* (Pavlenkova and Pavelenkova, 2006). Although chemical explosions continue to be used for WARR studies, powerful hydraulic-driven mechanical vibrators on land and large compressed-air sources (air guns) under water are preferred for NMRS; these have sufficient energy to return signals back to the surface from Moho and upper mantle.

Receivers used in DSRRP are similar to those used in seismology and in exploration seismics, but need some special characteristics. Long measurement profiles imply deployments over a large distance/area, often necessitating stand-alone capabilities, especially for power supply and storage capacity, see Mereu and Kovach, 1970, in which mention is also made of an early German effort (MARS-66) using a portable four-channel analog tape recorder. Modern DSRRP receivers digitize real-time and can often be programmed to record at certain prearranged time-windows (see Texan in the references). For near-vertical land/marine deployments, standard equipment from the exploration industry is used; nowadays even these are frequently cable-free, and use radio communication for data-transfer.

Time-of-shot transfer, with high fidelity, from the source to the recorder was the weakest link in DSRRP – especially for WARR deployment, with distances of several hundred kilometers. Early experiments used short-wave radio-link, or, the parallel recording of a continually broadcasting radio transmitter. Availability of GPS-based time-signals, and high-quality internal clocks, has mitigated this problem.

Field layouts

Receiver arrays were utilized early on for long-range refraction-seismic studies for their effectiveness in recording signals from preferred directions (possible nuclear-test sites), and gave rise to permanent installations in several countries, e.g., NORSAR (Norway), GBA (India), and WKA (Australia). More recently, dynamic arrays have also been deployed. The Program for Array Seismic Studies of the Continental Lithosphere (PASSCAL), an initiative under the Incorporated Research Institutions for Seismology (IRIS), has made hundreds of identical instruments available for temporary deployment (see PASSCAL in the references) at many places around the world. Using such receivers, a 15-year static/dynamic observation of seismic signals is currently under way in the USA (see USARRAY in the references), which uses natural sources (*passive seismics*) too.

Multi-channel near-vertical land/marine studies use standard industry equipments and deployments (see *Seismic Data Acquisition and Processing* for details), the main difference being a much longer recording time (15–30 s, or longer). When using vibratory sources on land, long sweep- and listening-times are needed too. If the continental crust is covered by a shallow water layer (e.g., British Isles), marine seismic data acquisition offers twin advantages of speed and better signal-to-noise ratio, leading to better imaging.

DSS – DSRRP – onshore–offshore in the early days recorded from the source (near-vertical) outward and continued at least till the P_n-phase (refraction below Moho) was recorded as the first arrival (Gamburtsev, 1952).

Outside Soviet Union, this technique was extensively used in India starting 1972, to study the tectonic

Deep Seismic Reflection and Refraction Profiling, Table 1 Some (inter)national DSRRP efforts

EAGLE	Ethiopia	2003	+ European and US universities

framework of the subcontinent (Reddy et al., 1999), and was later adapted for sub-basalt (*Deccan Trap*) exploration. Many DSRRP investigations nowadays combine the two modes somewhat differently, an industry standard *common mid-point* (CMP) -profile (NMRS) is frequently interspersed with a few widely spaced explosions, observed at large distances (WARR). Variations include two-ship marine recording (see below) and simultaneous onshore–offshore recording, particularly useful for investigating continental/accretionary margins.

(Inter)national consortia in DSRRP started in 1975, when an industry crew measured a reflection (CMP) profile in Texas, using a vibratory source, with a recording time of 15 s (Finlayson, 2010b). For the next two decades, a large amount of data was collected and analyzed in several national academic–industrial collaborations: Table 1 provides a partial overview and IGCP-559 (2010b) is a good internet resource with many more details.

More recently, international DSRRP efforts are studying specific geological problems, e.g., Himalaya and Tibetan Plateau (Zhao et al., 1993), or, active continental margin in Central Andes (ANCORP working group, 2003).

Special processing and interpretation tools

Processing schemes for DSRRP data followed, at first, the standard industry scheme, even as the latter was undergoing change, e.g., transition from 2-D to 3-D coverage and true-amplitude processing. Soon, however, the special needs of processing deep seismic data were realized. As a result, new schemes were established, including modules newly developed by the industry and academia, and older data were frequently reprocessed, often resulting in *better* images (Cook and Vasudevan, 2006).

Line-drawings sketched on paper plots were used at first, to prepare DSRRP data for further processing, e.g., migration and interpretation. This is because, unlike basin-reflections, deep-crustal seismic signals are generally characterized by weak, laterally discontinuous backscattered energy – embedded in a noisy background. Lines were therefore manually drawn on the seismic section to represent more-or-less continuous alignments, which were taken to represent boundaries meaningful for interpretation. Clearly, the process was strongly subjective. This approach was also linked to the tradition of interpreting long-offset data using long refraction segments; naturally, it neglected a large part of the recorded signals with limited lateral continuity.

Coherency filter was proposed to mitigate this. Kong et al. (1985) formulated a procedure to *automatically* identify *signals* present in the seismic section. Based upon the concept of *phase-coherency,* it uses a few user-defined (tunable) parameters, to yield *repeatable* results, and can detect weak but laterally continuous signals. Some form of coherency filtering has nowadays become a part of the standard processing flow for deep-reflection data.

Statistical processing of DSRRP data, for objective high-grading using a coherency criterion, has also received attention. Hansen et al. (1988) proposed a method based upon statistical hypothesis testing, which provided some estimate of the robustness of the results, albeit at the cost of additional computation time. Vasudevan and Cook (1998) introduced the concept of *skeletonization* to delineate regions of the deep crust based upon their seismic signature, Baan (2000) included local signal statistics for high-grading.

Attempts have also been made to treat the entire deep-reflection wave-field as the backscattering from a random medium (Hurich, 1996; Hurich and Kocurko, 2000; Pullammanappallil et al., 1997), and analyze it to extract parameters describing the medium – this will be further discussed below.

Vertical- vis-a-vis horizontal-tectonics used preferentially could lead to different interpretations of the same data. DSS-profiles in György, 1972 and later literature (e.g., Kaila et al., 1979) frequently contain, e.g., intra-crustal normal faults. With the hindsight of the paradigm shift associated with the formulation of plate tectonics, some of these may need to be revisited. Gibbs (1986) illustrated this intriguing possibility of an alternate interpretation by using a DSS-section sans the earlier interpretive lines.

Main results

NMRS recordings of 12–15 s contain coherent reflected energy from down to 35–45 km, depending upon the presence/absence of sedimentary cover. Crystalline crust

appears to be much more reflective than assumed earlier, although there are transparent zones too. In general, the mature continental middle crust is less reflective (more transparent) than the lower crust – probably indicating differences in their rheology (brittle vs. ductile). Intra-crustal dipping reflective zones – of both thrust- and normal-fault types – are encountered frequently. At times, these cut through the Moho into upper mantle as *frozen* evidence for palaeo-subduction. Moho appears frequently as the termination of *diffuse* reflectivity, the boundary itself occasionally showing sharp displacement (sign of strength).

Data from WARR recordings can be modeled in terms of longer boundaries separating tectonic/velocity blocks at a regional scale (see below). These also provide occasional evidence of *sharp* offsets in crustal boundaries including Moho, the latter seems, in some cases, to be *doubled.*

The role of deeper structures – especially *deep-faults* – in controlling the evolution of shallower geology, e.g., deposition, deformation, fluid-movement, etc., is being increasingly appreciated. The knowledge gained is of economic significance, both for understanding *systems* associated with economic accumulation of hydrocarbons and minerals, and to help steer search for them.

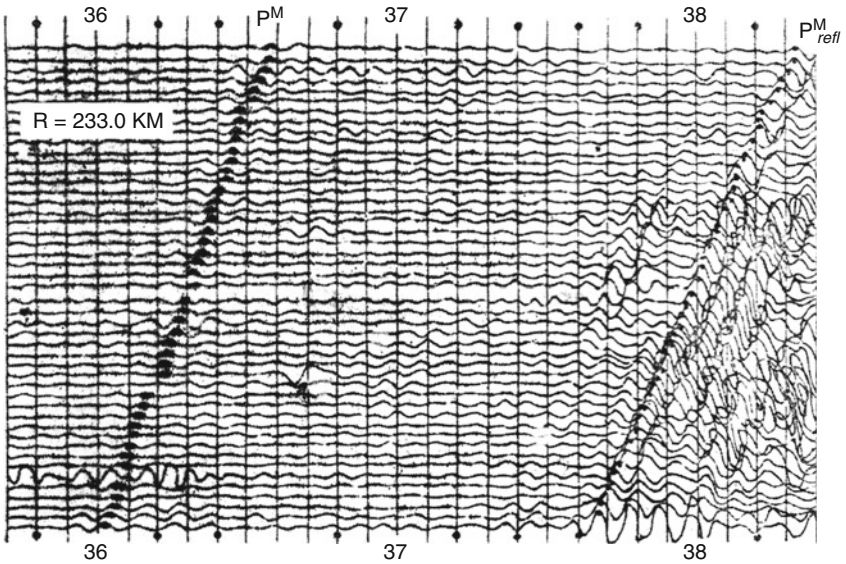
International Biennial symposia have been organized (roughly) every 2 years since 1984, to showcase the data and discuss the results from DSRRP surveys. The publications resulting from these meetings provide a historical record of the progress of DSRRP – both with respect to technological advancement and scientific knowledge (Barazangi and Brown, 1986a, b; Matthews and Smith, 1987; Leven et al., 1990; Meissner et al., 1991; Clowes and Green, 1994; White et al., 1996; Klemperer and Mooney, 1998a, b; Carbonell et al., 2000; Thybo, 2002; Davey and Jones, 2004; Snyder et al., 2006; Thybo, 2010; IGCP-559, 2010a).

(*Re*)*processing*, *synthesis*, *and interpretation* of the vast amount of DSRRP data – near-vertical and wide-angle – is not an easy task. The data quality depends mostly upon the respective geological settings and the data-acquisition technique and parameters used. Uniform processing of this dataset of mixed quality/vintage is necessary though for regional syntheses and interpretation, to understand the internal architecture of the continental crust (e.g., Phinney and Roy Chowdhury, 1989; Cook and Vasudevan, 2006).

The results from DSRRP are incorporated in several articles in this volume (please see the cross-references).

Through the years, DSRRP has made significant advances – technological in data-acquisition and methodological in processing/interpretation; its scientific results have included several surprising features – some of which are still being interpreted – and have yielded new insights into the processes that shape the continental crust. Below are a few of these highlights; the acronyms referring to the consortia/projects are explained in Table 1.

Early DSS(*RP*) *in Eastern Europe* has been nicely summarized in György (1972), from which Figure 2 is taken. It shows a part of a long-offset (≈233 km) DSS profile recorded in the Ukraine in the 1960s, as part of extensive DSS-surveys in the East-European countries mentioned earlier, which had established the observability of both



Deep Seismic Reflection and Refraction Profiling, Figure 2 DSRRP data recorded in Ukraine in the 1960s. Both refracted energy and reflected energy are clearly visible at a distance of about 233 km, and is correlatable trace-to-trace with a geophone spacing of 100 m. The first arrival, here marked P^M, is the head-wave from Moho (P_n), the strong later phase, marked P^M_{refl}, is the wide-angle reflection from the base of the crust. For further details, see György (1972, p. 50) (Courtesy *Geophysical Transactions*).

refracted- and reflected-phases in the wide-angle range. High apparent velocity of the refracted P_n-phase (first arrival at those distances), and its relationship with reflected (later) phase, help identify the base of the crust as their origin. Some figures in the above reference also show near-vertical reflections from the Moho, albeit with less clarity, not surprising in view of the older acquisition technology.

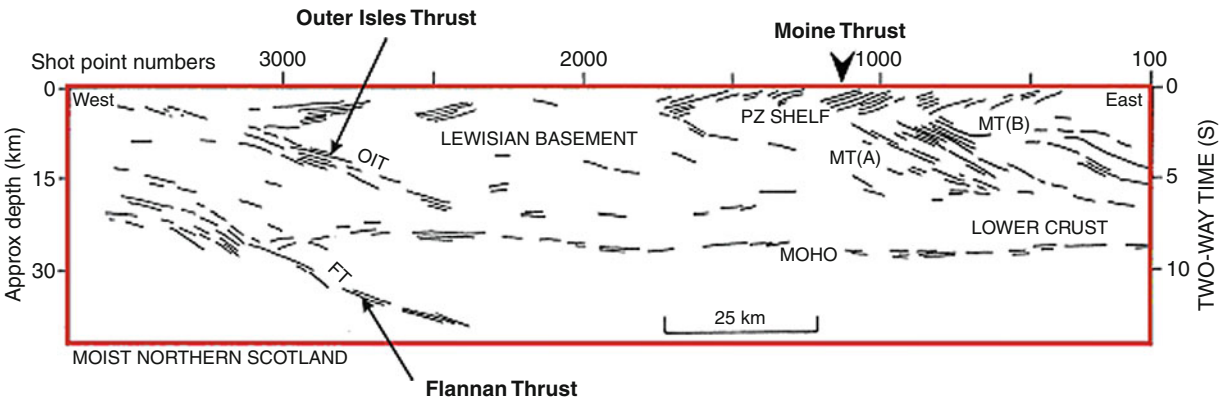
György (1972, p. 44–68) includes on page 66 a contour map of the Moho-depth below Ukraine, the detail of which, although debatable, is impressive, especially considering its vintage. It is based on an astounding 6,000 line-km of DSS profiling with a dense network, following the methodology described in Gamburtsev (1952). The contours indicate depths between 22.5 and 55 km, with rapid lateral variations at places. The latter were interpreted as *deep-faults* displacing the Moho.

Imaging deeper with multi-channel exploration seismics began in 1975. The COCORP consortium – the catchy acronym is reported to have been coined past midnight at a bar in Mexico – pioneered the use of industry standard sources (vibrators), recording layout (NMRS), and processing for deep seismic profiling on land. It was shown that under favorable geological and recording conditions, useful signals could be received back from depths of 40–50 km, by using four to five vibrators simultaneously and extending the recording time (Oliver et al., 1976). Later, similar studies confirmed that the crust underlying the basement possesses variable reflectivity, including some *transparent* regions. Moho, the base of the crust, often showed up on such images as the termination of a zone of diffuse reflectivity, and not as a long and sharp boundary inferred from earlier (refraction) studies.

One of the early surprises of the COCORP lines was the discovery of a mid-crustal zone of strong reflectivity below southern Georgia, USA; the *Surrency Bright Spot* was reconfirmed during a later survey (Pratt et al., 1993). Zones of strong reflectivity have since been reported in other surveys too, e.g., the *Quebrada Blanca Bright Spot* (QBBS) in Andean subduction zone (ANCORP working group, 2003) and the *Nyinzhong Bright Spot* (NBS) under Tibet (Makovsky and Klemperer, 1999). The possible cause(es) of this strong reflectivity remain controversial (see below).

Marine-seismic imaging of the continental crust was seized upon to (partly) alleviate the unfavorable *signal-to-noise ratio* (SNR) for deep seismic data-acquisition on land (noise from traffic, industry, etc.). Offshore surveys in waters underlain by continental crust were expected to provide better images of the latter (although marine seismics has its noise-sources too). Phinney (1986) confirmed this using data from a 48-channel marine survey (recorded by USGS during 1973–1979) over the Long Island Platform. The original stack-sections of Lines 36 and 23, processed to 12 s, showed clear evidence of a rich crustal architecture, with half-grabens, wedges, and other tectonic features indicating both the compressional- and extensional phases of a Wilson-cycle.

Existence of known and expected hydrocarbon-bearing basin structures had already attracted marine-seismic exploration activity in the 1970s and 1980s to the waters around the British Isles. The latter, surrounded by North Sea and the northeast margin of the Atlantic Ocean, are a part of the European continental shelf. Starting 1981, this situation was utilized to great advantage by the BIRPS consortium – essentially by extending the marine-seismic exploration recording time to 15 s. The very first profile, MOIST (recorded by the preceding BIRPS group), contained strong reflections from lower crust, Moho and upper mantle (see Figure 3), which could be connected



Deep Seismic Reflection and Refraction Profiling, Figure 3 Annotated line-drawing interpretation of the MOIST-profile data, showing coherent reflections from throughout the crustal column. Moho shows up as a more-or-less continuous boundary. Several dipping thrust-like features (e.g., Outer Isles Thrust) can be seen at all depth-ranges, which also include transparent zones. One dipping reflective zone (Flannan Thrust) is seen to penetrate through the Moho into the upper mantle. (Figure from Finlayson 2010a, see Brewer and Smythe 1984 for details).

to surface-geology on land (Smythe et al., 1982), and even prompted correlation of tectonic evolution across the Atlantic (Brewer and Smythe, 1984).

Later BIRPS profiles, e.g., WINCH (Brewer et al., 1983), continued to impress with very good data quality and evidence for shallower/younger tectonics being controlled by older/deep-crustal structures. The DRUM profile extended the recording to 30 s. The density of coverage and the quality of data allowed Flack and Warner (1990) to map deep reflections in 3-D, and enabled Chadwick and Pharaoh (1998, p. 268) to produce a contour map of Moho beneath the UK, which may be compared with a similar map below Ukraine (György, 1972, p. 66) mentioned earlier.

Integrated transects, using additional geophysical tools, e.g., magneto-tellurics, electro-magnetics, and geochrology, characterized the LITHOPROBE programme in Canada. It took advantage of the geology to investigate both ancient processes, e.g., assembly of continents, and modern crustal dynamics of active subduction, detachment, and imbrication. For example, the Kapuskasing uplift, one of few lower crustal exposures on earth surface, was imaged in the KSZ-transect (Percival et al., 1989), whereas the transects SNORCLE and SC examined younger mountain building processes (e.g., Clowes et al., 1983).

Relating to the ground truth, the strength of exploration seismics, is the Achilles' heel of DSRRP (and seismology). Super-deep drill holes provide the only opportunities of directly correlating observations to the rock-properties; the German DEKORP programme was able to utilize this in a symbiotic manner.

Besides WARR recordings of quarry-blasts, Germany had an early start in near-vertical recordings of deep reflections and statistical evaluation of their amplitudes (e.g., Dohr, 1957; Dohr and Fuchs, 1967). The DEKORP programme was formulated to study the evolution of the European continent through *Variscan* and later orogenic episodes. More recently, their efforts have included international investigations across active collisional zones, e.g., Alps (Gebrande et al., 2006) and the Andes (ANCORP working group, 2003).

DEKORP played an important role in the site-selection phase of the German super-deep drilling programme, KTB, which was set up to drill ≈ 10,000 m down through an ancient geodynamic suture (see Emmermann and Lauterjung (1997) for an overview of KTB). Later, besides providing a reference point for the seismics at the drill-site, the KTB programme has yielded direct evidence of shear-zones, anisotropy, and substantial amounts of fluids deep in the crust; the analysis of the latter has provided new insights into their origin and role in controlling/influencing geodynamic processes.

The Russian super-deep drilling programme in the Kola peninsula (Smythe et al., 1994) reached the record depth of 12,200 m, and also provided valuable *ground truth* regarding the macrostructure of the mature continental crust, and the origin of crustal reflectivity.

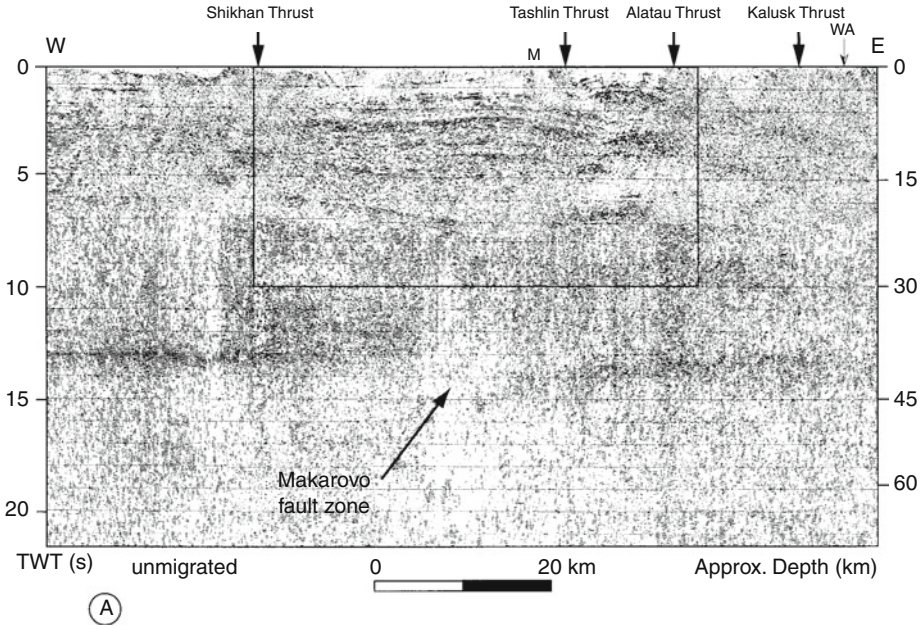
Upper-mantle reflectivity – frozen subduction has also seen a paradigm shift as a result of DSRRP investigations. Reflection signals from the upper mantle had already been reported in the wide-angle data (György, 1972). DSRRP has provided vivid proof that reflective zones may extend into the upper mantle too. Analysis of wave propagation through this region has helped us understand their structure and the possible role of scattering (see below). Dipping reflectivity in this region has provided information regarding palaeo-tectonics and may – in some cases (see Figure 3) – be evidence for palaeo-subduction. Such evidence has been reported from DSRRP experiments in different parts of the world (e.g., BABEL working group, 1990; Morgan et al., 1994).

Rheology of crust, *Moho*, *and upper mantle* depends upon their composition and in situ physical conditions. Intra-crustal faulting, affecting even the Moho, was already inferred from DSS data in Ukraine (György, 1972) and also from reflection/refraction in Southern Alberta (Kanasewich et al., 1969). DSS data from the Indian shield (Kaila et al., 1979) was used by Roy Chowdhury and Hargraves (1981) to infer constraints about the thermo-tectonic evolution of the early earth. With improved acquisition/processing, such features are now regularly reported from different parts of the world, and are no longer considered exceptions.

(Near) vertical offset in the Moho, inferred at many places from teleseismic, gravimetric, and other geophysical observations, is now often imaged in NMRS. This has important bearings regarding the *nature* of Moho. This first-order seismic boundary is often thought to be a surface that re-equilibrates after tectonic events above (e.g., thrusting), or, below (e.g., underplating). DSRRP images contain examples that contradict this view, showing that Moho topography can survive later orogenic cycles, e.g., BABEL working group (1990); Diaconescu et al. (1998) – Figure 4 is taken from the latter. The reason for this behavior is not well understood.

The thermal- and the stress-regimes in the lower crust and upper mantle determine the interaction between the two during the formation of Moho as the boundary layer. Chadwick and Pharaoh (1998) interpret a DSRRP line by associating increased reflectivity of the Moho *there* to its being a detachment surface resulting from low-angle shear (Figure 5). Local *doubling* of Moho has also been seen at places, especially in the WARR data – its evolutionary mechanism remains unclear though.

WARR had taken a back seat for a while with the increasing use of NMRS. With progress on some of the processing issues (see below), it has made a comeback though following the adage *structures from reflection and velocities from refraction.* Many recent DSRRP experiments have specifically included both the components. WARR is, sometimes, a part of onshore–offshore measurements, sometimes three-component receivers are used to study crustal anisotropy, etc. Mooney and Brocher (1987) provide a review of earlier coincident WARR studies. A more recent example is BABEL working group



Deep Seismic Reflection and Refraction Profiling, Figure 4 Unmigrated seismic section from URSEIS profile across southern Urals (Figure from Diaconescu et al., 1998, with permission from *Geology*). Moho (older than 1 billion years) is bright on the left and is offset sharply in the middle of the figure (Makarovo fault zone) by ≈5 km. Migrated image of the boxed upper part (not shown), contains laterally continuous stratification over this fault zone.

(1993). Stand-alone WARR measurements remain useful at places where continuous reflection profiling may be difficult, an example being the recent KRISP experiment in the Kenyan Rift Valley (Khan et al., 1999).

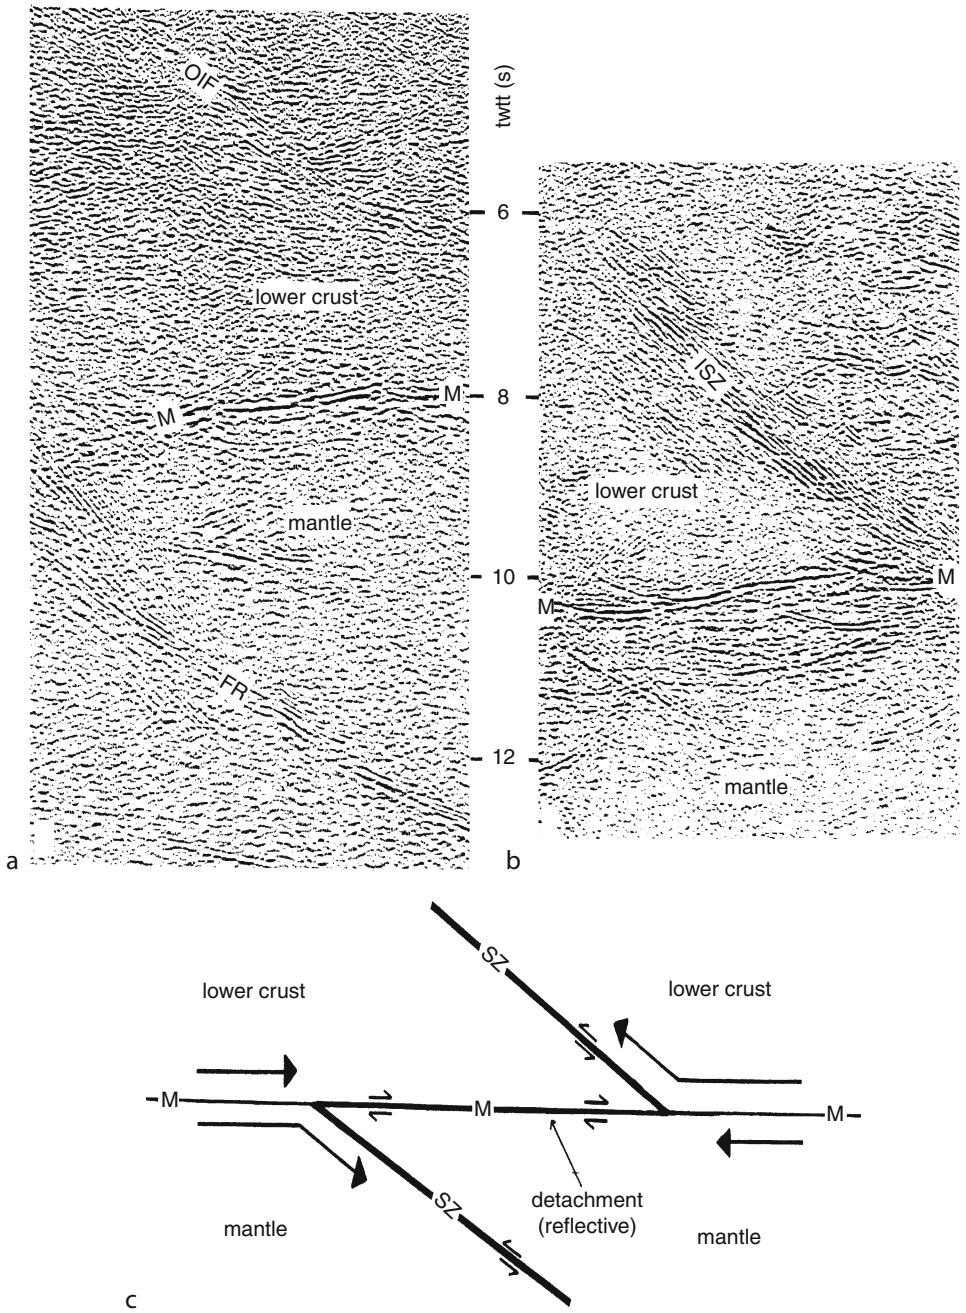
Deep seismic investigations using nuclear explosions: During 1965–1988 (before the comprehensive (nuclear) test ban treaty), the-then USSR had carried out a series of very long-range seismic experiments using *peaceful nuclear explosions* (PNEs), supplemented with chemical explosions placed every 100–150 km. (Benz et al., 1992). Employing three-component receivers, typically 10 km apart, and recording out to 1,550–3,000 km (Pavlenkova and Pavelenkova, 2006), these datasets will provide an invaluable basis for current and future research as they become widely available. QUARTZ, the profile studied most, 3,850 km long, used 400 three-component receivers, 3 PNEs, and 51 chemical explosions (Morozov et al., undated IRIS communication, see references); analysis of its data has already generated new ideas about wave propagation in lower crust and upper mantle (see below).

Analysis/Modeling of WARR data typically starts by picking *travel-times* of the phases (first and later arrivals) that are interesting, the choice being decided by the data quality and the geological aim. Usually, some prominent (mid) crustal reflected/refracted arrivals are identified and *picked,* along with arrivals from Moho, and possibly deeper ones. Methods of deriving crustal models from this data include ray-tracing (Zelt and Smith, 1992), tomography (Hole, 1992), computation of synthetics, etc. (see also *Traveltime Tomography Using Controlled-Source Seismic Data*). Frequently, a preliminary *velocity model* is iteratively fine-tuned to obtain a desired level of fit to the observed travel-times. There are several schemes for *ray-tracing,* see *Seismic, Ray Theory* and Zelt (1995) for overviews. Recently, amplitude information has also been incorporated in such schemes.

Maguire et al. (2006) contains examples of the different aspects of the procedure in the context of the EAGLE experiment (Figure 6). Different modeling/inversion schemes result, of course, in different models, even with the same input data. The DOBREfraction'99 Working Group (2003) provides an example of this, along with discussion of likely causes.

Analyzing amplitude of DSRRP signals was identified early on as a crucial step, to differentiate between competing models of the crust. Improvements in the data quality, and careful processing, allow attempts to quantify the material properties that influence the strength of the recorded deep seismic signals. Properties that are of primary interest include: reflection coefficients (RC) across various crustal boundaries, their variation with the angle of incidence (AVO), and the Q(uality) factor along the path (see *Seismic Data Acquisition and Processing* for definitions). These properties are especially important while considering the probable cause(s) of the bright spots, e.g., fluids, intrusions, layering, etc.

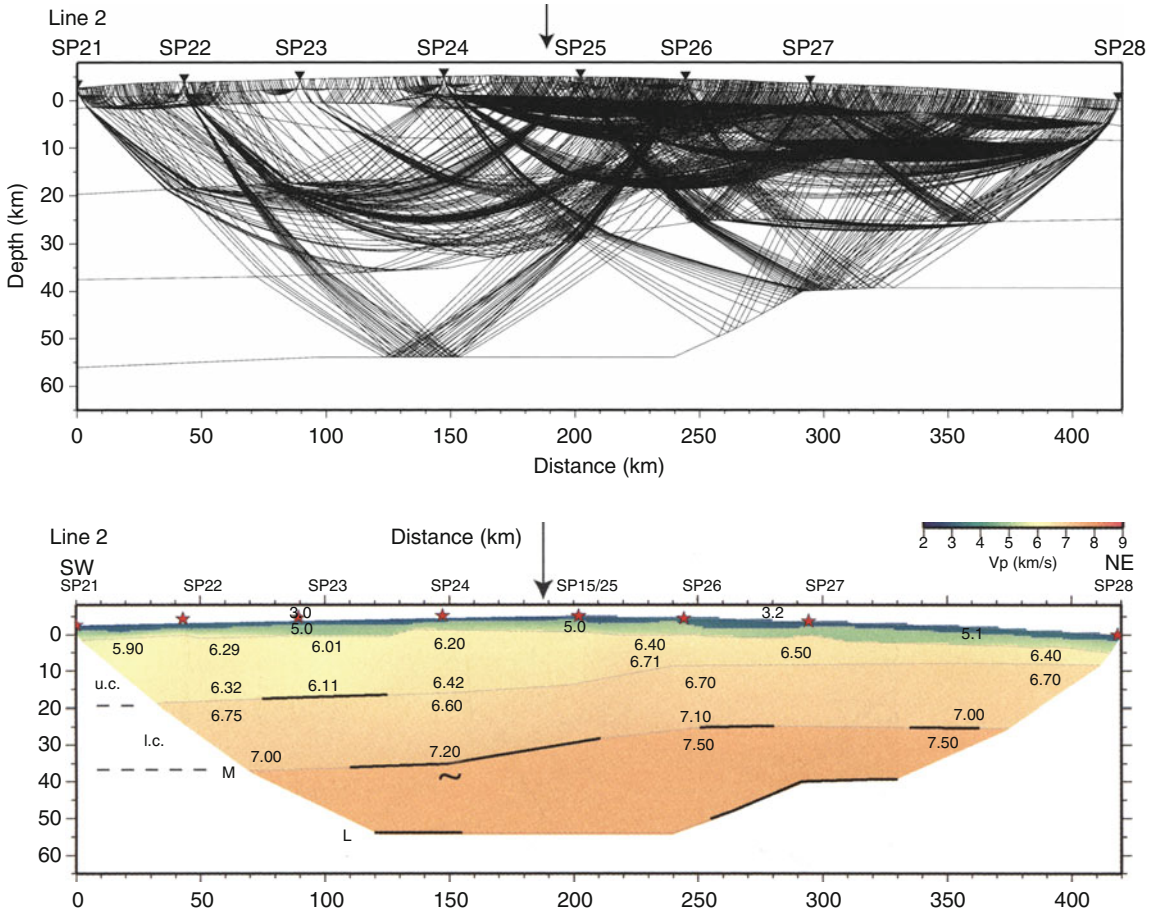
Warner (1990) reported RC values of about 0.1 for lower crustal layers and about 0.15 for Moho – both derived from the WAM profile (Peddy et al., 1989). The



Deep Seismic Reflection and Refraction Profiling, Figure 5 Schematic representation of low-angle shear near Moho (**c**) with parts of BIRPS seismic sections GRID (**a**) and NEC (**b**). For details, see Chadwick and Pharaoh (1998) (Courtesy *Tectonophysics*).

polarity (sign) of RC is important in differentiating between likely causes of bright spots sometimes seen in DSRRP images. However, even using polarity-preserving processing, it is often only possible to determine relative values of RC. ANCORP working group (2003) discusses the issues involved for a couple of strong reflectors – *Nazca and QBBS* – while reporting RC > 0.2 for the latter. Combining NMRS and WARR data, Makovsky and Klemperer (1999) report RC values between -0.3 and -0.4 for the NBS bright spot in the Tibetan middle crust.

Obtaining estimates of Q along the travel path of NMRS signals (relatively high-frequency body waves) is also difficult – the effects due to scattering, conversion,



Deep Seismic Reflection and Refraction Profiling, Figure 6 Velocity modeling by ray-tracing for the EAGLE project (in the Ethiopian rift). Note the variable coverage of the ray-tracing (*above*), and the *smooth* result, with a few long segments, in the final P-wave velocity model (*below*) – both these characteristics are typical for WARR data analysis. For details, see Maguire et al. (2006) (Courtesy *Geol. Soc. London*, with permission from the author).

etc. (apparent-Q), cannot be readily separated from the intrinsic attenuation (see also *Seismic, Viscoelastic Attenuation*). Combining the two, Hobbs (1990) obtained a value of 500 ± 200 for effective-Q for the lower crust below the WAM profile. Morozov et al. (1998) used the data from the QUARTZ profile mentioned above to obtain a 2-D Q-model for the upper mantle below this PNE-profile down to a depth of 500 km.

Research problems

The massive amount of DSRRP data collected during the past half century has not only produced many new insights, but has also brought up some (yet unsolved) problems.

Origin of crustal reflectivity, clearly visible in DSRRP images of mature continental crust, especially at greater depths, cannot be explained uniquely. Surface exposures of basement rocks mostly show steep dips; these could explain relatively transparent zones in reflection images at shallow depths. Starting at intermediate depths though, the images reveal sub-horizontal layering including strongly reflective zones. Smithson and Brown (1977, Figure 5) had already proposed a *complex* crustal model with a threefold subdivision based on geo-scientific data. DSRRP has since provided frequent evidence for both low- and high-angle intra-crustal deformation, sometimes even affecting Moho and upper mantle. The processes and the materials needed to explain these fully, remains a challenge; some of the possibilities will be briefly discussed below.

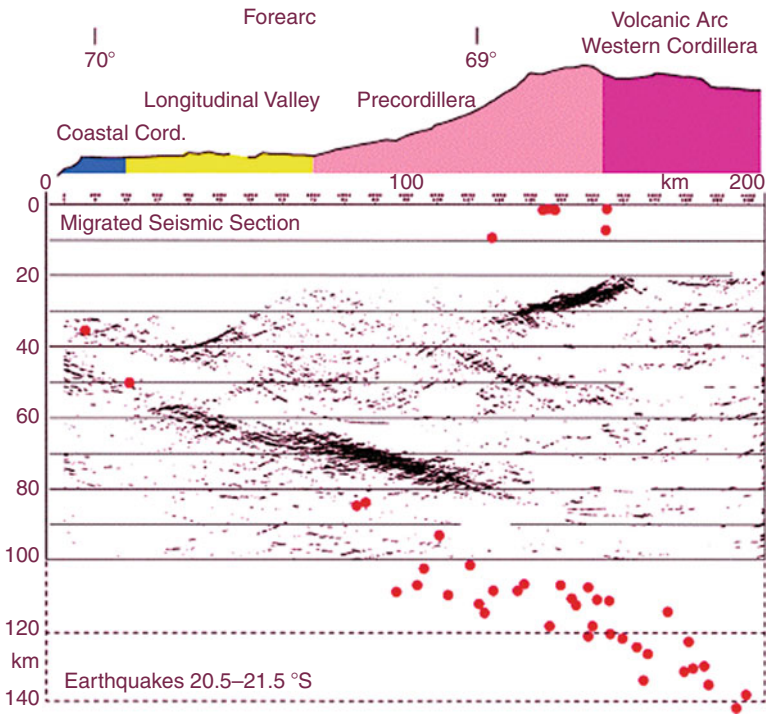
Shallow exposed structures, that are steep due to the earth's surface being stress-free, are expected to become sub-horizontal with increasing depth, and thus seismically imageable. Shear-zones, decollements, imbrications, laminae, metamorphism (facies changes, mylonitization), sill-like intrusions, and fluids (water, brine, melt, magma) have all been proposed as potential causes for crustal reflectivity, including that of Moho. Both the Kola (Smythe et al., 1994) and the KTB (Emmermann and

Lauterjung, 1997) super-deep drill holes have identified such conditions/structures at depth. Extrapolations from the drill-sites would point to the presence of crustal fluids in quantities more than that earlier expected, both in bound and free form; they undoubtedly play a major role in the tectono-thermal processes at depth (see Meissner et al. (2006) and the articles "*Earth's Structure, Continental Crust*" and "*Crustal Reflectivity (Oceanic) and Magma Chamber*" for further details).

Bright spots – zones of very strong reflectivity – present a particular challenge in this regard. Figure 7 is an interesting example of two reflective zones, probably with different, but related, origins. Nowadays, better data quality and amplitude-preserving processing often allow ruling out some causes, but may not always lead to positive conclusions. Pratt et al. (1993) investigated the Surrency bright spot (Georgia, USA), first assumed to be fluid related due to its flat nature, and concluded an (ultra)mafic body instead. Analyzing the Tibetan bright spots, Makovsky and Klemperer (1999) inferred 10% (volume) of free aqueous fluids as the cause.

Origin and nature of (*continental*) *Moho* is also not well understood, probably because this boundary – geophysically defined as a first-order transition of P-wave velocity from ≈ 6.8 to ≈ 8.2 km/s – does not always have the same evolutionary history. However, DSRRP has replaced the earlier model for (seismological) Moho, consisting of long refraction segments – more-or-less flat, by a (seismic) boundary with a complex and variable structure. At places, it seems to be the equilibrium surface established under the deviatoric stress-regime after a tectono-thermal event involving the lower crust and the upper mantle. At others, it seems to be underplated, or, overlain by sill-like intrusions, from a later magmatic episode. Elsewhere, Moho is only identifiable as the terminal zone of the diffused lower-crustal reflectivity. At many places, it exhibits enough strength though, to retain its deformation through later tectonic events; examples include *frozen subduction* (Figure 3) and *offset Moho* (Figure 4).

Role of (*multiple*) *scattering in lower crust* has attracted attention lately – both to explain observations and to relate to geological evidence. Surface outcrops of Moho (read: lower crustal and upper mantle) rocks are extremely rare in the continental setting, e.g., *Kapuskasing Uplift* (eastern Canada), Musgrave Range (central Australia), and *Ivrea-Verbano Zone, IVZ* (Northern Italy). While the first two have been studied by DSRRP (LITHOPROBE transect KSZ and Central Australian Basin transect respectively), IVZ – although sans seismics – has



Deep Seismic Reflection and Refraction Profiling, Figure 7 Migrated seismic section from the ANCORP line 2 in the Central Andean subduction zone (reproduced from http://www-app1.gfz-potsdam.de/www/pb3/dekorp/an-fig/An_line2.gif, with permission from the author). The strongly reflective zone on upper right is the *Quebrada Blanca* bright spot (QBBS), and the reflective zone dipping to the right is the Nazca reflector. Superimposed red dots show seismicity in this area of active subduction. For further details, see ANCORP working group (2003).

been extensively studied in the past by geologists, e.g., Zingg (1990) and geophysicists, e.g., Berckhemer (1969).

Recently, statistical analysis of detailed geological maps of several exposed (lower) crustal rocks have yielded the tantalizing possibility of a self-similar (fractal) description of their shapes in terms of typical *horizontal and vertical scale-lengths.* For the IVZ, a *2-D von Karman* distribution of the structure with bimodal petrology has been derived (Holliger and Levander, 1992). This raises important questions about the nature of the wave-field recorded in DSRRP experiments, and the techniques used to analyze/interpret the data. Holliger et al. (1993) computed synthetics for such a simulation of IVZ, and were able to qualitatively reproduce lower-crustal reflectivity observed in NMRS. At large distances (WARR configuration), the synthetics from the random-medium contained laterally correlatable events, which could be erroneously used for velocity analysis, migration, etc., a possibility already suggested earlier (e.g., Levander and Gibson, 1991; Emmerich et al., 1993), see also the *wide-angle squeeze* in Figure 1 between the refracted and reflected arrivals.

Another explanation offered for increased reflectivity in the lower crust, including transition zones, is lamellar structures with associated wave-propagation effects (amplitude, anisotropy); see Meissner et al. (2006) and "*Seismic Anisotropy*".

Both these possibilities, random heterogeneity and lamination, bring up the role of multiple scattering in the DSRRP wave-field and question the propriety of using conventional tools from basin exploration for processing such data. Douma and Roy Chowdhury (2001) used synthetics to show that multiple scattering has a limited effect for a 1-D bimodal model of IVZ, but also mentioned the need for 2-D full-wave numerical simulations.

In the upper mantle too, multiple scattering seems to play an important role. Menke and Chen (1984) had invoked this to explain long-range propagation of P_n-phase from earthquakes. More recently, DSRRP data from PNE profiles, e.g., QUARTZ, has shown surprisingly strong propagation of high-frequency (5 Hz.) P_n-phase to distances of 3,000 km!

Estimating descriptive parameters of a possibly random medium in lower crust and upper mantle remains an active field of research, with two different approaches – modeling and direct estimation. To explain the long-distance P_n-phase in the QUARTZ data, Ryberg et al. (1995) modeled an upper-mantle zone of *horizontally stretched, randomly distributed velocity anisotropy.* Nielsen and Thybo (2006) modeled a larger dataset (Figure 8), and inferred random heterogeneity for both lower crust and upper mantle.

Following some earlier work (Hurich, 1996; Pullammanappallil et al., 1997; Hurich, 2003; Carpentier and Roy Chowdhury, 2007), Carpentier et al. (2010) have recently analyzed the data from Line 48 of the LITHOPROBE transect AG statistically. Assuming a 2-D *von Karman* medium, they estimated the horizontal scale-length of the medium directly from the seismic wave-field (Figure 9, below), which also shows their interpretation. The comparison with an earlier line-drawing

(1995); figure courtesy *Nature*. *Below*: interpretation by Carpentier et al. (2010) overlain on their estimation of the horizontal scale-length (a_x) of the medium from the seismic data (Courtesy *Tectonophysics*).

based interpretation (above) illustrates the similarities and differences between the two approaches.

Summary

DSRRP has, over half-a-century, produced quality images of the continental crust and its margins, revealing their complex structure. These – including some unexpected results, e.g., *frozen subduction* – have contributed significantly to our ideas about the processes, current and ancient, involved in their evolution. As the deep structures, mostly inaccessible, play an important role in the development of the shallower geology, understanding these (*deep-faults*) also helps in the optimal exploration of economic resources, e.g., hydrocarbons, ore-deposits, etc., and in the study of natural hazards associated with volcanism and earthquakes.

DIFFERENTIAL ROTATION OF THE EARTH'S INNER CORE

Xiaodong Song
Department of Geology, University of Illinois at Urbana-Champaign, Urbana, IL, USA

Definition

Differential rotation of the inner core refers to the difference between the rotation of the Earth's solid inner core and the daily rotation of the Earth's crust and the mantle.

Background

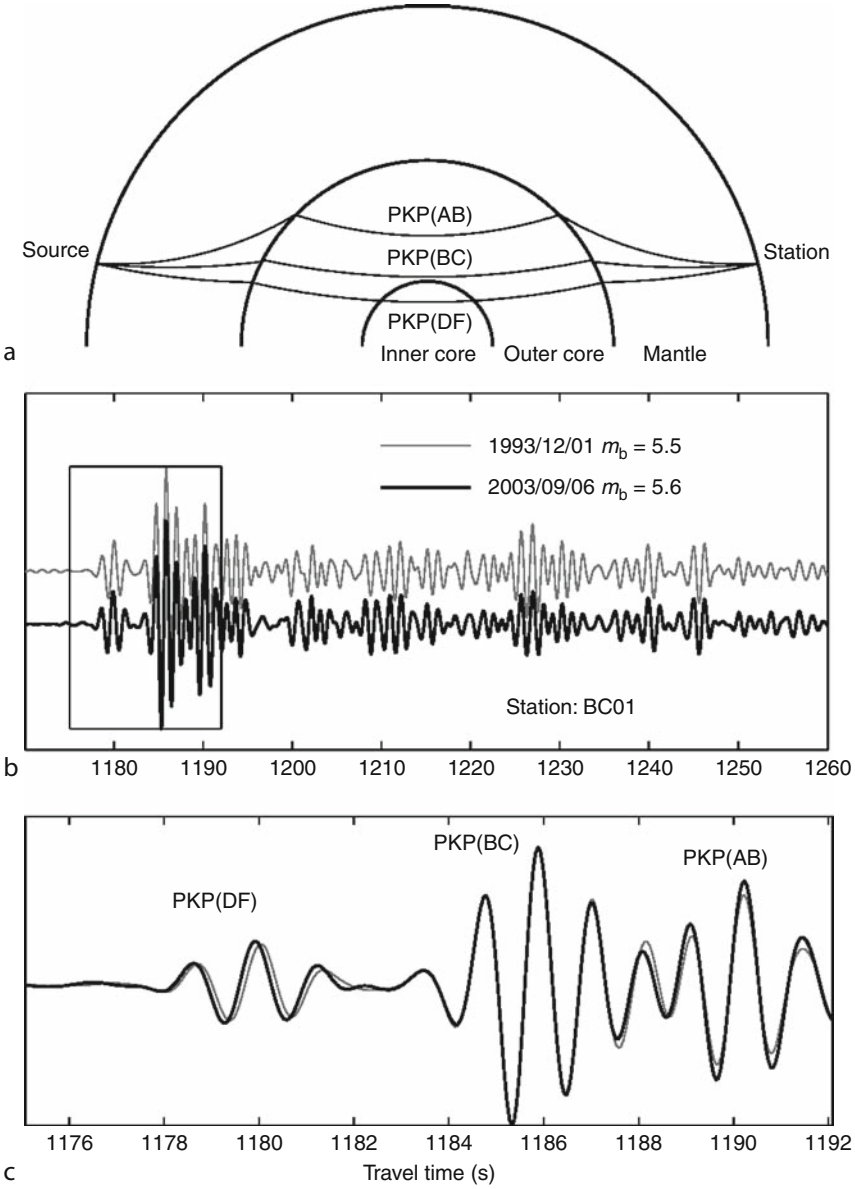
Driven by gravity, the Earth differentiated into iron core and rocky mantle at the early stage of its formation. The central core is liquid because of high temperature; but at the center of the Earth, an inner core is formed and gradually grows as the Earth cools, and the liquid iron freezes under tremendous pressure (3 million times the atmospheric pressure). The size of the inner core is slightly smaller than that of the moon. Separated from the solid mantle by the fluid outer core, the inner core is thus free to rotate independently under an external torque.

The early idea of inner core rotation came from studies of the geodynamo, which generated the Earth's magnetic field. Gubbins (1981) first suggested that electromagnetic forces between the electrically conducting inner core and the magnetic field generated in the fluid outer core would cause a differential rotation of the inner core. In a computer simulation of a three-dimensional, self-consistent geodynamo, Glatzmaier and Roberts (1995) predicted that the inner core is driven to rotate by electromagnetic coupling at a few degrees per year faster than the mantle and the crust.

Seismological observations

Song and Richards (1996) reported first evidence for differential rotation of inner core from seismic observations. The basic idea of their method is simple. They chose a fixed monitoring station and compare seismic waves that travel through the inner core from earthquakes at the same region but a few years apart. This is like the twinkling of a star, which is caused by disturbance of the light as it passes through the atmosphere (an analogy used by coauthor Paul Richards). The seismic waves used are short-period (about 1 s) longitudinal waves (P waves) that have propagated through the fluid core (generically called PKP waves) (Figure 1). At the distance range of about 146–154°, there are three possible paths, i.e., PKP(DF) waves that traverse the inner core, PKP(BC) waves that turn at the bottom of the outer core, and PKP(AB) waves that turn at the middle of the outer core. The basic data used in detecting the inner core rotation is the time difference between the PKP(BC) and PKP(DF) arrivals, abbreviated as the BC-DF time. Because these two waves travel very closely together in the crust and mantle and in most of the fluid core, the differential time BC-DF is relatively insensitive to uncertainty in source location and to three-dimensional heterogeneities of the crust and mantle along the ray paths. To remove influence of small difference in earthquake location and epicentral distance, the differential time residual is formed by subtracting the observed BC-DF time from the predicted difference for a standard earth model. In addition, residuals of the differential times between PKP(AB) and PKP(BC), which pass through the fluid core only, are used to examine possible systematic biases in source locations.

Song and Richards found that BC-DF residuals along certain paths have changed systematically with time over a few decades. In particular, the seismic waves that emanate from earthquakes in South Sandwich Islands in the South Atlantic travel through the inner core and reach



Differential Rotation of the Earth's Inner Core, Figure 1 Ray paths of PKP waves and example of waveform doublet used to detect temporal change of travel times through the inner core. (**a**) Ray paths of three branches of PKP waves turning in the solid inner core (DF), the bottom of the fluid outer core (BC), and the mid-outer core (AB). (**b**) Highly similar waveforms recorded at one station in Alaska from a waveform doublet from South Sandwich Islands. The two events are 10 years apart, one in 1993 and the other in 2003. (**c**) Superimposed and enlarged PKP waveforms from the box in (**b**). The waves through the outer core (BC and AB) are aligned, but the wave through the inner core (DF) shows a small time shift (about 0.1 s). (From Zhang et al., 2005).

College, Alaska seismic station. They have sped up systematically by about 0.3 s over 28 year-year time interval from 1967–1995. They interpreted the temporal change as evidence of an inner core rotation.

The estimate of the rotation rate depends on the underlying aspherical structure of the inner core that results the temporal change from a rotation. The inner core is known to be very anisotropic (i.e., seismic waves traveling through the inner core along different directions have different speeds) (Morelli et al., 1986; Woodhouse et al., 1986; see also review by Song, 1997; Tromp, 2001). The anisotropy is roughly axis-symmetric with the P-wave speed faster by some 3% along the Earth's rotation axis than along the equatorial plane. However, the anisotropy changes significantly laterally and with depth. The observed temporal change in BC-DF residuals was first interpreted as a change of the orientation of the fast axis of the inner core anisotropy, which yielded a rate of

1.1° per year (Song and Richards, 1996), but it was later and preferably interpreted as a shift of lateral velocity gradient in the inner core caused by the inner core rotation (Creager, 1997; Song, 2000), which yielded a rate ranging from 0.2–0.3 to 0.3–1.1° per year.

Subsequent studies provided further support and most estimates of the rotation rate are a few tenths of a degree per year faster than the rotation of the Earth (a super-rotation) (see reviews by Tromp, 2001; Song, 2003; and Souriau et al., 2003). The methods used include BC-DF times for additional paths (Ovchinnikov et al., 1998; Song and Li, 2000; Xu and Song, 2003), inner core scattering waves (Vidale et al., 2000), so-called earthquake waveform doublets (Li and Richards, 2003; Zhang et al., 2005; see below), and normal modes (Laske and Masters, 2003). However, whether the inner core rotation is real has also been hotly debated because of potential biases such as earthquake mislocation (e.g., Poupinet et al., 2000), failure to detect the motion (Souriau, 1998), and discrepancy in the inferred rotation rate (e.g., Creager, 1997; Vidale et al., 2000; Laske and Masters, 2003).

The most important source of errors is systematic event mislocation. Because global stations used to locate the earthquakes are not exactly the same in different years, the temporal variation could potentially be an artifact of the changes of the station distributions (Poupinet et al., 2000; Souriau et al., 2003). To resolve the debate, the two sides (Dr. Poupinet and the author) worked directly in 2004–2007. A thorough presentation of the collaborative work was published (Sun et al., 2006). The basic conclusion is that earthquake mislocation is too small to explain the observed time shifts in the data, and that inner core rotation is still the best explanation.

Perhaps the strongest support comes from studies of earthquake waveform doublets (Zhang et al., 2005). A waveform doublet is a pair of earthquakes occurring at different times but at essentially the same spatial position, as evidenced by their highly similar waveforms at each station recording both events (Poupinet et al., 1984). Zhang et al. (2005) observed that the waves that traveled through the area outside the inner core, in the crust, the mantle, and the outer core are all the same. Only when they travel through the inner core at different times are they different (Figure 1). The changes are two folds: first, and most prominently, the PKP(DF) waves (passing through the inner core) move faster in a systematic pattern over time, by about one tenth of a second per decade; second, the PKP(DF) waves themselves change in shape over time, an independent signature for motion of the inner core. The fact that the wave shapes are similar when they emanate from the source region allows them to measure precisely the small time shifts and to pin down precisely where the changes took place. The temporal change of BC-DF differential times for the South Sandwich Islands to College, Alaska path is constrained to be 0.0092 s/year with standard deviation of 0.0004 s/year. The best estimate of the rotation rate is 0.3–0.5° per year faster than the Earth's mantle. Subsequent studies of earthquake doublets suggest that the waves bouncing off the inner core boundary also shows temporal variation (Wen, 2006; Cao et al., 2007; Song and Dai, 2008).

Concluding remarks

The discovery of the inner core super-rotation has attracted attention of the academia and popular media. It has implications for understanding the geodynamo and angular momentum transfer in the interior of the Earth (Buffett and Glatzmaier, 2000). The origin of the Earth's magnetic field has been regarded as one of the great unsolved problems in modern physics. The observation of the inner core rotation provides a unique observational constraint on the geodynamo at the center of the earth.

The existence of the differential rotation of the inner core has now generally, although not universally, been accepted. However, major questions remain. What is the acceptable range of the rotation rate? Is the inner core rotation variable? Does the rotation change direction? Does the inner core oscillate within a certain range? The inner core possesses large hemispheric scale variations (Tanaka and Hamaguchi, 1997; Niu and Wen, 2001). This is difficult to reconcile with an inner core of a constant rotation, which may be expected to average out the lateral varying structure of the inner core over geological time as the inner core grows from the crystallization of liquid iron. If the rotation is variable or oscillating, what is the time scale? What is the driving force? How does it relate to the geodynamo processes? Recently, Lindner et al. (2010) proposed a nonparametric modeling method, which is able to separate mantle structure, inner core structure, and inner core motion. The study suggests an average rate of inner-core rotation of about 0.39° per year and that the rotation has accelerated from about 0.24° to about 0.56° per year within the last 55 years. The speed of the differential rotation, averaging about 10 km per year at the inner core equator, is by 50,000 times the fastest motion of the tectonic plates (20 cm per year) at the Earth's surface. The minimum torque acting on the inner core is estimated 1.19×10^{16} N m, which could easily result from the imbalance of much larger electromagnetic and gravitational torques. With the continuing accumulation of high quality seismic data, I believe we'll reach a new understanding on the inner core motion within next 50 years.

EARTH ROTATION

Harald Schuh, Sigrid Böhm
Research Group Advanced Geodesy, Institute of Geodesy and Geophysics, Vienna University of Technology, Vienna, Austria

Definition

Earth. Solid Earth including oceans and atmosphere.
Earth rotation. Temporal variation of the orientation and the rotation speed of the Earth.

Introduction

The rotation of the Earth or Earth rotation, respectively, specifies the spatiotemporal change of the Earth rotation vector. The direction of the Earth rotation vector corresponds to the instantaneous rotation axis of the Earth and its absolute value equals the rotation speed. The Earth's rotation is not uniform and is given in terms of Earth orientation parameters (EOP): *precession* and *nutation* are long-term and periodic changes of the direction of the Earth rotation vector with respect to a space-fixed reference system. *Polar motion* is the variation of the direction of the Earth rotation vector with respect to an Earth-fixed reference system (qv *Geodesy, Networks and Reference Systems*). Changes in the Earth rotation speed are expressed as deviations of *Universal Time 1* (UT1) from the uniform atomic time (*Universal Time Coordinated*, UTC) *dUT1* = UT1−UTC or as variations in the *length of day* (LOD). The subgroup of *polar motion* and *dUT1* or LOD is called Earth rotation parameters (ERP). Fundamental information on Earth rotation theory and observation and about the relations of Earth rotation variations with geophysical processes is given in the seminal works of Munk and MacDonald (1960), Lambeck (1980), and Moritz and Mueller (1987).

While the existence of *precession* was already known to the Greek astronomer Hipparch in the second century before Christ, *nutation* was not discovered before the eighteenth century by James Bradley. Observations of *polar motion* were taken for the first time by the Bonn astronomer Friedrich Küstner at the end of the nineteenth century by measuring latitude variations. From the seventies of the twentieth century onward, space geodetic techniques like *Very Long Baseline Interferometry* (VLBI) (qv *Very Long Baseline Interferometry (VLBI)*), *Satellite Laser Ranging* (SLR) (qv *Satellite Laser Ranging*), *Lunar Laser Ranging* (LLR), *Doppler Orbitography and Radiopositioning Integrated by Satellite* (DORIS), and the *Global Navigation Satellite Systems* (GNSS) like the *Global Positioning System* (GPS) (qv *GPS, Data Acquisition and Analysis*) have been employed in addition to astronomical methods. Approximately since the year 2000, the latter are no longer routinely applied. Nowadays, the achievable accuracies of the measurements are better than 2×10^{-4} arcsec or less than 0.6 cm, if projected to the Earth surface. EOP can be determined from space geodetic observations within the respective parameter estimation process. The transformation between Earth-fixed and space-fixed system and thus the EOP are thereby components of the technique's observation equation and can be solved for as unknowns. The most precise technique to observe polar motion is GNSS, whereas *nutation* and *dUT1* can be measured directly only by VLBI. Due to the correlation of *nutation* and *dUT1* with the orbital elements of the satellites, satellite techniques are only sensitive to the time derivation of those parameters i.e., *nutation rates* and LOD. Promising new devices for the observation of high frequency variations of the instantaneous Earth rotation vector are large ring laser gyroscopes. These instruments can access absolute rotation by measuring the beat frequency of two laser beams rotating in opposite direction, the *Sagnac frequency* (Schreiber

Harsh K. Gupta (ed.), *Encyclopedia of Solid Earth Geophysics*, DOI 10.1007/978-90-481-8702-7,

et al., 2004). Information about the long-term behavior of the EOP is obtained from historical records of lunar and solar eclipses and from the analysis of sedimentary deposition. Evidence for a secular increase in LOD can be found for instance in paleontological studies of coral growth rate.

The observed EOP show a wide spectrum of variations. Its interpretation allows for drawing valuable conclusions about the structure of the Earth and the dynamical features of the Earth's interior, the atmosphere, hydrosphere, and cryosphere. Even anthropogenic influences on Earth rotation such as the impact of mass transfer due to an increased CO_2 emission are subject of scientific investigations (de Viron et al., 2002).

Medium and long-period as well as long-term mass displacements affect Earth rotation (cf. e.g., Gross (2007) or Seitz and Schuh (2010) for a comprehensive compilation and further references). According to the conservation of total angular momentum of the Earth in short terms, the rotation of the solid Earth undergoes variations, which are mirror image to changes in atmosphere and oceans. Any mass variation in one or more components of the system Earth which changes the Earth inertia tensor leads to a corresponding variation in the Earth rotation. One can also think of a mass movement which does not change the inertia tensor, because once a mass element moved away it is replaced by another, like in a circular ocean current. Such a mass transport causes a motion relative to the considered reference frame which affects Earth rotation as well. In which way changes of the inertia tensor and relative motions can be related to variations in Earth rotation is shown in the successive section.

Mathematical formulation of Earth rotation

The dynamical equation of motion of a rotating body with respect to a space-fixed system is given by

$$\boldsymbol{L} = \frac{\mathrm{d}\boldsymbol{H}}{\mathrm{d}t} \tag{1}$$

relating the torque L acting on the body to the temporal change of its angular momentum H. This is the basic relation for the development of (Newtonian) *precession/nutation* theories, since it describes the motion of the rotating body in a space-fixed reference system. To characterize *polar motion* and changes of the rotation rate of a rotating body, Equation 1 has to be referred to body-fixed axes, rotating with the angular velocity ω:

$$\boldsymbol{L} = \frac{\mathrm{d}\boldsymbol{H}}{\mathrm{d}t} + \boldsymbol{\omega} \times \boldsymbol{H} \tag{2}$$

This is one form of *Euler's dynamical equations* for rigid body rotation referred to a body-fixed coordinate system. The angular momentum H can be expressed as the product of the tensor of inertia I and the angular velocity vector ω. The inertia tensor is a symmetric matrix containing the moments of inertia and the products of inertia of a rotating body and thus characterizing the mass distribution in the body. Since single particles do not move with respect to the body-fixed system, this tensor is invariant in the case of a rigid body. For a nonrigid (deformable) body, the inertia tensor becomes time variable and the particles can move with respect to the body-frame, thus allowing for relative motions which introduce relative angular momentum. The angular momentum H of a rotating deformable body is then written as

$$\boldsymbol{H} = \boldsymbol{I}\boldsymbol{\omega} + \boldsymbol{h} \tag{3}$$

with h denoting relative angular momentum. The first summand is often referred to as *mass* or *matter term* and the second is called *motion term*. As the Earth is a nonrigid body, the equation of rotational motion 2 has to be extended considering the above stated differences to the motion of a rigid body, leading to

$$\boldsymbol{L} = \frac{\mathrm{d}}{\mathrm{d}t}(\boldsymbol{I}\boldsymbol{\omega} + \boldsymbol{h}) + \boldsymbol{\omega} \times (\boldsymbol{I}\boldsymbol{\omega} + \boldsymbol{h}) \tag{4}$$

These are the *Euler–Liouville equations* or simply *Liouville equations*. The deviations from uniform, rigid rotation are formulated as follows for the rotation vector $\boldsymbol{\omega}$:

$$\omega_1 = \Omega m_1,\ \omega_2 = \Omega m_2,\ \omega_3 = \Omega(1 + m_3) \tag{5}$$

where Ω is the mean angular velocity of the Earth. The m_i are small dimensionless quantities describing the excursions of the rotation vector from its uniform rotation due to time-variable changes in the mass distribution of the Earth system and relative particle motion. Assuming the body-fixed axes to be principal axes of inertia and the body to be rotationally symmetric, these mass changes can be taken into consideration by composing the tensor of inertia from constant and time-variable parts:

$$\begin{aligned} &I_{11} = A + \Delta I_{11} \quad I_{22} = A + \Delta I_{22} \quad I_{33} = C + \Delta I_{33}, \\ &I_{ij} = \Delta I_{ij}, \qquad\qquad i \neq j \end{aligned} \tag{6}$$

where the constant parts are the polar moment of inertia C and the equatorial moment of inertia A of the undeformed Earth and the time-variable components are the quantities ΔI_{ij}. If second-order terms are neglected and the relations 5 and 6 are introduced, the linearized equations of motion can be rewritten as

$$\begin{aligned} m_1 - \frac{1}{\sigma_E}\dot{m}_2 &= \psi_1, \\ m_2 + \frac{1}{\sigma_E}\dot{m}_1 &= \psi_2, \\ m_3 &= \psi_3 + const. \end{aligned} \tag{7}$$

with $\sigma_E = \left(\frac{C-A}{A}\right)\Omega$ being the *Euler frequency*, which would be the frequency of the resonance of a rigid Earth, corresponding to a circular motion of the rotation axis with a period of approximately 305 days. If the Earth is considered to be an elastic or at least deformable body the *Euler frequency* is replaced by the complex *Chandler frequency*

$\sigma_C = \frac{2\pi}{T_C}\left(1+\frac{i}{2Q}\right)$, with $T_C \sim 433$ days denoting the observed period of the *Chandler wobble* and $Q = 30\ldots200$ being a dimensionless dissipation factor (see next section for a brief discussion of the *Chandler wobble*). The ψ_i are called *excitation functions*. They contain the changes of the tensor of inertia and the relative angular momenta:

$$\begin{aligned}
\psi_1 &= \frac{1}{\Omega^2(C-A)}\left[\Omega^2\Delta I_{13}+\Omega\Delta\dot{I}_{23}+\Omega h_1+\dot{h}_2-L_2\right]\\
\psi_2 &= \frac{1}{\Omega^2(C-A)}\left[\Omega^2\Delta I_{23}-\Omega\Delta\dot{I}_{13}+\Omega h_2-\dot{h}_1+L_1\right]\\
\psi_3 &= \frac{-1}{\Omega^2\mathbf{C}}\left[\Omega^2\Delta I_{33}+\Omega h_3-\Omega\int_0^t L_3\,\mathrm{d}t\right]
\end{aligned} \tag{8}$$

The first two equations of 7 for m_1 and m_2 express *polar motion*, while the third equation for m_3 describes the magnitude of the rotation speed and hence LOD variations. Provided that all the time-variable parts of the *excitation functions* (changes of the inertia tensor ΔI_{ij}, relative angular momenta h_i, and external torques L_i) are introduced as known quantities from models or observations, the *Euler–Liouville equations* can be solved for ω. Earth rotation variations can be thus calculated or predicted, respectively, from observed or modeled changes in the components of the system Earth, such as atmosphere or oceans. In general, relative motions (relative angular momenta) contribute more to LOD variations while the major effect on *polar motion* comes from alterations of the inertia tensor. The *excitation functions* are in practice mostly replaced by so-called *angular momentum functions*, introduced by Barnes et al. (1983). Elaborate explications of the basic Earth rotation formalism can be found in the fundamental books mentioned in the introduction.

Definition and observation of Earth orientation parameters

The elements which are used to perform the transformation between a space-fixed and an Earth-fixed reference system are commonly referred to as EOP. The realizations of such reference systems by assigning coordinates to selected celestial objects or terrestrial sites, respectively, are called reference frames. The definition and maintenance of the reference frames is one major task of the *International Earth Rotation and Reference Systems Service* (IERS). Conventional reference frames are the space-fixed *International Celestial Reference Frame* (ICRF) and the Earth-fixed *International Terrestrial Reference Frame* (ITRF). The current version of the ICRF is its second realization, the ICRF2 (Fey et al., 2009). The ITRF2008 has been adopted as the official terrestrial reference frame, following ITRF2005 (Altamimi et al., 2007). The definition of the EOP actually depends on the kind of the applied transformation method. The IERS recommends the transformation according to the IAU (*International Astronomical Union*) 2000 Resolutions (McCarthy and Petit, 2004). The transformation procedure is defined from the *Geocentric Celestial Reference System* (GCRS) to the *International Terrestrial Reference System* (ITRS) or vice versa. The ICRS is not a geocentric system – its origin is located in the barycenter of the solar system. To transfer from a barycentric system to a geocentric system, effects, which are not directly related to Earth rotation, like aberration and parallaxes have to be taken into account. The orientation of the ICRS however corresponds to the orientation of the GCRS. The transition from the GCRS to the ITRS is described as a sequence of time-dependent rotation matrices:

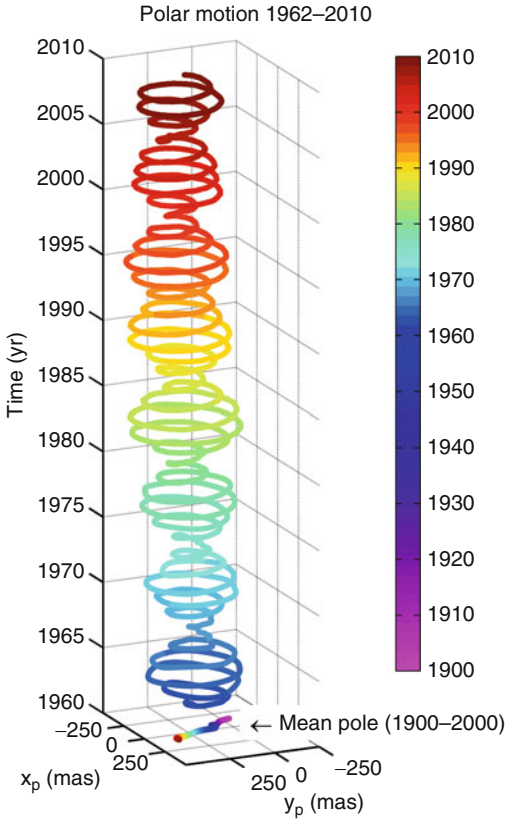
$$[\mathbf{ITRS}] = \boldsymbol{W}(t)\cdot\boldsymbol{R}(t)\cdot\boldsymbol{Q}(t)\cdot[\mathbf{GCRS}] \tag{9}$$

$\mathbf{W}(t)$ (with "W" for wobble) designates the *polar motion* matrix. It contains the coordinates x_p and y_p of the reference pole CIP (*Celestial Intermediate Pole*) in the Earth-fixed system and the angle s', which provides the position of the TIO (*Terrestrial Intermediate Origin*) on the equator of the CIP. The TIO and the *Celestial Intermediate Origin* (CIO) realize an instantaneous prime meridian in the respective system. These terms are part of the transformation concept using the *Non-Rotating Origin* (NRO), which replaced the older transformation scheme with ecliptic (plane of the Earth orbit) and equator (McCarthy and Petit, 2004). The rotation between TIO and CIO is performed with $\boldsymbol{R}(t)$ using a quantity named *Earth Rotation Angle* (*ERA*). The *ERA* is directly related to UT1, which is relevant for Earth rotation research. *Precession* and *nutation* are represented by the matrix $\boldsymbol{Q}(t)$. It comprises rotations around the angles X and Y, the coordinates of the CIP in the celestial system and around the angle s, which locates the CIO on the equator of the CIP. In case of using the transformation according to IAU 2000 resolutions, the five quantities $\{x_p, y_p, dUT1, X, Y\}$ therefore represent the EOP. If the older transformation concept based on ecliptic and equator is applied, X and Y are replaced by $\Delta\varepsilon$ and $\Delta\psi$, *nutation* in obliquity and longitude. The before cited *Celestial Intermediate Pole* is the reference pole measurements of space geodetic techniques are related to. The CIP thus defines the observed axis. This is a pure convention, which is realized by an accordingly adapted *precession-nutation* theory. The direction towards the CIP does not correspond to any physically defined axis, like the rotation axis, the figure axis, or the angular momentum axis; nevertheless, it is possible to mathematically connect it to each of those axes. Casually, it is often said that Earth rotation observations represent the motion of the Earth rotation axis. Regarding the measurements of space geodetic techniques, this is actually not entirely correct, since they are not sensitive to the instantaneous Earth rotation vector but to the complete rotation matrix only. The CIP defines an intermediate pole, separating the motion of the pole of the ITRS in the GCRS into a celestial part and a terrestrial part. The celestial part

(*precession* and *nutation*, $\{X, Y\}$) comprises all motions with periods greater than 2 days, as seen from space. This is equivalent to frequencies between −0.5 and +0.5 cycles per sidereal day (cpsd). With the minus sign labeling retrograde motions (opposite to the sense of Earth rotation) and the plus sign labeling prograde motions (in the sense of Earth rotation), all motions outside of the retrograde diurnal band in the Earth-fixed system, i.e., frequencies below −1.5 and above −0.5 cpsd, are allocated to the terrestrial part (*polar motion*, $\{x_p, y_p\}$).

The celestial motions, *precession* and *nutation,* are long-term and periodic changes of the direction of the Earth rotation axis or actually of the CIP axis, with respect to a space-fixed reference system, which is realized, for example, by the positions of extragalactic radio sources observed by VLBI. Due to *precession*, the Earth axis moves with respect to the space-fixed system on a cone with an aperture of 23.5°, which corresponds to the angle between the Earth equator plane and the ecliptic. The revolution period amounts to approximately 25,800 years. This time interval is also called Platonic year. The tidal forces of moon and sun are responsible for this steady motion. Since the Earth is not a sphere, but can be characterized as an oblate spheroid (qv *Geodesy, Figure of the Earth*) and its rotation axis is inclined by 23.5° with respect to the ecliptic normal, the gravitational torques force the equatorial plane into the ecliptic. Because of its rotation, the Earth acts like a gyroscope and swerves by moving on the above-mentioned cone, whose surface can be calculated very precisely.

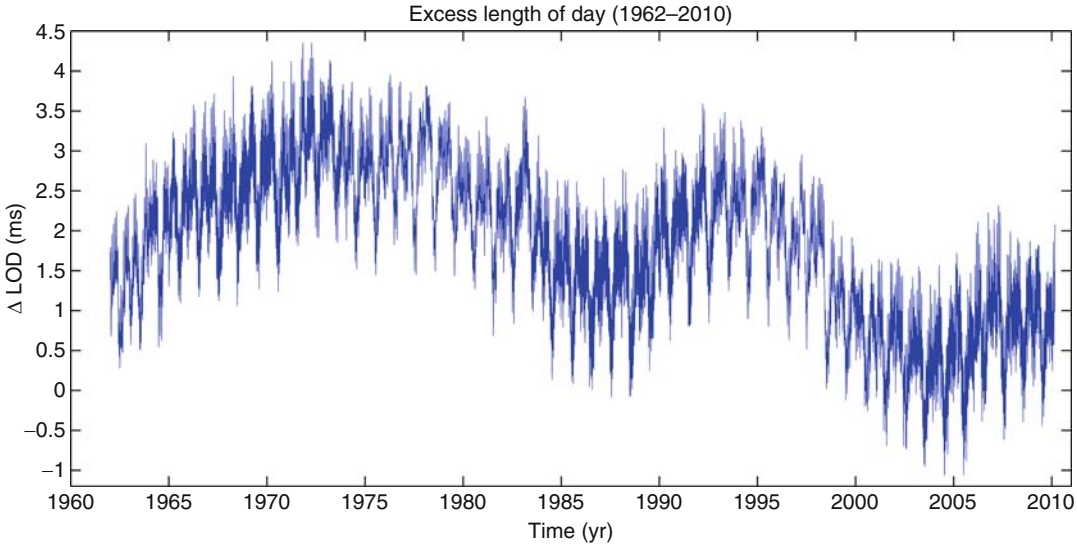
The smaller periodic change in the direction of the Earth rotation axis that is superimposed to *precession* is called *nutation*. This comprises motions of the Earth rotation axis with respect to the space-fixed system with periods from a few days to 18.6 years, caused by gravitational influences of sun, moon, and the planets of our solar system. *Precession* and *nutation* can be modeled and predicted precisely using time-dependent harmonic series expansions. The arguments of the individual harmonic terms are thereby calculated from combinations of five fundamental astronomical arguments. The currently most precise *precession-nutation* model adopted by IAU resolutions 2000 and 2006 (IAU Resolutions, 2000; IAU Resolutions, 2006) is IAU 2006/2000A. In this model effects of planets, ocean tides, mantle anelasticity, and electromagnetic coupling mechanisms between core and mantle as well as between inner and outer core are considered (Mathews et al., 2002). As for the planets, their direct effect on Earth as well as the indirect effect of the sun acting on a planet, which also causes subtle *nutation* terms, are taken into account. Remaining parts of the axis motion with respect to the space-fixed system that are not covered by the *precession–nutation* model can be measured by means of VLBI and are provided by the IERS as so-called *Celestial Pole Offsets*. These residuals originate from still deficiently modeled and unpredictable effects, like the *Free Core Nutation* (FCN). The FCN is a proper mode of the Earth, caused by a misalignment of the rotation axes



Earth Rotation, Figure 1 *Polar motion* from the combined EOP series C04 05 of the IERS (1962–2010, daily resolution) and position of the mean pole from 1900 to 2010.

of mantle and core. Whereas first theoretical estimations indicated a period of about 460 days for this mode, VLBI measurements show that the FCN period is more likely to be around 430 days with highly variable amplitude.

The terrestrial part of the change of the direction of the Earth axis or rather the CIP axis is designated *polar motion* (Figure 1). *Polar motion* has an order of magnitude of several meters and is expressed in a two-dimensional coordinate system by the *pole coordinates* x_p and y_p. According to the definition of the IERS and its precedent organizations, the *x*-axis is oriented in the direction of the Greenwich Meridian and the *y*-axis is oriented positively towards 90° west longitude. Already in 1765, the Swiss mathematician Leonhard Euler calculated a circular motion of the pole (of an Earth at that time assumed to be rigid) with a period of around 304 days. Today, we know that *polar motion* is mainly composed from an annual variation and the *Chandler oscillation* or *Chandler wobble*, named after Seth Carlo Chandler who first detected a period of approximately 14 months when analyzing *polar motion* observations at the end of the nineteenth century. The *Chandler wobble* is another proper motion of the Earth with strongly varying amplitude. More precisely, this nearly circular motion is a damped oscillation, which would have vanished due to



Earth Rotation, Figure 2 Excess length of day from the combined EOP series C04 05 of the IERS (1962–2010, daily resolution).

friction in the Earth interior after a few decades if there was not a constantly revolving excitation. Although the *Chandler oscillation* is known for more than 100 years, its underlying excitation mechanism is still under investigation. Today, there is broad consensus that the necessary excitation energy emerges from irregular processes in the atmosphere-ocean-system (Gross, 2000). A radical change in the phase of the *Chandler wobble* around 1925 could also not yet fully be explained. Variations of the Earth magnetic field are nowadays quoted as potential causes for the phase variations. The interference of the *Chandler wobble* and the annual motion leads to a beat-like rising and ebbing of the *polar motion* amplitude to a maximum of 9 m with a beat period of about 6.3 years. The *polar motion* spectrum below 1 year is dominated by irregular variations appearing in 3- and 5-months intervals. The most important short-period variations are due to the ocean tides caused by sun and moon with essentially diurnal and semidiurnal periods, albeit the total effect is only about 1/100 of the *Chandler wobble*. Analysis of long-term *polar motion* shows a distinct variation of approximately 11 years. It is usually associated with processes in the Earth interior but could also be connected to a corresponding cycle of the solar activity. In addition there are other, decadal variations with periods around 30 years and between 70 and 80 years. These are assumed to be caused by geodynamic couplings between Earth core and mantle. Secular *polar motion*, i.e., the long-term linear trend in the position of the pole, amounts to about 3.3 mas/year to the direction 76–78° west longitude (e.g., Schuh et al., 2001). This effect is supposed to be predominantly due to melting of the polar ice masses and postglacial rebound.

LOD is used to express the speed of Earth rotation alternatively to the difference *dUT1* between UT1, which is directly connected to the Earth rotation speed, and the regular atomic time UTC. The parameter, which is usually quoted to characterize changes in LOD, is actually *ΔLOD*, the so-called excess LOD which represents the deviation of the effective LOD from the nominal value of 86,400 s (Figure 2). Variations of LOD can be assigned to different period ranges. In the short-period range with periods from around 1 day and half a day, the strongest influence emerges from the ocean tides caused by sun and moon. Hydrodynamic models or altimetry (qv *Geoid Determination, Theory and Principles*) provide variations of ocean heights and velocities of the water masses, from which global changes of angular momentum of the world oceans are calculated. These are subsequently used to estimate the oceanic influence on the Earth rotation parameters. In this way high-frequency ERP variations can be predicted from tide and circulation models and they can already be observed by the high-precision space geodetic techniques mentioned above. In the range of a few weeks to months, periods of ∼14 and ∼28 days, due to solid Earth tides (qv *Earth Tides*), are dominant. In addition, there are other strong variations between 40 and 90 days basically excited by zonal winds. Seasonal variations due to changes in the angular momentum of the atmosphere show semiannual and annual periods. The variation of LOD with a period of approximately 1 year is predominantly due to annually changing wind patterns. A definite amplification of the annual variation every 4–6 years is associated with large-scale climate signals related to the El Niño phenomenon by which an ocean circulation with a very characteristic pattern in the Southern Pacific is connected to variations of the meteorological parameters. Decadal fluctuations of LOD are attributed to angular momentum changes in the fluid core, which are transferred to the mantle via mechanic or

electromagnetic coupling. Because of tidal friction and long-term mass variations, a secular prolongation of the day by about 1.8 ms in 100 years is observed as well (Morrison and Stephenson, 2001). This is, of course, an average long-term trend deduced from eclipse data over the last 2,500 years. Besides the secular trend, there is also evidence of fluctuations of LOD on a timescale of centuries with an amplitude of around 4 ms.

IERS International Earth Rotation and Reference Systems Service

The IERS is an international service for the determination of EOP and their dissemination to interested users. The definition and realization of reference systems for geodesy and astronomy can be regarded as its superior task. According to the terms of reference (Dick and Richter, 2009), the primary objectives of the IERS are to serve the astronomical, geodetic, and geophysical communities by providing the following:

- The International Celestial Reference System (ICRS) and its realization, the International Celestial Reference Frame (ICRF).
- The International Terrestrial Reference System (ITRS) and its realization, the International Terrestrial Reference Frame (ITRF).
- EOP required to study Earth orientation variations and to transform between the ICRF and the ITRF.
- Geophysical data to interpret time/space variations in the ICRF, ITRF, or EOP, and to model such variations.
- Standards, constants, and models (i.e., conventions) encouraging international adherence.

In addition, the IERS collects, archives, and distributes several products such as reference frames, monthly Earth orientation data, daily rapid service estimates of near real-time Earth orientation data and their predictions. The IERS also announces the differences between astronomical and civil time for time distribution by radio stations and leap seconds which – if necessary to keep the differences *dUT1* smaller than 0.9 s – are added at midnight of July 31st or December 31st. Further products are related to global geophysical fluids such as mass and angular momentum distribution, annual reports, and technical notes on conventions and other topics, and long-term Earth orientation information. The IERS began operation on 1st of January 1988 as common institution of the IAU and the *International Union of Geodesy and Geophysics* (IUGG) and replaced thereby the former *International Polar Motion Service* (IPMS) and the Earth rotation section of the *Bureau International de l'Heure* (BIH). The service consists among other parts of a Central Bureau, technique centers of the single-space geodetic techniques and several product centers, for example, for the collection of data about geophysical influences on Earth rotation (*Global Geophysical Fluids Centre*, GGFC). These are atmospheric and oceanic variations, hydrodynamical effects like groundwater variations and processes in the Earth interior which lead to changes in the rotational behavior of the Earth. The Central Bureau is located at the BKG (*Bundesamt für Kartographie und Geodäsie*) in Frankfurt am Main, Germany. Apart from regular publication of EOP, the IERS also issues guidelines (IERS Conventions, McCarthy and Petit (2004)), which contain models and standards recommended for the data processing of space geodetic techniques.

Summary

Earth rotation is conventionally described by the EOP, which represent the link between a space-fixed (celestial) and an Earth-fixed (terrestrial) coordinate system. Those EOP expressing the temporal variations of the orientation of the Earth correspond to *nutation/precession* (changes of the direction of Earth rotation axis with respect to a space-fixed reference frame) and *polar motion* (wobbling of the Earth with respect to its axis). Small variations of the speed of Earth rotation are expressed by UT1 minus the uniform atomic time (UTC) or as variations in the LOD. A precise knowledge of the Earth's attitude is needed for all positioning and navigation tasks on Earth and in space. It also gives fundamental information about the interactions between the various geophysical components of system Earth and allows deriving conclusions about phenomena of celestial mechanics. The EOP are nowadays monitored by space geodetic techniques and assembled and published by the IERS.

EARTH TIDES

John M. Wahr
Department of Physics and Cooperative Institute for Research in Environmental Sciences, University of Colorado, Boulder, CO, USA

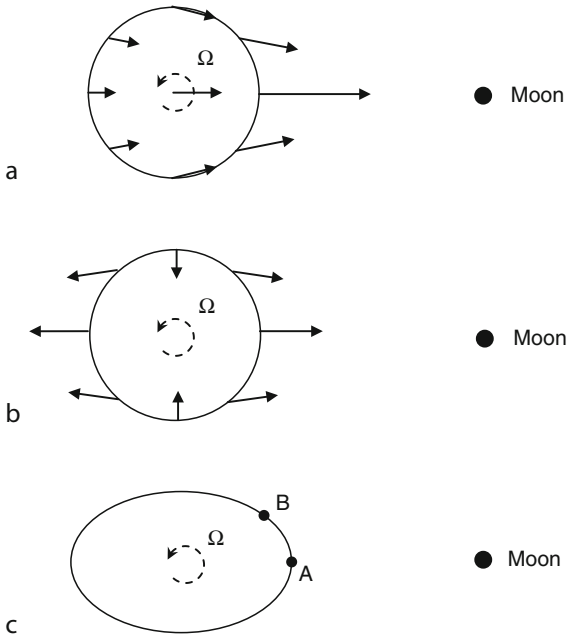
Definition

The earth tide is the deformation of the solid earth caused by the gravitational attraction of the Sun and moon. The most striking gravitational effects of the Sun and moon are the orbital motion of the earth's center of mass. The moon causes the earth to orbit the earth–moon center of mass, and the Sun causes that center of mass to orbit the Sun.

The Tidal Force

But the Sun and moon also cause points within the earth to be displaced relative to each other: they cause the earth to deform. For example, the side of the earth nearest the moon is attracted toward the moon more than is the center of the earth. And the side farthest from the moon is attracted less than the center of the earth. Consequently, both the far and near sides of the earth are pulled radially outward away from the center. The regions of the earth that are at right angles to the earth–moon vector are pulled radially inward.

This deformation pattern is illustrated in Figure 1. The total gravitational acceleration vectors due to the moon are shown in Figure 1a. The vectors all point toward the moon, but are of unequal length and direction, although the differences are greatly exaggerated in the figure. The orbital acceleration is, to a high degree of accuracy, equal to the acceleration vector at the earth's center of mass. Subtracting that vector from the other vectors in Figure 1a results in the pattern of vectors shown in Figure 1b. These residual vectors represent that portion of the lunar gravitational force tending to deform the earth. The residual acceleration field multiplied by the local material density is defined as the lunar tidal force, and the deformation it induces is called the lunar tide.



Earth Tides, Figure 1 All three panels show the earth as seen from above the north pole. The earth's diurnal rotation is represented by W. The *arrows* in (**a**) illustrate the magnitude and direction of the gravitational acceleration toward the moon. The differences in the lengths and directions of the *arrows* are greatly exaggerated. The lunar tidal acceleration is defined by subtracting the acceleration vector at the earth's center of mass from the other acceleration vectors. The resulting vectors are shown in (**b**). The tidal force (the local density times the acceleration) deforms the earth into the elliptical shape shown greatly exaggerated in (**c**). Points A and B are used in the text to illustrate tidal strain and tilt.

Note from Figure 1b that because of the earth's diurnal rotation the tidal force at a fixed point in the earth varies through two complete cycles in 1 day; a fixed point rotates through one outward bulge, then through an inward bulge, and then into the other outward bulge, all within a half a rotation period (i.e., within 12 h). This semidiurnal time dependence is split into many periodic terms with frequencies closely spaced about 2 cycles/day, due to the time variability of the orbital motion of the moon. Furthermore, because the moon is not always in the plane of the earth's equator, there is also significant variability at frequencies closely spaced about 1 cycle/day (imagine, e.g., that the earth–moon vector is inclined at 45° to the earth's rotation axis) and about 0 cycles/day (imagine that the moon is directly above the north pole). The solar tidal force and the solar tide are defined in a similar manner, and can also be decomposed into semidiurnal, diurnal, and long period terms.

For a quantitative description, it is useful to work with the tidal potential, denoted here as V_T and defined so that its gradient is the tidal force per unit mass. Define a nonrotating coordinate system with origin at the center of the earth. The total lunar gravitational potential at the point **r** inside the earth is (assuming the moon to be a point mass)

$$V = \frac{GM}{|\mathbf{r} - \mathbf{R}|} \tag{1}$$

where M is the mass of the moon, G is Newton's gravitational constant, and **R** is the position vector of the moon. Let r, θ, ϕ be the radial distance, colatitude, and eastward longitude of the earth-fixed point, **r**, so that $\phi + \Omega t$ (where $\Omega = 1$ cycle/day is the earth's angular velocity of rotation) is the azimuthal angle of **r** in nonrotating, inertial space. The factor $1/|\mathbf{r} - \mathbf{R}|$ can be expanded as a sum of complex spherical harmonics, $Y_n^m(\theta, \phi)$, so that

$$V = \mathrm{Re}\left[\frac{GM}{R}\sum_{n=0}^{\infty}\sum_{m=0}^{n}\left[\frac{r}{R}\right]^n d_n^m Y_n^m(\theta,\phi)e^{im\Omega t}\right] \tag{2}$$

where *Re* denotes the real part (included in Equation 2 so that the sum over m includes only $m \geq 0$), R is the radial coordinate of the moon, and d_n^m are coefficients that depend on the angular position of the moon relative to nonrotating inertial space. The coordinate R and the moon's angular position depend on time, due to the moon's orbital motion.

The $n = 0$ term in Equation 2 is a spatial constant and so is physically meaningless. It can be ignored.

The $n = 1$ term represents a spatially constant force, equal to the lunar force at the earth's center of mass. Consequently, the n=1 term is removed from Equation 2 when defining the tidal potential V_T.

Since $r \leq a$ where a is the earth's radius, and since $a/R \approx 1/60$ for the moon (and is much smaller for the Sun), the factor $(r/R)^n$ in Equation 2 causes the contributions to Equation 2 to fall off rapidly with increasing n. For most purposes it is sufficient to keep only the $n = 2$ terms in V_T, so that V_T has the approximate form

$$V_T = \mathrm{Re}\left[\left[\frac{r}{a}\right]\sum_{m=0}^{2} c_2^m Y_2^m(\theta,\phi)e^{im\Omega t}\right] \tag{3}$$

where $c_2^m (= GM/R(a/r)^2 d_2^m)$ are complex, time-varying coefficients that depend on the orbital coordinates of the moon.

The dominant time dependence in Equation 3 comes from the $e^{im\Omega t}$ term. This term results in semidiurnal, diurnal, or long period tides, depending on whether m is 2, 1, or 0, respectively. The time-dependent c_2^m in Equation 3 split the $e^{im\Omega i}$ time dependence into terms with frequencies closely spaced about mΩ.

The Earth's Response

The tidal force causes ocean tides as well as earth tides. The observed ocean tide is actually the difference between the response of the ocean and the response of the solid earth. Ocean tides are complicated and difficult to model, for a number of reasons that need not concern us here. Open ocean tides are typically less than 1 m in height, although ocean tides at some coastal locations can be as large as several meters peak-to-peak.

Earth tides are much easier to understand and model. The tidal force shown in Figure 1b tends to deform the solid earth into the elliptical shape shown greatly exaggerated in Figure 1c. Tidal displacements of the solid earth are typically several tens of centimeters. But, unlike ocean tides, earth tides cannot be observed without sensitive instruments. The reason is that earth tides cause both the ground and the observer to be displaced by the same amount.

One way to detect earth tides is to use a gravimeter. There are three contributions to the observed tidal variation in the gravitational acceleration: (1) the direct attraction of the Sun and moon, (2) the change in the earth's gravity field due to tidal deformation within the earth, and (3) the change in the gravitational acceleration at the gravimeter caused by the radial tidal displacement of the earth's surface beneath the gravimeter (if the surface moves outward, gravity decreases, and vice versa). All three contributions are roughly of the same order.

The total tidal variation of the observed gravitational acceleration is on the order of 100 μgals or more (1 gal = 1 cm/s^2). The unperturbed gravitational acceleration at the earth's surface is about 10^3 gals. So, tides affect gravity at about the 10^{-7} level. This is roughly the relative importance of tides on any physical observable, and can be traced to the fact that tidal displacements (a few tens of centimeters) are about 10^{-7} of the earth's radius (about 6×10^8 cm).

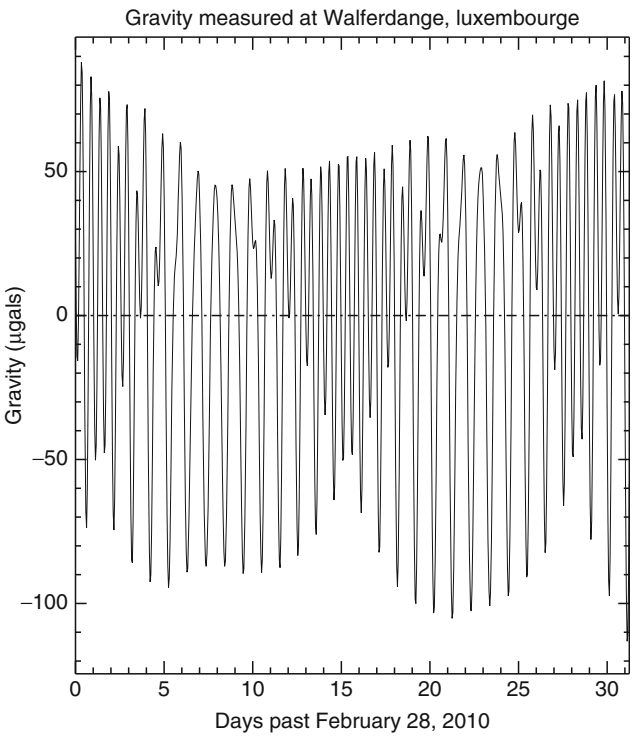
A simple, idealized gravimeter is a mass hanging from a spring. The amount the spring is stretched at equilibrium is proportional to the local gravitational acceleration. So

by continually monitoring the length of the spring, tidal variations in gravity can be determined. Although real gravimeters are more complicated than this, the basic idea is the same. Most instruments, in fact, do use springs.

To illustrate the effects of tides on gravity, Figure 2 shows 1 month of hourly gravitational acceleration data as observed with a spring-type instrument at Walferdange, Luxembourg (data courtesy of Olivier Francis). The tides are the dominant signal in the data. The semidiurnal and diurnal tides are especially evident. The longer period (2 weeks and 1 month) amplitude modulations evident in the figure are caused by beating between frequencies separated by 1 cycle/13.7 days and between frequencies separated by 1 cycle/27.6 days. Long period gravity tides have small amplitudes at the latitude of Walferdange, and are hard to distinguish in Figure 2.

One problem common to all relative gravimeters is calibration. For spring-type instruments, the proportionality constant between the length of the spring and gravity depends on the spring constant, which can never be precisely known. This, for example, could cause errors in the vertical scale in Figure 2.

Another method of detecting earth tides is to use a strainmeter. This is an instrument that continually monitors the distance between two points on the earth's surface, separated by anywhere from a few centimeters to a kilometer. The fact that earth tides perturb the distance between points can be seen by considering points A and B in Figure 1c. The distance between those points has been changed by the tidal deformation, because A has moved radially outward more than B. Also, not evident in the figure, A and B have been displaced horizontally by different amounts. Typical tidal variations in the distance between two points are on the order of 10^{-7} times the unperturbed distance.



Earth Tides, Figure 2 One month of hourly gravity data, taken with a spring-type gravimeter at Walferdange, Luxembourg (data courtesy of Olivier Francis). The tides are the dominant signal and are described further in the text.

A third way to detect tidal deformation is with tiltmeters. These instruments measure the tilt of the earth's surface with respect to the direction of gravity. Tidal tilt of the surface can be understood from Figure 1c by noting that the tidal bulge has affected the slope of the line between points A and B. The direction of gravity also tips during the deformation, but by a different amount. It is this difference that is observed. Typically, observed tidal tilts are a few tenths of a microradian.

Tidal deformation can also be observed using space geodetic techniques, including satellite laser ranging (SLR), very-long-baseline-interferometry (VLBI), and GPS positioning. These techniques are sensitive to displacements of the ground beneath the observing stations. In fact, one of the primary geophysical objectives of these techniques is to detect tectonic motion of the stations. The effects of earth tides are evident in the data, but they cannot generally be determined with as much relative accuracy as can the tidal effects on surface gravity, strain, or tilt.

Satellite orbit tracking can also be used to detect tidal variations in the earth's gravity field. Those variations affect the orbit of a satellite, and so can show up in the satellite tracking data. In fact, for lower-flying satellites the ranging data are usually more sensitive to these tidal gravity variations than they are to tidal displacements of the ground stations.

These various observable tidal effects can be conveniently described, mathematically, by using dimensionless parameters known as Love numbers, defined as follows. The deformation of a spherically symmetric, nonrotating earth in response to a $Y_n^m(\theta, \lambda)$ applied external potential can be described with that same $Y_n^m(\theta, \lambda)$ angular dependence. Mathematically, this is because the Y_n^m separate spherically symmetric differential equations. The change in the earth's gravitational potential at $r = a$ (the unperturbed surface of the earth) and the radial displacement at $r = a$ are both proportional to Y_n^m, and the horizontal displacement vector at $r = a$ is proportional to ∇Y_n^m. The proportionality constants depend on n but are independent of m. Thus, the same constants are pertinent for all three Y_2^m terms in Equation 3.

Let $\Phi(\theta, \lambda)$, $U_r(\theta, \lambda)$, $U_\theta(\theta, \lambda)$, and $U_\lambda(\theta, \lambda)$ denote tidal effects at the earth's surface ($r = a$) on, respectively, the earth's gravitational potential, and the radial, southward, and eastward displacements of the point (θ, λ). Then, Φ, U_r, U_θ, and U_λ for our assumed spherical earth have the form

$$\begin{aligned}\Phi(\theta,\lambda) &= kV_T^a(\theta,\lambda)\\ U_r(\theta,\lambda) &= \frac{h}{g}V_T^a(\theta,\lambda)\\ U_\theta(\theta,\lambda) &= \frac{l}{g}\partial_\theta V_T^a(\theta,\lambda)\\ U_\lambda(\theta,\lambda) &= \frac{l}{g\sin\theta}\partial_\lambda V_T^a(\theta,\lambda)\end{aligned} \tag{4}$$

where k, h, and l are the dimensionless Love numbers, g is the unperturbed gravitational acceleration at $r = a$, and

$$V_T^a(\theta,\lambda) = \mathrm{Re}\left[\sum_{m=0}^{\infty} c_2^m Y_2^m(\theta,\lambda)e^{im\Omega t}\right] \tag{5}$$

is the tidal potential (Equation 3) evaluated at $r = a$.

Tidal variations in gravity, strain, tilt, surface displacements, and satellite orbital motion can all be parameterized in terms of k, h, and l. As one example, consider the gravitational acceleration at a fixed point on the earth's surface. There are three contributions to this acceleration, as discussed above. First, the direct gravitational acceleration from the moon (or Sun) in the inward radial direction is $-\partial_r V_T(r=a) = -\frac{2}{a}V_T^a$ (using the r^2 radial dependence of V_t shown in Equation 3). Second, Φ (the tidal change in the earth's gravitational potential at $r = a$) has an angular dependence Y_2^m and so, outside of the earth, has radial dependence r^{-3}. Thus, the effect of Φ on the radially inward gravitational acceleration is $-\partial_r\Phi(r=a) = \frac{3}{a}\Phi = \frac{3}{a}kV_T^a$ Third, in the absence of tides, the surface gravitational acceleration, g, varies with radius as r^{-2}. So, if the surface point is displaced radially by U_r, the resulting perturbation in the gravitational acceleration at the displaced surface point is $U_r\partial_r g = -\frac{2}{a}gU_r = -\frac{2}{a}hV_T^a$.

Adding these three contributions together gives the total tidal effect on the observed acceleration as

$$\Delta g(\theta,\lambda) = -\delta\frac{2}{a}V_T^a(\theta,\lambda) \tag{6}$$

where $\delta = 1 - \frac{3}{2}k + h$ is called the gravimetric factor. Similar exercises show that tidal tilt is described by the diminishing factor $\gamma = 1 + k - h$, and that tidal strain, although more complicated than either tilt or gravity, depends on the Love numbers h and l.

The numerical values of the Love numbers depend on the earth's internal properties. It is possible to learn about some of those properties by comparing tidal observations with predictions based on theoretical results for the Love numbers. For example, tidal observations have been used to place constraints on the earth's anelastic properties. The effects of anelasticity are frequency- and stress-dependent, but are not well understood. Because tides sample the earth in unique frequency and stress regimes (at lower frequencies and larger deep-earth stresses than seismology, e.g.), tidal studies have proven useful as complements to other types of anelastic observations.

The use of tides to study the earth's internal structure can be difficult, for several reasons. One problem is instrument calibration, as described above for gravimeters. Any error in the calibration maps directly into a frequency independent, multiplicative error in the estimated Love numbers.

But there are also a number of other complicating effects, most related to the fact that the earth is not really spherically symmetric and nonrotating. Some of those effects are potentially useful. For example, the earth does rotate, and because of that rotation the earth's internal properties are closer to being elliptically, rather than spherically, symmetric. In this case, the results of Equation 4 are still approximately valid, but the Love numbers k, h, and l are notably dependent on frequency near 1 cycle/day. This diurnal frequency dependence is particularly sensitive to the shape of the core-mantle boundary, and so diurnal tidal results can be used to help constrain that shape.

Another omission in the theory described above is the ocean. Tides in the ocean cause time-varying pressure loads on the surface of the solid earth with the same frequencies as the earth tides. These loads cause the earth to deform, and this "load tide" (the tidal deformation that would occur in the absence of oceans is called the "body tide") affects all earth tide observations to some extent. Tidal gravity observations, for example, can be perturbed by up to 10% near coasts, and typically a few percent in the interior of continents. Tidal tilt and strain can be perturbed by several hundred percent near coasts.

It is often difficult to model and remove the load tide well enough to use the remaining body tide to learn about the earth's deep interior. There are uncertainties in ocean tide models. Furthermore, the earth's response to the ocean tides, particularly the contributions to tilt and strain near coasts, can be sensitive to the local material properties that may or may not be adequately known. On the other hand, because of these possible uncertainties, people have sometimes been able to use tidal observations to help constrain the nearby ocean tide or the underlying material properties.

In fact, for tilt and strain local effects can be important on both the load tide and the body tide. By comparing observed tidal amplitudes from instruments in an array of tiltmeters or strainmeters, geophysicists can learn about the local geology and underlying structure. There have even been attempts to look for time-dependent variations in tidal amplitudes near active earthquake faults that might be caused by sudden changes in local material properties preceding an earthquake.

A related problem is that tilt and strain amplitudes are also affected by the local topography and by the shape and size of any cavity the instrument is placed in. (Tiltmeters and strainmeters are often placed in boreholes or tunnels to minimize the effects of the surface environment.) These effects are rarely interesting, and they cannot be observationally separated from the effects of local geology. Instead, they must be modeled separately and removed from the data.

Summary

The effects of earth tides can be detected in several types of geophysical measurements. These tidal observations can be inverted to learn about large-scale material properties of the earth's deep interior and about local geological structure. In practice, a useful inversion is often difficult due to the large number of possible geophysical interpretations, and due to uncertainties associated with instrument calibration, topographic and cavity effects, and ocean tidal loading of the solid earth.

EARTH, DENSITY DISTRIBUTION

Frank D. Stacey[1], Paul M. Davis[2]
[1]Division of Exploration and Mining, CSIRO, Kenmore, Australia
[2]Earth and Space Sciences, UCLA, Los Angeles, CA, USA

Definition

Except for iron meteorites, the Earth is the densest body in the solar system. As has been recognized for more than two centuries, it is, on average, about twice as dense as common surface rocks. But many of the early speculations on its internal structure were bizarre, ignoring the most basic physics and the simplest density information, and prompting a remark in one of the early papers on the subject with a sound scientific base (Oldham, 1906): "Many theories of the earth have been propounded . . . till geologists have turned in despair from the subject, and become inclined to confine their attention to the outermost crust of the earth, leaving the centre as a playground for mathematicians." Seismological studies, for which Oldham was one of the pioneers, have changed that by giving us a clear picture of the interior. But debates on many details and improvements in the methods of investigating them continue.

The mean density

The first well-informed estimate of the Earth's mean density was by Isaac Newton, who appealed to four pieces of evidence: the Earth's surface gravity, the period of the Moon's orbit, the size of Jupiter, and the orbital periods of its satellites. It was evident to him that the density of Jupiter is a quarter of the density of the Earth. Arguing that the density of Jupiter would not be lower than that of water (it is now known to be 1,327 kg m^{-3}), and recognizing that the densest Earth materials would have sunk to the deep interior, he inferred that the mean Earth density is between 5,000 and 6,000 kg m^{-3}, a remarkable coincidence with the now established value, $\bar{\rho}$ = 5513.4(6) kg m^{-3}. More precise estimates awaited the determination of the gravitational constant, G. Any astronomical or geophysical measurement of gravity, g, or, equivalently the acceleration of a body in a gravitational field, depends on the product of G and a mass. In the approximation of a spherical, nonrotating Earth, mass M, and radius R, as Newton showed, the surface gravity is $g = GM/R^2$ (the departure from this simple equation caused by rotation and ellipticity is about 0.5%). Since g and R have been reasonably well known since Newton's time, a determination of G is equivalent to a determination of M, or $\bar{\rho}$, and was referred to as such by early investigators. Satellite measurements have given the most precise value of the product $GM = 3.986004415(8) \times 10^{14}$ m^3 s^{-2}, where M includes the mass of the atmosphere, 8.84×10^{-7} of the total.

The first attempts to measure G were by M. Bouguer, who, in the 1730s, was conducting an astrogeodetic survey in the extreme topography of the Andes and noted a plumb line deflection by Mount Chimborazo, in Ecuador. He also compared the gravity on a plateau, at Quito, with observations on the nearby flood plain of the Esmeralda River, the first use of what we now know as the Bouguer method of gravity interpretation. In both cases Bouguer recognized that he was thwarted by heterogeneity of the geological structures and that his estimates of $\bar{\rho}$ were unsatisfactory, but in 1774 his plumb line deflection method was repeated more successfully by N. Maskelyne on the slopes of Mt. Schiehallion in Scotland. Maskelyne's estimate was revised several times by others, using different assessments of the density of the mountain. This introduced a measure of uncertainty, so that geophysical measurements were generally disregarded for about 50 years after 1798, when H. Cavendish made a series of measurements of the gravitational force between laboratory masses, using a torsion balance developed for the purpose by J. Michell. However, Cavendish's result was also a subject of doubt. Although the measurements were excellent, the final result was clouded by an arithmetic error, recognized in 1842 by F. Baily, leading to a revival of

interest in geophysical methods. The most significant of these was by G. B. Airy, who, in 1856, measured the variation of gravity with depth in a coal mine near Newcastle, in northeast England. Although limited by inadequate measurements of rock density, Airy's experiment was well conceived. It did not require an absolute measurement of gravity but only the differences in its value at different levels in the mine, as indicated by the fractional differences between the periods of pendulums operated by observers who exchanged electrical signals to indicate their timing. The linked variations in gravity and density, recognized by Airy, are central to the development of earth models. The Airy method was used by others for the following 50 years, but with mixed results, and by 1900 the superiority of torsion balance measurements was clear. Now, it appears that conventional balance experiments, pioneered in the late 1800s by P. von Jolly and J. H. Poynting, are better still and the current best estimate of G derives primarily from them: $G = 6.6743(7) \times 10^{-11}$ m^3 kg^{-1}s^{-2}. The uncertainty (1 standard deviation), 1 part in 10^4, is far larger than the uncertainties in the other fundamental physical constants and translates to a similar uncertainty in M, and therefore $\bar{\rho}$, through the very precise value of (GM).

The moment of inertia constraint

The understanding of the Earth's density structure made little progress, beyond Newton's inference that denser materials would have sunk to the centre, until the late 1800s. By then astronomical measurements of precession, combined with astrogeodetic measurements of ellipticity, had given an estimate of the moment of inertia of the Earth, C. This is expressed as a coefficient, f, relating C to the mass, M, and equatorial radius, a

$$C = fMa^2 \tag{1}$$

For a uniform sphere $f = 0.4$ and a lower value is a measure of the concentration of mass toward the centre. Using recent data the value for the Earth is $f = 0.330968(2)$, with the uncertainty in parenthesis. This number represents a quite strong central concentration of mass and prompted speculation on the Earth's deep composition. The cosmic abundance of iron, apparent from meteorites and the solar spectrum, invited the supposition that the Earth has an iron core. This idea was pursued by E. Wiechert who, in 1897, showed that both M and f could be matched by a model with an iron core and rocky mantle, with both materials approximating their familiar low pressure densities, if the core radius was about $0.78a$. But in 1906 R. D. Oldham reported seismological evidence for a smaller core, with a radius that he estimated to be about $0.4a$ (it is now known to be $0.546a$), requiring higher densities for both the core and the mantle. Two developments were needed: recognition of the increase in density by the compression of deep burial and the introduction of a transition zone of increasing intrinsic density within the mantle. Both required more detailed seismological data than were available to Wiechert and Oldham.

Self-compression

Williamson and Adams (1923) recognized that information about self-compression in a homogeneous layer was available from seismic wave velocities. Using the velocities of both compressional and shear waves

$$V_\mathrm{P} = \{[K_S + (4/3)\mu]/\rho\}^{1/2}; V_\mathrm{S} = \{\mu/\rho\}^{1/2} \tag{2}$$

they separated the adiabatic bulk modulus, K_S, from the rigidity modulus, μ, by writing

$$\Phi = V_\mathrm{P}{}^2 - (4/3)V_\mathrm{S}{}^2 = K_S/\rho = (\partial P/\partial\rho)_S \tag{3}$$

That is, the seismological parameter Φ gives directly the variation of pressure, P, with density, ρ, in a homogeneous region with an adiabatic temperature gradient. Since $\mathrm{d}P/\mathrm{d}z = \rho g$, g being gravity at depth z,

$$\mathrm{d}\rho/\mathrm{d}z = \rho g/\Phi \tag{4}$$

This is the Williamson–Adams equation for the variation of density with depth in a homogeneous region. An additional term, $-\alpha\rho\tau$, was added by F. Birch to account for a temperature gradient differing from the adiabat

$$\tau = \mathrm{d}T/\mathrm{d}z - (\mathrm{d}T/\mathrm{d}z)_\mathrm{Adiabatic} \tag{5}$$

where α is the volume expansion coefficient. However, this term is very small except at the limited depths of steep temperature gradients, the lithosphere, and the base of the mantle (D″). In the outer core it is certainly negligible.

Another reason for imperfection of the Williamson–Adams equation is that, for composite materials, such as mantle rocks that are comprised of several minerals with different properties, there is a frequency dependence of elasticity. The unrelaxed elastic moduli that apply to rapid cycles of low stress, as in seismic waves, are slightly higher than the relaxed moduli applying to strong static compression. Averaged over the lower mantle the difference is about 0.5% (Stacey and Davis, 2008, Table 18.1). This means that $\mathrm{d}\rho/\mathrm{d}z$ is 0.5% greater than by the Williamson–Adams equation. Interpreted as an error in the inferred temperature gradient, it amounts to ~100 K over the depth of the lower mantle, but earth models are not so accurate that this is regarded as serious.

When self-compression, as represented by the Williamson–Adams equation, is allowed for, a simple two-layer model with the observed core size and a rocky mantle cannot match the moment of inertia. It is necessary to bring some mass up higher into the mantle. This was the vital next step to realistic earth models, introduced by K. E. Bullen and B. Gutenberg in the 1930s: the mantle transition zone. By then, seismological information was sufficiently detailed to indicate the depth range of the transition zone and the earth models that followed were quite close to our present understanding. As we now know, the transition zone is a combination of transitions at several levels in the depth range of 220–660 km, where mantle minerals are converted to denser phases. The transition at 660 km is conventionally regarded as the boundary

between the upper and lower mantles. The lower mantle, which has two-thirds of the mantle volume and three-fourths of its mass, appears to be more or less homogeneous over almost the whole depth range to the core, at 2,900 km depth, and conforms well to the Williamson–Adams equation with a density 18% higher than for the low pressure forms of the minerals. The upper mantle is more complicated. Bullen (1975) reviewed this stage in the development of our understanding of the Earth's density.

Free oscillation data

In the 1960s observations of the Earth's modes of free oscillation introduced a new constraint on the density structure. Whereas body wave seismology gives the ratio K_S/ρ throughout the Earth but provides no formal separation of K_S and ρ, the spheroidal modes involve oscillations in the radial distribution of mass with consequent gravitational as well as elastic restoring forces. The equations of motion and the mode frequencies involve not just the ratios K_S/ρ and μ/ρ but also $G\rho$. With G a known constant, the $G\rho$ term allows an assessment of absolute density independent of elasticity. This is illustrated by considering the frequencies of two modes for the simple case of a uniform solid sphere. The spheroidal mode ${}_0S_2$ is an alternation between prolate and oblate deformations and, since there is radial motion, the $G\rho$ term has an important control on the frequency, f, which is given by

$$f^2({}_0S_2) = (2/3\pi)G\rho + (5/3\pi^2)\mu/\rho R^2 \quad (6)$$

whereas the lowest toroidal mode, ${}_0T_2$, is an alternating twist between two hemispheres, with no radial motion, and a frequency given by

$$f^2({}_0T_2) = (7/4\pi^2)\mu/\rho R^2 \quad (7)$$

so that

$$G\rho = (3\pi/2)f^2({}_0S_2) - (10\pi/7)f^2({}_0T_2) \quad (8)$$

The frequencies of more than 500 modes have been identified (Masters and Widmer, 1995), providing a direct measure of global average properties, including the radial density profile. Fine details, such as the sharpness of boundaries, still require analysis of body wave data, but the broad scale structure is derived from the mode frequencies. The Preliminary Reference Earth Model (PREM) of Dziewonski and Anderson (1981) was produced in this way. It signalled a turning point in seismological studies, with less attention to global average properties and increasing emphasis on lateral heterogeneities, boundary structure, and anisotropy.

A powerful new use of free mode data to clarify the radial density structure was presented by Masters and Gubbins (2003), who selected a combination of modes sensitive to a restricted depth range, rather than inverting the whole data set. By concentrating on a region close to the inner core boundary, they obtained an estimate of the density difference between the inner and outer cores, 820 kg m^{-3}, compared with the PREM difference, 597 kg m^{-3}. The revision amounts to 1.8% of the density at that level, compared with the estimated 0.5% precision of the new technique, and may be interpreted as a measure of the revisions to PREM that may be expected in an updated model. From the splitting of mode frequencies, free oscillation data allow identification of lateral density variations independently of elasticity. This is referred to in a later paragraph on lateral heterogeneity.

A density gradient anomaly

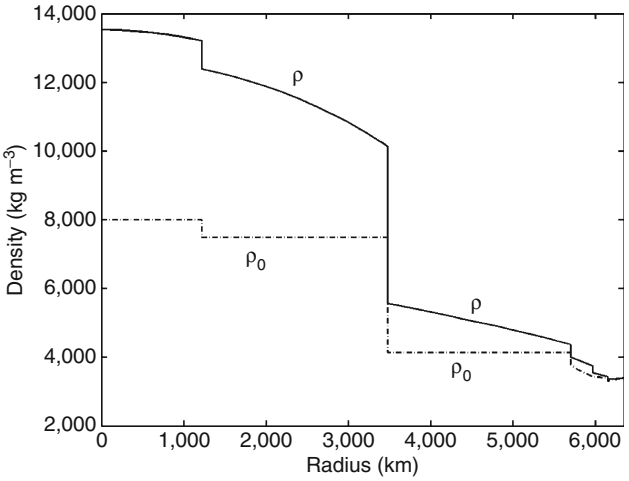
An interesting feature of PREM is the decrease in density with depth in the lithosphere and asthenosphere, over the depth range 24.4–220 km. The obvious interpretation is a steep temperature gradient, but this presents difficulty. The inverted density gradient is slight, little more than 0.1 kg m^{-3} per kilometer of depth, but the difficulty would arise even with zero gradient. For a uniform layer, density is a function only of pressure and temperature, so we can write

$$\begin{aligned} d\rho/dz &= (\partial\rho/\partial P)_T dP/dz + (\partial\rho\partial T)_P dT/dz \\ &= -0.109 \text{ kgm}^{-3}/\text{km} \end{aligned}$$

and substitute the physical properties of mantle material in this depth range to obtain $dT/dz = 8.6$ K/km. (For $d\rho/dz = 0$ this would be 7.9 K/km). Over the depth range of 195.6 km the anomalous gradient gives a temperature range of 1,680 K and since the temperature at 24.4 km (the averaged crust-mantle depth of PREM) cannot be taken as less than about 700 K, the implied temperature at 220 km is close to 2,400 K. This is about 600 K too high; the temperature at 660 km depth required to meet the (P,T) conditions of the phase transition there is about 1900 K (Boehler, 2000) and the 220 km temperature must be lower than that. The discrepancy can be understood if PREM underestimates the effect of anisotropy in the asthenosphere, causing the inverted density gradient as a modelling artifact.

Extrapolation to zero pressure and inferences about composition

The density profile of PREM, with minor equation of state adjustments, is plotted in Figure 1, together with equation of state extrapolations to zero pressure and a temperature of 300 K. The extrapolations use equations of state fitted to each of the ranges, assuming that the materials can be decompressed and cooled without phase changes. Thus, the broken line in the figure represents the densities that the high pressure phases would have under ambient conditions. For each of the inner and outer cores and lower mantle the extrapolated densities are uniform, within the uncertainties of the calculation, and so indicate homogeneity. However, this is not true for the upper mantle, where the model indicates heterogeneity additional to the boundaries that mark recognized phase changes.



Earth, Density Distribution, Figure 1 Density profile of the Earth based on PREM (*solid line*) and the profile of $\rho_{0,0}$, the density obtained by extrapolating to zero pressure and a temperature of 300 K (*broken line*).

The density estimates provide the basic data needed for a discussion of composition. Two long-standing debates that hang on this are the composition of the core, that is, the light elements that must be dissolved in iron-nickel alloy to reduce its density to that of the core, and the possibility of a significant compositional difference between the upper and lower mantles. As Birch (1952) recognized, there is no plausible alternative to iron as the major core constituent, but the outer core is about 10% less dense than pure iron and Poirier (1994) reviewed the arguments for rival candidate light solutes. At core pressures iron occurs as a hexagonal close-packed (ε) phase, for which the extrapolated density would be $\rho_{0,0} = 8{,}352 \pm 23$ kg m^{-3} (Stacey and Davis, 2004), compared with the core density, extrapolated to the same conditions and also in the ε phase, 7,488 kg m^{-3} for the outer core and 7,993 kg m^{-3} for the inner core. The effects on the iron density of each of the candidate light elements are known from metallurgical literature; although none of the observations were made on ε iron, they are taken as a sufficient guide to their potential contributions to the core density deficit. There are undoubtedly many elements dissolved in the core, but the favored important ones, with the mass percentages required in the outer core if each were the only light ingredient, are H (1.4%), C (10.6%), O (12.7%), Si (17.7%), and S (18.2%). The core densities can, in principle, be explained by any combination of these elements, but geochemical arguments restrict the range. The mass percentages of each, in the inner and outer core, respectively, favored by Stacey and Davis (2008, Table 2.5) are H (0.07%, 0.08%), C (0.45%, 0.50%), O (0.11%, 5.34%), Si (nil, nil), and S (8.02%, 8.44%).

There are two main arguments bearing on the similarity of the compositions of the upper and lower mantles, the seismological evidence for penetration of the 660-km boundary by subducting slabs and the densities of high pressure phases of mantle minerals. The perovskite phase of $(Mg,Fe)SiO_3$ is believed to be the dominant lower mantle mineral. It is produced by high pressure laboratory experiments and survives in a metastable state at $P = 0$ provided it is not heated. With no Fe the density at ambient conditions is 4,107 kg m^{-3}. The second most important lower mantle mineral is almost certainly ferro-periclase (magnesiowustite), (Mg, Fe)O, which may account for as much as 20% of the composition. It is less dense than the perovskite (3,585 kg m^{-3} for MgO) but more readily accepts substitution of Fe for Mg and would be 5,956 kg m^{-3} for FeO. The magnesium silicate perovskite can accept Al ions, but neither of these minerals readily accepts Ca, so a calcium perovskite is believed to occur also, but, unlike the magnesium perovskite and periclase, it does not survive decompression and is not as well studied. It is evident that, with a modest iron content, a mixture of these minerals can match the lower mantle density, $\rho_{0,0} = 4{,}144$ kg m^{-3}, and that, on the basis of density, there is no evidence for a compositional difference between the upper and lower mantles.

Lateral density variations

Convection is ubiquitous in the Earth and this means that lateral density variations, with hot, dilated materials rising, and replaced by denser, cool materials. Heterogeneity of the mantle inferred from body wave tomography is generally consistent with the convective pattern, acknowledging that relics of earlier convective patterns are still apparent, but elastic moduli are more sensitive to temperature than is density and a thermodynamic analysis is needed for interpretation (Stacey and Davis, 2008, Sect. 19.7). The splitting of mode frequencies presents evidence of lateral density variations that does not rely on such interpretation, but, in spite of several detailed studies, the difficulties are such that available results must be regarded as preliminary (Ishii and Tromp, 1999; Masters et al., 2000; Romanowicz, 2001). The general conclusion is that, in addition to temperature variations, compositional heterogeneity of the deep mantle must be invoked to explain the observations, in confirmation of a thermodynamic assessment (Forte and Mitrovica, 2001; Stacey and Davis, 2008, p. 288) of results of body wave tomography (Robertson and Woodhouse, 1996; Su and Dziewonski, 1997).

With respect to the outer core, observable lateral heterogeneity must be discounted as quite implausible, in view of the speed of convective motion apparent from the geomagnetic secular variation. Compositional layering, with a stable low density layer at the top of the core has been suggested (Braginsky, 1999), but is not generally supported.

Summary

The Earth's density structure is now known in sufficient detail to provide a sound basis for discussions of internal

composition. High pressure equations of state (Stacey and Davis, 2004), the modern version of finite strain theory, provide reliable extrapolations of density to zero pressure, as well as distinguishing internal heterogeneities caused by temperature variations from compositional and mineralogical differences. Although fine details in the deep interior are not all resolvable, it is evident that the bulk of the Earth does not have very strong lateral heterogeneities, such as are obvious in the crust. Nevertheless, the heterogeneities that are seen are indications of the dynamics of the Earth, making them prime targets for continuing investigation.

EARTH'S STRUCTURE, CORE

Lianxing Wen
Department of Geosciences, State University of New York at Stony Brook, Stony Brook, NY, USA

Definition

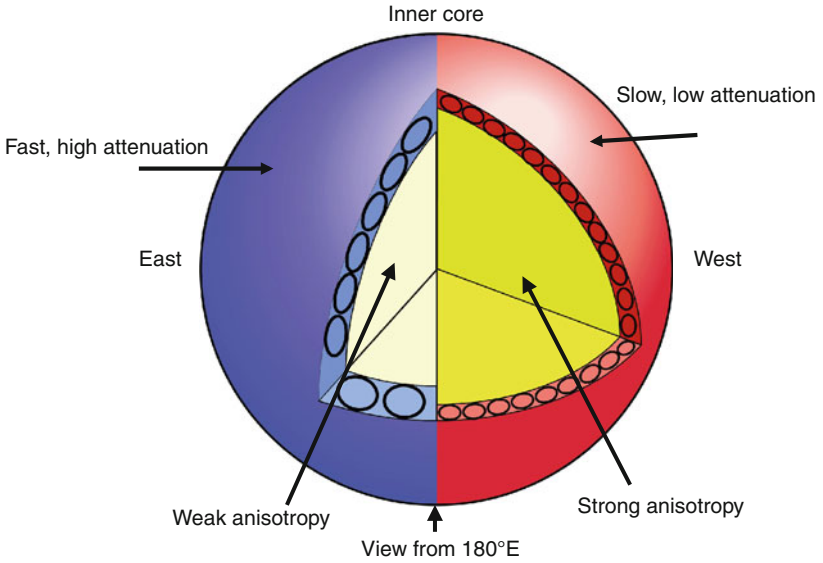
The Structure of Earth's core is referred to as the properties of velocity, density, attenuation, anisotropy, and composition of Earth's core, and how these properties change with depth, geographic location, and time.

Attenuation is a measure of material's ability to absorb energy as seismic waves pass through it.

Anisotropy is a material property that is directionally dependent.

Overall structure: The Earth's core occupies the center portion of Earth with a radius of 3,480 km. It consists of a liquid outer core and a solid inner core. Earth's core is composed of Fe/Ni and some minor light elements, such as S, C, O, and Si. Those light elements are preferentially enriched in the outer core. Seismic compressional velocity and density exhibit sharp jumps at the inner core boundary at the radius of 1,221 km. The inner core is anisotropic in both velocity and attenuation, with seismic waves exhibiting higher velocities and higher attenuation as they propagate along the polar paths than along the equatorial paths. The anisotropy in the inner core is probably caused by preferential alignment of anisotropic Fe crystals.

Radial and lateral variations: With possible exception at the bottom and the top, the outer core is homogeneous due to vigorous mixing of the liquid iron/nickel. The inner core exhibits a complex structure, with the most prominent feature being the hemispheric difference in seismic velocity, attenuation, and anisotropy, between the "eastern" hemisphere (defined between longitudes from 40°E to 180°E) and the "western hemisphere" (defined between longitudes from 180°W to 40°E). The eastern hemisphere exhibits a higher velocity, higher attenuation, weaker anisotropy, and a larger transitional depth from top isotropy to deep anisotropy. The top 235 km of the eastern hemisphere also exhibits a flat velocity gradient with depth (Figure 1). At depth, the innermost 300 km of the inner core may have different forms of anisotropy from the rest of the inner core.



Earth's Structure, Core, Figure 1 Cartoon illustration of hemispheric differences in seismic velocity, attenuation, anisotropy, and depth extent of anisotropy in the Earth's inner core.

Temporal changes: In some localized regions, the inner core surface changes its radius by several kilometers in a decadal scale. Physical mechanisms for such rapid change remain unknown.

EARTH'S STRUCTURE, CONTINENTAL CRUST

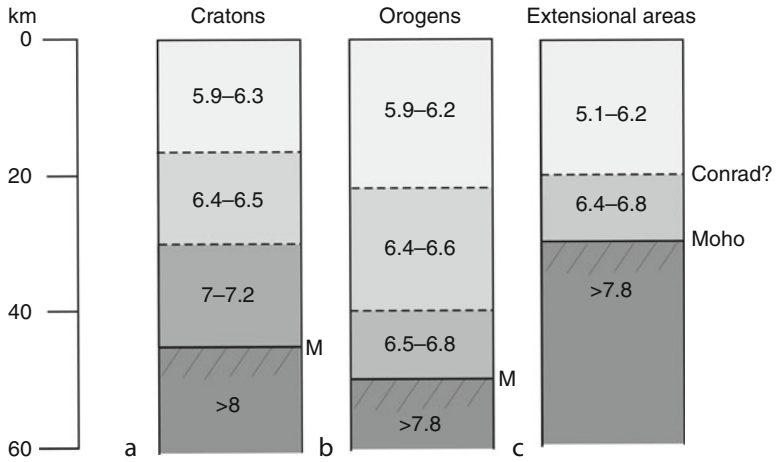
Rolf Meissner, Hartmut Kern
Institut für Geowissenschaften, Universität Kiel, Kiel, Germany

Introduction

In the last 20 years much progress has been made in the development of geophysical techniques that increased our knowledge about the variability of crustal structure substantially. A big misunderstanding, still often presented today, is the use of the phrase "THE" crust. This is a marked oversimplification. Continental crust has been found to be extremely different. There are at least three main types to be distinguished:

1. Thick, old cratons, shields and platforms
2. Orogens, often related to continental subduction
3. Extensional areas, including shelves and rifts

Thick Precambrian cratons, disrupted by early plate tectonics, are presently found in all continents; they contribute more than 70% to the continental lithosphere. They are characterized by a thick crust (45–50 km) with high velocities (>7.2 km/s) in the lower part. The two other crustal types were generated by modern plate tectonics: the *orogens* by convergence and plate collisions, most of them showing deep crustal roots, and the *extensional areas* by divergence and wrench tectonics, often accompanied by thermal and magmatic processes. They generally show a shallow crustal thickness without a high-velocity lower crust. Special forms are rifts, basins, and igneous



Earth's Structure, Continental Crust, Figure 1 Type sections of the three main crustal structures (**a**–**c**) and ranges of P-wave velocities in the upper, middle, and lower crust. Numbers are velocities in km/s.

provinces. Type sections of the three main crustal structures are presented in Figure 1.

In general, the continental crust has lower seismic velocities and consists of lighter material than the underlying mantle; V_P is smaller than 7.8 km/s, V_S smaller than 4.3 km/s, and ρ below 3.1 g/cm^3. Crustal thickness is between 20 km (shelves) and more than 70 km (some orogens) (Mooney et al., 2005). Mohorovičić was the first to determine the base of the crust, today called the "Moho" for short. It is observed worldwide and is clearly recognized by seismic methods. It is worthy to note that the position of the seismic Moho is not always identical with the petrological Moho (defined as the boundary between non-peridotitic crustal rocks and olivine-dominated rocks). In case mafic rocks are transformed into eclogites at the base of orogenically thickened crust, P-wave velocities of eclogites largely overlap with those of peridotites so that seismic field studies may not detect eclogites as crustal rocks (e.g., Mengel and Kern, 1992). An intracrustal boundary – the "Conrad" – seems to separate upper sialic from more mafic lower crust in some areas. Transport of crustal material into the mantle and delamination of the lithosphere and the lowermost part of a thickened crust may give rise to a reduction of crustal thicknesses.

Methods

Reliable studies of the continental crust were started in the late 1940s by seismic methods, applying first refraction studies with man-made explosions and lines of simple geophones. Wide-angle reflection seismics followed, and steep-angle reflection seismics became more and more important. In the last 30 years, digital technology, computer programs for ray-tracing and tomography, and large national and international research programs with an increased number of recording devices and energy sources were initiated. Large, national reflection programs, often with a substantial support by the industry or large funding agencies were developed in nearly all industrialized countries, spearheaded by COCORP in the USA. Both methods – refraction-wide-angle and steep-angle reflection – complement each other, the former supplying velocity-depth functions and relations to petrology, the latter providing reflectivity images of the subsurface that reveal past tectonic processes. Both methods form the backbone of crustal interpretation. They confirmed identical Mohos, either by a jump of velocities or by termination of (crustal) reflectivity because the mantle is less reflective (Meissner and Brown, 1991). Vibroseis or dynamite shooting are used for reflection programs, the latter one generally providing a higher energy output, which is sometimes used for piggy-back wide-angle work. In the last 20 years, a relatively cheap seismological method, the "seismic receiver function technique," supported interpretation of seismic data, making use of global seismicity and a wave change at seismic boundaries. This "seismic receiver function technique" is based on seismic phase conversions of teleseismic waves at the Moho and at boundaries in the crust and mantle.

Non-seismic geophysical techniques are complementary to seismic methods: gravity, for instance, for investigating isostatic problems or selecting between competing seismic interpretations or – together with magnetics – looking for inhomogeneities or controlling structure. Electromagnetic and magnetotelluric methods help to find and to interpret conductivity anomalies. Measurements of heat flow help to observe heat sources and decipher the thermal or magmatic history of a specific area. Depending on the heat flow, temperature-depth functions and viscosities that control rheology can be estimated. The brittle upper crust extends to a depth of 12–20 km and is a zone where generally earthquakes occur. It is separated from the more ductile, aseismic part of the middle and lower crust (some

exceptions). Various experimental studies of creep, stress, and strength support seismic interpretation.

Cratons

Cratons are relatively stable Precambrian continental units with a rather deep lithosphere (Figure 1a). They are called shields when a sediment cover is lacking and platforms when covered by sediments. Today, cratons are found in all continents, possibly created from a few early Supercontinents that were later disrupted by plate tectonics. No consensus exists about the number of cratons. They comprise up to ten in Africa and even more in North America. The latter were finally combined into the big "North American Craton" forming the whole interior of North America (without its margins in the west and east). Even "stable" cratons are influenced by Proterozoic and Phanerozoic processes like rifts or plumes. In North America there is a 2,500 km long Proterozoic Midcontinental rift with a thick cover of sediments, volcanic intrusions, and a reduced crustal thickness. There are also Paleozoic rifts in the southern part of the East European Craton, and there is an unusual 60 km thick crust in the cold Baltic Shield, well within the eclogite stability field in the lowermost part. However, high velocities (>7.8 km/s) corresponding to eclogitic rocks are not observed in the lowermost crust of the Baltic Shield (Korja et al., 2009).

The crystalline crust of cratons is similar worldwide. Cratons are characterized by low heat-flow values. Their thickness is in the range 35–55 km with a "classical" 3-velocity structure (Pawlenkowa, 1996), as shown by wide-angle plus refraction studies. In general, cratons have an upper crust with V_P around 6 km/s, a middle crust around 6.5 km/s, and a roughly 10-km thick lower crust with velocities around 7–7.2 km/s, sometimes 6.7–7.5 km/s (Figure 1a). A typical example is the EUROBRIDGE profile (Guterch et al., 1997) crossing the crust of the East European platform (Figure 2).

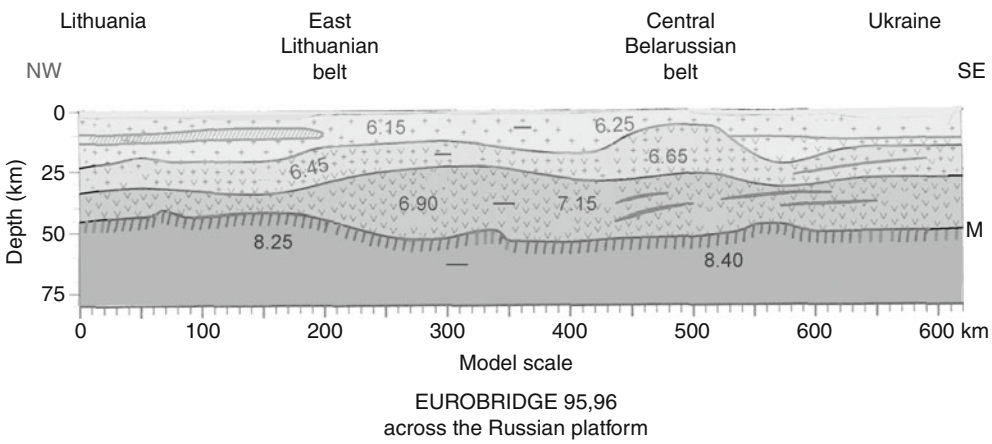
Reflection seismic experiments generally show no special enhancement of reflectivity in the (mafic?) lower crust, as shown by the large transects of LITHOPROBE in Canada, by the COCORP data in the USA or by the BABEL surveys in the northern Baltic Sea (some exceptions).

Orogens

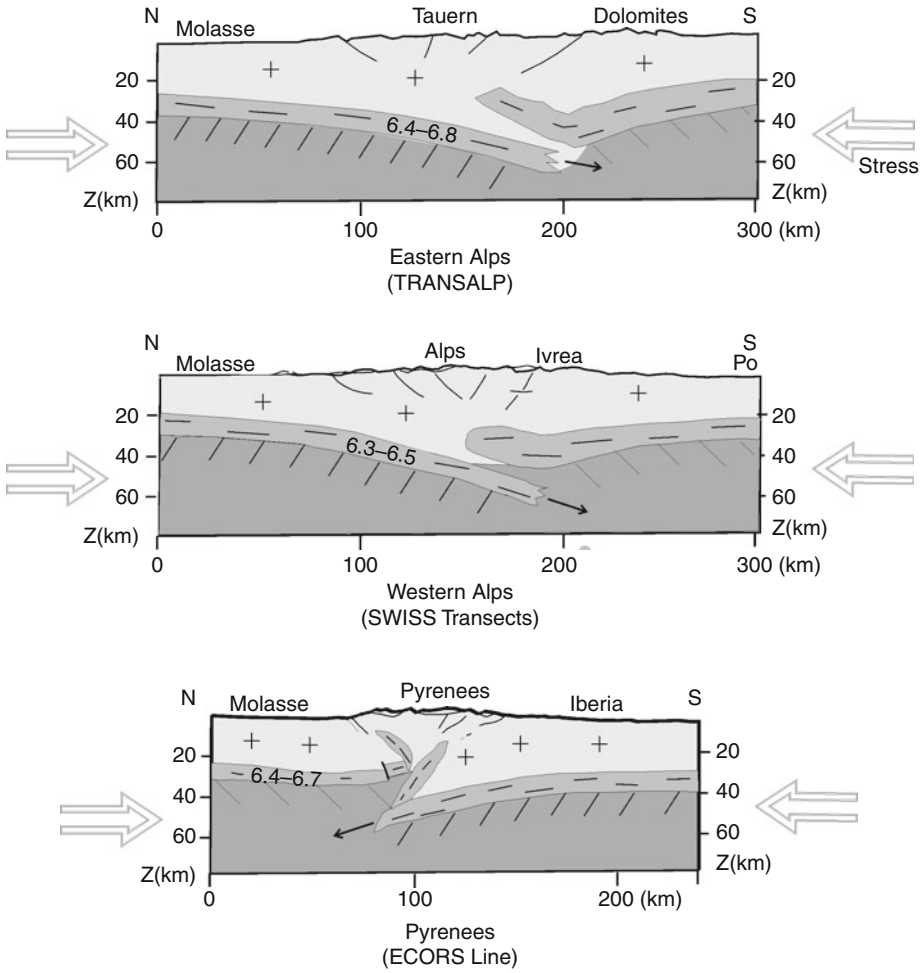
Collisions of plates or terranes create orogens by compressing material upward (mountain ranges) and downward (roots), and dynamic processes initiate oceanic or continental subduction. While the elevation of an orogen apparently depends on the time and speed of the colliding plates (example: Himalaya, Tibet), processes of crust/mantle interaction are quite complex. Magmatic processes are found behind subducting plates in many orogens (Alps, Sierra Nevada, Andes). In continental collision zones, rock types of the lower crust resemble those of the neighboring plates, guided into the orogens. There are high-velocity (cratonic) crustal rocks with mafic lower crusts in the Uralides (from the East European Platform) and sialic, extensional crusts with a reflecting lower crust in the Alps (mostly from the Variscides). Continental subduction often follows oceanic subduction. Remnants of these processes may be reflected by the crustal "roots." Figure 3 shows simplified cross sections through the Alps and Pyrenees. Orogens are more or less isostatically compensated; its Bouguer Anomaly is strongly negative (Ebbing, 2004).

Extensional areas

Extensional processes cover many dimensions: from rifts, basins, (the Basin and Range of North America), continental shelves up to large Phanerozoic areas like Europe, west of the Tesseyre-Tornquist line. This large extensional area was created in Post-Avalonian, Post-Variscan time at the end of the Paleozoic. A surprisingly uniform crust has been formed, showing three prominent differences



Earth's Structure, Continental Crust, Figure 2 Typical cratonic crust from the East European platform (after Guterch et al., 1997).



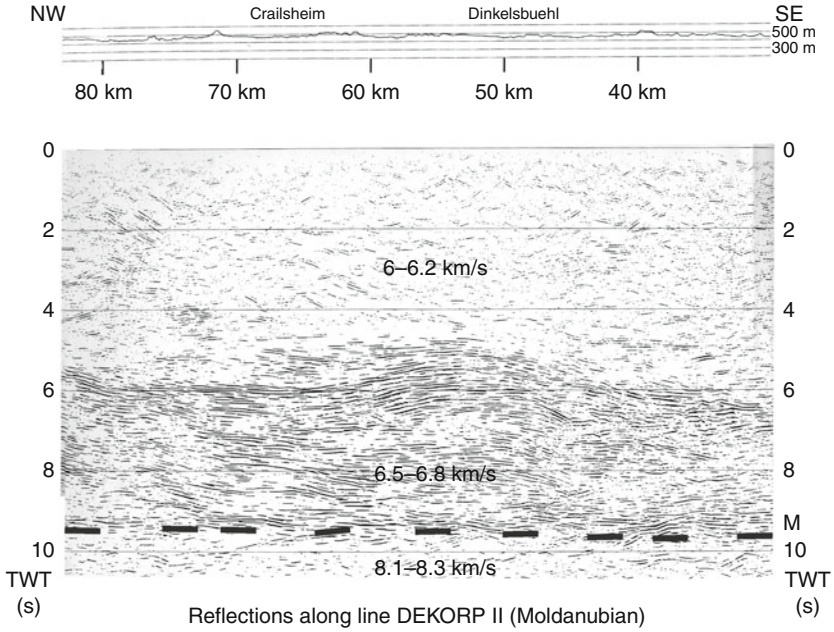
Earth's Structure, Continental Crust, Figure 3 Typical sections of orogenic crust (Alps and Pyrenees).

compared to the cratons: their thickness is only 30 km (Figure 1c), their velocities being lower than 6.8 km/s, and in many places they show prominent reflectivity (lamellae) in the lower crust.

Apparently, all three characteristic crustal patterns are genetically interrelated. While a former lower crust (in the Basin and Range province and in the Variscides) got lost in the previous orogeny (by delamination or subduction) subsequent moderate, but widespread, extension dominated. Mafic-ultramafic dykes intruded into the lower crust and formed sill-like intrusions, giving rise to high impedance contrasts after cooling. Importantly, sills are mostly rather thin and do not generally increase the lower crustal overall (sialic) seismic velocities. Figure 4 gives an example of strong lower crust reflectivity and low average velocities.

In contrast, the formation of rifts and basins is a result of local (extensional) stress and/or strong local heat anomalies. As a consequence, large volumes of mantle-derived basaltic magmas intrude into the crust, and after cooling, the mafic rocks (gabbros or metamorphic equivalents) cause the observed high velocities at the base of most rifts and basins. Examples are the Oslo Graben, the Danish Basin, and other adjacent rifts and basins north of the Variscan front, the great East African rift, the Donetz Basin, and the Mid-continental North American rift. In general, the massive intrusions created a transparent lower crust, but some basins with high lower crust velocities (above 7.2 km/s) show some thin lamellae (apparently ultramafic?) on top of the Moho. Also in some areas of continental/ocean transition high-velocity lamellae are observed in the lower crust (Roberts et al., 2009).

In general, lower crustal reflectivity seems to depend on the volume and thickness of the mafic intrusions compared to the host rock. Whereas sill-like intrusions are suggested to generate the observed lower crustal reflectivity, massive intrusions in the lower crust reduce reflectivity and enhance the average velocities to values of 6.8–7.2 km/s. The volcanic Messum ring complex in Namibia shows no lamellae in the high-velocity interior, but a good reflectivity in the surrounding (Bauer et al., 2003). In contrast, the Viking Graben in the North Sea



Earth's Structure, Continental Crust, Figure 4 Multiple reflections (laminations) in the Moldanubian lower crust along the DEKORP II line, along with ranges of V_P-velocities at different depths.

shows lower crust reflectivity and no reflection around it (McBride et al., 2004).

Most continental shelves show extension and a stretched continental crust with a thickness of only 20–30 km, often containing aborted rifts (Korja et al., 2009). Reflectivity in the lower crust is found in the West Atlantic margin (Faroe or Hatton) and along the Greenland coast. Often, seaward dipping reflections, caused by intrusive and extrusive magmatism, mark the onset of oceanic crust with high velocities. BIRPS's WAM–profile from the British Isles toward the Atlantic ocean shows a preferred lower crust reflectivity below the (continental) Mesozoic basins, while the oceanic crust is free from reflections.

Constraints on crustal petrology

The measured seismic velocity structures are very helpful in providing a rough characterization of the earth's crust in different tectonic environments, but they are nonunique so that inferences about composition cannot be drawn from wave velocities (at least P-wave velocities). The seismic properties at depth are determined by a number of lithologic and physical factors that control the in situ rock properties in a very complex manner. Velocities are controlled by the intrinsic properties of the rocks (mineralogical composition, chemical composition, metamorphic grade, crystallographic preferred orientation of constituent minerals, etc.) and by the physical environment of the crust (temperature, pressure, porosity, fluid content, etc.).

Direct information about the composition and structure of the deep crust can be obtained either from crustal terrains exposed at the surface (e.g., Fountain and Salisbury, 1981; Kern and Schenk, 1988) or from xenoliths brought to the surface by magmas (Downes et al., 1990). Deeply eroded Precambrian terrains (e.g., Sri Lanka), and upthrust tectonic slices in orogenic belts (e.g., Ivrea Zone, N. Italy; Serre Mountains, S. Calabria; Kapuskasing Zone, Canada) provide perhaps the best geologic guides to structural style and composition at depth. Such rocks are important in providing direct data although they contain a mixed message as they are no longer the in situ deep crust.

A unique ability to correlate the seismic data with the structure and composition of the in situ deep crust can be provided by coupling experimentally determined or calculated P- and S-wave velocities for relevant crustal rocks collected from surface outcrops or from xenoliths, simulating in situ conditions: (1) by laboratory seismic measurements at actual PT conditions (e.g., Christensen and Wepfer, 1989; Kern et al., 1999) and (2) by calculations from modal analyses and elastic properties of the rock-forming minerals and their pressure and temperature derivatives (e.g., Jackson et al., 1990).

High P-wave velocities (>6.9 km/s) generally defining the lowermost crust (below about 20–25 km depth) are typical for metamorphic rocks in the granulite facies. These are mafic granulites, mafic amphibolite facies rocks, anorthosites, and high-grade metapelites.

Intermediate P-wave velocities (6.5–6.9 km/s) represent the upper-lower to mid-crust and are characteristic for intermediate granulites and metapelites.

Low P-wave velocities (6.2–6.5 km/s) occurring at mid-crustal levels in Palaeozoic and more recent fold belts

and in the uppermost crust in shields and platforms are likely to be composed of felsic rocks in the amphibolite and granulite facies. It should be noted, however, that not all felsic (granitic) upper crustal rocks are intermediate- to high-metamorphic grade. The Superior Province (Canada) is an example of low metamorphic shield rocks.

Mineralogically, feldspar (K-feldspar, plagioclase) is the most abundant mineral, followed by quartz and hydrous minerals (such as mica and amphiboles).

The bulk chemical composition of the upper crust is felsic, and the middle crust is intermediate in composition. The average composition of the lower crust is in general mafic in cratons, but it tends to be intermediate or even felsic in some regions. The continental crust as the whole (average of all crustal types) is suggested to be intermediate in average bulk composition (Rudnick and Fountain, 1995).

Importantly, most of the rocks constituting the earth's crust exhibit marked anisotropy of elastic properties (e.g., Kern et al., 2001; Ji et al., 2002). Typical values of intrinsic P-wave anisotropy (quartz-mica-schists, felsic gneisses, granulite-facies metapelites, amphibolites) range from 5.4% to 10.7%. Anisotropy may be caused by crystallographic (CPO) and morphological (or shape) preferred orientation (SPO), by oriented microcracks, or by thin layers of otherwise isotropic materials with different properties.

Whereas oriented cracks may contribute a large fraction of observed seismic anisotropy in the uppermost crust (Crampin, 1987), CPO- and SPO-related seismic anisotropy is a major contribution in ductily deformed and foliated crustal structures (shear zones, gneiss sections) of the deeper crust. It is mainly due to the alignment of mica and hornblende minerals and their strong single crystal anisotropies (Meissner and Kern, 2008). In addition to mineral and chemical composition and rock fabric, pore fluids may have an important bearing on in situ seismic properties. Saturation of pore space ($P_{pore} \approx 0$) increases V_P, whereas V_S remains unaffected (Nur and Simmons, 1969). In case of pore pressure approaching lithostatic pressure ($P_{pore} \approx P_{lith}$), microcracks and grain boundaries are more or less kept open. As a consequence, both P- and S-wave velocities are smaller than in dry rocks, due to a reduction of the effective pressure ($P_{eff.} = P_{lith.} - n \times P_{pore}$; $n \approx 1$). Importantly, V_P-anisotropy is significantly higher in dry rocks than in water-saturated rocks at atmospheric pressure conditions (Popp and Kern, 1994). As pressure is increased, differences progressively decrease. The corresponding S-wave velocities and S-wave splitting data are only weakly affected by intergranular fluids.

Seismic anisotropy is becoming increasingly important also in understanding the evolution of the Earth's crust (and upper mantle). Since the measured seismic anisotropy has a structural (macro- and/or micro-) origin, seismic azimuthal anisotropy manifested by shear wave splitting, in particular, can provide important geophysical evidence of deformation because the orientation and magnitude of anisotropy is, in general, strongly related to the internal strain-induced rock fabric. Although variations of lithology is suggested to be most important for the generation of seismic reflections in the lower crust (laminated lower crust) (e.g., Meissner et al., 2006), seismic reflectivity may be enhanced by the fabric-related anisotropy of ductily deformed structures (Kern and Wenk, 1990). It should be noted, however, that in crustal rocks the variability due to variation in composition is generally higher than the variation caused by velocity anisotropy (except for schists). The reverse is true in the olivine-rich upper mantle rocks. This probably implies that, on a regional scale, fabric-related anisotropy is more important in the oceanic and continental upper mantle than in the continental crust.

Summary

Seismic refraction and reflection surveys have revealed three main types of continental crust: (1) the thick old cratons, constituting large parts of all continents; (2) the orogens, generated by plate collisions; and (3) the extensional areas with a relatively thin crust, exhibiting ample reflectivity (lamellae) in the lower part. Crustal thickness is between 20 km (shelves) and more than 70 km (some orogens). The Mohorovičić discontinuity (Moho), defined by a jump in velocity and density, separates the lowermost crust from the upper mantle. High P-wave velocities (>6.9 km/s) are typical for the lowermost crust of platforms and orogens; they stand for high-grade mafic rocks in the granulite facies. In the thin lower crust of extensional areas, high-velocity mafic rocks are almost lacking. The upper-lower to mid-crust is characterized by intermediate P-wave velocities (6.5–6.9 km/s) and is likely to be composed of intermediate granulites and metapelites. Low P-wave velocities (6.2–6.5 km/s) of mid-crustal levels in Paleozoic and more recent fold belts as well as in the uppermost crust in shields and platform point to felsic rocks in the amphibolite and granulite faces. Seismic anisotropy is an important property of most rocks constituting the earth crust. It is basically caused by crystallographic and morphological (or shape) preferred orientation, by oriented microcracks, or by thin layers of otherwise isotropic material with different properties.

Acknowledgments

We greatly appreciate the assistance of Gudrun Reim (Kiel) in preparing the figures, and we thank Walter Mooney (Menlo Park) for his review leading to many improvements of the manuscript.

EARTH'S STRUCTURE, GLOBAL

Jean-Paul Montagner
Seismological Laboratory, Institut de Physique du Globe, University Paris-Diderot, UMR CNRS/7154, Paris, France

Definition

Structure of the Earth. The manner in which the Earth is constructed. It is characterized through physical and chemical parameters.
Crust. The outer layer of the solid Earth that lies above the Mohorovicic discontinuity.
Mantle. A thick layer of rock below the crust down to the core–mantle boundary CMB at 2,900 km depth.
Core. The central part of the Earth below CMB. It is composed of the fluid outer core (2,900 km down to 5,100 km) and the solid inner core below.
Anelasticity. Property of a substance in which there is no definite (linear) relation between stress and strain.
Anisotropy. Property of a substance being directionally dependent, as opposed to isotropy (identical properties in all directions).

Introduction

The Earth is the largest in size and mass of the Solar System's four terrestrial planets. Of these four planets, Earth also has the highest density, the highest surface gravity, the strongest magnetic field, and fastest rotation.

It is also the third planet from the Sun, and the densest and fifth largest of the eight planets in the Solar System. Earth is a terrestrial planet, meaning that it is a rocky body, rather than a gas giant like Jupiter. Earth is currently the only place where life is known to exist, and the only terrestrial planet with active plate tectonics.

Earth Sciences in general, and Geophysics in particular, are built on the foundations of physics, mathematics, geology, astronomy, and are closely connected to other disciplines such as chemistry and biology. Its roots therefore go far back in history, but the science has blossomed only in the last century with the explosive increase in our ability to measure the properties of the Earth and the processes in play inside the Earth, on and above its surface. Geophysics includes the study of the Earth's solid layers, fluid envelopes, and its near-space environment. However, in this contribution, the subject is narrowed to the solid Earth.

The interior structure of the Earth, similar to the outer and like that of the other terrestrial planets, is divided into layers by their physical (rheological) or chemical properties. Scientific understanding of Earth's internal structure is based on geological, geochemical, and geophysical observations at the surface of the Earth including topography and bathymetry, observations of rock in outcrops, samples brought to the surface from greater depths by volcanic activity. Geophysics can make use of measurements of different physical fields such as the gravity, magnetic fields, and the fields associated with the propagation of seismic waves passing through the Earth. This interdisciplinary observational approach is completed by laboratory experiments with minerals at pressures and temperatures characteristic of the Earth's deep interior.

The technological advances of the last century in laboratory and field instrumentation, computing, and satellite-based remote sensing are largely responsible for the explosive growth of geophysics. These advances enabled geophysicists to make more and more accurate measurements, to collect and to analyze enormous amounts of data, and to model more and more complex systems. This new view of how the Earth works enabled a fundamental understanding of structure of the Earth as well as earthquakes, volcanoes, mountain building, indeed all of geological processes and objects.

1D structure of the earth

The global structure of Earth can be defined in two different ways, either by considering its physical properties, or its chemical properties. Different physical fields are used by geophysicists. The Earth's gravity field can be used to calculate its mass, its moment of inertia. By adding some additional physical constraints, the density variations within the Earth can be calculated. The magnetic field of internal origin provides fundamental information on the deepest layer of the Earth, the Core (see *Magnetic Data Enhancements and Depth Estimation* and *Magnetic Methods, Principles*). Geophysics is the only Earth science discipline enabling the imaging of the invisible deep inner structure of our planet by a direct measurement of its physical properties. To first order, the structure of the earth is dominated by its radial structure (spherically symmetric model). During the first part of the twentieth century, geophysicists determined the onion-like fine structure of the Earth. Seismic waves enable the investigation of the elastic and to some extent anelastic properties of the whole Earth.

Characterizing the interior of the Earth with earthquake waves

Global seismology starts in 1889 when Ernst von Rebeur-Paschwitz in Potsdam (Germany) associated a disturbance recorded on a tiltmeter to the occurrence of a remote Japanese earthquake. Since then, seismologists modeled the propagation of seismic waves from teleseismic events by using the ray theory considering seismic waves as virtual particles following rays between earthquake focus and receivers and their travel times are sensitive to the structure of the Earth.

During the first decades of the twentieth century (see Dziewonski and Romanowicz (2007) for details), the layering of Earth was indirectly inferred using the travel times of refracted and reflected seismic waves generated by earthquakes. The changes in seismic velocity of P-waves (compression waves) and S-waves (shear waves) between different layers cause refraction owing to Snell's law. Reflections are caused by a large increase in seismic velocity and are similar to light reflecting from a mirror. Seismologists were able to find and characterize the main seismic discontinuities (depth and velocity jump) within the different layers of the Earth (see *Seismic Discontinuities in the Transition Zone*). First of all, the Mohorovicic discontinuity between crust and mantle in the depth range 10–60 km then the core–mantle boundary at 2,900 km depth by Oldham (1906). The core does not allow shear waves to pass through it, showing that its outer part is fluid. Finally, Inge Lehmann (1936) demonstrated the existence of a solid inner core.

Mantle itself can be divided into upper mantle and lower mantle by a discontinuity at 660 km depth. In the upper mantle, the finding of a discontinuity around 410 km depth defines the "transition zone" between 410 and 660 km depth. At the base of the mantle, about 200 km above the core–mantle boundary, a discontinuity was discovered, identifying the still mysterious D″-layer. There are some other candidates for entering the club of seismic discontinuities, the Hales discontinuity at 80 km depth, the Gutenberg discontinuity at the base of continental and oceanic lithosphere, the Lehmann discontinuity at 220 km, and also at 520 km and around 900 km depths, but their global nature is still debated. Most seismic discontinuities are interpreted as a mineralogical phase transition between minerals of mantle silicates (olivine–perovskite system) but some of them might be a boundary between different chemical compositions.

From its elastic properties, the different layers are presented in Table 1 and Figure 1. The Earth can be divided into the outer silicate solid crust, the upper mantle (including lithosphere, asthenosphere, and transition zone), the lower mantle (with the D″-layer at its base), the liquid outer core much less viscous than the mantle, and the solid inner core.

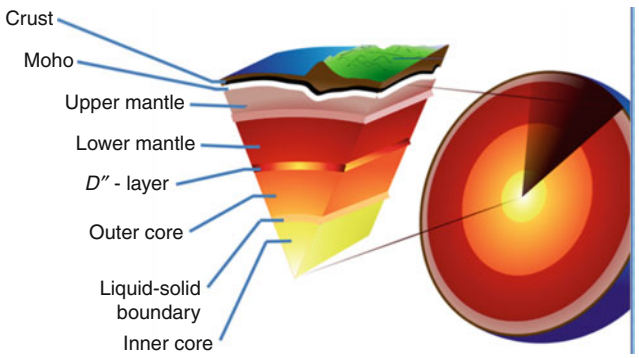
From 1D models to 3D tomographic models

Many reference models (spherically symmetric models) have been developed during the last century, but the most popular ones are the PREM (Preliminary Reference Earth Model by Dziewonski and Anderson, 1981) (Figure 2), IASP91 (Kennett and Engdahl, 1991) and later AK135 (Kennett et al., 1995). PREM introduced for the first time an anisotropic layer (with the specific case of radial anisotropy with a vertical symmetry axis) in the uppermost 220 km of the mantle. Montagner and Kennett (1996) by trying to reconcile body wave and normal mode data showed that a significant amount of radial anisotropy is also necessary in the mantle transition zone in a broad sense between 410 and 900 km depth.

However, important deviations between observed and theoretical travel times of seismic waves with respect to 1D reference models cannot be explained by these simple 1D models. These differences, though relatively small (<10%) are due to the existence of lateral heterogeneities of physical properties within the different layers of the Earth. In the 1960s, the acceptance of the paradigm of plate tectonics and mantle convection leads the seismological community to a better appraisal of the coupling between lithosphere and the underlying mantle convection. Plate tectonics demonstrated that the internal dynamics is very active and that tectonic plates are the surface evidence of deeper convective phenomena. According to geodynamic calculations, large lateral variations in temperature must be associated with lateral variations of seismic velocities. This new approach of global geodynamics has been facilitated by the revolution of broadband seismology in the 1980s (see *Seismological Networks*), which came up with the rapid expansion of seismic networks, the free accessibility of digital data, and more and more powerful computers. Time was ripe for the new era of seismic tomography (imaging of 3D seismic anomalies) and its application to global geodynamics.

Earth's Structure, Global, Table 1 The 1D structure of the Earth

Layer (Km)	
0–80	Lithosphere (locally varies between 5 and 200 km)
0–35	. . . Crust (locally varies between 5 and 70 km)
35–80	. . . Uppermost part of mantle
35–2,890	Mantle
80–220	. . . Asthenosphere
410–660	. . . Transition zone
35–660	. . . Upper mantle
660–2,890	. . . Lower mantle
2,740–2,890	. . . D″-layer
2,890–5,150	Outer core
5,150–6,360	Inner core

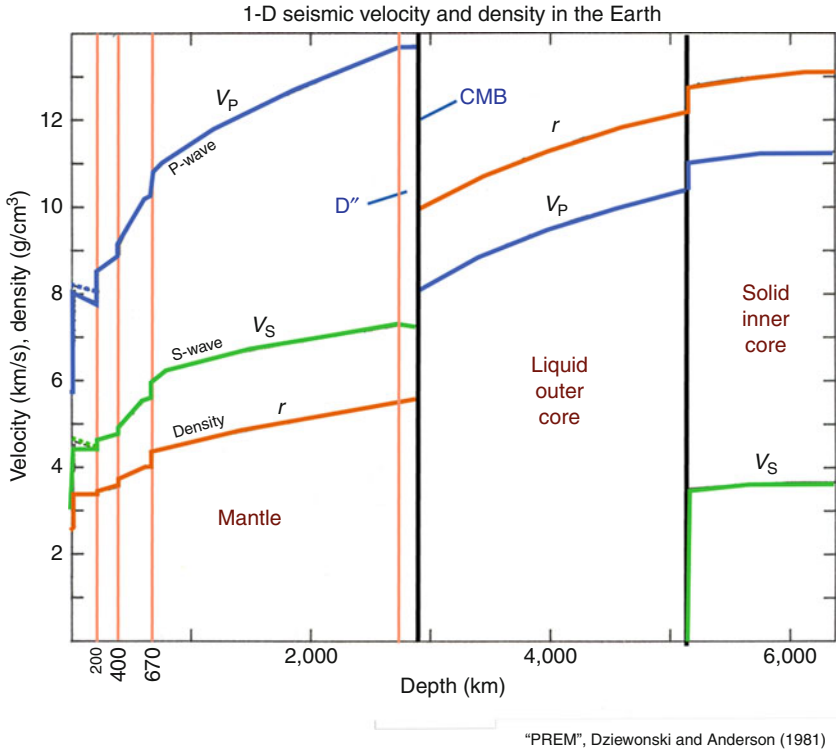


Earth's Structure, Global, Figure 1 The different layers of the Earth.

Mantle convection jigsaw

The investigation of mantle convection is the best example of the implementation of these new available tools in the framework of an interdisciplinary approach. Thermal convection in the Earth has been recognized for a long time (Holmes, 1928; Pekeris, 1935) as the cause of dynamic processes such as mountain building, volcanic and seismic activity, and, more recently, of seafloor spreading. With the advent of plate tectonics, it has become possible to describe quantitatively the motions at the surface of the Earth. The plates, considered as rigid bodies, are the surface manifestation of deep-seated movements related to mantle convection (e.g., Turcotte and Schubert, 2002). This evidence constitutes the first manifestation of pecularities of mantle convection, for it demonstrates large variations in the rheological properties of Earth material between rigid plates and underlying mantle, which cannot be explained by 1D models. Meanwhile, hotspots were identified (Wilson, 1963) and their fixity with respect to plate motions demonstrated (Morgan, 1971). There is a good consensus on the origin of plumes in a thermal boundary layer, but the depth of origin of hotspots is still an open question. The rheology of the lithosphere and the existence of hotspots are two simple examples that illustrate the fact that mantle convection differs in many respects from "classical" convection (such as Benard convection) observed in usual viscous fluids.

The understanding of mantle dynamics is similar to a police investigation: Each earth science field provides miscellaneous and often contradictory clues, which must



Earth's Structure, Global, Figure 2 Preliminary Reference Earth Model (PREM Dziewonski and Anderson, 1981).

be assembled like a jigsaw puzzle pieces. Different approaches have been used to characterize and understand mantle convection (see *Mantle Convection*). None of them could provide a general and consistent explanation of simple features such as the shape and geometry of plates, the origin of hotspots, and the number of layers in the mantle. Many questions arose: How is surface geology (continents, plate boundaries, mountain ranges, hot spots) reflected at depth? How are characterized the interactions and the coupling between the different layers of the Earth? How deep mantle flows affect the surface geology or conversely how surface phenomena affect deep dynamics?

Another issue was the characterization of the spatial scales of heterogeneities at the global scale. Geology makes evident a multiplicity of scales. Some tectonic plates are gigantic (larger than 10,000 km), some others smaller (1,000 km). Continents have as well very various sizes. The different plate boundaries (subduction zones, ridges, transform faults) have a very small lateral extent (a maximum of 100 km except continent–continent collision zones). Hotspots are even smaller and their role in global geodynamics cannot be explained by plate tectonics. This multiscale approach is also present for the temporal scales. Whereas times associated with plate tectonics count in tens of millions of years, catastrophic events such as hotspot birth, mantle avalanches, seismic and volcanic cycles last only for centuries. According to time scales, rheological properties change. Therefore, natural phenomena are by essence, multiscale and make it necessary a multidisciplinary approach. The role of geophysicists consists in quantifying, understanding processes, proposing simple laws in spite of the complexity of processes.

One of the most powerful approach to investigate mantle convection is the numerical approach. The basic equations of physics governing mantle convection are well known (Navier–Stokes equations and thermal equation of energy conservation). This system of equations is very complex and nonlinear, expressed in terms of adimensional numbers such as the Rayleigh number Ra. Actual estimates of Ra make it largely beyond the critical Rayleigh number, which means that mantle convection is thermally turbulent. In other words, mantle convection is chaotic at the geological time scales, meaning that the convective flow is not stationary in time and space. With the rapid expansion of computer facilities, it is now possible to numerically simulate the equation system. However, it turns out difficult to reproduce plate behavior with numerical experiments. Laboratory experiments complete the whole numerical battery, enabling the fine investigation of some specific phenomena. Material science, by studying physical properties of earth minerals (rheology, anelastic and elastic properties) at very high pressure

(by using diamond anvil cells and synchrotrons, etc) also provide important information on mineralogical composition of the mantle. Most seismic discontinuities can be interpreted as pressure- and temperature- induced phase changes in the olivine system (Birch, 1952), such as the 410- and 660-km discontinuities. However, some composition changes might also occur around these depths and deeper in the lower mantle where thermochemical convection might be predominant.

In that context, the determination of 3D models of seismic parameters of the mantle (also coined tomographic models) can be considered as a pragmatic approach that consists in imaging the structure of convection in order to provide clues to the nature of driving mechanism and to investigate mantle convective processes, the engine of plate tectonics. Thanks to the intensive use of computers that can handle very large data sets, the techniques of seismic tomography (see *Seismic Tomography*) can image the 3D deep structure of the Earth and provide unavoidable constraints of possible models of mantle convection and makes it possible to test different competing hypotheses. However, the main limitation of seismic tomography is that it only provides an instantaneous image of our planet Earth and it is necessary to confront seismic results with other Earth science fields providing information on the history of our planet.

Seismic 3D tomography: the Earth scanner

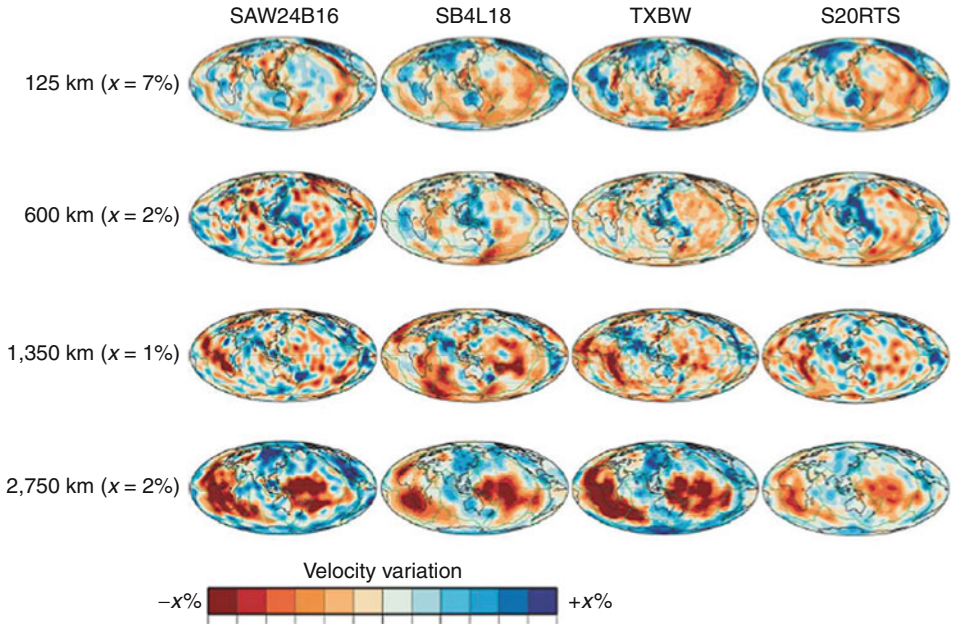
Seismic wave propagation is very sensitive to temperature, chemical, and mineralogical anomalies. These anomalies reflect the active dynamics of the Earth which should be a dead planet without them. It was observed for many decades that seismic velocity below old continents is much larger than the velocity beneath young oceans. This difference between tectonic provinces can be explained by a different history: Cratons older than 1 billion years had a lot of time to get colder, whereas below oceans, the younger and warmer lithosphere is permanently recycled within the mantle. An increase in temperature is usually translated into decrease in seismic velocity, whereas an increase in pressure is translated into velocity increase. At a given depth (approximately constant pressure), the lateral variations of seismic velocity can be primarily interpreted in terms of temperature variations. A large variety of tomographic techniques similar to ultrasonography or scanner has been developed for getting the 3D structure of the Earth, notwithstanding the geological nature of the surface.

The first 3D models of the Earth's mantle were proposed by the end of the 1970s (Dziewonski et al., 1977; Sengupta and Toksoz, 1976), but the true revolution of seismic tomography took place in the mid-1980s when a complete set of tomographic models was proposed from the surface down to the center of the Earth (see Woodhouse and Dziewonski (1984), Nataf et al. (1984), Tanimoto and Anderson (1985) for the upper mantle, Dziewonski (1984) for the lower mantle). The present lateral resolution at global scale for the whole Earth is approximately 1,000 km. Tomographic models (Figure 3) fundamentally renewed our vision of Earth dynamics, and shed new light on deep processes.

At 100 km depth, the distribution of seismic velocity anomalies reflects the geological surface structure. Almost all plate boundaries are slow since they are often associated with active volcanism. In oceanic zones, seismic velocity increases with the age of the sea floor confirming the cooling of plates with age. This remarkable agreement between observed seismic structure and structure deduced from geology was the first proof of the validity of tomographic approach. At larger depths, the correlation between surface geology and seismic structure progressively vanishes and the amplitude of seismic anomalies decreases. The continental roots can be found down to 250–300 km but mid-ocean ridges are no longer visible. In contrast, subducting slabs associated with high velocities can be traced down very deeply. The transition zone (410–660 km) is still one of the less well-resolved depth ranges. It is characterized by weak heterogeneities but the velocity distribution is dominated by a simple scheme, with high velocities around the Pacific Ocean and slow velocities below central Pacific and Africa, the so-called degree 2 pattern (Masters et al., 1982).

At the global scale, it is usual to expand the velocity anomalies in terms of spherical harmonics $Y_l^m(\theta,\phi)$, where θ,ϕ are the spherical geographical coordinates, l the angular degree, and m the azimuthal order. The spectral amplitude of individual degree l enables the assessment of the importance of different spatial wavelengths λ, since λ is inversely proportional to l. The "degree 2 pattern" predominant in the transition zone as well as in the D″-layer is associated with large-scale mantle flows, upwellings on both sides of Pacific, and upwellings below central Pacific and Africa. The spectrum of heterogeneities is "red" (see Dziewonski and Romanowicz, 2007 for a review), therefore dominated by very large wavelengths but the role of smaller scale objects such as slabs and mantle plumes is still discussed.

The behavior of slabs in regional studies does not seem to be uniform (Figure 4a). Some slabs seem to fall down to the core–mantle boundary (van der Hilst et al., 1997), whereas others, e.g., beneath Japan (Fukao et al., 2001) are stagnant in the transition zone. Mantle plumes and the associated hotspots might initiate continental breakup, inducing the opening of new ridges of oceans, and might dramatically affect biodiversity. After plate tectonics, will we see the development of plume tectonics? There is still a controversy on the origin of plumes. It is likely that they do not have a single origin, but can originate from the different boundary layers within the Earth, in the asthenosphere, transition zone, and D″-layer. There are still lively debates about the origin at depth of mantle plumes (Figure 4b shows an example of plume imaging), and two opposite extreme models (plate model and plume model) are summarized in Figure 5. At the base of the mantle, the D″-layer is still very mysterious since it is



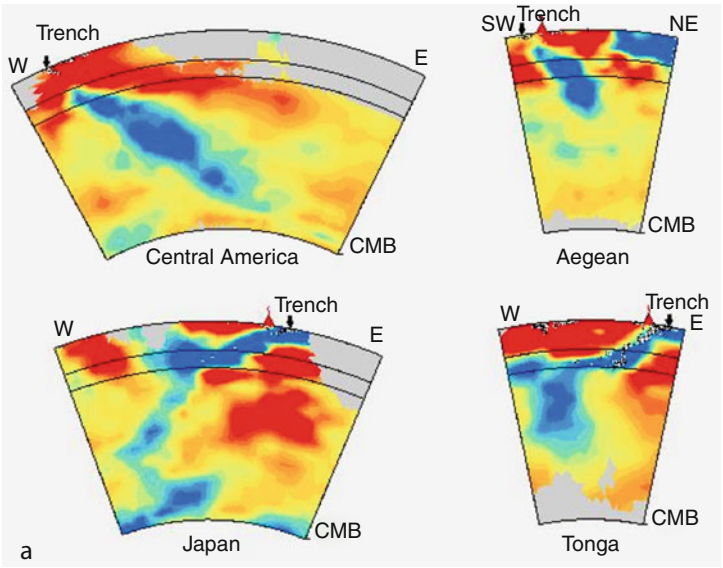
Earth's Structure, Global, Figure 3 Maps through S-velocity models SAW24B16, SB4L18, TXBW, and S20RTS and P-velocity models P-MIT and FF-PRI at depths of 125, 600, 1,350, and 2,750 km (From Thurber and Ritsema, 2007).

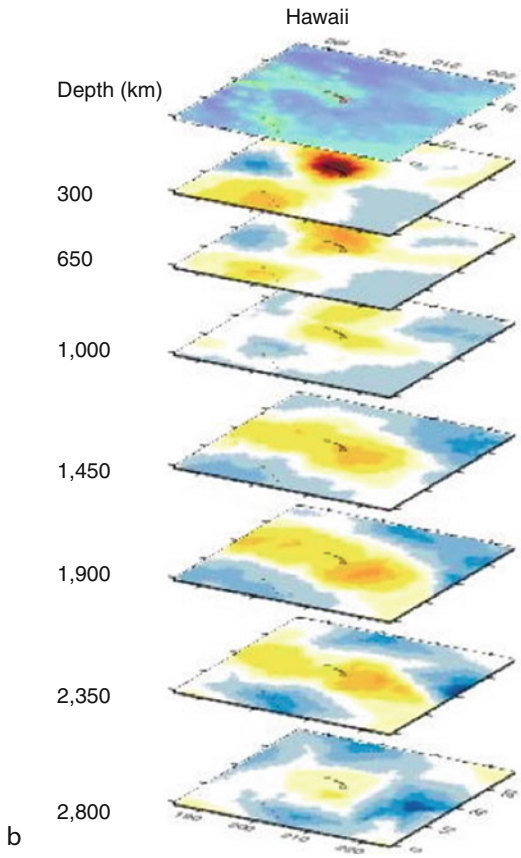
the probable graveyard of slabs and a good candidate for being the matrix of some mantle plumes giving birth to hotspots at the surface of the Earth. The recent and unexpected discovery of post-perovskite (Murakami et al., 2004), which might be present in the lowermost mantle has implications for the D″-layer that influences the convective mixing in the mantle responsible for plate tectonics.

An anisotropic and anelastic Earth

Most earth minerals cannot be limited to their isotropic and elastic properties. When they are deformed over geological timescales, mineral grains and aggregates tend to align by lattice-preferred orientation (LPO), which can lead to bulk anisotropy (see Becker, *Seismic Anisotropy*). Additional anisotropy can also come up when crack distribution (in the crust) or fluid inclusions (asthenosphere, inner core) are present within the material (shape-preferred orientation, SPO). Water content might also play a key role in alignment mechanisms (Karato et al., 2008). In the upper mantle, the different minerals present are strongly anisotropic. The difference of velocity between the fast axis and the slow axis is larger than 20% for olivine, the main constituent of the upper mantle. Other important constituents such as orthopyroxene or clinopyroxene are anisotropic as well (>10%) (see Babuska and Cara (1991), Anderson, (2007), Mainprice, (2007) for reviews). Consequently, the petrological models that are assemblages of different minerals are less anisotropic than pure olivine. The amount of anisotropy is largely dependent on the percentage of these different minerals and on the mechanisms aligning the crystallographic axes according to LPO. For example, the anisotropy of the pyrolitic model, mainly composed of olivine and orthopyroxene (Ringwood, 1975), will depend on the relative orientation of the crystallographic axes of different constituents (Christensen and Lundquist, 1982).

For sake of mathematical simplicity, it was usually assumed that the propagating elastic medium is isotropic, in spite of the large amplitude of anisotropy in several depth ranges. And only 1D reference models of attenuation are incorporated in seismic modeling. Global tomographic models improved over years not only by an increase in the number of data but also by more general parameterizations. They are now including anisotropy (radial anisotropy in Nataf et al. (1984); general slight anisotropy in Montagner and Tanimoto (1991), and anelasticity (Romanowicz, 1995). Whereas isotropic heterogeneities enable the mapping of hot and cold regions within the Earth, seismic anisotropy gives access to the convective flow. Gaboret et al. (2003) and Becker et al. (2003, 2008) demonstrated that mantle circulation inferred from geodynamic models is in good agreement with radial and azimuthal anisotropy distributions (Figure 6). Seismic anisotropy has many other applications such as the determination of the base of continental roots (Montagner, 1994; Gaherty and Jordan, 1995; Silver, 1996; Gung et al., 2003; Debayle et al., 2005), the

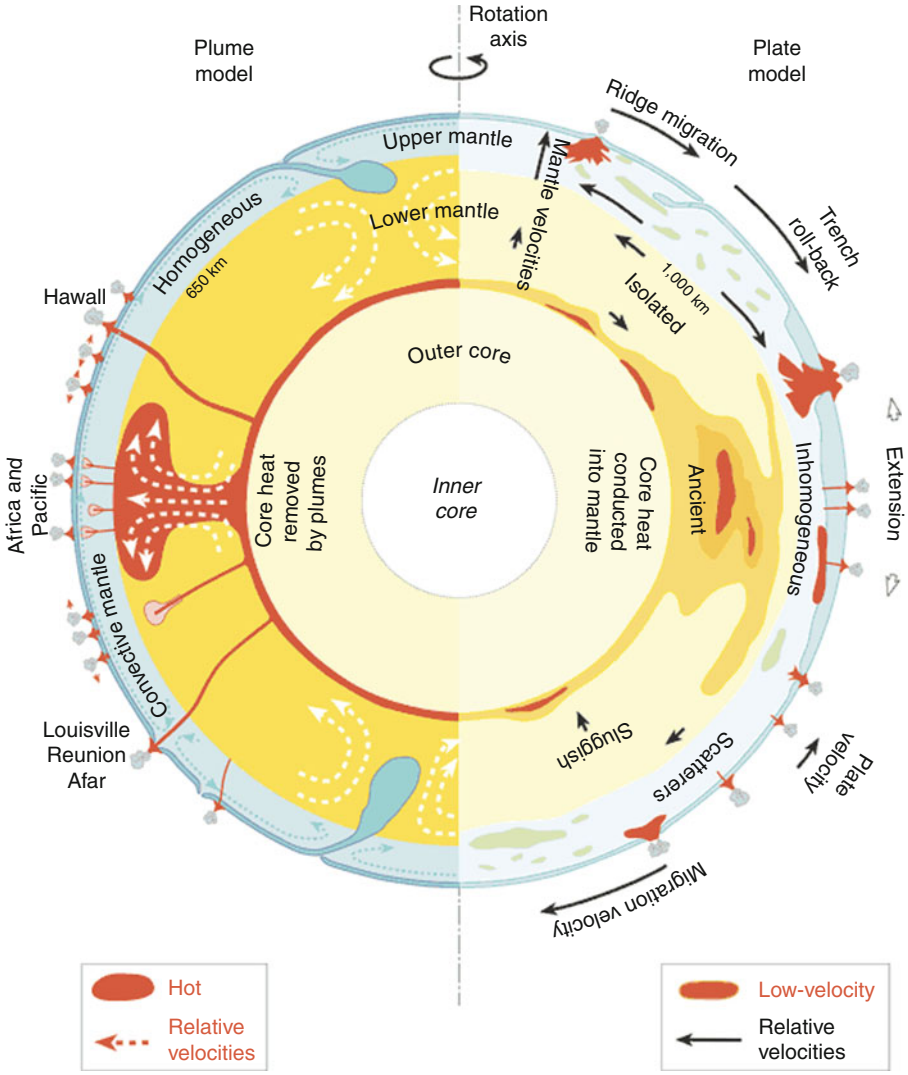




Earth's Structure, Global, Figure 4 Tomographic images of slabs (**a**, van der Hilst et al., 1997) and plume (**b**, Montelli et al., 2004).

investigation of small-scale convection at the base of the lithosphere, of convection boundary layers within the Earth, in the transition zone (Trampert and van Heijst, 2002), D″-layer (see Lay, and Garnero et al.,) and even within the inner core (see Souriau (2007), Wen in structure of the inner core).

Because of its strong dependence on temperature, partial melting, and water content, mapping anelastic



Earth's Structure, Global, Figure 5 Competing models for explaining the origin of hotspots (Left, Courtillot et al., 2003; Anderson, 2001) (From Foulger et al., 2005).

attenuation in the Earth has the potential to provide valuable information on Earth's three-dimensional (3D) structure and dynamics, in complement to what can be learned from mapping elastic isotropic velocities and anisotropic parameters. A significant challenge is to separate the effects of anelastic (or intrinsic) attenuation from those of elastic scattering and focusing due to propagation in elastic 3D structure.

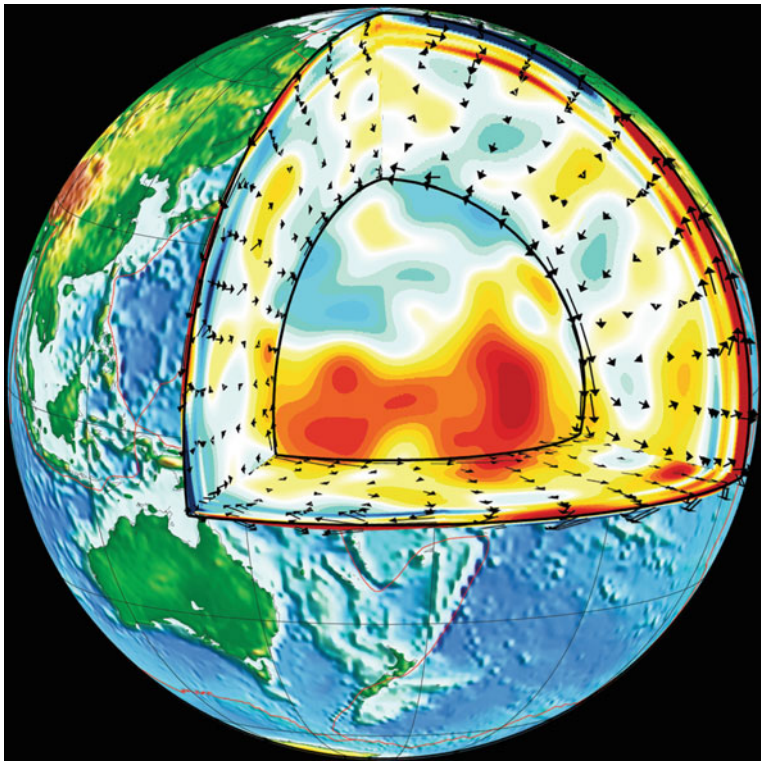
Seismic anisotropy and anelasticity provide new ways to investigate geodynamic processes within the different layers of the Earth.

Conclusions and new challenges

So far, global 3D tomographic models are well resolved for very large spatial scales (>1,000 km). And the global flow circulation in most of the mantle is dominated by the "degree 2 pattern." However, smaller wavelengths are not so well resolved even though many geological objects with a lateral extent of the order of 100 km, such as slabs or mantle plumes play a key role in global geodynamics.

New innovative numerical techniques for forward modeling (such as Spectral Element Method) and for inverse problems (adjoint tomography of Tarantola, 1986; Tromp et al., 2005) are now available and make it possible to use the full waveforms of seismograms. Figure 4b shows an image of the Hawaiian plume (Montelli et al., 2004) obtained by incorporating finite frequency effects. Therefore, we can expect that they should lead to a new revolution in global tomography.

Impressive progress through global tomography, geochemistry, and mineral physics has been made during the last 20 years in our understanding of global geodynamics,



Earth's Structure, Global, Figure 6 Numerical modeling of flow circulation superimposed to 3D tomographic model (Gaboret et al., 2003).

demonstrating how active and turbulent is our planet. All layers are heterogeneous, interact, and exchange matter. The geosciences community must improve the lateral resolution and the quality of the 3D images and incorporate on a routine basis, anisotropy, and anelasticity. There is a real need for a 3D seismic reference Earth model in agreement with geological, mineralogical data, and fluid dynamics modeling.

This progress brings about the expansion of new instruments such as very dense seismic networks on land (e.g., US-array, Hi-Net, Euro-Array, . . .), on the sea floor, by exploring other planets, and by incorporating new data such as seismic noise (Shapiro et al., 2005; Nishida et al., 2009) implementing more powerful numerical techniques. Geophysics only provides some pieces for our puzzling global geodynamics and a multidisciplinary effort is necessary to fully understand the spatiotemporal evolution of our planet. The exploration of other telluric planets will provide other examples of solutions chosen by nature.

Synonyms

Deep mantle; Deep Earth

Definition

Seismic tomography. An inverse method that utilizes seismic wave travel times and/or waveforms to estimate Earth's seismic velocity and density structure, either regionally or globally.

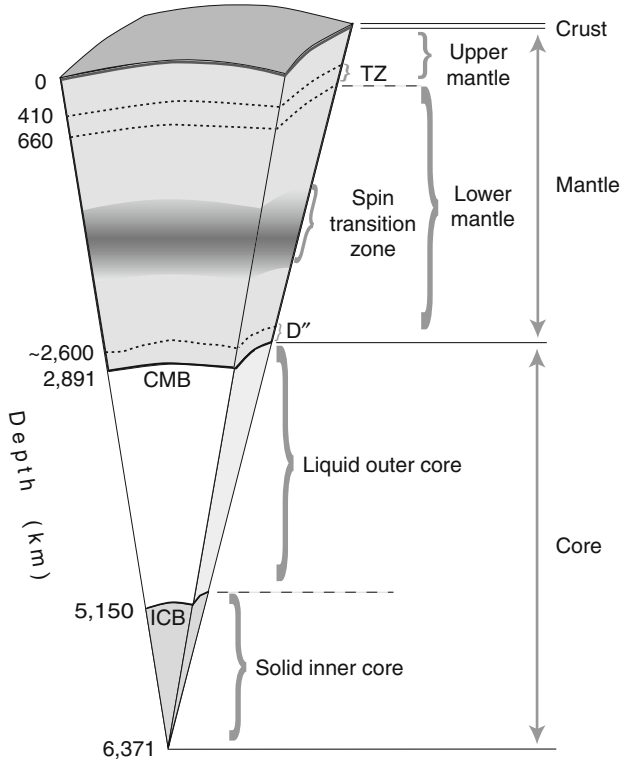
Forward modeling. The procedure involving the generation of models that predicts observations, which is frequently used in deep Earth seismology.

Phase transition. A crystallographic rearrangement of atoms in a mineral that occurs at high pressure.

D″. The depth shell of Earth occupying the lowermost 200–300 km of Earth's lower mantle. (Pronounced "D-double-prime").

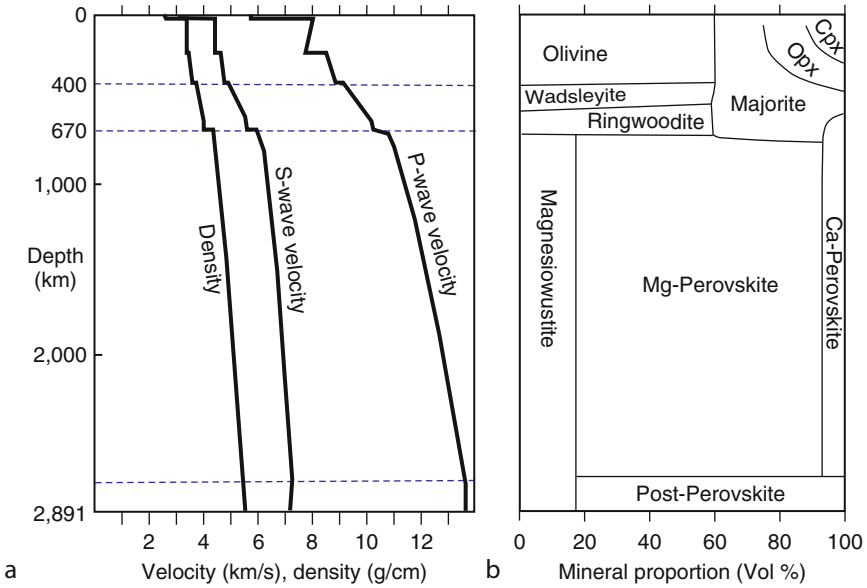
Introduction

Earth's interior has three fundamentally distinct divisions: (1) the relatively buoyant and thin outer crust, which averages roughly 6–7 km in thickness beneath oceans and 30–40 km in continents; (2) the mantle, which extends to nearly half way to Earth's center; and (3) the dominantly iron (Fe) core, which has a fluid outer part and a solid inner part. Figure 1 highlights these basic shells,



Earth's Structure, Lower Mantle, Figure 1 Major depth shells of Earth, along with a number of subdivisions. TZ = transition zone (the upper mantle between 410 and 660 km depth); CMB = core–mantle boundary; ICB = Inner core boundary.

along with a number of additional significant mantle subdivisions. The mantle is divided into an upper and lower part, with the boundary near 660 km depth. The upper mantle has another distinct discontinuity near 410 km depth. As shown in Figure 2, the dominant mineral in the upper mantle is olivine, a magnesium-iron silicate mineral with composition $(Mg,Fe)_2[SiO_4]$, that undergoes phase transitions to higher density mineral forms (or polymorphs) near 410, 520, and 660 km depths. The region between 410 and 660 km is referred to as the mantle transition zone. Below 660 km, mantle silicates undergo another phase transformation, compacting into the perovskite structure, with composition $(Mg,Fe)[SiO_3]$, plus magnesium-iron oxides, (Mg,Fe)O (known as ferropericlase and also referred to as magnesiowüstite in earlier literature). In the lowermost several hundred km of the mantle, a region referred to as D″, perovskite has been shown to undergo an additional phase transition into the "post-perovskite" structure (Murakami et al., 2004 [Science]), and depending on the temperature, post-perovskite might back-transform into perovskite at greater depth, remaining as perovskite down to the CMB (see *Mantle D″ Layer*). The lower mantle depth shell accounts for nearly 56% of Earth's volume, and extends from 660 km depth down to the core–mantle boundary (CMB) at 2,891 km depth (and thus includes the D″ layer).



Earth's Structure, Lower Mantle, Figure 2 (**a**) Variations in seismic properties of the Earth's mantle with depth, from the surface to the core–mantle boundary, showing the major discontinuities in P-wave velocity, S-wave velocity, and density. (**b**) Mineralogical makeup of the mantle. Cpx = clinopyroxene; Opx = orthopyroxene.

The major discontinuities throughout Earth's mantle are thus well-explained by phase transitions in the olivine-perovskite system.

While uncertainties are present in our understanding of the exact compositional make-up of Earth's mantle, it is generally believed that magnesium-iron silicate perovskite is the dominant mineral structure of the lower mantle, possibly accounting for ~80% of the lower mantle, and hence is the most abundant mineral on Earth. This perovskite mineral structure is the same as that occurring in well known electronic and piezoelectric materials, such as barium titanate. A fundamental difference between the silicate minerals of the upper mantle and lower mantle perovskite is that every silicon (Si) atom in perovskite is surrounded by six oxygen (O) atoms (silicon is octahedrally coordinated), whereas for upper mantle silicates the silicon is bonded to four O atoms (tetrahedral coordination). A primary effect of the higher pressure in the lower mantle is that O atoms occupy a smaller volume, thus more can be organized around (coordinated with) Si. This more compact rearrangement of atoms in lower mantle phases means that they have higher density than upper mantle materials, as well as differences in other properties such as the material's stiffness and resistance to shearing. These changes affect the velocities of seismic waves; thus, at depths where phase transitions occur, there are jumps (i.e., discontinuous increases) in seismic compressional and shear wave speeds (referred to as P-wave and S-wave velocities, or V_P and V_S, respectively). Velocity and density depth distributions in Earth's mantle are presented in Figure 2; these values represent an estimation of the globally averaged properties.

The exact depth of a phase transition in any given mineral group depends upon temperature and pressure (and chemical composition). Earlier conceptions of the lower mantle (Birch, 1952) postulated that the lower mantle had a constant composition, and hence the temperature and velocity variations could by described by simple adiabatic compression. However, in light of more recent studies, it is interesting to consider the fact that lateral temperature variations are likely in the lower mantle, because the mantle is convecting, and hence phase boundaries are not expected to be perfectly flat (e.g., Lebedev et al., 2002). Rather, they should have relief that directly relates to the temperature field (or to perturbations in chemical composition, since minerals may transform at different pressures if there are variations or impurities in the mineral composition). The Earth presumably was significantly hotter in the distant geologic past (from heat generated during formation and differentiation of the mantle and core), therefore we expect phase boundaries in the earliest Earth to have been at different depths than today.

Tools for studying the lower mantle

Earth's mass and moment of inertia, determined from orbital and rotational dynamics, provide important information about the planet's internal density distribution. These data, combined with assumptions about starting materials for Earth's formation from analyses of meteorites, have long indicated a predominantly iron core with a silicate rock mantle (Carlson, 2003). Seismic studies early in the twentieth century confirmed the existence of the core (outer and inner), as well as the fact that the outer core is liquid (from the absence of shear waves on the opposite side of the planet following an earthquake, because shear waves cannot propagate in fluids).

A number of Earth science disciplines contribute to our body of knowledge of the lower mantle (and the deep Earth in general). For example, the field of mineral physics includes high pressure laboratory experiments aimed at simulating the pressures and temperatures within the deep Earth. Predictions of the melting temperature of iron at the conditions of the boundary between the inner and outer core (at radius of ~1,220 km), as well as measurements delineating the temperature of the olivine to perovskite plus ferropericlase phase transition at 660 km depth provide two important temperature tie-in points that help to constrain Earth's geotherm; temperature must be extrapolated from these points toward the CMB, where a very large temperature jump occurs. Based on such studies, the top of the lower mantle at 660 km depth is at a pressure of about 23 GPa (1 Pa = 1 N m^{-2} and 10^5 Pa corresponds to approximately 1 atm of pressure) and a temperature of about 1,800 +/− 200 K (e.g., Ito and Katsura, 1989; Frost, 2008). The CMB is at a pressure of about 130 GPa; the temperature, while less constrained, has been recently estimated to be about 4,000 +/− 500 K (Van der Hilst et al., 2007). The temperature jump from the CMB to the outermost core may be as much as 1,000–1,500 K.

A number of notable uncertainties are present that currently preclude precise knowledge of lower mantle temperature, including the amount of heat-producing radiogenic materials, the vigor of mantle convection, the heat flux from the fluid core into the mantle, and important thermal properties of perovskite at lower mantle pressure and temperature conditions (e.g., thermal conductivity, heat capacity, and the coefficient of thermal expansion). However, using a diamond anvil cell high-pressure device to achieve pressures as great as those of the lower mantle and even the core, researchers have recently refined our understanding about two important characteristics of perovskite. As mentioned above, perovskite (*pv*) can transform into a higher pressure (and density) structure termed "post-perovskite" (*ppv*) at D″ pressures (around 120 GPa). Thus, if the systematics of this phase transition can be well defined from laboratory experiments or theory, then seismic mapping of the $pv \rightarrow ppv$ transition depth (as well as that of possible $ppv \rightarrow pv$ back-transformation) adds an additional temperature tie-in point for the geotherm (Hernlund et al., 2005). Another discovery describes a change with increased pressure in the electronic spin state of iron in magnesiowüstite and perovskite (a change from a high-spin configuration with a maximum number of unpaired d-shell electrons to a low-spin configuration in which d-shell electron pairing is maximized). Experiments indicate that this will occur between the depths of 1,000 and 2,200 km (Lin et al., 2007). Current research predicts that this spin transition may result in a softer material, which can be more easily compressed thus increasing the density of the deeper mantle, possibly affecting convective dynamics.

The vigor of mantle convection plays a central role in the cooling of Earth. The most commonly used parameter to determine if convection is occurring and to describe the strength of convection is the Rayleigh number, *Ra*:

$$Ra = \frac{\alpha g \rho \Delta T D^3}{\eta \kappa},$$

where α is the coefficient of thermal expansion, g is the acceleration due to gravity, ρ is density, ΔT is the non-adiabatic temperature change across the convecting layer (in this case, the whole mantle) of thickness D, η is the viscosity, and κ is the thermal diffusivity. *Ra* in the lower mantle is estimated to be on the order of 10^7; values greater than $\sim 10^3$ indicate that convection is occurring and values as high as 10^7 indicate vigorous convection. Factors such as the temperature dependence of viscosity can strongly affect the style of convection. Thus, numerical convection calculations incorporate our best understanding of Earth's properties and provide important information about the dynamics and evolution of the mantle (and the planet as a whole).

Erupted materials offer an opportunity to study mantle chemistry. Specifically, some hot spot volcanoes are thought to be caused by mantle plumes that originate in the lower mantle. There is currently debate regarding whether all hot spots tap the lower mantle, as well as the depth of origin of different plume sources (Courtillot et al., 2003). However, it is widely accepted that magmas from hot spot volcanoes contain isotopes that are different compared to lavas erupted at mid-ocean ridges. This has led to a view that the lower mantle represents a distinct reservoir that has undergone little or no mixing with the upper mantle (Hofmann, 1997). Subsequent and ongoing work continues to challenge that perspective, which we address in the three-dimensional structure and dynamics section below.

Seismic imaging is the primary tool that gives us the ability to map lateral variations of mantle properties from the upper mantle to the CMB. Seismic tomography provides an image of the full three-dimensional heterogeneity field, albeit at relatively long horizontal wavelengths, on the order of 3,000 km or so (e.g., Ishii and Tromp, 1999; Ritsema and van Heijst, 2000; Mégnin and Romanowicz, 2000; Grand, 2002). Variations in seismic velocity as well as density (Trampert et al., 2004; Ishii and Tromp, 2004) have been mapped, and when compared to surface tectonics, help to depict convective flow in the interior.

Information about the small-scale heterogeneity field is provided by a number of forward-modeling seismic studies. For example, some studies have suggested that small-scale scatterers exist throughout the lower mantle (Hedlin and Shearer, 2000). Other studies find evidence for discrete reflectors in some locations, particularly beneath subduction zones (Rost et al., 2008; Kito et al., 2008). The exact nature of such small-scale heterogeneity is unknown, but may indeed relate to an incompletely mixed mantle, or heterogeneities entrained from the top (dense material falling) or the bottom (buoyant material rising).

Three-dimensional structure and dynamics

For decades, it has been known that Earth's mantle contains significant lateral variations in seismic properties, which are due to variations in temperature and or chemical composition compared to the local average properties. Results from seismic tomography depict V_P, V_S, and ρ changes throughout the mantle. Variations are neither expected nor detected in the fluid outer core; the extremely low viscosity and relatively fast convection promote homogenization (Stevenson, 1987). Seismically detected mantle heterogeneity is the strongest in the outermost few hundred kilometers of the mantle (i.e., near the planet's surface), due to the strong variations in temperature and composition associated with plate tectonic and mantle convection processes (Masters et al., 2000). The next most seismically heterogeneous depth shell is the D″ region at the base of the mantle (see *Mantle D′′ Layer*). Figure 3 shows seismic velocity variations in the lower mantle. D″ silicate rock is juxtaposed against the fluid iron outer core, which represents roughly a 75% increase in density. Thus, the mantle side of the CMB can accommodate long-lived stable structures over a wide range of densities (between the mantle and core density); it is possible that cumulates denser than average lowest mantle silicates can survive entrainment by the convective currents in the overlying mantle (e.g., McNamara and Zhong, 2005). However, other possibilities are viable (Deschamps et al., 2007).

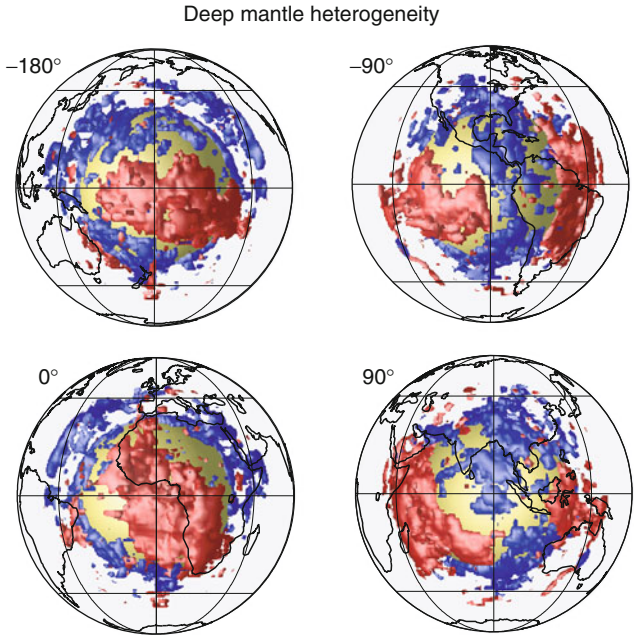
The lower mantle above D″ displays variability in seismic properties, but at a much weaker level than that imaged at the top and bottom of the mantle. In some regions it is plausible that low amplitudes of mid-mantle heterogeneity may reflect our limited ability to confidently image the mantle there (due to a lack of seismic information because earthquakes and seismic recorders are not uniformly distributed on Earth). Nonetheless, all seismic tomography studies to date agree that heterogeneity is greater at the top and bottom of the mantle relative to the middle of the mantle.

Plate tectonics involves the creation of plates at mid-ocean ridges, and destruction or consumption of plates at subduction zones, where the cold and dense oceanic crust and lithosphere (compared to the surrounding mantle) descend into the interior. Tomographic analyses have shown that planar features with high wave speeds beneath subduction zones (e.g., Grand et al., 1997) are consistent with cold material subducting deep into the lower mantle. While the penetration depth of subducting slabs is not adequately constrained beneath all subduction zones, it is widely accepted that most slabs descend through the 660 km discontinuity, in some cases reaching to the CMB (such as beneath the Caribbean). It is important to understand the large-scale long-term flux of material from Earth's surface to great depths in the interior because of the significance for long-term (geological time) effects on surface volatiles, the atmosphere, and global climate.

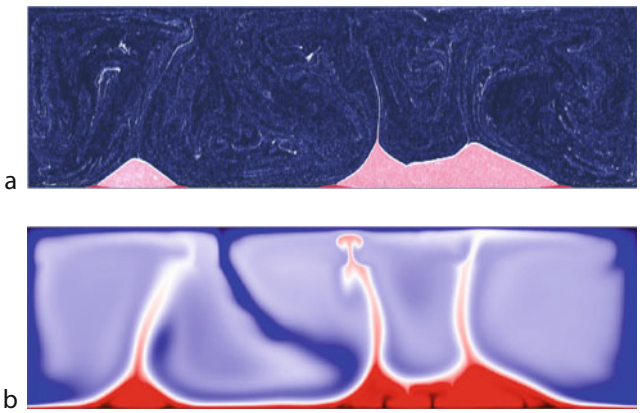
The amount and rate of mass flux between the upper mantle down into the lower mantle depends on several poorly known quantities such as the viscosity of the descending slab and mantle, the viscosity increase at the 660 km discontinuity, as well as the degree of viscous coupling between the oceanic lithosphere and underlying asthenosphere (before and after subduction). Time-integrated mass transfer into (and out of) the lower mantle plays a role in long-term mixing and lower mantle residence time of deep mantle minerals. For example, weak viscous coupling between slabs and the surrounding mantle predicts lower flux rates into (and out of) the lower mantle, and hence less mixing between the upper and lower mantle. A strong coupling between the slab and mantle predicts the opposite. Current data and predictions do not yet distinguish between these possibilities.

An analogous dependency between mixing and convective parameters exists for the bottom of the mantle, where recent work argues for a chemically distinct origin of tomographically identified large, low shear wave velocity regions (Garnero and McNamara, 2008). Convective currents associated with subduction sweep basal dense material to regions away from downwellings, forming thermochemical "piles" (Figure 4) (McNamara and Zhong, 2005). The contrast in properties (e.g., density, viscosity, temperature) between piles and surrounding mantle will determine the morphology and vertical extent of the pile material, as well as the degree of entrainment (and hence its evolutionary behavior). The two, nearly antipodal low shear velocity regions, one beneath the central Pacific and the other beneath the southern Atlantic and Africa (Figure 3), are accompanied (in certain areas) by low-velocity conduits that are associated with mantle plumes (Montelli et al., 2004). Thus, the present-day large-scale structure and circulation pattern of the lower mantle represent a time-integrated effect of anomalous temperature and/or chemistry in Earth's lowermost and uppermost mantle boundary layers (D″ and the lithosphere, respectively).

At smaller scale lengths, seismic studies have found evidence for seismic wave scattering. The imaged size of heterogeneities in the lower mantle ranges from a kilometer to tens of kilometers in scale (e.g., Vidale and Hedlin, 1998; Wen and Helmberger, 1998). This observation indicates chemical anomalies at a spectrum of physical scales and a mantle that is not fully mixed. Indeed, analyses of magmas from hot spot volcanoes have yielded characteristic isotopic signatures distinct from those of mid-ocean ridge basalts, arguing for unique, possibly isolated deep mantle reservoirs that feed mantle plumes. Irregular convective patterns (e.g., see Figure 4) are consistent with such heterogeneities spreading through the lower mantle as well as being entrained into mantle plumes, but not necessarily in a systematic fashion (since convection patterns appear multi-scaled and may be complex). Alternatively, scattering of seismic energy can occur from small pockets of partially molten mantle material. This scenario has been motivated by the detection of thin (a few km) laterally discontinuous layers right at the CMB, called ultra-low-velocity zones (ULVZs). ULVZs have been argued to



Earth's Structure, Lower Mantle, Figure 3 Heterogeneity in the deep mantle at a depth of 2,800 km is seen in the tomographically derived shear wave speed variations (Ritsema and van Heijst, 2000). Iso-surfacing at the + 0.7% (*blue*) and −0.7% (*red*) levels show the higher and lower velocity regions, respectively. Two large low shear velocity provinces are present, and high velocities tend to be located below present-day (or recent past) subduction.



Earth's Structure, Lower Mantle, Figure 4 Numerical geodynamics calculations for a model mantle consisting of three distinct chemistries are shown for the whole mantle, from Earth's surface to the core–mantle boundary. Panel (**a**) displays the chemical field, showing the bulk of the upper and lower mantle in blue, as one chemistry type, dense lower mantle piles (*pink*) as a second distinct chemistry, and thin ultra-low-velocity zones at the core mantle boundary (*red*) that accrue near the pile margins. (**b**) The temperature field associated with (**a**) is shown. Red and blue are hotter and colder regions, respectively. The dense piles can be stable for billions of years, though a low level of entrainment is constant, as evidenced by the white streaks throughout the mantle in panel (McNamara et al., 2010).

contain some degree of partial melt, and hence offer a plausible source of scatters composed of melt pockets (whether or not they are of a distinct chemical composition).

Future progress

As seismic sensors are deployed in new regions across Earth's surface, new geographical regions will be sampled with greater certainty, and thus our understanding of global processes will greatly improve. As sensor deployments become denser (with smaller distances between sensors), Earth's deep structure can be imaged with a much greater resolution. Thus small-scale structures and processes can be inferred with greater certainty and tied to estimations of global processes. The seismic work only maps present-day structure, which must be put in a dynamical and evolutionary framework with the predictions from geodynamical convection calculations, which in turn must first be informed by an understanding of the material properties. The latter comes from the field of mineral physics, both in laboratory experiments at high temperature and pressure, as well as with computer simulations of material behavior at the atomic scale. The time evolution of Earth is also informed by geochemical analyses of erupted materials and meteorites. Thus, future work that advances our understanding of the structure, dynamics, and evolution of Earth's interior will be multidisciplinary in nature.

Summary

Earth's lower mantle represents the largest volume of any depth shell on Earth. It is unique in that its chemistry, structure, dynamics, and evolution represent a time-integrated effect of the chemistry and dynamics of the surface (lithosphere, asthenosphere) and lowermost mantle (D″, ULVZ, CMB) boundary layers. The degree to which the lower mantle is recycled into the upper mantle depends upon many poorly known convective parameters, such as the viscosity and viscous coupling of descending slabs, as well as material properties, such as the nature and origin of dense deep mantle chemically distinct piles. Future work of improved seismic imaging coupled with continued advancements in other deep Earth disciplines, such as geodynamics, mineral physics, and geochemistry, will greatly help to reduce uncertainties in our understanding of Earth's evolutionary pathway, and present-day structure and dynamical state.

EARTH'S STRUCTURE, UPPER MANTLE

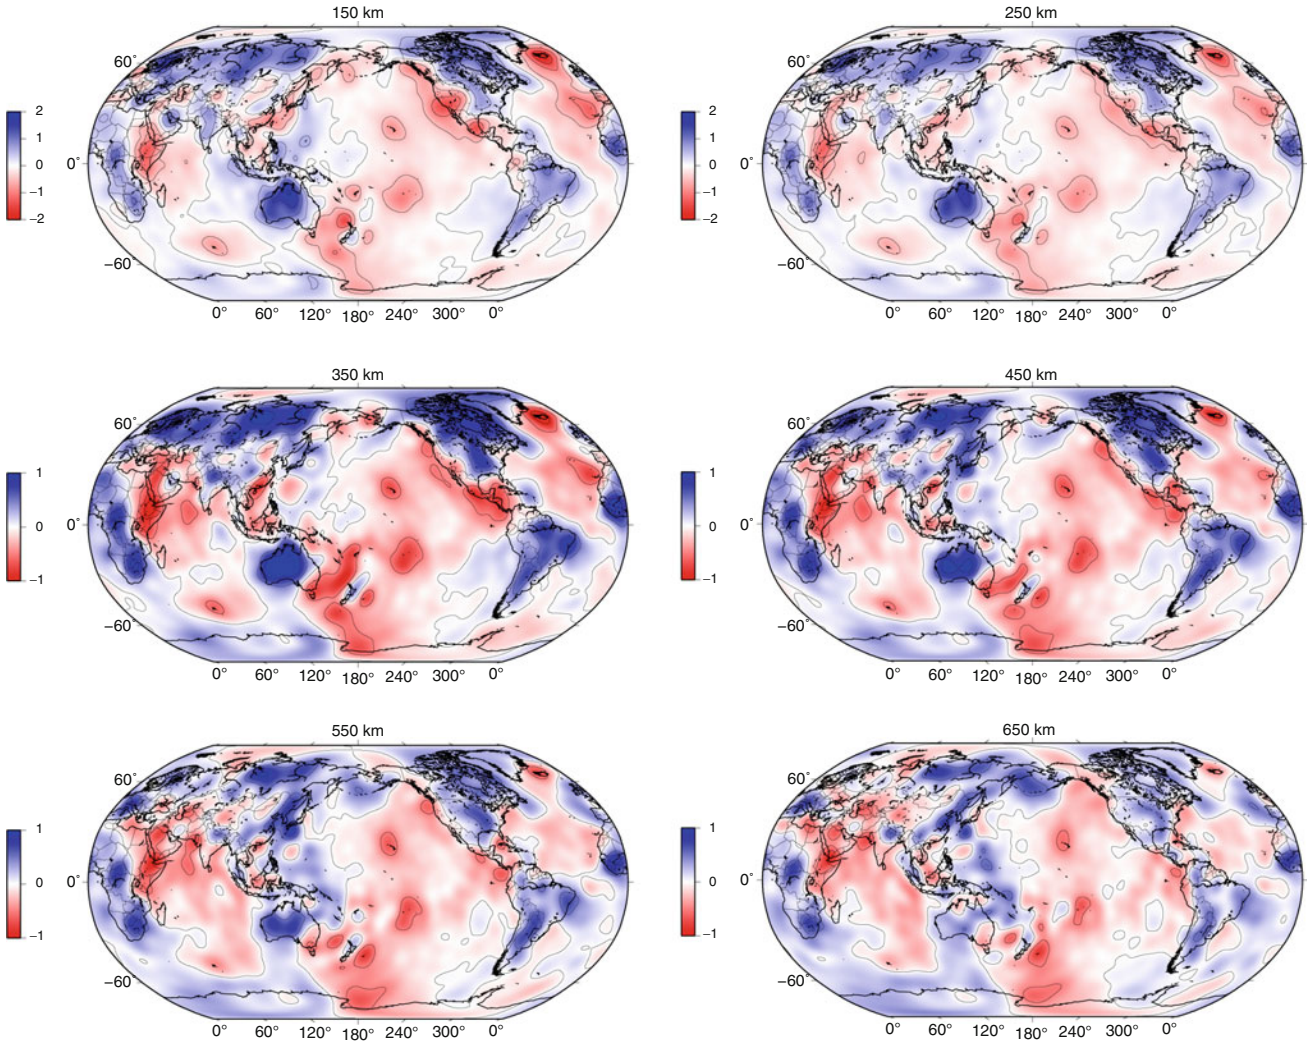
Guust Nolet
Geosciences Azur, Sophia Antipolis, France

Definition

The upper mantle is defined as that part of the mantle between the crust and the phase transition of γ-olivine to perovskite. The total mass of the upper mantle is 1.06×10^{24} kg, about a quarter of the total mass of the mantle. Its volume, 2.95×10^{11} km^3, is a third of the total volume of the mantle.

Until the discovery of a major transition near 660-km depth, the upper mantle was better known as Bullen's "layer B," extending to 400-km depth. A sharp gradient or discontinuity in seismic velocity causes a bend in the travel time curves of P-wave arrivals near 20°, such that the slowness drops from more than 12 s/deg to 10 s/deg. This phenomenon was observed as early as 1931 by Jeffreys, who correctly adopted a suggestion by J.D. Bernal that it represents a high-pressure modification of olivine. The modern notion of the upper mantle actually extends into Bullen's next layer, "layer C," which has now been abandoned as a physically meaningful subdivision.

The depths to the top and the bottom of the upper mantle cannot be given precisely because they depend on the region. The Mohorovičić discontinuity marks the transition from the crust to the upper mantle, with a density jump of the order of 10%. It is found at very shallow depth near ocean ridges where oceanic crust is formed, but extends to more than 70-km depth beneath the Himalayas



Earth's Structure, Upper Mantle, Figure 1 Model pmean, an averaged mantle model for the P velocity from Becker and Boschi (2002), plotted at six different depths in the upper mantle. The contour interval is 0.5%.

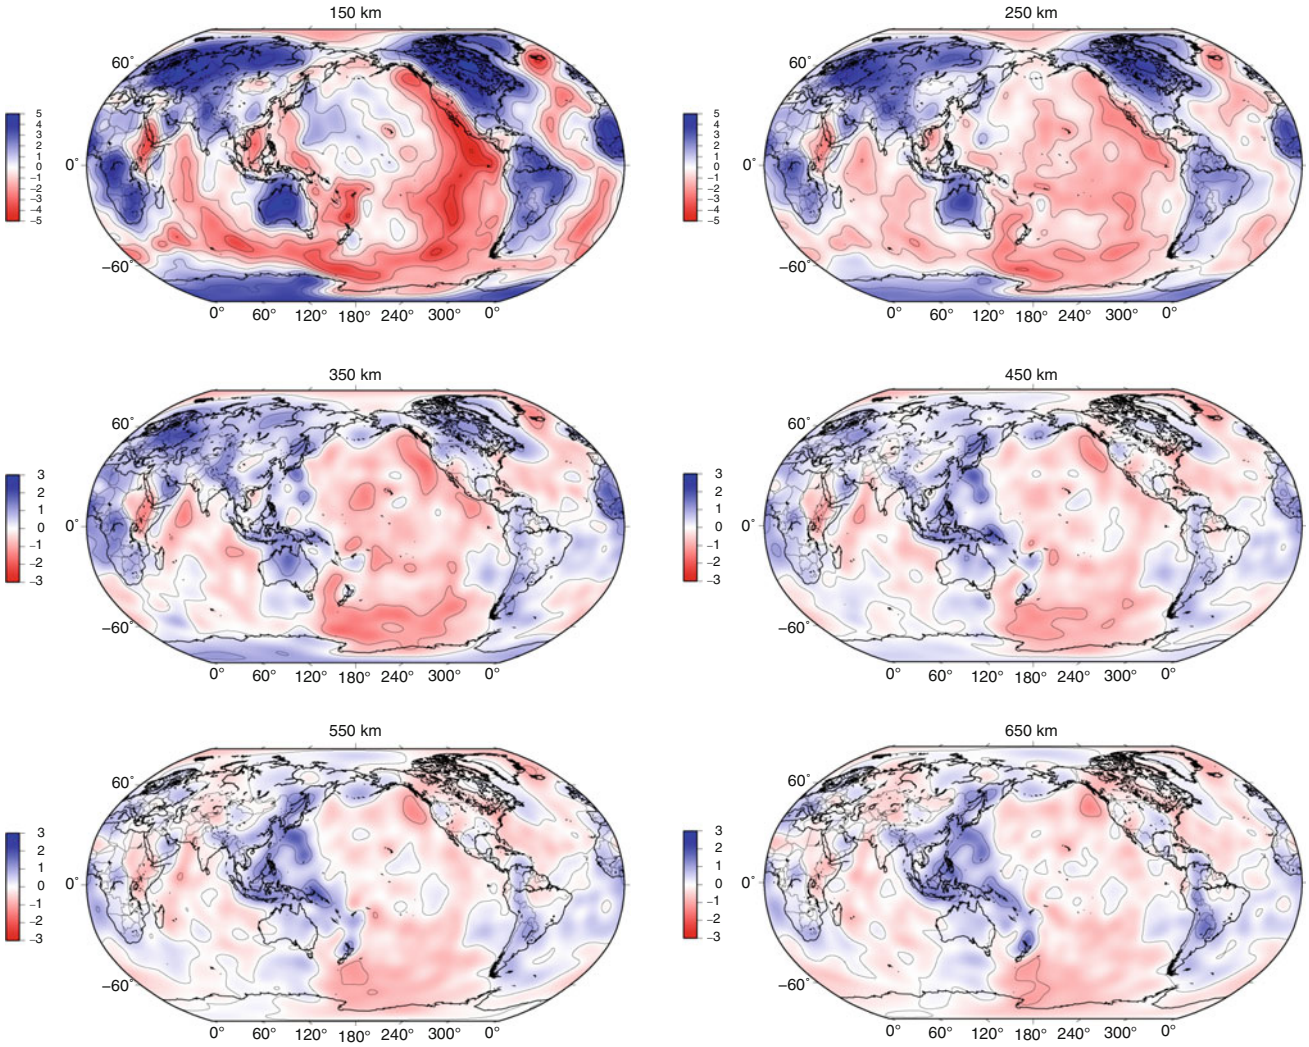
and the Andes. The "transition zone" between upper and lower mantle is marked by the transition of olivine (Mg_2SiO_4) to its polymorph β-olivine (Wadsleyite) near 410-km depth to γ-olivine near 520-km depth and finally to perovskite ($MgSiO_3$), which occurs near a depth of 660 km, but with variations of ±20 km depending on temperature and composition, and possibly with variations more than twice that large for narrow areas inside hot plumes and cold slabs. A typical temperature estimate for the phase transition gives a temperature of about 1,600°C. The upper mantle is one to two orders of magnitude less viscous than the lower mantle, and its electrical conductivity is much lower, with the possible exception of regions of partial melt.

The upper mantle itself is subdivided into several depth regions, characterized by their differences in density, mechanical properties, and/or seismic velocity:

Lithosphere: A strong layer with a viscosity of the order of 10^{21} Pa s and a thickness typically about 80–150 km, though it may exceed 200 km beneath old cratons, representing the rigid "plates." The temperature gradient is superadiabatic. The geotherm in the lithosphere connects the low temperature at the bottom of the crust, 600–900°C under continents but as low as 250°C in the oceans, to the (approximately adiabatic) temperature in the asthenosphere (1,200–1,300°C).

Asthenosphere: A mechanically weak layer with viscosity of the order of 10^{19} Pa s, characterized by a drop in S velocity and possibly also in P velocity. This layer is present under the oceans and the younger part of continents, but its existence beneath the oldest cratons is uncertain. It may contain a small degree of partial melt.

Lehmann discontinuity: A positive velocity jump named after Inge Lehmann who first observed this feature



Earth's Structure, Upper Mantle, Figure 2 Model smean, an averaged mantle model for the S velocity from Becker and Boschi (2002), plotted at six different depths in the upper mantle. The contour interval is 1%.

beneath Europe and North America near 150-km depth. It is generally interpreted as a sharp boundary representing the bottom of the asthenosphere, but not globally observed (Gu et al., 2001).

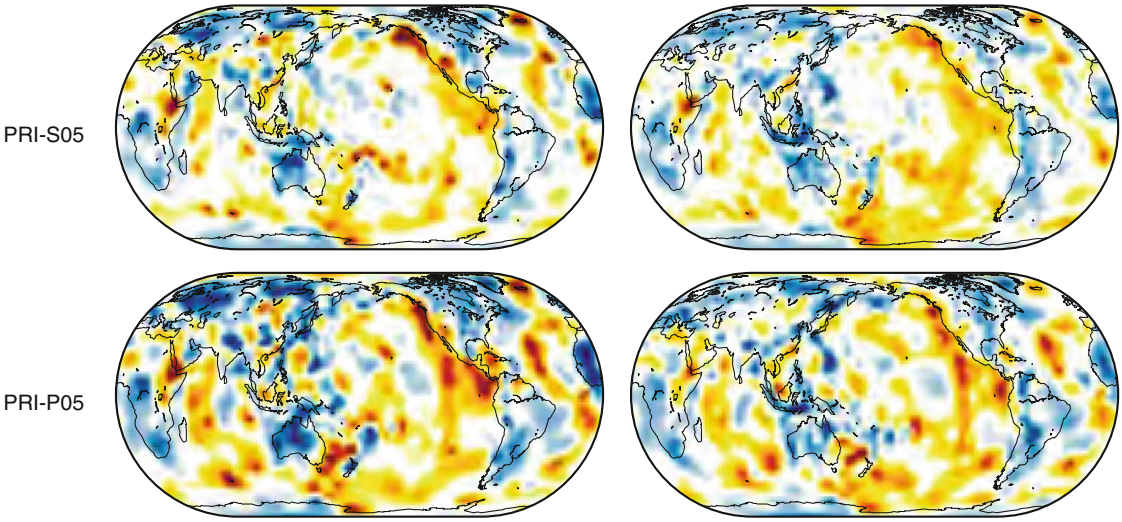
"410-*km*" *discontinuity*: A globally observed jump over a narrow depth interval in seismic velocity, marking the transition from the $\alpha \rightarrow \beta$ phase of olivine near 400-km depth. This transition occurs at a temperature of about 1,400–1,450°C.

"520-*km*" *discontinuity*: Predicted by the phase diagram for olivine, which transforms to the γ phase under certain temperature conditions, this gradient in seismic velocities is occasionally observed.

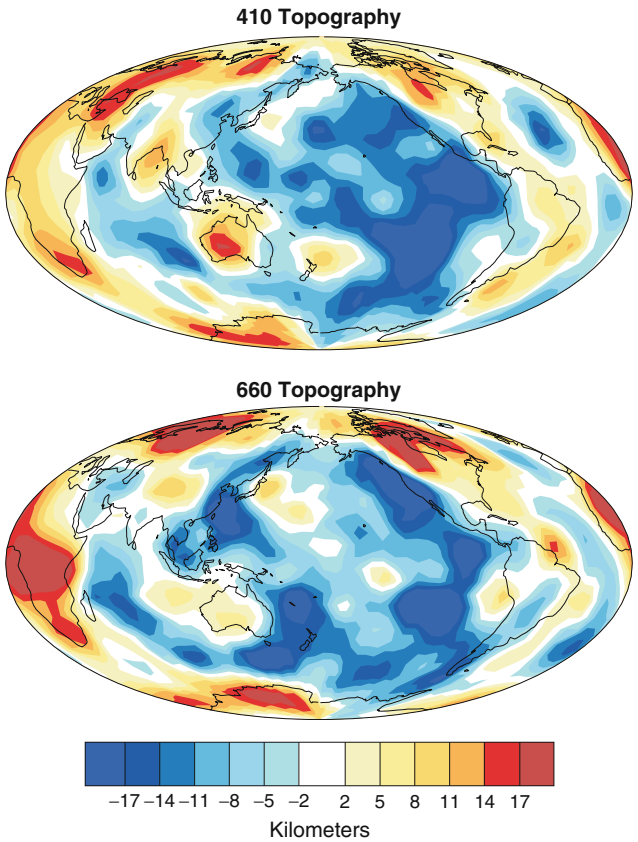
Reflections or refractions from other depths have been observed – such as the "Hales discontinuity" within the lithosphere – and are occasionally attributed to a global physical or chemical transition, but a lack of consistency between such observations makes it more likely that the observations should be explained as wave energy returned from three-dimensional structure rather than from a discontinuity that represents an omnipresent layering.

Early regionalized refraction studies of the upper mantle already showed a marked variability in P and S velocity with depth. Surface wave studies, which are the preferred tool to investigate layers of low velocity, indicate minimum S velocities as low as 4.05 km/s under the western USA, 4.09 km/s under the East-African Rift, and 4.14 km/s under the Pacific ocean, but body waves show a minimum V_s as high as 4.63 km/s under the North American craton.

The Lehmann discontinuity is observed in few regional models, but it is present in the Preliminary Reference Earth Model (PREM) (Dziewonski and Anderson, 1981), which shows a major velocity increase in V_p of



Earth's Structure, Upper Mantle, Figure 3 Models PRI-P05 (P velocity) and PRI-S05 (S-velocity anomaly) at a depth of 350 km (*left*) and 600 km (*right*). The color scale ranges from −1.5% (*red*) to +1.5% (*blue*) in P velocity and ±3% in S velocity. Upper mantle plumes show as narrow quasi-circular slow anomalies in *red* (From Montelli et al., 2006. With permission from the AGU).



Earth's Structure, Upper Mantle, Figure 4 The depth variations to the "410-" and "660-" km discontinuities, with respect to 410 and 650 km depth, respectively (From Houser et al., 2008. With permission from the AGU).

7.1% at 220 km. By way of compensation, PREM has only a minor increase of 2.6% from 8.90 to 9.13 km/s at the "410-km" discontinuity. This, however, disagrees with all regional observations and reveals a major shortcoming of the reference model PREM. In fact, the variability in the velocity jump at 410 km is not very pronounced in the early refraction models. Typically, V_p in such models jumps about 5%. An average over seven regional models gives a V_p jump from 8.78 ± 0.06 to 9.26 ± 0.03 km/s, where the uncertainty represents 1 standard deviation. The jump in V_p at 660 km over the same set of models is roughly 4%, but more variable than that at 410 km: from 10.22 ± 0.20 to 10.72 ± 0.10 km/s. Near 660-km depth model, PREM is in agreement with regional studies.

Though the regional models based on refracted waves provide the most accurate estimates of *absolute* velocities, the velocity–depth relationships represent horizontal averages over thousands of kilometers. We know that velocity variations exist over length scales much smaller than that. New tomographic techniques are able to delineate such variations and allow us to image them.

Tomographic techniques

Knowledge of the three-dimensional upper mantle structure comes from tomographic techniques, notably:

- Transmission tomography of body wave delay times for both P- and S-velocity structure
- Inversion of the splitting of normal mode frequencies by lateral heterogeneity, for long wavelength heterogeneity in both P and S velocity
- Phase or group delay tomography using surface waves, primarily sensitive to S velocity
- Imaging of waves reflected or converted at discontinuities ("receiver functions"), sensitive to the depth location of such discontinuities

For an extensive overview of transmission tomographic techniques, see Rawlinson et al. (2010). Each of these techniques has seen important progress in recent times. Ray theory is being replaced with first-order scattering theory that allows for the modeling of the frequency-dependent dispersion in delay times. Single station (or "single channel") stacking of converted or reflected phases is being replaced by multichannel techniques, in particular Kirchhoff-type stacking along diffraction hyperboles much as one does to migrate seismic sections in exploration seismics (see Bostock, 2009).

Seismic tomography allows the mapping of "anomalies," or deviations from a regular layering of the upper mantle. The most remarkable anomalies are listed here:

Subduction zones and the associated low velocity structure in the mantle wedge can be very clearly imaged because of increased seismicity when actively subducting. The observed velocity anomalies are consistent with average (cold) temperature anomalies of several hundred degrees.

Oceanic ridges are mapped best with surface waves, which leave the exact depth extent as well as the temperature anomaly somewhat uncertain.

Cratonic roots were originally detected through the large negative delay times they cause for S waves, consistent with a cold lithosphere (as much as 400° colder than oceanic lithosphere), but the depth extent is mapped using teleseismic surface waves. In the tectosphere model of Jordan (1981), the high density induced by the cooling is compensated by a chemical composition that is depleted in basaltic components.

Upper mantle plumes are rather narrow anomalies in the upper mantle, but can be imaged adequately using body wave delays as well as surface wave observations from field deployments of portable seismographs. The velocity anomalies are consistent with temperature anomalies of 200–300°C inferred from petrological studies.

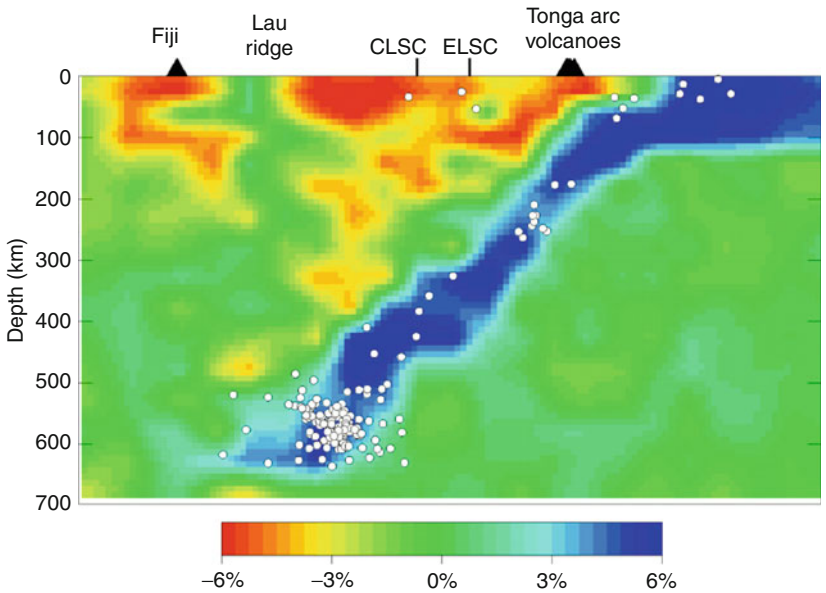
Topography of the "410"- *and* "660"-*km discontinuity* is globally imaged using underside reflections of waves such as SS. This involves some geographic averaging but topographic anomalies of 20 km or more are observed.

These anomalies are all visible in the variations of isotropic velocity variations. There is strong evidence, notably from the birefringence of SKS waves, that the seismic velocity in the shallow part of the upper mantle depends locally on the propagation direction of the wave; under favorable circumstances, this could in principle allow the mapping of mantle flow, since the crystal structure is assumed to align itself to the flow direction. However, at present there is little agreement between different tomographic models of anisotropy, partly because the SKS information is insensitive to depth, while the crustal correction, which is badly known, is in itself as large as the signal from anisotropy in surface waves (Ferreira et al., 2010).

Global models

Becker and Boschi (2002) review a large number of global tomography models of the mantle, and construct average models from a small selection of global models.

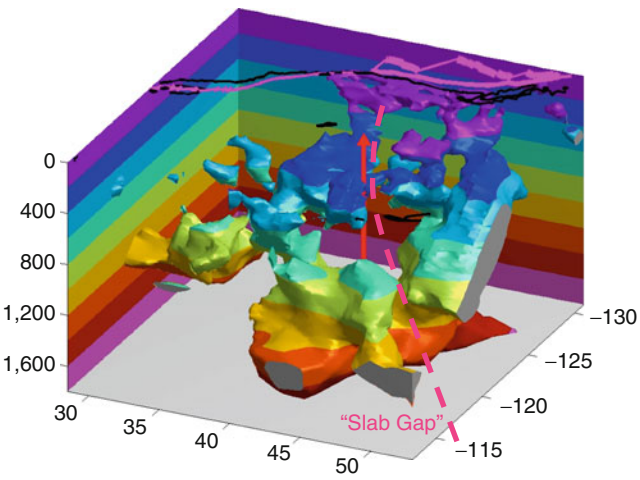
The map views displayed in Figures 1 and 2 illustrate the global features that are present in the upper mantle:



Earth's Structure, Upper Mantle, Figure 5 A west-to-east cross section through the Tonga subduction zone crossing the trench at 19S, 173W shows the subducting slab as a continuous feature down to 600 km depth (*blue positive anomaly*), and coinciding with the deep seismicity (*circles*). The negative velocity anomaly above the slab represents most likely the effect of dehydration. Active volcanism on Fiji and Tonga is indicated by *black triangles*. Also indicated are the Central and Eastern Lau Spreading Centers (Zhao et al., 1997).

old continental shields (Canada, Scandinavia, Western Australia, west and south Africa) are characterized by high S velocities down to depths of about 250 km. These anomalies extend to more than 400 km in the maps of P velocity, but P-wave delay times lack the depth resolving power that the surface wave data give to the S tomography. The oceanic ridges extend at least to 150-km depth in the S-velocity maps (Figure 2). The oceans are generally characterized by low S velocity throughout much of the upper mantle, with the exception of the S Atlantic and the westernmost Pacific. Plume-like anomalies, with a high degree of vertical continuity in the upper mantle, are visible in the P-velocity model beneath Hawaii, Society Islands (Tahiti), the East-African rift area (Afar). For a proper imaging of plumes, tomographic techniques that correct for the effects of diffraction around small or narrow anomalies are more suitable. Figure 3 shows models PRI-05 for P and S velocity in the upper mantle from Montelli et al. (2006), which clearly show a number of narrow upper mantle plumes.

Underside reflections from the upper mantle discontinuities allow the depth variations to the "410-" and "660-km" discontinuity to be mapped globally. This has most recently been done by Houser et al. (2008) using precursors to SS waves (Figure 4).



Earth's Structure, Upper Mantle, Figure 6 A view from the north-east at the subducted Farallon slab beneath western North America shows major ruptures that allow mantle rock to flow around it, such as the "slab gap" indicated by the *broken line*. The slab itself is delineated by a surface with an anomaly of +0.4% in P velocity (high velocity anomalies associated with the lithosphere are not mapped). The location of Yellowstone, another suspected passage of hot mantle rock toward the surface, is indicated by the *arrow*. Numbers along the axes indicate depth in kilometer, latitude, and longitude (negative for West). *Color shading* indicates depth. The plate boundaries between the North America, Pacific, and Juan de Fuca plates are indicated as *purple lines* at the surface (Figure courtesy Karen Sigloch).

Regional models

Regional studies are able to offer a better resolution than the global efforts, certainly when using data from large and dense seismic arrays such as Skippy (Australia), USArray (USA), or HiNet (Japan), but also using temporary deployments of portable seismic arrays. Efforts to image the upper mantle beneath them have led to very precise images of subduction zone structure in particular. Figure 5 shows the slab subducting in the Fiji–Tonga region.

Though this slab image is continuous down to 600-km depth, slab geometry in the upper mantle is very variable. Whereas some slabs remain for at least some time lodged in the transition zone others have no trouble sinking through the phase transition barrier at 660-km depth, with a negative Clapeyron slope and an increase of as much as two orders of magnitude in viscosity (Fukao et al., 2001).

A very different fate of subducting slabs is shown for the now inactive Farallon subduction beneath western North America, where the former Farallon plate is slowly disintegrating, letting mantle rock flow through major ruptures such as the "slab gap" in Figure 6 (Sigloch et al., 2008).

Outlook

It is now clear that the simple, layered, models of the upper mantle are inadequate to explain many of the dynamic processes we observe at the Earth's surface. The resolving power of tomographic techniques is still growing because of theoretical improvements and the densification of seismic networks. The coming decades will undoubtedly reduce the high degree of nonuniqueness that still plagues tomographic images, and allow for more reliable estimates of temperature and anisotropy. New instrumentation will open up the oceans for dense seismic observations.

Luminous phenomena associated with earthquakes

Definition

Earthquake lights are anomalous luminosities associated with and presumably caused by the accumulation and release of stress of the earthquake process, observed prior to or during a seismic event and/or during the aftershock sequence. There is some disagreement over whether the classification Earthquake Lights (EQL) applies to similar luminous phenomena observed in earthquake-prone areas or along faults without immediately associated seismic activity. These may be due to locally high stress levels in the Earth's crust that are subsequently relieved without catastrophic rock failure, or by earthquakes that are too distant or late relative to the observed EQL.

Classification of earthquake lights

The earliest known report of earthquake lights dates to 373 BCE when the Greek cities Helice and Buris were destroyed by an earthquake accompanied by "immense columns of fire" (Seneca). Ancient references will always be questionable, especially when the surviving accounts are written later, but such references indicate that the people at that time were aware that lights might accompany earthquakes. Many sightings from various countries around the world have since been reported. They have been summarized in a number of papers (see, e.g., St-Laurent et al., 2006; Derr, 1973). As a result of extensive observations associated with the Saguenay earthquake sequence from November 1988 to January 1989, St-Laurent (2000) examined and extended earlier EQL classifications (e.g., Montandon, 1948). Six types of luminous phenomena have been documented:

1. "Seismic lightning," similar to ordinary lightning, but seismic lightning is typically of longer duration, sometimes illuminating large areas of the sky from below without thunder. "Seismic lightning" can be mistaken for "sheet" or "heat" lightning at night, which is too distant for thunder to be heard.
2. Luminous bands in the atmosphere at indeterminate height, sometimes horizontally or vertically and sometimes in a bundle, similar in appearance to some polar auroras although at much lower altitude, possibly even extending from the ground level upward.
3. Globular incandescences (moving or static), sometimes attached to luminous bands, called "orbs," "globes," or "meteors." They have the appearance of ball lightning, for example, of luminous spheres floating in midair, sometimes coalescing, lasting for up to a few minutes.
4. Fire tongues, small "flames" flickering or creeping along or near the ground, or like ignis fatuus.
5. Seismic "flames" seen emerging from the ground like an evanescent gas flame but very rarely causing visible burns.
6. Coronal and point-discharge-like lights.

A possible seventh type might be "luminous clouds" like those filmed shortly before the M7.9 Wenchuan, China, earthquake of May 12, 2008 (Panoramio photo, 2008). These are phenomena in the high atmosphere, similar to "fire rainbows," possibly linked to processes at the upper edge of the atmosphere, and/or to ionospheric perturbations.

Examples of EQL

While reliable pictures of EQL are scarce, one example of type 1 comes from the Matsushiro earthquake swarm from 1965 to 1967, Figure 1 (Yasui, 1968, 1971; discussed in Derr, 1973). An example of type 3 was photographed at Tagish Lake, Yukon Territory, Canada, Figure 2 (Jasek, 1998). While it is not possible to say that this picture is definitely EQL, these orbs are typical of the most-

frequently observed EQL, as described by Montandon (1948). The only known photo of "flames," type 5, was taken during the aftershock sequence to the Vrancea, Romania, earthquake on March 4, 1977, Figure 3 (Hedervari, 1983; discussed in St-Laurent, 2000). A sketch of type 6 comes from the account by Joseph A. Dallaire during the Saguenay 1988 mainshock, Figure 4 (presented in St-Laurent, 2000). These examples are notable for the differences they exhibit: illumination of a broad area of the sky, discrete glowing plasmas, evanescent "flames," and an electric discharge bursting through the surface of the Earth. They are representative of a number of other sightings, although the last one, the rapidly moving electric discharge, is so far unique in the detail of its description.

Earthquake Lights, Figure 1 Earthquake lights from Mt. Kimyo, Matsushiro area, Japan, September 26, 1966, 0325 (JST). Luminosity lasted 96 sec (Derr, 1973; Yasui, 1968). (© Seismological Society of America).

Example of type 3 EQL

Schmidt and Mack (1912; Translation by Steven Soter, personal communication) give a number of eye-witness descriptions of type 3 EQL. The most detailed was by Friedrich Konzelmann, foreman in an Ebingen factory:

> On the evening of 16 November between 10 and 10:30 I went home with my wife. My house is about 200 m from the city on the national road to Strassberg. As we were about 30 m from our house, I heard a distant noise like thunder from Sigmaringen, followed by a faint vibration. As I glanced in the direction from which the noise came, I suddenly noticed at some distance a bright flash from the ground, which then at a considerable height turned into a ball of light, about the size of 20 suns. This ball maintained its brightness about 2–3 seconds and then divided itself like lightning in the direction of Ebingen. In my opinion the earthquake came from southeast to northwest. The earthquake began with the lighting of the fireball. After the rolling went past, I looked backwards to the city and saw above the Katzenbuckel a similar but somewhat smaller fireball. The whole surroundings were brightly illuminated.

Source of EQL and associated electromagnetic (EM) phenomena

The leading theory of how these various light phenomena are generated, based on extensive laboratory experiments, attributes them to effects by mobile positive hole charge

Earthquake Lights, Figure 2 Earthquake lights from Tagish Lake, Yukon-Alaska border region, around July 1, probably 1972 or 1973 (exact date unknown). Estimated size: 1 m diameter. Closest orbs slowly drifted up the mountain to join the more distant ones (Jasek, 1998). (Photo credit: Jim Conacher, used with permission).

Earthquake Lights, Figure 3 One of five pictures taken around March 23, 1977 near Brasov, Romania, about 100 km NW from the Vrancea epicenter and during the aftershock sequence of the M 7.2 mainshock that occurred on March 4. The image corresponds to what the witness observed. (St-Laurent, 2000; Hedervari, 1983) (© Seismological Society of America).

Earthquake Lights, Figure 4 Drawing by artist from witness' description of a bright, fast moving bluish-white light, preceded and accompanied by crackling noise emitted by the trees. Laterrière, Québec, 19 km N of the epicenter, observed a few seconds before the M 5.9 mainshock on November 25, 1988. Not to scale. (St-Laurent, 2000) (© Seismological Society of America).

carriers, which become activated when rocks are subjected to high levels of stress (Freund, 2002, 2010). Positive holes exist in common rocks in a dormant state as peroxy links, $O_3Si/^{OO}\backslash SiO_3$. Under stress, dislocations sweeping through the mineral grains cause the peroxy links to break. They thereby activate positive holes, which flow down stress gradients, constituting an electric current with attendant magnetic field variations and electromagnetic (EM) emissions. As these electronic charge carriers accumulate at the Earth surface, they create electric microfields strong enough to field-ionize air molecules and produce EQL. Positive holes can also recombine at the surface, leading to a spectroscopically distinct IR emission identified in laboratory experiments and night-time infrared satellite images. The positive hole theory accounts not only for EQL but also for other pre-earthquake phenomena such as:

1. Air ionization at the ground-to-air interface.
2. Changes in the electrical conductivity of the soil.
3. Geo-electric and geomagnetic anomalies in the Earth's crust.
4. Ionospheric perturbations.
5. Ultralow and extremely low frequency (ULF/ELF) and radio frequency (RF) emissions.
6. Anomalous infrared emissions from around a future epicentral area.
7. Anomalous fog/haze/cloud formation and unusual animal behavior.

Conclusion

At present there is no consensus among seismologists on the phenomenology and physical mechanism of EQL and associated EM phenomena. However, if the positive hole theory is correct, the entire suite of pre-earthquake phenomena, including EQL, may become useful in forecasting earthquakes.

Definitions and introduction

Earthquake (EQ) prediction or forecast is to specify the source location, magnitude M, and occurrence time of EQ with certain accuracy before its occurrence. The terms prediction and forecast are often used with different nuances, the latter allowing for more stochastic nature. We will mainly use the former term in this article. EQ prediction is often roughly classified by the length of concerned time into Long Term (10^2–10^1 years), Intermediate Term (10^1–1 years) and Short Term (<1 year). The latter of course includes "Imminent" or "Very Short Term" ones like weeks to hours prediction. EQ precursors are anomalous phenomena, which take place before EQs so that prediction is made on their information. This article will focus on the precursors for Short Term prediction. At this stage, however, the existence itself of the precursors has to be more firmly established as a scientific fact and further details of them must be thoroughly investigated.

Various EQ precursors have been noticed throughout human history until present day (Tributsch, 1982). They are mostly short term precursors on animals, plants, clouds, and sounds (see *Earthquake Sounds*). Precursors perceived without aid of scientific instruments are called macro- or macroscopic anomalies.

Precursors instrumentally recorded are classified into long/intermediate and short-term ones. Long/intermediate Term precursors: Active faults serve as geological precursors. Trenching of active seismic faults provides the dates and displacements of past large EQs, from which those of the next large EQ may be inferred. Other long/intermediate precursors include (1) geodetic: land deformation, changes in sea-level, tilt, strain; (2) seismological: seismic gaps (see *Characteristic Earthquakes and Seismic Gaps*), quiescence (see *Seismic Quiescence and Activation*), S wave splitting (see *Shear-Wave Splitting: New Geophysics and Earthquake Stress-Forecasting*), changes in micro-seismicity, seismic wave velocity, *b*-values, characteristic EQs (see *Characteristic Earthquakes and Seismic Gaps*); (3) changes in electrical resistivity; and (4) geochemical/hydrological: changes in radon, CO_2 and other gas discharge (earthquakes, thermal anomalies), and level and temperature of underground water (see *Seismic Signals in Well Observations: pre, co, post*). Some, in particular, those in (3) and (4) serve for short-term EQ prediction also.

Short-term precursors which are of major concern of this article are mainly geochemical/hydrological and electric, magnetic, and electromagnetic (EM). The latter are changes in (1) geoelectric field (telluric current), geomagnetic field, EM emissions at various frequencies (DC to VLF), (2) transmission properties of man-made EM waves of VLF to VHF range, (3) Ionosphere (foF2 and total electron contents, TEC), and (4) infrared (IR) radiation. These changes are measured by apparatus on the ground or those mounted on artificial satellite.

History

Zechariah of Israel (ca. 520 BC) is said to have issued the first long-term EQ forecast, based on the surface rupture of an EQ in 759 BC. Precursors were recorded as early as in 373 B.C in Greece. Many followed from many parts of the world in the form of documents and folklore. In later years, even larger number of macro-anomalies are kept accumulated (Tributsch, 1982), now including such items as radio and TV noise, e.g., at 1995 M7.3 Kobe, 1999 M7.4 Izmit, 1999 M7.7 Chichi EQs (Ikeya, 2004). Most of the macro-anomalies, however, have not been well studied systematically, although they apparently played significant roles, e.g., in the success of 1975 M7.3 Haicheng EQ prediction (Raleigh et al., 1977).

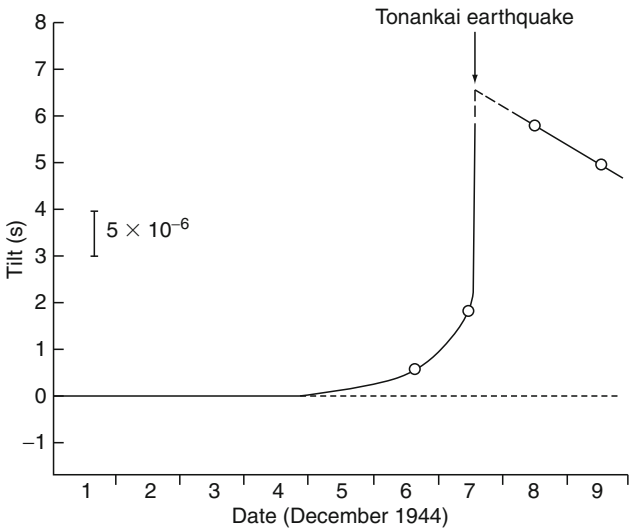
After the 1906 M8.3 San Francisco EQ, through investigation of geodetic data on faults, the elastic rebound theory (see *Earthquakes and Crustal Deformation*) was developed, laying the theoretical foundation for EQ prediction. From the 1960s to the 1970s, countries including USSR, Japan, China, and USA embarked on national-scale EQ prediction projects. Projects consisted mainly of statistical approach for long-/intermediate-term prediction (see *Statistical Seismology*) but there was also deterministic approach to short-term prediction. In early 1970s, the dilatancy-diffusion model (Sholtz et al., 1973) appeared. This model took advantage of results of field and laboratory studies obtained in various countries, like 10–20% Vp/Vs change in Garm, USSR. (Semyenov, 1969) and USA (Aggarwal et al., 1973), crustal uplift in Japan (Danbara, 1981), radon emission and electrical resistivity (Sadovsky et al., 1972) and so forth. All the quoted precursors, long and short term, appeared to support the physical picture of the dilatancy-diffusion model. The famous prediction of the 1975 M7.3 Haisheng EQ also was based on all kinds of precursors (Raleigh et al., 1977). Intermediate term measures were taken in June 1974, and short term in December, 1974. Emergency Alert to the public was issued in the early afternoon of February 4, 1975, several hours before the main shock to evacuate the public in time. These and other encouraging works in the 1960s–1970s made the whole prediction community highly optimistic (e.g., Press, 1975).

However, the period of optimism did not last long. First, later studies using controlled sources (McEvilly and Johnson, 1974) did not confirm the significant change of Vp/Vs, which was the most critical background of the dilatancy-diffusion model. Second, for the 1976 M7.8

Tangshan EQ, no timely alert was issued because there was no foreshock activity (see *Earthquake, Foreshocks*), despite many other precursors, causing the loss of over 240,000 lives (Chen et al., 1988).

In fact, the traditional seismological/geodetic methods were unable to short term predict any great EQs (see *Great Earthquakes*) other than the Haisheng EQ. For none of these EQs, any pre-slip, the most legitimate short-term precursor from seismological point of view (e.g., Shibazaki and Matsu'ura, 1995; Kato and Hirasawa, 1999) has been detected. Yet, the main strategy of Japan Meteorological Agency (JMA) for short-term prediction of the Tokai EQ is to catch pre-slips as reported for 1944 M7.9 Tonankai EQ (Figure 1, Mogi, 1985). The Tokai EQ has already been at a forecasted status for well over 30 years (Ishibashi, 1981). Another well-publicized, unsuccessful example is the Parkfield case, where M6 class event was predicted in 1985 to come within 5 years and 72 hour; alert was issued in 1992 (Roeloffs, 1994). It did not come until 2004, 12 years later (Bakun et al., 2005).

As a matter of fact, seismological precursors and methods, such as seismic gap (see *Characteristic Earthquakes and Seismic Gaps*), M8 algorithm (see *Earthquake Prediction, M8 Algorithm*), ZMAP (Wiemer and Wyss, 1994), hotspots (Holliday et al., 2006), etc., were not aiming at short-term prediction. The new development and discoveries in seismology such the asperity models (Yamanaka and Kikuchi, 2004), slow/silent EQs (see *Slow Earthquake*), and low-frequency nonvolcanic tremors (Obara, 2002) greatly contributed to the understanding of EQ mechanisms, but their direct relevance to short-term prediction has not been made clear. Characteristic EQ (see Characteristic Earthquakes and Seismic Gaps) may be the only case that can be quasi-short-term predictable by seismic monitoring, but they are rare cases. By the late 1970s, the general view of the main stream community became entirely pessimistic (e.g., Evernden, 1982). This pessimism has persisted until now, making the word prediction almost "forbidden."



Earthquake Precursors and Prediction, Figure 1 Precursory crustal deformation observed just before the M7.9 Tonankai EQ in 1944 (Mogi, 1985).

It may be noted, however, that numerous undeniable short-term precursors were observed mainly in non-seismic/geodetic (non-mechanical) fields. On top of many macro-anomalies, they were radon, CO_2 and other gas discharges, water level and electric, magnetic and EM anomalous changes.

Short-term EQ prediction may be realized by a more intensive search for short-term precursors not only through traditional, e.g., GPS detected pre-seismic deformation in Kamchatka as shown in Figure 2 (Gordeev et al., 2001), pre-seismic velocity changes at the Parkfield SAFOD drill site (Niu et al. 2008), but also through developing non-mechanical approach.

Non-mechanical short-term precursors

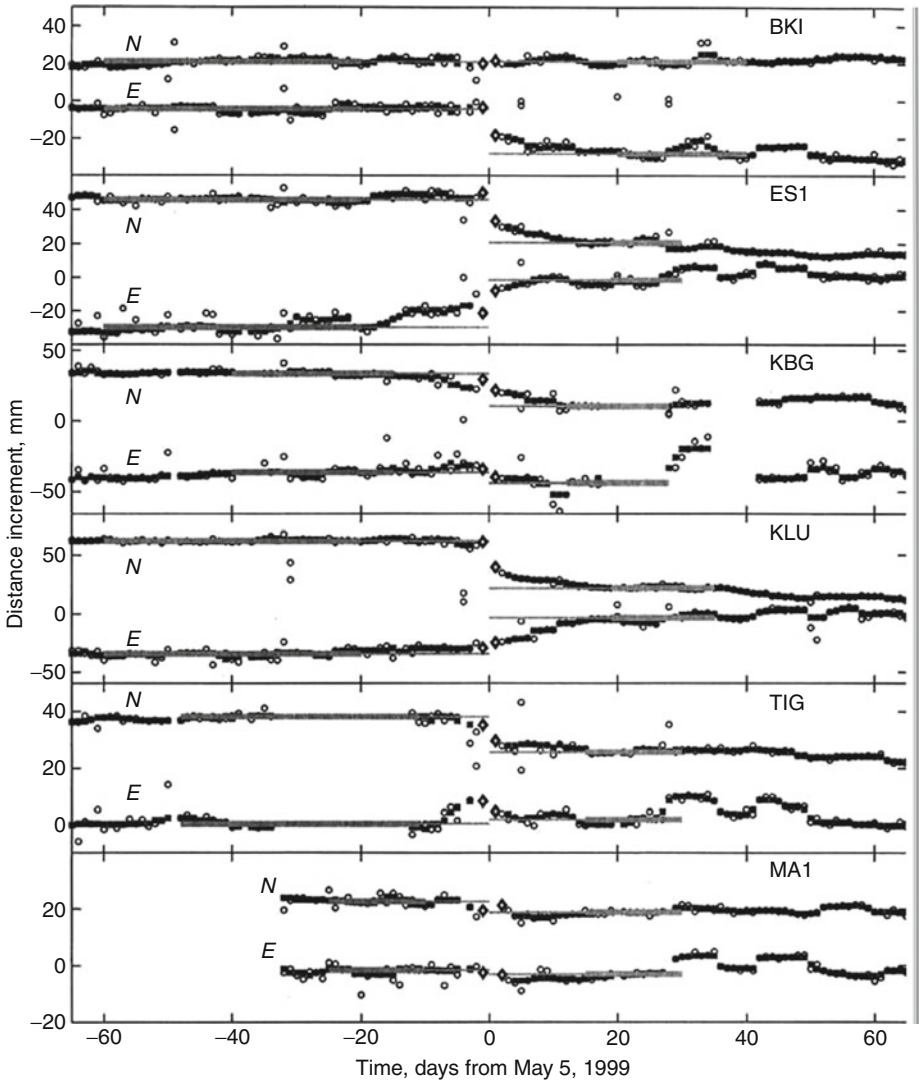
Difficulties inherent to short-term precursors

Short-term EQ prediction by standard mechanical approach seems to have scarce chance because the instant the stress reaches critical state can hardly be pinpointed by the present seismic or geodetic observations. Non-mechanical precursors make use of some phenomena which necessarily occur at that instant as by-products of the same cause, the stress build-up. The only necessary condition to make them useful for prediction is that their critical stress is slightly smaller than that of EQ. EQ would occur soon after the detection of them, perhaps aided by the last push of some triggers.

There are two rates to evaluate precursors. One is success rate, which is the number of successful predictions divided by the number of issued predictions, and the other is alarm rate, which is the number of successfully predicted EQs divided by the number of target EQs. In applying these evaluating rates, criteria of success and failure, i.e., the allowable errors in the three prediction targets, the dates, location and magnitude, must be clearly stated. When they are presented properly, however, criticizing them as causal relation is not clear or there are no other supporting geophysical simultaneous phenomena seems unreasonable.

Macro-anomalies

Macro-anomalies are numerous and the well-known examples, after the Haisheng EQ, are 1995 M7.3 Kobe, 1999 M7.4 Izmit, 1999 M7.7 Chichi EQs (Ikeya, 2004), and 2008 M8.0 Shuchuan EQ (Figure 3, Li et al., 2009). The causes of modern macro-anomaly precursors, such as radio, TV noise, malfunctioning of electrical appliances, are most probably related to pre-seismic EM emissions.



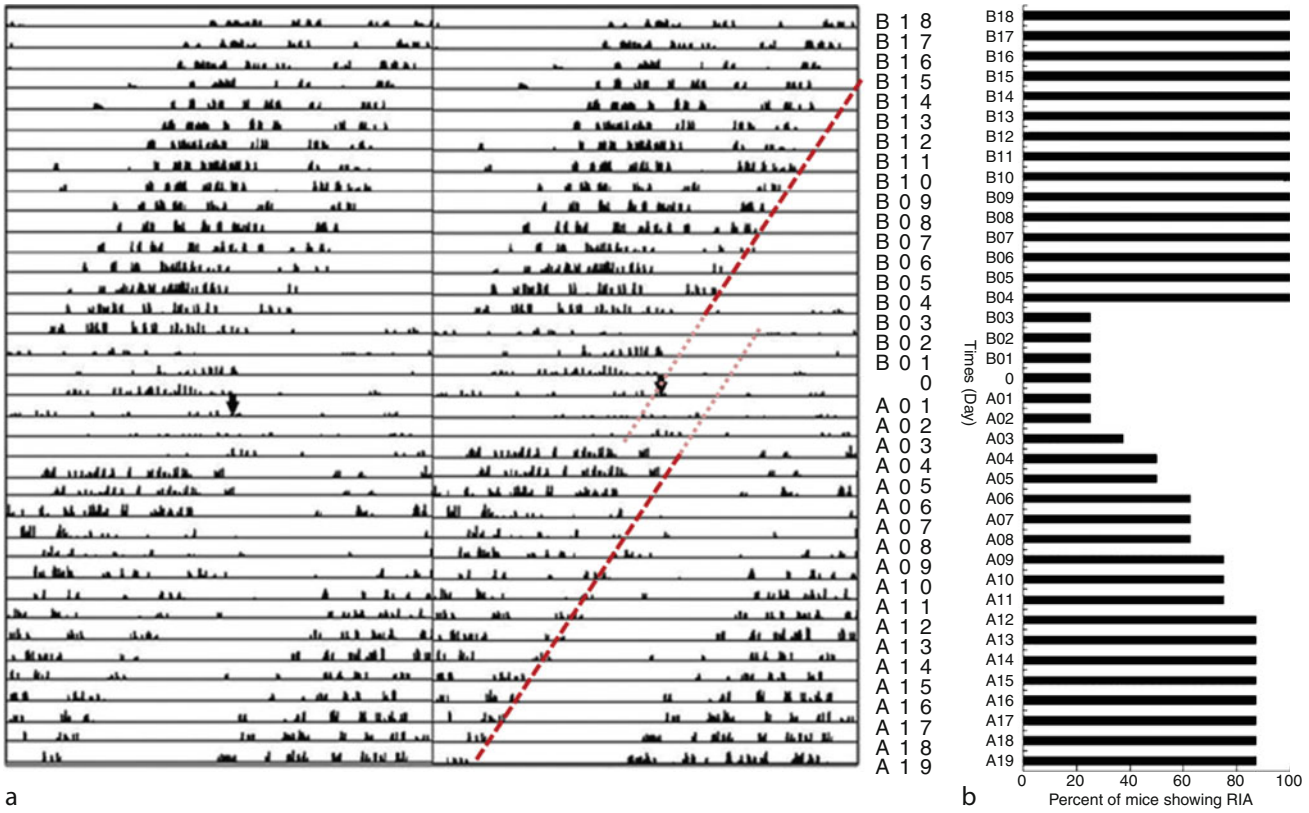
Earthquake Precursors and Prediction, Figure 2 The record of possible pre-slip before the M7.8 Kronotskoe EQ in 1997 (Gordeev et al., 2001).

Geochemical/hydrological precursors

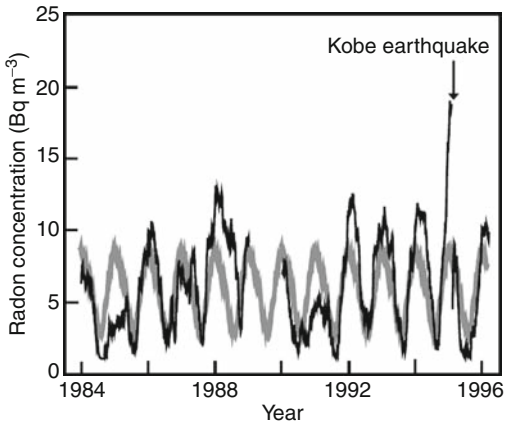
Geochemical/hydrological precursors are also diverse. Examples are discharges of radon, carbon dioxide, helium, H_2, and CH_4 (see Toutain and Baurbron 1999). Among them, radon emission has been most widely monitored, e.g., the 1976 M7.1 Gazli EQ, Uzbekistan, the 1985 M8.1 Mexico EQ, and the 1995 M7.2 Kobe EQ shown in Figure 4 (Yasuoka et al., 2009). Level changes of underground water are also potential precursors (e.g., Sidorenko et al., 1984 for the 1978 M7.8 Kuril EQ, Wang et al., 1984 for the Tangshan EQ, Igarashi et al., 1992 for the 1992 M5.9 Tokyo Bay EQ.). Geochemical/hydrological precursors are often observed at localities far (100 km or more) away from epicenters. Perhaps their appearances are heavily controlled by local geological situations such as faults and poroelastic conditions (see *Seismicity, Intraplate*). For water level and temperature, co-seismic changes are much more eminent and commonly observed than pre-seismic ones, in contrast to EM precursors (see later).

Satellite IR images as possible surface temperature

Anomalous satellite IR images as possible ground surface temperature precursor have been reported over seismic regions (earthquakes, thermal anomalies). The meaning of satellite-observed IR anomalies, however, is not clear. An alternative interpretation is that the satellite-observed IR image is not a temperature anomaly. When the p-holes (see later) arrive at the earth's surface, they recombine



Earthquake Precursors and Prediction, Figure 3 Abnormal animal behavior observed just before the M8.0 Wenchuan EQ in 2008 (Li et al., 2009). (**a**) Under free-running conditions, mouse locomotor activity presents circadian rhythm from B18 (18 days before EQ) to B04 (4 days before), and no rhythm from B03 (3 days before EQ) to A02 (2 days after EQ) including the day of EQ. Horizontal axis is 48 h (2 days). *Diagonal solid lines* mean the circadian rhythm does not coincide with 24 h. (**b**) The percentage of mice showing RLA (circadian rhythm of mouse locomotor activity) among the eight mice, indicating that some mice lost RLA around the EQ.



Earthquake Precursors and Prediction, Figure 4 Time series of the daily radon concentration observed from January 1984 to February 1996. The daily minimum variation is shown by a *black line* and the normal variation by a *gray line* (Yasuoka et al., 2009). Clear enhancement of radon concentration can be seen before the M7.3 Kobe EQ.

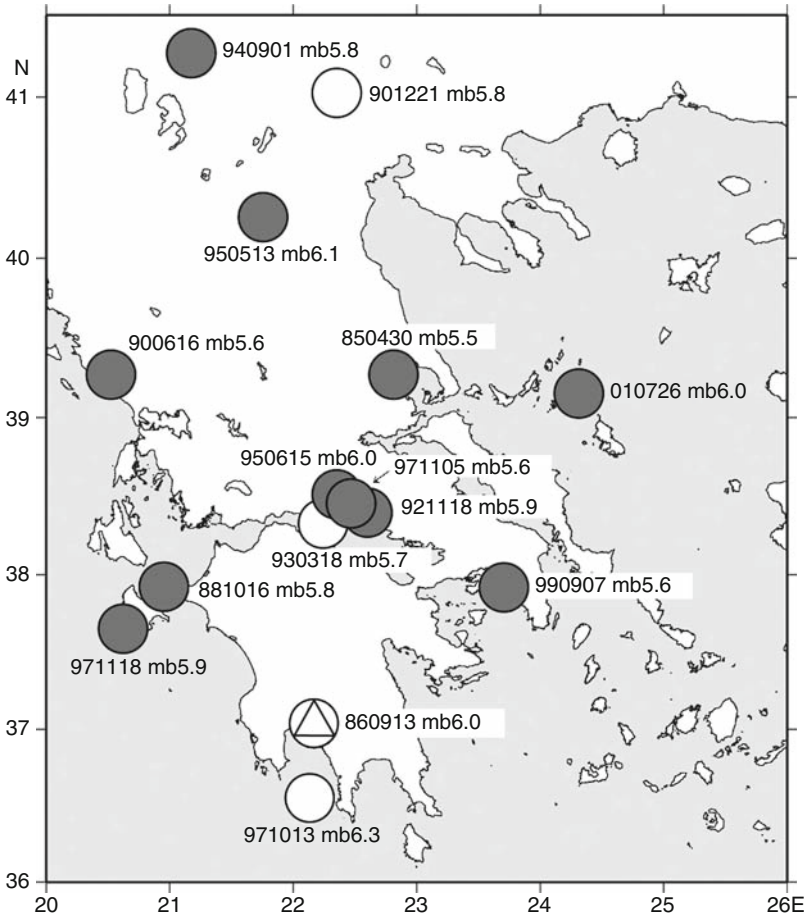
to cause a spectroscopically distinct non-thermal IR emission (Freund, 2009, 2010).

Electric, magnetic and EM precursors

Systematic research on EQ-related electric, magnetic, and EM phenomena were initiated more or less simultaneously in varied parts of the world in the 1980s. This relatively new branch of science is now called seismo-electromagnetics.

Telluric current precursors: the VAN method

The VAN method, developed in Greece since early 1980s, is named after initials of the founding scientists, P. Varotsos, K. Alexopoulos, and K. Nomikos (Varotsos and Alexopoulos, 1984a, b). This has been the only working system for real short-term prediction for more than two decades (Figure 5). For $M \geq 5$ Greek EQs, the criteria for successful prediction imposed by themselves are: $<$ a few weeks in time, <0.7 units in M, and <100 km in epicentral location. SES (seismic electric signals) are transient DC geopotential variations observed before EQs by dipoles of buried electrodes at separate sites and continuously monitored at many



Earthquake Precursors and Prediction, Figure 5 Evaluation of VAN prediction. All EQs with USGS PDE magnitude larger than 5.5 for 1985–2003 (Uyeda and Meguro, 2004). Shaded, white with triangle, and white circles represent "successfully" predicted, unsuccessfully predicted, and missed EQs.

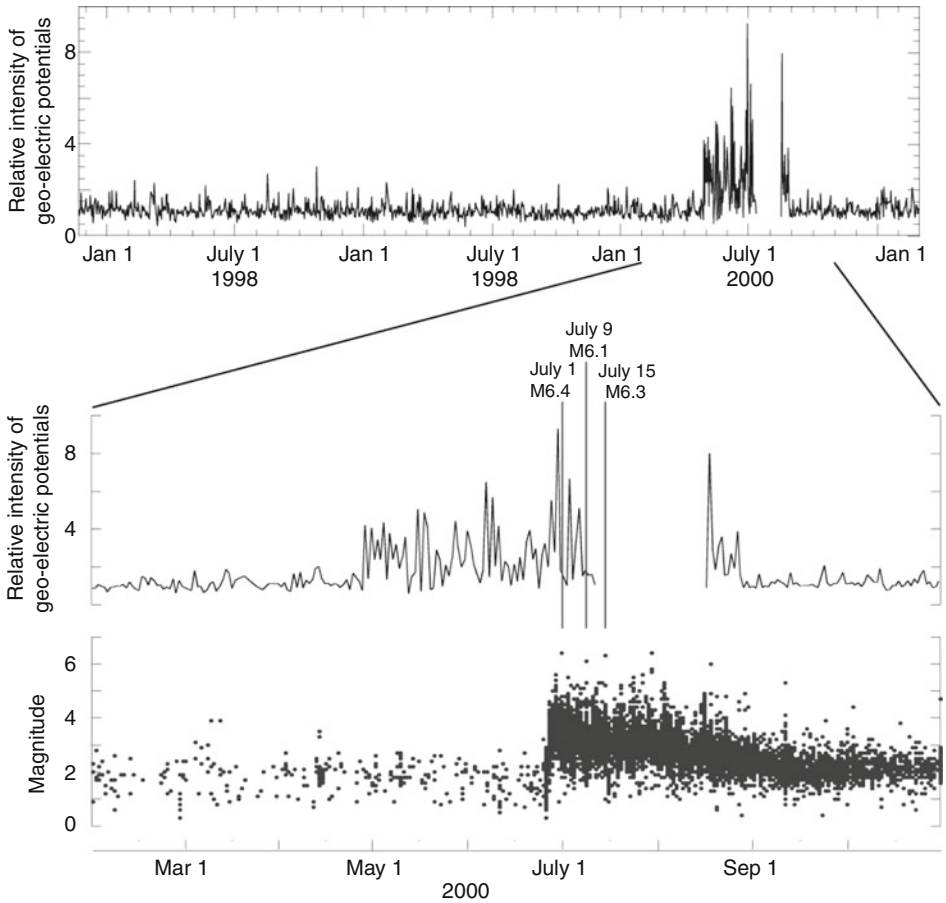
stations (e.g., Varotsos, 2005). At each station, several short (50~200 m) dipoles in both EW and NS directions and a few long dipoles (2~20 km) were installed. By adoption of multiple dipole system they accomplished successful noise rejection. Single SES precedes single EQ, whereas the so-called SES Activity, which consists of a number of SES in a short time, is followed by a series of EQs.

The VAN group made two major discoveries. One is the "Selectivity", which means that only some sites are sensitive to SES, and a sensitive site is sensitive only to SES from some specific focal area(s). This gives information for estimating the epicenter area. The selectivity is considered to be originated from the inhomogeneity of the subterranean electrical structures, i.e., SES goes only through underground conductive channels to sensitive sites. The other is the "VAN-relation" which means that the focal distance r, EQ magnitude M and the potential difference ΔV for dipole of length L are related by $\log(\Delta V/L \times r) = aM + b$ where a is a constant 0.34~0.37 and b is a site-dependent constant. Once the epicentral location is estimated from the selectivity data, M can be assessed since both $\Delta V/L$ and r are known. The VAN method has been a contentious subject (e.g., Geller, 1996; Lighthill, 1996). However, it has well survived all the criticism.

In Japan, VAN-type monitoring has been tried since the late 1980s (Uyeda et al., 2000). Despite the high-level noise of DC trains, the existence of the VAN type SES has been confirmed. In the year 2000, a two-month-long seismic swarm, with 7,000 $M \geq 3$ shocks and 5 $M \geq 6$ shocks, occurred in the Izu Island region. For this swarm activity, significant pre-seismic electric disturbances were observed (Figure 6, Uyeda et al., 2002).

Ultralow-frequency (ULF) precursors

A well-known example is the case of the 1989 M7.1 Loma Prieta EQ (Fraser-Smith et al., 1990). The horizontal component measured at a site 7 km from the epicenter started anomalous enhancement about 2 weeks prior to and a sharp increase a few hours before the EQ, as shown in Figure 7. The disturbance lasted for about 3 months after the EQ. These have never been observed at any other time

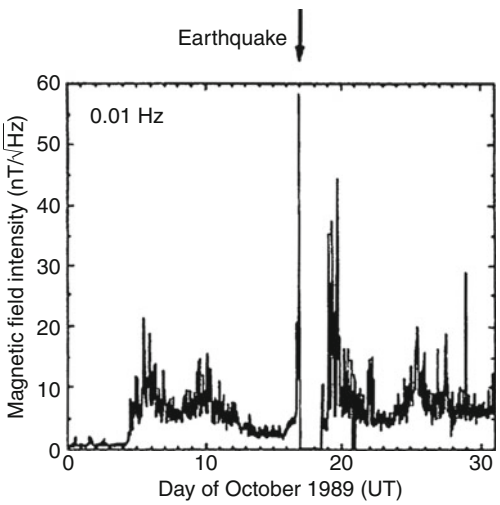


Earthquake Precursors and Prediction, Figure 6 Anomalous geo-electric potential changes in ULF (0.01 Hz) band prior to 2000 seismic swarm activity in Izu island region, Japan. The bottom panel shows seismicity. (Modified from Uyeda et al., 2002.)

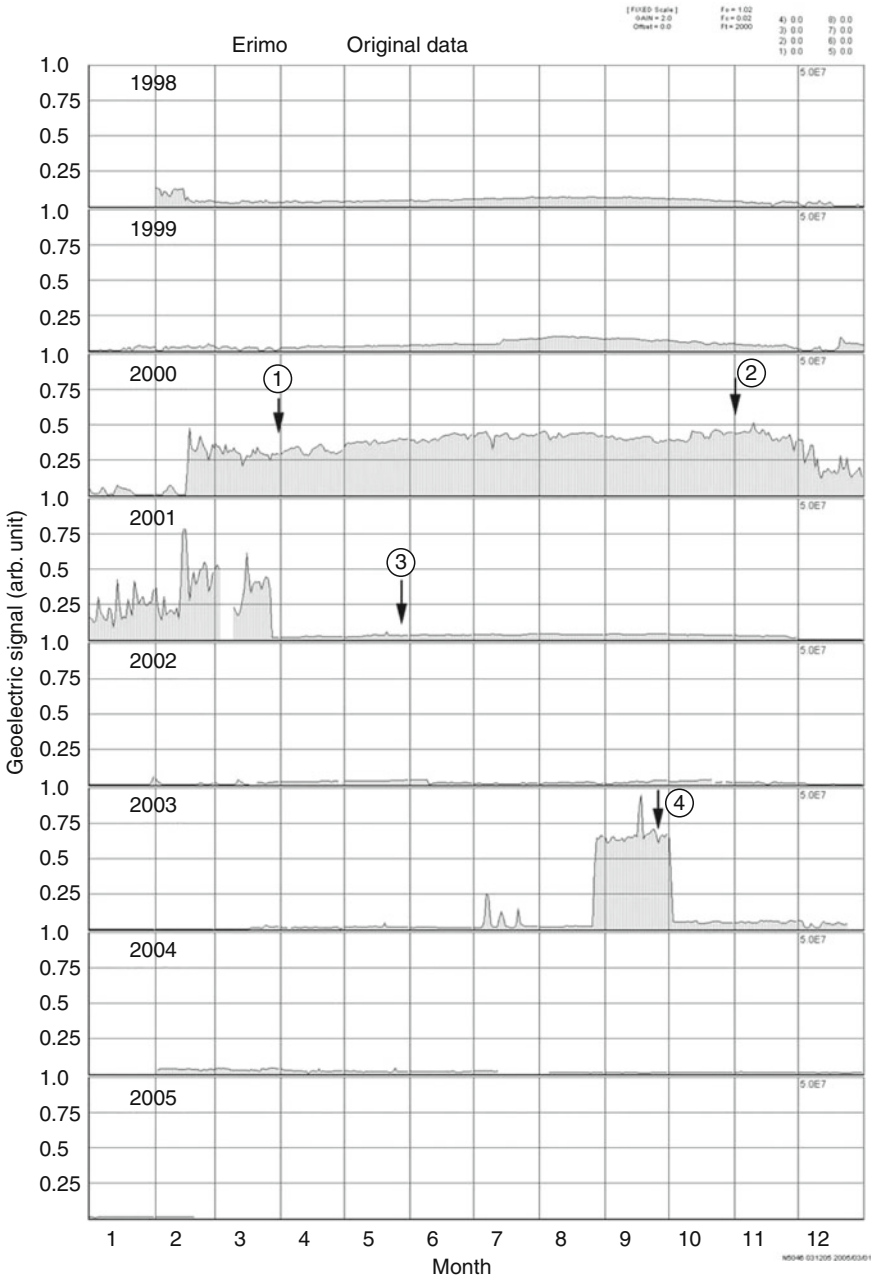
during the observation of more than 15 years. Reports of observing pre-seismic ULF geomagnetic anomalies have been made also for 1988 M6.9 Spitak (Armenia) EQ (Kopytenko et al., 1993) and 1993 M8.0 Guam (Marianas) EQ (Hayakawa et al., 1996). There are some discussions pointing out that these ULF signals might have been artifact or magnet-telluric origin (e.g., Thomas et al., 2009).

Higher-frequency EM emission

Gokhberg et al. (1982) was a pioneering observation of pre-seismic EM wave emission in the LF range. Asada and his group in Japan monitored the wave forms of two horizontal magnetic components of VLF EM waves, through which apparent incoming directions of VLF pulses were assessed (Asada et al., 2001). They found that, a few days before M5 class land EQs within 100 km of their stations, pulses with fixed incoming direction appeared and the EQ actually occurred in that direction, whereas the sources of overwhelmingly more numerous and stronger noises were moving along with lightning sources.



Earthquake Precursors and Prediction, Figure 7 Amplitude of the geomagnetic horizontal component at 0.01 Hz band observed before and after the M6.9 Loma-Prieta EQ (Fraser-Smith et al., 1990).



Earthquake Precursors and Prediction, Figure 8 Envelope of the geoelectric signal recorded at the Erimo site over 7 years since 1998. Japan Meteorological Agency (JMA) announcement of (1) the first eruption of Mt. Usu volcano, (2) decline in magma activity, (3) complete cessation of the magma activity, and (4) the main shock of M8.0 Tokachi-Oki EQ (Enomoto et al., 2006).

Warwick et al. (1982) reported on the observation of high-frequency radio waves possibly related to the precursory activity of 1960 Great M9.5 Chilean EQ. This was probably the first report of this kind. Enomoto et al. (2006) recorded two events of anomalous geo-electric current pulses (HF-band) at Erimo station, Hokkaido, Japan (Figure 8). One in 2000–2001 occurred before and during the volcanic activity of Mt. Usu (200 km away) and the second started one month before 2003 M8.0 Tokachi-Oki EQ (80 km away). These were the only anomalies during their 10-year observation period.

Possible mechanism of pre-seismic EM emissions

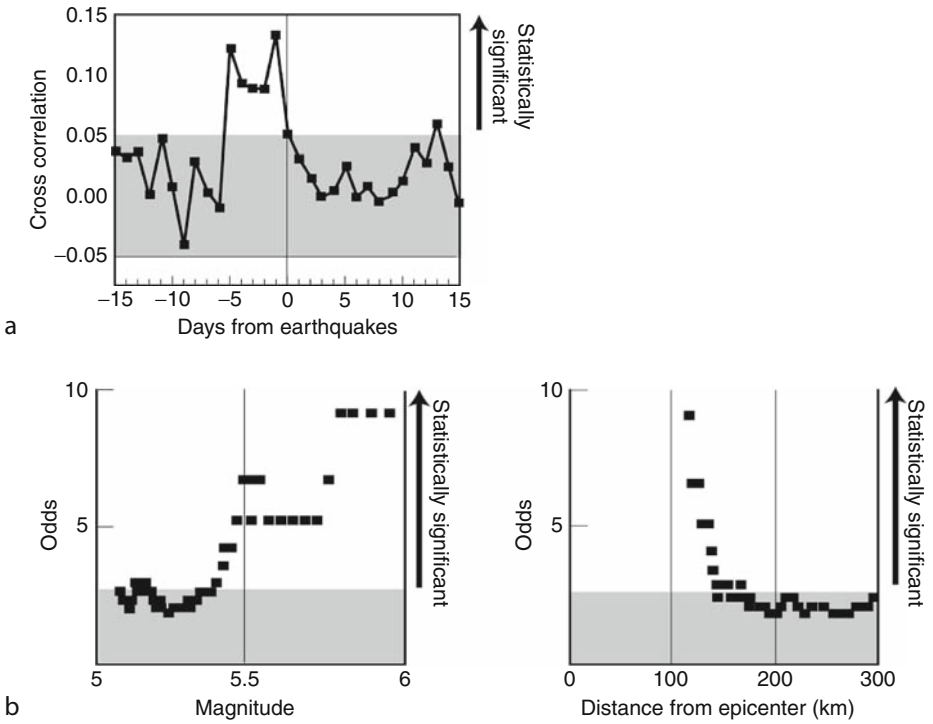
It is often questioned why EM signals, such as SES, appear only pre-seismically and not co-seismically. This point makes scientific community dubious about

EQ-related EM precursors in general because EQ is by far the most energetic event. Actually, co-seismic signals are routinely observed but they are not useful as precursors. Moreover, all the so called co-seismic EM signals observed so far were found to occur at the time of the arrival of seismic waves. They are, therefore, "co-seismic wave" and not "true" co-seismic. The fact that no true co-seismic signals are observed may be an important clue in exploring the physical mechanism of generation of both EM signals and EQs themselves. In fact, the slow pre-seismic stress buildup and the instantaneous stress release at EQ are physically very different processes and there is no compelling reason why they generate similar EM signals.

The generation mechanism is different for different frequencies. It may be the electro-kinetic effects (e.g., Mizutani et al. 1976; Fitterman, 1978) or pressure stimulated current (PSC) effects for DC to low-frequency signals, and piezo-electric effects and exo-electron emission (Enomoto and Hashimoto, 1990) for higher frequency signals. A mechanism involving the positive holes (p-holes) in rock forming minerals under stress has also been proposed.

The PSC was proposed by Varotsos and Alexopoulos (1986). The impurities and vacancies in crystals form randomly oriented local electric dipoles, which align their orientation in avalanche following an activation process to generate the electric current. PSC model is unique in generating currents during gradual stress build-up without requiring any sudden change of stress. Freund and his colleagues are proposing a different mechanism for ULF electric signals (Freund et al., 2006). They discovered in laboratory that when a block of igneous rock is put under local stress, the rock turns into a battery without external electric field. The charge carriers in this case are semiconductor-type positive holes (p-holes) which is oxygen in one-valence state. They attribute the satellite image of pre-seismic IR anomalies to the result of recombination of two p-hole charge carriers at earth's surface as mentioned earlier. However, whether their model based mainly on experiments on dry rocks works in nature where rocks are mostly wet is not so far clear.

Although models related to micro-cracking based on laboratory experiments such as discharge of screening charge of piezo-electric polarization (Ikeya, 2004; Yoshida et al., 1997), electrification of fresh crack surfaces (Yamada et al., 1989), and exo-electron have been proposed, there have been no reliable field reports on the occurrence of pre-main shock micro-cracking. Furthermore, it might be pointed out that in all these models much stronger co-seismic signals would be expected.



Earthquake Precursors and Prediction, Figure 9 Statistical significance of pre-seismic ionospheric anomaly (PEIA). (After Liu et al., 2006.) (**a**) Cross-correlation coefficient between EQs and anomalies with time lag. The shaded area denotes the rejection bounds at significance level 0.01. (**b**) Odds of the shallow EQs with the PEIA against the magnitude and distance. Odds versus related mean magnitude (*left*), and odds versus related mean distance (*right*). The *shaded areas* in the two plots denote the rejection value of odds as 2.5 under significance level of 0.01.

Lithosphere-atmosphere-ionosphere coupling

Sub-ionospheric anomalies before large EQs were reported (e.g., Molchanov and Hayakawa, 1998) through monitoring 10–20 kHz VLF ship-navigation waves, although Clilverd et al. (1999) did not obtain similar results. A decrease in electron density of ionosphere within 5 days before $M \geq 5$ class EQ was found in Taiwan by the ionosonde measurements of critical plasma frequency, foF2 (see Figure 9, Liu et al., 2006). Fujiwara et al. (2004) found pre-seismic atmospheric anomalies causing FM radio transmission anomalies (Kushida and Kushida, 2002) within 5 days before $M \geq 4.8$ EQs. Moriya et al. (2010) further promoted this study and obtained statistical relations between the total time length of anomalous reception and EQ magnitude. The concept of pre-seismic lithosphere-atmosphere-ionosphere coupling (LAI coupling) arising from these investigations became an important issue in precursor studies (Pulinets and Boyarchuk, 2005; Kamogawa, 2006), because some causative factor should exist in the lithosphere and there should be some mechanism to transport its energy to the high atmosphere. Recently, the French satellite DEMETER observed anomalous depression of VLF EM wave intensity at ionospheric height 0–4 h before EQs, which implies that the ionospheric disturbance may modulate the VLF propagation path (Němec et al., 2009). Possible LAI coupling processes have been proposed by many researchers but they are still at hypothetical stage.

Critical phenomena

EQ may be a critical phenomenon defined in statistical physics (e.g., Bak and Tang, 1989) which means that the short time EQ prediction is synonym for indentifying the approach to criticality. Although this is difficult to achieve (see Main, 1995), it has been recently shown that by analyzing time-series of seismicity in a newly introduced time domain "natural time," the approach to the state of criticality can be clearly identified (Sarlis et al., 2008). This way, they seem to have succeeded in shortening the lead-time of VAN prediction to only a few days (Uyeda and Kamogawa, 2008). This means, seismic data may play an amazing role of short-term precursor when combined with SES data.

Summary and future outlook

Most of the precursors mentioned above are possibilities, but so far they (except VAN's SES) were recognized or documented only after main shocks and they gave scarce constraints on the source location and magnitude M. Much more enhanced research is needed to make them practically useful precursors.

1. Some macro-anomaly short-term precursors are real. Scientific research on them is inadequate so far.
2. Seismic and geodetic precursors can be useful for long/intermediate EQ prediction. However, it is unlikely that they can be useful short-term precursors in near future.
3. Non-mechanical precursors, such as some geochemical, hydrological, and EM precursors, are plausible candidates for short-term EQ prediction. For sooner realization of practical short-term prediction, more research on them should be promoted.

Definition

An *earthquake* is a sudden movement within the Earth's crust or the upper mantle that releases tectonic stress and, usually, originates seismic waves. The hierarchy of movable lithospheric volumes composes a large nonlinear dynamical system. Prediction of such a system in a sense of extrapolation of trajectory into the future is futile. However, upon coarse-graining the integral empirical regularities emerge opening possibilities of earthquake prediction (Keilis-Borok et al., 2001).

Earthquake prediction is a statement about future earthquake occurrence based on the information, data, and scientific methods that are available now. To predict an earthquake, someone "must specify the expected magnitude range, the geographical area within which it will occur, and the time interval within which it will happen with sufficient precision so that the ultimate success or failure of the prediction can readily be judged. Only by careful recording and analysis of failures as well as successes can the eventual success of the total effort be evaluated and future directions charted. Moreover, scientists should also assign a confidence level to each prediction" (Allen et al., 1976).

Introduction

According to the definition of earthquake prediction one can classify an earthquake prediction of certain magnitude range by duration of time interval and/or by territorial specificity. Four major stages can be distinguished in temporal earthquake predictions: (1) long-term, (2) intermediate-term, (3) short-term, and (4) immediate (see Table 1).

Long-term prediction is essentially based on the determination of probabilities of active fault segments to rupture for the next few decades (e.g., Working group on California earthquake probabilities, 1999). This kind of prediction can guide engineering and emergency planning measures to mitigate the impact of a target earthquake.

An intermediate-term prediction for the next few years is an update of the long-term prediction by some indicators (e.g., an increase in background seismicity, clustering of events in space and time, transformation of magnitude

distribution, and some others). The M8 algorithm is designed for an intermediate-term prediction of earthquakes (Keilis-Borok and Kossobokov, 1990).

In the 1980s, P. Varotsos, K. Alexopoulos and K. Nomicos proposed the VAN method (named after the researchers' initials) of short-term earthquake prediction for the next few months/weeks, which is based on detection of characteristic changes in the geoelectric potential via a telemetric network of conductive metal rods inserted in the ground (Lighthill, 1996).

Immediate earthquake prediction for the next few hours is sometimes mixed with "early warning," which is usually based on the first arrival of seismic waves and transmission of an electronic alert within a lead-time of seconds. Early warning is used (e.g., in Japan) to shut down gas and electricity grids and to stop high-speed trains in the event of a strong earthquake.

Following common perception, some investigators concentrate their efforts on predicting the "exact" fault segment to rupture, e.g., the Parkfield earthquake prediction experiment (Bakun and Lindh, 1985), which is by far more difficult and might be an unsolvable problem (Main, 1999). Being related to the rupture size L of the incipient earthquake, predictions could be summarized in a classification that distinguishes several options of wider spatial ranges of certainty and not only "exact" mode of prediction (Table 1). The Gutenberg–Richter power law relation between the number of earthquakes and their magnitude suggests limiting magnitude range of prediction, $Mm+ = [m, m + \Delta m]$, to about one unit or less (i.e., $\Delta m \leq 1$).

From a viewpoint of such a classification, the earthquake prediction problem might be approached by a hierarchical, step-by-step prediction technique, which accounts for multi-scale escalation of seismic activity to the main rupture (e.g., Keilis-Borok, 1990; Kossobokov et al., 1999). It starts with term-less recognition of the earthquake-prone zones (Gorshkov et al., 2003) and then follows with determination of the areas of different spatial ranges, where long- and intermediate-term *times of increased probability* (TIP) of a target earthquake occurrence are estimated. Finally, a forecast may come out with short- or immediate-term alerts at specific sites.

Earthquake Prediction, M8 Algorithm, Table 1 Classification of earthquake predictions

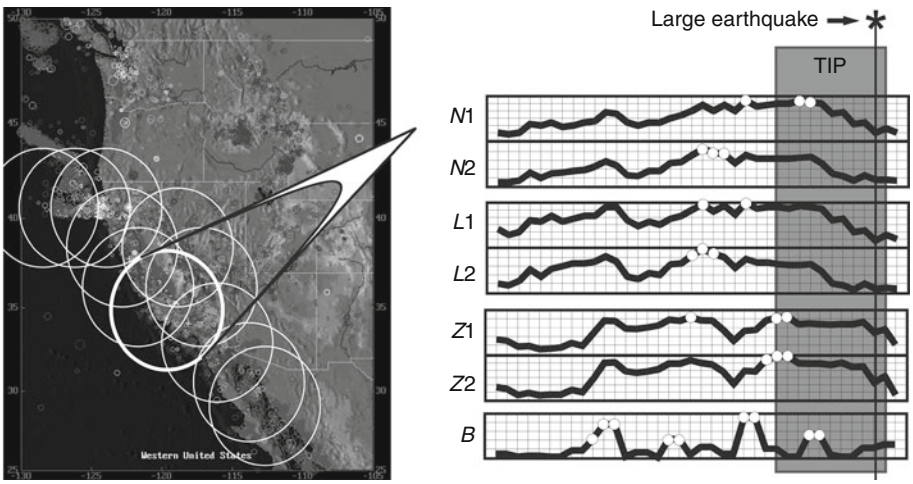
Temporal, in years		Spatial, in source zone size L	
Long-term	10	Long-range	Up to 100 L
Intermediate-term	1	Middle-range	5–10 L
Short-term	0.01–0.1	Narrow	2–3 L
Immediate	0.001	Exact	1 L

Spatial accuracy of predictions depends on the source size L of target earthquakes.

The M8 algorithm

The intermediate-term middle-range earthquake prediction method, called briefly the *M8 algorithm*, was designed by retroactive analysis of dynamics in seismicity preceding the great, magnitude 8.0+, earthquakes worldwide, hence its name. The exact definitions and computer code of the M8 algorithm can be found in Keilis-Borok and Kossobokov (1990), Healy et al. (1992), and Kossobokov (1997).

Prediction is aimed at the earthquakes of magnitude M, where $M \in [M_0, M_0 + \Delta m] = M_0+$. The territory of the seismic region under study is analyzed by moving overlapping circles of the fixed size (by a factor of about 5–10 larger than a source size of target magnitude M_0 events) (Figure 1). The sequence of earthquakes with



Earthquake Prediction, M8 Algorithm, Figure 1 General scheme of the M8 algorithm. *Left panel*: Circles of investigation overlay the targeted seismic region; seismic sequences in each circle give a description of seismic activity, which is then used to diagnose an alert (TIP). *Right panel* presents the plots of the M8 algorithm's functions (explained below) with time. The interval of TIP is shaded by gray; the asterisk denotes the large event occurred; and the white dots show anomalously high values of the functions.

aftershocks removed is considered within each circle. Sequences in different circles are normalized to the annual number of earthquake $\bar{N}$ by selecting the lower magnitude cutoff $\underline{M} = M_{\min}(\bar{N})$.

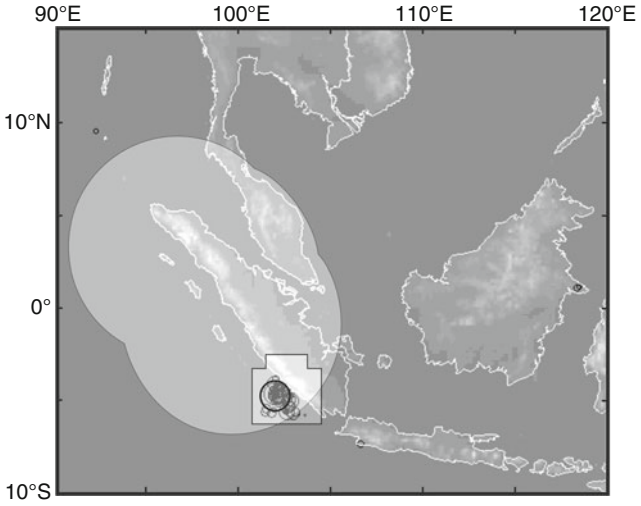
For this sequence, several functions are computed in the trailing time window (*t-s, t*) and the magnitude range ($\underline{M} \leq$ *magnitude* $< M_0$). These functions include (1) the number of earthquakes *N(t)* of magnitude *M* or greater; (2) the deviation of *N(t)* from longer-term trend *L*(*t*); (3) concentration *Z*(*t*) estimated as the ratio of the average source diameter to the average distance between sources; and (4) the maximum number of aftershocks *B*(*t*). Each of the functions *N*, *L*, and *Z* is calculated twice with $\underline{M} = M_{\min}(\bar{N})$ for $\bar{N} = 20$ and $\bar{N} = 10$. As a result, the earthquake sequence is given a robust averaged description by seven functions *N*1, *N*2, *L*1, *L*2, *Z*1, *Z*2, and *B* (Figure 1). An alarm or a TIP is declared for 5 years when at least six out of seven functions, including *B*, become "anomalously large" within a time window of 3 years.

Retrospectively the M8 algorithm was applied to predict earthquakes from different magnitude ranges in a number of regions worldwide. Its modified versions targeting earthquakes from magnitude ranges down to M5.5+ were found efficient in regions of seismic activity lower than required by the original version (Kossobokov and Shebalin, 2003; and references therein).

The MSc algorithm

The second approximation prediction method, called briefly the *MSc algorithm* (Kossobokov et al., 1990), was designed by retroactive analysis of the detailed regional seismic catalog prior to the Eureka earthquake (1980, M = 7.2) near Cape Mendocino in California, hence its name, *Mendocino Scenario*, and an abbreviation. The MSc algorithm is applied to reduce the area of alarm by analyzing dynamics at lower magnitude levels of seismic hierarchy. Sometimes, the data is enough to get a near-perfect outline of the incipient large earthquake. More often the catalog of earthquakes is just enough for the M8 analysis but insufficient for the MSc application.

Qualitatively, the MSc algorithm determines an area of the territory of alarm, where the activity recognized by the first approximation prediction algorithm (e.g., by the M8 algorithm) within a sufficient temporal and/or spatial span is continuously high and infrequently drops for a short time. The phenomenon, which is used in the MSc algorithm, might reflect the second (possibly, shorter-term and, definitely, narrow-range) stage of the premonitory rise of seismic activity near the incipient source of the main shock. The MSc algorithm reduces area of the M8 predictions much better (by at least a factor of 2) than a few simple alternatives like all earthquake-prone or the most active cells that contain certain part of the recent seismic activity (Kossobokov et al., 1990). Figure 2 shows, as an example of the M8-MSc forecast in the real time, the case history of June 4, 2000, M8.0 Sumatra earthquake.



Earthquake Prediction, M8 Algorithm, Figure 2 Prediction of June 4, 2000, M = 8.0 Sumatra earthquake. The highlighted overlapping circular areas of alarm determined by the M8 algorithm and the highlighted overlapping rectangular areas of alarm by the MSc algorithm. The main event and its aftershocks are marked by circles.

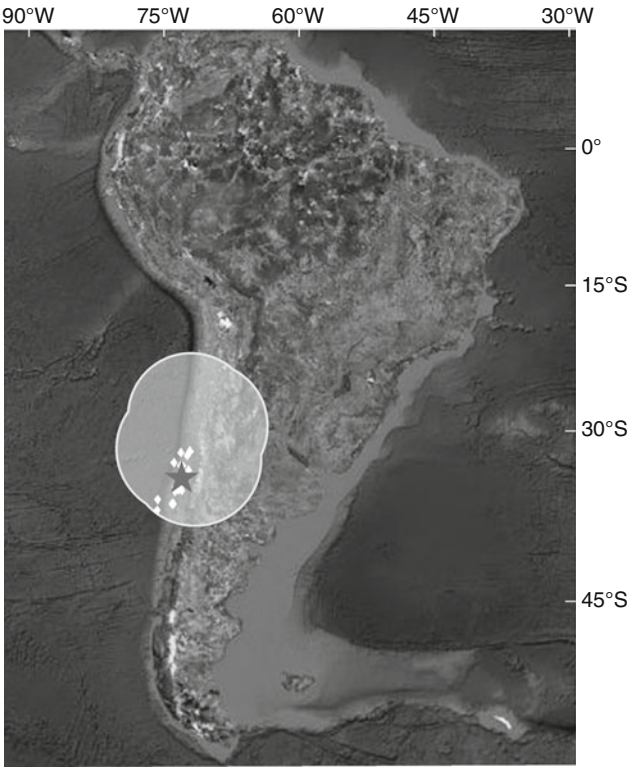
The earthquake prediction algorithms M8 and MSc receive a fair amount of attention due to ongoing real-time experimental testing unprecedented in rigor and global coverage (Healy et al., 1992; Kossobokov et al., 1999). Relevant predictions are communicated, with due discretion, to several dozens of leading scientists and administrators in many countries. The accumulated statistics of this experiment confirm intermediate-term predictability of large earthquakes with middle- to exact-range of location (Kossobokov, 2006). Table 2 summaries the prediction outcomes for the great (magnitude 8.0+) earthquakes. For the last 25 years, 13 out of 18 great earthquakes were predicted by the M8 algorithm, while the M8-MSc algorithm narrows the area of alarm at the cost of additional three failures-to-predict. The ratio of the *space-time volume alerted by the algorithms* (i.e., alarms) to the total space-time volume is about 33% in the case of the M8 algorithm and 17% in the case of the M8-MSc algorithm. A confidence level estimate tells how sure one can be that the achieved performance of the algorithm is not arisen by chance. To bring the confidence level down to generally accepted value of 95%, the ongoing experimental testing has to encounter eight failures-to-predict in a row, which appears absolutely unlikely to happen.

Targeting mega-earthquakes

The December 26, 2004, M = 9.2 Sumatra-Andaman (S-A), March 28, 2005, M = 8.5 Nias, and February 27, 2010, M = 8.8 Chile mega-earthquakes, which ruptured the 1300-, 400-, and 600-km portions of subducting margins of the Indian and Pacific Oceans, are not included

Earthquake Prediction, M8 Algorithm, Table 2 Worldwide performance of earthquake prediction algorithms M8 and M8-MSc

	Large earthquakes						
	Predicted by			Alarms, %		Confidence level, %	
Test period	M8	M8-MSc	Total	M8	M8-MSc	M8	M8-MSc
1985–2009	13	10	18	32.93	16.78	99.93	99.98



Earthquake Prediction, M8 Algorithm, Figure 3 Prediction of February 27, 2010, offshore Maule, Chile M_W8.8 mega-earthquake. The epicenters of the main shock (star) and its aftershocks (white diamonds) fill the 600-km portion of the South American subduction zone, which is about one half of the major seismic segment recognized (gray outline) as capable of producing a magnitude M8.0+ event before mid-2012 in the ongoing real-time experimental testing.

in Table 2 because of their rupture size. According to the M8 methodology, much larger circles of investigation (CI) with diameter of several thousand kilometers should then be employed to search for a precursory seismic activation in advance of mega-earthquakes. An application of the M8 algorithm targeting M9.0+ earthquakes could have predicted the S-A earthquake (see http://www.mitp.ru, section "Predictions").

Actually, the retrospective application of the M8 algorithm (with the 6,000-km diameter CI) showed that in July 2004 the precursory seismic activation was widespread over the most of the earthquake-prone areas of the Earth (Romashkova, 2008). This activation reduced to four clusters of TIPs by 2008. The largest cluster includes S-A and adjacent major seismic zones from Kashmir in the North-West to Timor Islands in the East, where March 28, 2005, Nias, M_W8.7 M-earthquake and coupled September 12, 2007, Southern Sumatra, M_W8.5 and M_W7.9 great earthquakes have already confirmed the M8 algorithm diagnosis (see http://www.mitp.ru; *note that an access to the current predictions is available only for experts; contact volodya@mitp.ru for the access code*). One of the other three smaller clusters of TIPs (i.e., the circle centered at 31°S and 70°W) got the confirmation with the occurrence of February 27, 2010, offshore Maule, Chile M_W8.8 M-earthquake (Figure 3).

Figure 3 does not show this CI, but the cluster of TIPs in four smaller (667-km diameter) CIs of the regular M8 algorithm diagnosis aimed at M8.0+. Evidently, this provides a narrow-range reduction of the prediction uncertainty acting as the second approximation to diagnosis aimed at M9.0+.

Conclusion

High statistical significance of intermediate-term earthquake prediction methods, achieved in the ongoing experimental testing worldwide, confirms the following paradigms: (1) precursory seismicity patterns exist; (2) the dimension of an area where precursory seismicity pattern appear is by far (about ten times) larger than that of source zone of the incipient large earthquake; (3) many precursory seismicity patterns are similar in regions of different seismic and tectonic environment; and (4) some precursory seismicity patterns are universal. Their analogs take place in advance extreme catastrophic events in other complex nonlinear systems.

Our knowledge of earthquake physics and earthquake dynamics is not sufficient to predict strong earthquakes with a high accuracy. We do not know well (1) how earthquakes, especially large events, originate; (2) when an earthquake starts, when it stops, and what magnitude could it be; (3) how and why earthquakes cluster; and (4) what were the initial conditions of stress state before a large event in terms of stress transfer.

The scientific community should use the full potential of mathematics, statistics, statistical physics, and computational modeling and the data derived from seismological

(monitoring of physical parameters of earthquakes and tectonic stress, fluid migration, etc.), geodetic (GPS, InSAR, and other measurements of the crustal deformation), and geological (e.g., determination of the time intervals between large earthquakes using paleo-seismological tools) studies to improve intermediate- and short-term earthquake predictions (Ismail-Zadeh, 2010).

Though the current accuracy of earthquake prediction is limited, any scientifically validated prediction can be useful for earthquake preparedness and disaster management, if the accuracy of the prediction is known, even though it is not high. An inexpensive low-key response to intermediate-term middle-range predictions described here is well justified, if even a little part of the total damage due to a strong event is prevented.

EARTHQUAKE RUPTURE: INVERSE PROBLEM

Shamita Das
Department of Earth Sciences, University of Oxford, Oxford, UK

In seismology, as in all geophysics, an area of major interest is inverse problems. That is, given the effect, one would like to determine the cause. The inverse problem of earthquake source mechanics consists of analyzing seismograms to obtain detailed information on the earthquake rupturing process. In particular, scientists are interested in how the slip develops over the fault area during the time period that the two sides of the fault are moving past one another, at what speed do these two sides slide past, what the resulting stress drop is, as well as the speed at which rupture itself spreads out over the fault. Such information is essential for reliable seismic hazard assessment.

The solution of this problem is far from trivial, because it is unstable (Kostrov and Das, 1988), and from the computational point of view, this instability manifests itself as non-uniqueness of the solution. Adding constraints to the solution of the relevant equations has been shown to stabilize the problem. Such constraints appear best when based on the physics of problem, that is, the physics of the earthquake faulting process. Unfortunately, our knowledge of the physics of the earthquake process is still rather limited. So, seismologists have had to use those few properties that are considered to be reliably known. For example, forward modeling showed that it is not likely that there is major

back-slip on the fault. So, a constraint that is often used is the requirement that the slip rate vector be positive, that is, no back-slip is permitted on the fault. While, in principle, slip in the opposite direction is possible due to interference of waves on the fault, especially at the fault edges, experience from three-dimensional forward modeling shows that this is unlikely. This constraint has been used by Olson and Apsel (1982), by Hartzell and Heaton (1983), and by Das and Kostrov (1990, 1994), among others, and has been shown to stabilize the solution. Other possible constraints, such as requiring the solution to be in agreement with the seismic moment obtained from the centroid moment tensor solution or from geodetic measurements, or, requiring the fault rupture speed to be limited by some wave velocity, can also been used. Further constraints such as requiring the maximum slip rate on the fault to be limited by some considerations from fracture mechanics, could be considered. It has been found that minimizing the seismic moment often provides stable solutions.

As stated by Olson and Apsel (1982), in order for a particular rupture process to be an acceptable solution to the inverse problem it must satisfy the following three conditions:

1. The solution must explain the data.
2. The solution must be physically reasonable (consistent with independent constraints).
3. If more than one solution fits the data equally well, additional information must be supplied to uniquely define which solution is being obtained.

The rupture process is solved for by determining the slip rate distribution over the fault with time, and the entire rupture process is reconstructed from it. For example, the final slip distribution is found simply by integrating the slip rate distribution over time. The rupture speed can be found simply by tracking the rupture front, and so on.

To invert for the three-dimensional slip rate distribution (two spatial dimensions on the fault and time) is a computationally difficult task. Not surprisingly, simplified methods of solving the problem have been used. For example, in order to reduce the number of unknowns, one often restricts for how long a point on the fault can slip. But, in reality, if some region of the fault re-slips, or has delayed slip, both shown to be feasible in forward models, this may not be found by the solution. This restriction would inhibit discovering fault complexity. The discretization itself may implicitly impose some constraint on the solution. It is thus important to ensure that the solution methods do not impose any implicit (and unknown) constraints on the solution, and if implicit constraints are unavoidable, they must be kept in mind when interpreting such solutions in geophysical terms.

To formulate the problem, we start from the representation theorem (e.g., Aki and Richards, 1980), where the ground displacement at a station located at a point $\mathbf{x}$, on the Earth's surface can be expressed in terms of the slip distribution over a fault Σ as

$$u_k(\mathbf{x}_1, t_1) = \int_0^{t_1} dt \iint_\Sigma K_{ik}(\mathbf{x}_1, \mathbf{x}, t_1, t) a_i(\mathbf{x}, t) dS \qquad (1)$$

where $i, k = 1, 2, 3$, $u_k(\mathbf{x}_1, t_1)$ are the components of the displacement vector, $a_i(\mathbf{x}, t)$ are the components of the slip and $K_{ik}(\mathbf{x}_1, \mathbf{x}, t_1, t)$ are the components of the impulse response of the medium at $(\mathbf{x}_1, t_1)$, due to a dislocation point source at $(\mathbf{x}, t)$. Assuming a planar fault and the slip direction on the fault to be constant, we can write, after some transformations:

$$S_j(t_1) = \int_0^{t_1} dt \iint_\Sigma W_j(\xi, t_1 - t) \dot{a}(\xi, t) dS \qquad (2)$$

where j identifies the station and ground displacement components of the seismogram $S(t_1)$, $W_j(\xi, t)$ is the Heaviside response of the medium at (ξ, t) corresponding to a fixed slip direction, $\dot{a}(\xi, t)$ is the fault slip rate, the two-dimensional vector ξ gives the position on the fault relative to some reference point (for example, the earthquake hypocenter) and t is the time measured from the origin time of the earthquake. With a continuous distribution of stations, Equation 2 would represent an integral equation of the first kind (and such equations are known to be unstable).

The following additional constraints are often used:

$$\dot{a}(\xi, t) \geq 0 \text{ for all} (\xi, t) \qquad (3a)$$

$$\dot{a}(\xi, t) = 0 \quad \text{for} \quad t < T(\xi) \qquad (3b)$$

where, $t = T(\xi)$ gives the boundary of the area where slip is permitted (due to some chosen causality condition) at time t. Note that this is not the actual rupture front, which should not generally by assigned a priori, and should be determined as part of the solution.

$$\int_0^\infty dt \iint_\Sigma \mu(\xi) \dot{a}(\xi, t) dS = M_0 \qquad (3c)$$

where M_0 is the seismic moment and μ is the modulus of rigidity of the medium. The constraint (3*a*) is the "no-back-slip" or the "positivity" constraint, the constraint (3*b*) is a "causality constraint," which could be taken as the *P*- or *S*-wave causal front, or any other chosen region. The constraint (3*c*) is the "seismic moment constraint."

We restrict this discussion to long-period body waves at teleseismic distances ("far-field") because they are less sensitive to the details of Earth structure. This problem has been looked at using ground motion data from seismograms located at regional distances from earthquakes, for example, for the 1985 Mexican earthquake (Mendoza and Hartzell, 1989) and the 1992 Landers, California earthquake (Cohee and Beroza, 1994; Wald and Heaton, 1994), but the problem has not yet been considered for the case of true "near-field" data where the higher order terms are kept in the Green function calculations. The (Green) functions W_j for the teleseismic problem can be calculated using, for example, the ray

approximation and the Thomson–Haskell technique or ray-tracing methods to account for the layered crustal structure at the source and the station. These techniques take into account all surface reflections near the source and at the receiver, such as *pP*, *sP*, *pS*, and *sS*, as well as all reflections and transmissions at every layer of the crustal structures. For the numerical solution, the integrals in (2) must be discretized. For this, the area Σ where slip is permitted must be divided into a number of cells (usually square or rectangular) and $\dot{a}$ within each cell approximated by linear functions in time and along strike and dip (if the width of the cells are small, the variation along dip can be taken as constant). The W_j's must then be integrated over each cell (analytically, if possible, as done by Das and Kostrov (1990, 1994)), and the integrals over the fault are replaced by sums. The time at the source is discretized by taking a fixed time step, Δt say, and it could be assumed that the slip rate $\dot{a}$ during the time step is a constant, or varies in some prescribed way, say, linearly with time. Both the fault area and the total source duration should be determined as part of the inversion process. One can use the aftershock area as starting area, and then refine it further during the inversion. The initial source duration cannot be longer than the longest record used, in other words, the time length of the seismograms needs to be long enough to study the entire source process. It is important to keep in mind that at many distances, other phases, such as core reflections, arrive within this time window, and either the seismogram used has to be terminated at this time, or these additional phases correctly modeled. Unfortunately, often, neither is done in some studies, based on the incorrect assumption that such reflections are always small compared to the direct arrivals. The seismograms are sampled at some chosen time step Δt_1, not inconsistent with the spatial cell size of the fault and time step of the source duration. Then Equation 2 takes the form

$$A\mathbf{x} \approx \mathbf{b} \tag{4}$$

where A is the matrix obtained by integration of W_j, each column of A being a set of Green function seismograms for all stations corresponding to different cells and time instants of the source duration, ordered in the same way as the observed seismograms. The arrangement of Equation 4 is shown in Figure 1. Different stations and components can be weighted differently in Equation 2. This is very useful when inverting P- and S-waves simultaneously.

For the discrete problem, condition (3*a*) becomes:

$$\mathbf{x} \geq 0, \tag{5a}$$

the inequality meaning that every component of $\mathbf{x}$ is non-negative. The condition (3b) can be replaced by

$$x_i = 0 \tag{5b}$$

for those i corresponding to cells and time samples outside the "rupture front" and the condition (3*c*) becomes:

$$\Sigma c_i x_i \approx M_0 \tag{5c}$$

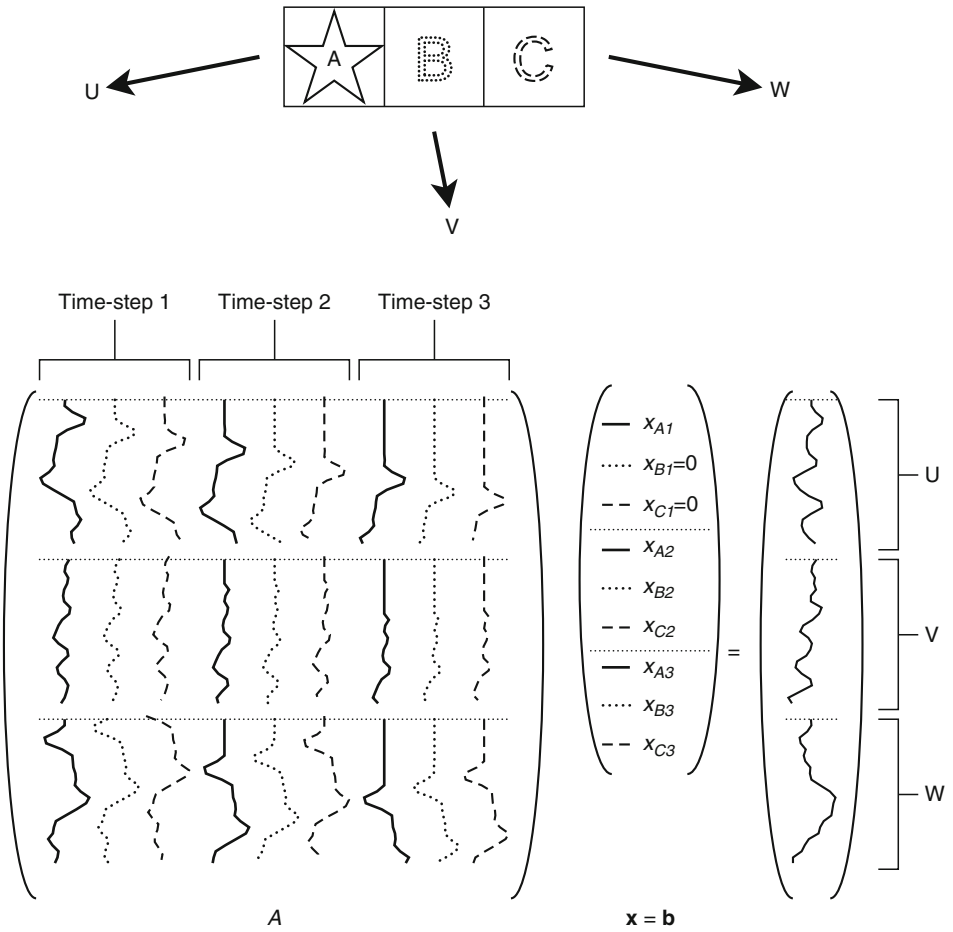
where c_i is time-independent and for each cell is equal to the product of the average rigidity multiplied by the area of the cell. So, the inverse problem has been reduced to the solution of the linear system (4) under one or more of the constraints (5). In the system (4), the number of equations, m, is equal to the total number of samples taken from all the records involved and the number of unknowns, n, is equal to the number of cells multiplied by the number of time steps at the source. We shall take $m > n$ to reduce the influence of the noise contained in the observations $\mathbf{b}$ on the solution. Then, the system (4) is overdetermined and we can only obtain a solution $\mathbf{x}$ that provides a best fit to the observations, under constraints (5). It is important to note that, in theory, for the constrained system, it is not necessary for $m > n$, though it has been so in all actual studies of earthquakes.

It is now well understood that the matrix A can be ill-conditioned, which implies that the system (4) admits more than one solution, equally well fitting the observations. The constraints (5) are introduced just for the purpose of reducing the set of permissible (feasible) solutions. When a "best-fitting" solution is obtained, other solutions almost satisfying the equations are also of great interest. This is because the data used in geophysical applications often contains noise and the models used are themselves approximations to reality, so that the "best-fitting" solution may not represent actuality. In addition, though the different solutions may be very close together in data-space, it is possible that they may be somewhat different in model space. Thus, more than one solution must be found and the set of (almost) equally well-fitting solutions examined to find features common to the solutions. To examine the stability of the inverse problem, Das and Kostrov (1990, 1994) obtained not only a "best-fitting" solution but also investigated the solution space around it. These other solutions, though they may lie very close to one another in model space, may physically represent rather different solutions. Das and Kostrov (1990, 1994) suggested additional tests to determine the robustness of such features. Only features clearly required by the solutions should be interpreted in a geophysical context.

For the system of Equations 4 together with the constraints (5) to comprise a complete mathematical problem, it is necessary to formulate the exact form of what the "best-fit" to observations means. We include only constraint (5*a*) in the mathematical formulation for the sake of simplicity, the inclusion (5*b*) and (5*c*) being simple, and is discussed, for example, by Das and Kostrov (1990, 1994). We have to minimize the vector of residuals:

$$\mathbf{r} = \mathbf{b} - A\mathbf{x} \tag{6}$$

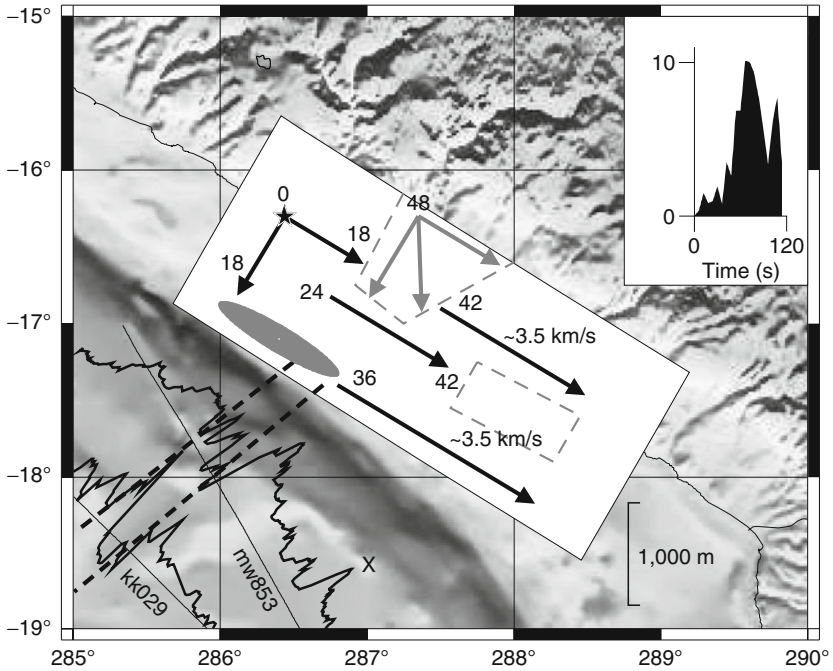
For this purpose, some norm of the vector $\mathbf{r}$ must be adopted. One may choose to minimize the ℓ_1, the ℓ_2, or the ℓ_∞ norm, all three being equivalent in the sense that they tend to zero simultaneously. Hartzell and Heaton



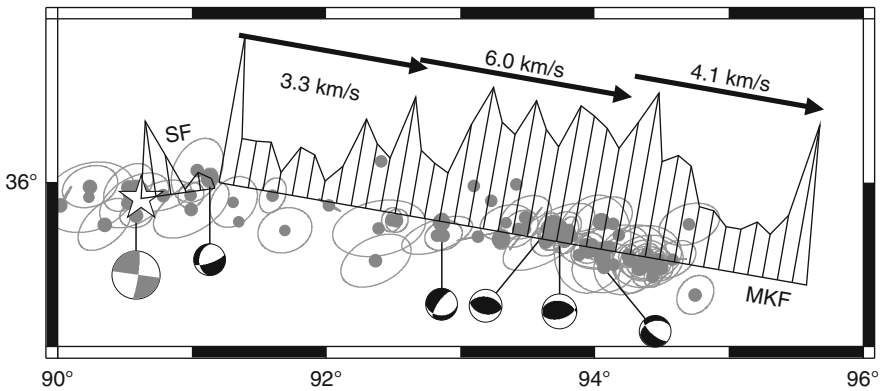
Earthquake Rupture: Inverse Problem, Figure 1 Schematic showing the arrangement of the linear system $A\mathbf{x} = \mathbf{b}$.
A simplified faulting model is shown at the top, with three spatial cells along the fault length and one cell along its width. The rupture initiates at time step 1, in cell A, marked by the star. Rupture proceeds to the left, breaking cell B and then cell C. The resulting seismograms are recorded at three stations named U, V, and W. In the matrix A, containing the Green functions, portions relating to the cells A, B, and C are coded with solid, dotted, and dashed lines, respectively. The vector $\mathbf{x}$ is the slip rate in each cell A, B, or C, at time steps 1, 2, and 3. In reality, there will be many more time steps, and A will have many more columns. If only cell A is allowed to slip at the first time step, by invoking the causality condition, then the unknown slip rates $\mathbf{x}_{B1}$ and $\mathbf{x}_{C1}$ will vanish. The vector of seismograms $\mathbf{b}$ simply consists of the seismograms at the stations, placed one after another, *but having the appropriate sample length* consistent with the l.h.s. of the equation.

(1983) used the ℓ_2 norm to solve the optimization problem with the positivity constraint, employing computer programs in Lawson and Hanson (1974). Das and Kostrov (1990, 1994) have used the linear programming method (Press et al., 1986) to solve the system (4) and minimize the ℓ_1 norm subject to the condition (5*a*). The ℓ_1 norm is considered more robust (Tarantola, 1987), and Hartzell et al. (1991) have investigated the effect of minimizing different norms on the solution, and shown that the most robust features are properly obtained in the solutions, whichever norm is used. Das and Kostrov (1990, 1994) have checked that when the ℓ_1 norm is minimized, the ℓ_2 and the ℓ_∞ norms for the solution are also small.

In reality, the actual scale at which the rupture propagation takes place in the Earth is microscopic, whereas the inverse problem must be solved using finite grids. Therefore, it is important to consider how well the inverse solution obtained gives a picture of the actual solution. To do this, it is necessary to decide how large the cells in the inversion should be. Clearly, the smaller the cells, the better the approximation to the integral equation being solved (Equation 1), but the larger the number of unknowns. On the other hand, though the approximation to the integral equation improves by going to smaller and smaller cells, the condition number of the matrix increases (due to columns becoming very similar) making the problem more and more unstable. As pointed out by Backus and Gilbert (1967), since the amount of data is finite, the problem of finding a continuous function from it is indeterminate. In other words, the stability of the system of equations



Earthquake Rupture: Inverse Problem, Figure 2 Tectonic setting of the June 23, 2001 great Peru earthquake (M_w8.4), together with bathymetry constructed from a GEBCO (2003) 1′ × 1′ grid. The rupture zone of the earthquake is shown as a white rectangle and the epicenter by a star. The black and gray lines show the rupture process, the numbers indicating the seconds after rupture initiation. The gray ellipse shows the region where large slip was induced by delayed rupture of the trapezoid-shaped barrier, shown by dashed lines. A second rectangular barrier is also seen. Figure based on Robinson et al. (2006a).



Earthquake Rupture: Inverse Problem, Figure 3 The rupture process of the M_w 7.8 Kunlun, Tibet earthquake of 2001. Relocated aftershocks for the 6-month period following the earthquake are shown by dots, together with their 90% confidence error ellipses. The two faults on which rupture occurred are marked as MKF (Main Kunlun Fault) and SF (Secondary Fault), the star showing the rupture initiation region. Schematic graphs showing the final slip on the two faults are shown, with the rupture speeds in the three phases of rupture indicated at the top. The central portion is where rupture reached the compressional wave speed. Figure based on Robinson et al. (2006b).

decreases (that is, the condition number of the matrix A increases) as we use finer and finer discretization of the fault for the inversion. Das and Suhadolc (1996) and Das et al. (1996) have suggested that synthetic tests using artificially created data should be used to best estimate the spatial and temporal grid sizes. It is important to keep in mind that the spatial and temporal grid sizes should be consistent. Henry et al. (2000) have also compared the Green functions obtained using various grid sizes to aid in the grid size selection. Sarao et al. (1998) have studied the effect of nonuniform seismic station distribution around the earthquake epicenter.

Finally, we discuss some examples of what we have learned regarding the mechanics of the earthquake source from the solution of such inverse problems. The first great earthquake for which the slip history and distribution was obtained was the great M_w 8.0 Michoacan, Mexico earthquake in 1985 (Mendoza and Hartzell, 1988). It was found that the main slip took place in two patches on the fault, and that aftershocks occurred in the regions of low fault slip or regions of transition from high to low slip, that is, where stresses were increased due to the earthquake. Many studies since then are summarized by Das and Henry (2003), and from them we have learned important features of earthquake mechanics. For example, the M_w 8.1 Antarctic plate earthquake in 1998 showed that ruptures can jump over barriers as large as 70–100 km and then continue propagating significant distances. The M_w 7.8 Wharton Basin earthquake in 2000 in the Indian Ocean showed that rupture could occur simultaneously on both nodal planes.

Some very recent examples include the great M_w 8.4 Peru earthquake in 2001 (Figure 2), which showed how a barrier on the fault could stall the rupture process (Robinson et al., 2006a). Based on marine geophysical data from the portion of the Nazca plate that was subducting in this region, this barrier was identified as being due to bathymetry (such as seamounts located on the inner corner of a fracture zone) related to a subducting fracture zone. Another important example was the large M_w 7.8 Kunlun, Tibet, earthquake in 2001 (Figure 3), where it was seen that the rupture speed during this strike-slip not only exceeded the local shear wave speed but actually reached the compressional wave speed of nearly 6 km/s, and propagated for nearly 100 km at this speed. The fault geometry was shown to be a controlling factor for the changes in rupture speed along the nearly 400 km long fault (Robinson et al., 2006b). This has important implications for earthquake hazard mitigation (Das, 2007).

Summary

In the last 2 decades, seismologists have solved the "inverse problem" of using broadband digitally recorded seismograms to infer the details of the earthquake rupturing process. The theory and some examples of particular earthquakes studied are given.

EARTHQUAKE SOUNDS

Andrew J. Michael
U.S. Geological Survey, Menlo Park, CA, USA

Definition

Earthquake sounds. Atmospheric pressure waves associated with earthquakes, especially those audible to humans.

Introduction

". . . previous to an earthquake, a roaring is usually heard," wrote Lucius Annaeus Seneca, circa 65 CE, in the sixth volume of "Naturales Quaestiones" (translation by Clarke and Geike, 1910). While Seneca's explanations for earthquakes now seem fanciful, this statement remains accurate and historical records of earthquake sounds have been joined over the last few decades by instrumental studies of this phenomenon.

A particularly interesting case of earthquake sounds concerns the long reported noises near Moodus, Connecticut, whose town name is derived from a Wangunk word meaning "where noises come from the ground." Reports of these noises predate the arrival of European settlers who described them as accompanying shaking "as though in an earthquake" (Davis, 1897). Seismographic studies of the earthquakes that accompany the Moodus Noises demonstrate that these sounds are caused by swarms of magnitude −2 to 2.1 events with shallow (less than 2.4 km) hypocenters (Ebel, 1982). Similarly, explosive sounds similar to cannon fire have been documented during earthquake swarms in the lower Rhone Valley of France since 1772 and have now been explained by events with ultrashallow focal depths of only 200 m. With magnitudes as small as −0.7 many of these events are heard even if the shaking cannot be felt (Thouvenot et al., 2009).

Because human hearing is an effective spectral analyzer, the sonification of seismograms provides a useful educational tool. And because sound is commonly associated with earthquakes, audio can be an effective element of artistic works about earthquakes. This entry reviews the role of earthquake sounds in science, education, and art.

Records of sounds

People have reported hearing earthquakes for as long as we have earthquake reports. *The Earthquake Catalog of the British Association* (Mallet and Mallet, 1858) lists reports of earthquake sounds back to 122 BCE, although these are referenced to histories written by Julius Obsequens in the fourth century CE.

Catalogs of intensity data are good sources of reports on earthquake sounds. Davison (1938) explored a global set of catalogs, including the Mallet and Mallet catalog mentioned above, and the references in his paper provide a guide to these classic sources. Most of his data came from Britain and he classified about 20,000 descriptions into seven classifications that are largely consistent with low rumbling sounds but also include some descriptions of impulsive sounds, which are heard more often at short epicentral distances. A more recent intensity catalog with special emphasis on sounds was collected by Pierre Stahl in the French Pyrenees (Sylvander and Mogos, 2005), and the USGS "Did You Feel It?" catalog of Internet-collected intensity data includes information on sounds in its 1.25 million observations (Wald et al., 1999).

A problem with sounds described in intensity catalogs is that they depend on peoples' ability to describe an ephemeral experience in words. In the 1979 M4.0 earthquake near Bath, Maine, sounds were widely heard and mostly described as high frequency booms (Pulli et al., 1980). Many respondents described the sound in terms of the explosion of a heating system boiler. One exception was a resident who had actually heard a boiler explode and said the earthquake sounded nothing like that. Regardless of the words used to describe the sound, some residents who had previously lived in southern California explained that they were different than the longer-lasting, low frequency rumbles they remembered from earthquakes there. Those descriptions are consistent with Hill et al. (1976) who described earthquake sounds heard in southern California as "ranging from the rumble of distant thunder to the rushing of a wind." The high frequency content of the sounds in Maine could be due to high frequency ground motions created by a combination of shallow hypocenters, low crustal attenuation, and relatively high stress drops in that region (Pulli et al., 1980). The Moodus area shares similar characteristics and thus the shaking should also have substantial high frequency energy. However, many observers there described the noises in 1981 as "distant thunder" (Ebel, 1982). Thus, the subjective observations in intensity catalogs can make interpretation difficult.

The first known recording of earthquake sounds is from 1954 when a recording that was being made inside a two-story wood-frame dwelling in Eureka, California, accidently captured an M6.6 earthquake. It is likely that the recording, which was cut short by a power outage, largely captured sounds created by the building (Steinbrugge, 1974). The catalog of earthquake sound recordings compiled by Steinbrugge is available from the Seismological Society of America. All of these recordings mix together natural earthquake sounds with those produced by man-made structures and human reactions to the shaking. A notable entry in this catalog is a 5-min recording done by Robert Pate during the 1964 M9.2 Alaska earthquake, including his narration of several minutes of felt shaking.

The first purposeful recordings of earthquake sounds away from man-made structures were made in studies of the 1965–1967 Matsushiro swarm in Japan (Japan

Meteorological Agency, 1968) and the 1975 earthquake swarm near Brawley, California (Hill et al., 1976). Hill et al. recorded the audio on one stereo channel of an audio cassette tape and recorded both a time signal and the seismic sensor on the other channel by using FM multiplexing. Unfortunately, the seismograms recorded by this analog system were clipped and that made some of their analysis more uncertain. Sylvander et al. (2007) made digital audio and seismic recordings in the Pyrenees that stayed on scale.

How are sounds produced?

The existence of earthquake sounds is hardly surprising given that seismic waves from the solid earth will refract, albeit weakly, into the atmosphere. This was first demonstrated by Ewing, who considered the simple case of a P-wave in a body of water being transmitted into the atmosphere (Ewing, 1883).

As described by Seneca and in the observations cataloged by Mallet and Mallet (1858) and Davison (1938), earthquake sounds are often heard slightly before the shaking is felt. Because people often feel the stronger, but later arriving S-wave, this suggests that the sounds are produced by the P-wave. The instrumental studies referenced above used collocated seismometers and microphones to demonstrate that the sounds coincide with the arrival of the P-wave. The coincidence of the sounds with the arrival of the P-wave demonstrates that the onset of the sounds is generated by transmission of the seismic waves into the atmosphere very close to the listener. This is consistent with Davison's conclusion that the audible sound and the felt shaking travel at the same velocity. Hill et al. (1976) extended the simple analysis done by Ewing and explored the transmission of sound from a realistic shallow crustal structure to the atmosphere, the frequency content of the shaking from the seismic source, and the sensitivity of human hearing. That analysis showed that the higher frequencies of the seismic shaking (up to 50 Hz) overlap with the lower range of human hearing (over 20 Hz) and are transmitted into the atmosphere with sufficient amplitude to be heard.

Thus, what people hear is in the frequency range of 20–50 Hz. These low frequency sound waves have wavelengths much longer than the size of a human head and therefore people cannot localize the source of such sounds. The description of earthquake sounds as distant is based on association with other low frequency sounds that actually are distant, despite that the earthquake sounds are generated close to the listener. It is noteworthy that because earthquake sounds are at such low frequencies, humans are at least as sensitive to these sounds as many animals (Hill, 1976).

At Brawley, the later and stronger S-wave arrival was not associated with an audio signal while at Matsushiro and in the Pyrenees the S-wave was coincident with sound in some cases. The relative rarity of sound associated with the stronger S-wave shaking can be explained by the attenuation of higher seismic, and therefore audible, frequencies in the S-wave (Hill et al., 1976).

Applications of sounds

Mallet's classic study of the Great Neapolitan earthquake of 1857 includes many reports of people hearing the earthquake and he devotes Part III, Chapter VIII, titled "Of the Sounds that Attended the Shock," to discussing these observations and attempting to interpret them in terms of a finite source model by drawing an analogy to a long line of troops firing their rifles in succession (Mallet, 1862).

Davison's (1938) study of earthquake sounds attempted to relate his seven classifications to the maximum intensity on the Rossi–Forel scale, the distance from the event, and the region within which the event occurred. He found that earthquakes were heard over the entire felt area for small earthquakes but only half of the felt area for larger events and that at greater distances the sound was described as being smoother and more monotonous. The smoother and more monotonous sound with increasing distance is consistent with the attenuation of high frequency shaking at greater distances from the event. Due to this attenuation, low frequency motion from large earthquakes is felt at distances beyond the point where shaking in the higher frequency human hearing range is transmitted. Thus, for large earthquakes the area of felt shaking is larger than the area where the earthquake can be heard.

In a more recent study, Sylvander and Mogos (2005) developed relationships between the locations of sounds heard, earthquake magnitude, and epicentral distance and considered sound as a factor in human detection of small earthquakes. Souriau (2006) also explored relationships between heard sounds and shaking and points out that sound may be responsible for waking people and thus could contribute to intensity values at the low end of the scales. That builds on Hill et al.'s (1976) observation that the sound can be audible even when the P-wave is not felt. Tosi et al. (2000) examined whether records of sounds could be used to infer focal mechanisms. Partially because the sound observations do not include polarity information, they concluded that the uncertainties were too large to use such data to infer unknown focal mechanisms.

Despite these efforts, it is not clear that earthquake sounds make a significant contribution to the analysis of pre-instrumental earthquakes beyond helping us understand how such sounds contribute to observations of lower intensities. As noted above, there are problems with interpreting subjective reports of sounds that mix together both the natural transmission of shaking into the atmosphere and the shaking of man-made objects. These objections could be removed for future earthquakes by making audio recordings, which could easily be integrated into existing digital seismic acquisition systems (Sylvander et al., 2007). Unfortunately, audio recordings may not be a very useful addition to the collocated seismograms because little of the seismic energy is transmitted into

the atmosphere and because audio captures only a scalar recording of the 3-component ground motion.

While microphones may not be an effective way to record seismic data, seismometers can produce useful records of acoustic waves in the atmosphere that are strong enough to shake the ground. For instance, seismic records of acoustic waves have contributed to forensic seismology investigations into the 1995 Oklahoma City bombing (Holzer et al., 1996), the 1998 truck bombing of the American embassy in Nairobi (Koper et al., 1999), a chemical plant explosion in Nevada (Ichinose et al., 1999), and a pipeline explosion in New Mexico (Koper et al., 2003).

Infrasound

Very low frequency acoustic waves known as infrasound can travel great distances through the atmosphere, although with frequencies below 20 Hz these waves are not audible to humans. Bolt (1964) demonstrated that micropressure recordings after the 1964 Mw 9.2 Alaska earthquake included acoustic waves with periods of 20–40 s (frequencies of 0.025–0.050 Hz) generated near the earthquake and recorded 3,100 km away at Berkeley, California. Donn and Posmentier (1964) further explored these recordings and showed that earlier infrasound arrivals were generated near the recording station by the passing Rayleigh waves. Away from the earthquake, infrasound can also be generated when surface waves travel through mountainous regions. A good review of these mechanisms is Mutschlecner and Whitaker (2005) and the references therein. More recently Le Pichon et al. (2006) suggested that infrasound could be used to study the amplification of ground displacement by topography, especially in regions with inadequate seismic networks. And Green et al. (2009) demonstrated that coastal cliffs could also be a source of infrasound. While infrasound arrays have recorded many earthquakes, their primary applications continue to be the study of atmospheric phenomena such as meteorites and the study of explosions whether chemical or nuclear tests.

Sonification, education, and art

Sonification is the process of producing sound from nonauditory data. Most seismic data contains frequencies below human hearing and the simplest way to sonify seismograms is to speed them up, which increases the frequency content, and play them back through an audio system. Steinbrugge (1974) mentions that, in 1952 or 1953, Hugo Benioff and Cook Laboratories (Stamford, Conneticut) used this method to produce an LP record with one side called "Earthquakes of this World." Many seismologists have followed in Benioff's footsteps and this has become particularly easy now that digital seismograms can be converted to audio files using common software such as MatLab.

The human ear is an excellent spectral analyzer and most people are more used to listening to music than looking at seismograms. Therefore, sonification of seismograms can be an effective educational tool. Michael (1997) (http://earthquake.usgs.gov/learn/listen/index.php) developed a set of audio playbacks of seismograms that explores how the frequency of shaking varies with source dimension, epicentral distance, and site geology. This Web site includes a recording of the 1992 M7.3 Landers earthquake recorded at Mammoth Lakes where local earthquakes were triggered by the passing seismic waves. The local earthquakes are easily heard in the raw sonified seismogram but required filtering to be detected visually in the plotted seismograms (Hill et al., 1993). This demonstrates that audio can be a powerful educational tool.

Sound is a common part of experiencing earthquakes and so naturally it is part of artistic explorations of seismic events. The seismograms from the above site were used as the basis for my Earthquake Quartet #1 for Trombone, Cello, Voice, and Seismograms (Michael, 2000) which is available online at http://earthquake.usgs.gov/learn/music/. Earthquake Quartet #1 starts by describing the earthquake cycle and then explores the idea that society and culture, including music, take place with the earthquakes as an often-ignored backdrop. The earthquakes play the role of percussion because they have abrupt beginnings and broad, nonharmonic, spectra.

Another musical approach was taken by Loos and Scherbaum (1999) in a CD titled "Inner Earth, a seismosonic symphony" which used many different methods of shifting, converting, and transposing seismograms to make them audible. They produced music with harmonic properties that is purely based on seismograms but sounds nothing like the ones that have simply been sped up.

Overlaying a seismogram on a musical staff provides a form of graphical musical notation that can then be played back using synthesized instruments. Some seismograms from the Mt. Etna volcano can be heard as piano music at http://grid.ct.infn.it/etnasound/page4/page8/page8.html. The goal of that project was to provide a way to detect changes in the behavior of the volcano by hearing changes in the sonified seismograms (http://grid.ct.infn.it/etnasound/) and it also extended into the arts.

The "Great California ShakeOut" earthquake preparedness drills (Jones et al., 2008) use audio combining synthesized earthquake sounds with sounds of damage occurring and sirens to simulate an earthquake experience at the start of the drills. These files can be downloaded from http://www.shakeout.org/drill/broadcast/index.html.

"Memento Mori: an internet based earthwork" by Goldberg et al. (1999) used live seismic data to trigger nonseismic audio in a dark installation that also included a visual display of the seismic particle motion. This approach was later used for "Ballet Mori: a ballet conducted by the earth" performed by Muriel Maffre at the San Francisco Ballet to commemorate the centennial of the 1906 earthquake (Goldberg et al., 2006). Video of the dance can be seen at http://goldberg.berkeley.edu/art/Ballet-Mori/.

In 2009, the Parkfield Interventional Earthquake Fieldwork (PIEQF) (Rogers, 2010), and online at http://pieqf.allshookup.org/, consisted of a large shake table whose motion was triggered by earthquakes throughout the state of California. Both the table itself and a set of rods mounted on the table created noise when an earthquake occurred. This mechanical amplification of the shaking replaced the natural "roaring" discussed by Seneca with a clatter that allowed the viewers to hear distant seismic activity in a way that is not possible through natural shaking and sounds.

Summary

Earthquake sounds form an important part of the earthquake experience, and thus are a large part of artistic explorations of these events, but their study forms a small niche within seismology. The last few decades have produced the data necessary to finally understand this phenomenon along with its role in the study of earthquakes and explosions.

Definition

Aftershocks. Smaller earthquakes following a large earthquake (the mainshock) in the same ruptured area.

Introduction

Earthquakes typically occur in sequences that may include foreshocks, the mainshock (the largest event or events), and aftershocks. Earthquake sequences without a clear mainshock are called swarms.

Aftershocks generally refer to the smaller earthquakes that follow a mainshock within certain spatial and temporal windows. However, the criteria for choosing these windows are somewhat arbitrary. Typically, aftershocks are defined within an area around the mainshock's source region (i.e., the ruptured fault segment, which is about 100 km long for a magnitude 7.0 earthquake). Most aftershocks occur on the main rupture surface; hence, they are often used to define the complex geometry of the rupture plane. However, in many cases, especially for earthquakes in subduction zones, the aftershock area increases significantly following the mainshock (Tajima and Kanamori, 1985). Some aftershocks also occur off the main rupture surface. Distant earthquakes triggered by the mainshock's seismic waves (see *Artificial Water Reservoir Triggered Earthquakes*) may also be regarded as aftershocks (Gomberg and Johnson, 2005). Temporally, aftershocks are defined as seismicity above the background activity following a main shock. This definition also leaves room for ambiguity, as the background seismic activity can be difficult to define in some places.

Aftershocks usually count for less than 5% of the total seismic energy release of the entire seismic sequence, so they are secondary products (Scholz, 2002). However, besides their spatial and temporal relations to the mainshock, aftershocks are fundamentally no different from other earthquakes and are recognized as aftershocks only retrospectively (Helmstetter et al., 2003; Utsu, 2002).

Scaling laws for aftershocks

A large earthquake is usually followed by many smaller events (aftershocks); their occurrence rate decreases with time, typically following a pattern known as the Omori's law, named for Fusakichi Omori's observation of the 1891 Nobi earthquake in Japan (Omori, 1894) and later modified by Utsu (1961):

$$n(t) = \frac{K}{(c+t)^p}$$

where $n(t)$ is the number of aftershocks by time t after the mainshock; K, p, and c are constants. The value of c is typically positive close to zero, and p close to 1. Hence, the number of aftershocks drops nearly hyperbolically with time (Figure 1). The values of these constants are obtained by fitting to the data for each aftershock sequence.

It has been observed that the largest aftershock is usually about 1 magnitude unit smaller than the mainshock, independent of the mainshock magnitude. This is known as Båth's law (Bath, 1965; Richter, 1958). However, because the data selection is retrospective and subjective, the size of aftershocks can vary substantially for different earthquake sequences.

Like all earthquakes, the size distribution of aftershocks follow the Gutenberg–Richter law (Gutenberg and Richter, 1954):

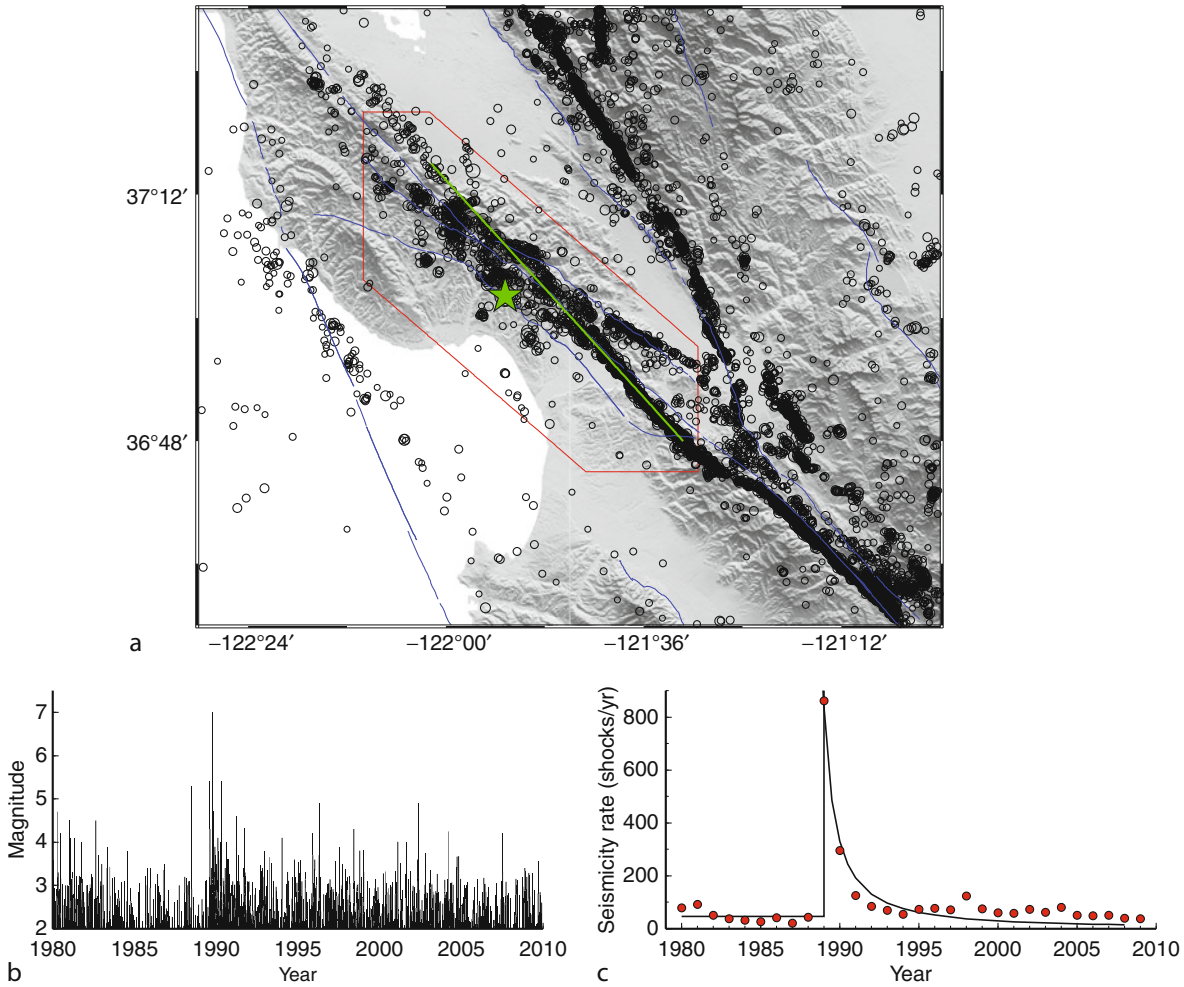
$$\log_{10} N(M) = a - bM$$

where $N(M)$ is the number of earthquakes of magnitude $\geq M$, a and b are constants. This relationship plots as a straight line with slope b, whose value, often referred to as the b-value, is typically in the range of 0.8–1.2. For $b = 1$, the number of earthquakes increases by a factor of 10 for every unit drop. The b-value varies in time and space even for the same fault. Some studies have suggested that the b-value can be used as a stress indicator, with lower b-values often associated with higher stresses (Schorlemmer et al., 2005).

Causes of aftershocks

Because most aftershocks occur on or near the rupture surface, they are thought to result from incomplete rupture and heterogeneous slip (e.g., Bullen and Bolt, 1947). This notion is consistent with some case studies that found aftershocks concentrated around the perimeter of the rupture zone or around asperities within the rupture zone where most of the coseismic slip occurred (Beroza, 1991; Scholz, 2002).

The main causes of aftershocks are thought to include mainshock-induced changes of frictional properties of the fault zone and stress perturbations. Laboratory experiments indicate that frictional properties change with the duration of stationary contact and the instantaneous sliding velocity (Scholz, 2002). A constitutive relationship based on such results, known as the rate-and-state law (Dieterich, 1979; Ruina, 1983), can explain the time-dependent changes of seismic rates that are consistent with the Omori's law (Dieterich, 1994). Stress perturbations may arise from creep recovery of rocks in the immediate areas of the fault (Benioff, 1951), viscous relaxation from the lower crustal and upper mantle (Lieber and Braslau,



Earthquake, Aftershocks, Figure 1 (**a**) Topography and seismicity (*circles*, size proportional to magnitude) around the epicenter (*star*) of the 1989 Loma Prieta earthquake (Mw 6.9) on the San Andreas Fault. *Green* line marks the fault rupture; *red* lines enclose the spatial window for the aftershocks. (**b**) Earthquake occurrence between 1980 and 2010 within the spatial window. (**c**) Plot of seismicity showing the t^{-1} decay of aftershocks.

1965; Stein and Liu, 2009), and pore-elastic effects (Scholz, 2002). In particular, the changes of the Coulomb static stress resulted from the mainshock have been shown to cause spatial migration of seismicity and trigger earthquakes (Parsons, 2002; Stein, 1999). Other causes may include dynamic triggering (Gomberg and Johnson, 2005) and pore fluid flow (Miller et al., 2004; Nur and Booker, 1972).

Aftershocks and earthquake hazard

Aftershocks can be large and damaging (e.g., Wiemer et al., 2002). The durations of aftershock sequences for plate-boundary earthquakes are typically around 10 years (Parsons, 2002) (Figure 1). However, aftershock sequences away from plate-boundary faults tend to last longer. In the broadly deforming western United States, for example, aftershocks are found to last 50–100 years. Within the stable continental interior, aftershock sequences may last hundreds of years or even longer (Stein and Liu, 2009). Such long aftershock sequences in continental interiors, where large earthquakes are infrequent and historic records are often incomplete, could bias hazard assessment.

Further complication may arise from the fact that earthquakes tend to cluster in time and space, which is best shown in aftershock sequences. Studies of large shallow earthquakes in the world show that these large events often occur in pairs or groups (called doublets or multiplets); the later events, which could be regarded as aftershocks, can be bigger than the triggering event (the mainshock) (Kagan and Jackson, 1999). Such clustering patterns are consistent with the emerging view that all earthquakes can trigger their own earthquakes that in turn trigger more quakes, and the triggered events may be bigger than the

triggering event (Helmstetter et al., 2003; Ogata, 1998). Because the triggered events (the aftershocks) statistically follow the Omori's law, statistical models can be developed to assess time-dependent probability of future damaging earthquakes after each event (Gerstenberger et al., 2005; Jones, 1985; Reasenberg and Jones, 1989).

Summary

Aftershocks are smaller earthquakes following the mainshock. They typically occur on or near the rupture plane of the mainshock, resulting from changes of stress and frictional properties of the fault zone caused by the mainshock. The duration of aftershock sequences is typically a few years for earthquakes at plate boundaries, but can last much longer within stable continental interiors.

EARTHQUAKE, FOCAL MECHANISM

Emile A. Okal
Department of Earth & Planetary Sciences, Northwestern University, Evanston, IL, USA

Definition

Focal mechanisms are geometrical or mathematical representations of the faulting during an earthquake. In very simple terms, the latter consists of the relative motions of two blocks of Earth called *walls* along a planar surface called *fault*. Figure 1 shows that the description of an earthquake rupture needs three angles. The *strike* angle ϕ is the azimuth (with respect to North) of the trace of the fault on a horizontal plane such as the Earth's surface; the *dip* angle δ characterizes the steepness of the fault, and the *rake* or *slip* angle λ, the direction of motion, within the fault plane and relative to the horizontal, of the hanging wall relative to the foot wall. A full description of the earthquake rupture requires an additional scalar, related

(**c**: After Stein and Wysession, 2003.)

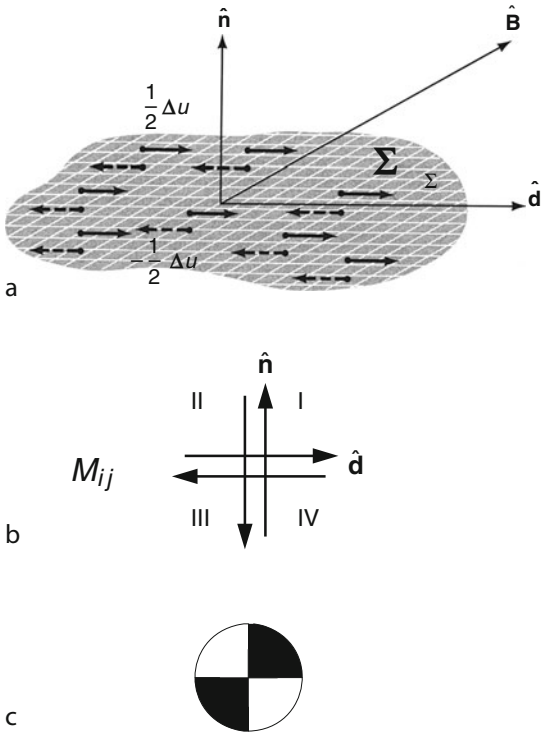
to the length of slip of the fault walls, and thus to the size or *magnitude* of the event.

Representation by a double-couple

As such, an earthquake source, described by three angles and a scalar, is a more complex mathematical entity than a simple vector (described by two angles and a scalar), and in particular cannot be represented physically by a single force. Vvedenskaya (1956), followed in the West by Knopoff and Gilbert (1959), introduced the concept of the double-couple, a system of forces shown on Figure 2 and consisting of two opposing torques of equal moment M_0; this system has no dynamic effect (translation or rotation) on a rigid body, but results in deformation of a medium of finite rigidity.

The representation theorem (e.g., Aki and Richards, 1980, pp. 38–41) considers an elastic medium of rigidity μ and states that a dislocation with slip Δu (in the direction $\hat{\mathbf{d}}$) along a fault of surface Σ cut into the medium (Figure 2a) will generate the same field of dynamic deformation (expressed as seismic waves) as a double-couple of moment $M_0 = \mu\Sigma\,\Delta u$, embedded in the medium in the absence of the cut, with the direction of forces and levers in Figure 2b along those of the slip, $\hat{\mathbf{d}}$, and of the normal to the fault plane, $\hat{\mathbf{n}}$.

The double-couple shown in Figure 2b separates the space around it into four quadrants containing respectively the heads and tails of the arrows. They are delineated by the fault plane and the plane normal to the slip $\hat{\mathbf{d}}$. In quadrants I and III, the seismic motion will be "*anaseismic*," or away from the source, while in II and IV, it will be "*kataseismic*" or toward the source. The quadrants are accordingly shaded black and white in Figure 2c. Note that in Figure 2b and c, the source is



Earthquake, Focal Mechanism, Figure 2 (**a**) Seismic slip along a fault (represented as the hatched area of surface $\boldsymbol{\Sigma}$). The total slip $\boldsymbol{\Delta u}$ is the difference between the displacements of the top wall (shown as *solid arrows*) and of the bottom wall (*dashed arrows*). (**b**) "Double-couple" system of forces, equivalent, in the unruptured medium, to the dislocation shown in (**a**). (**c**) "Beachball" representation of the quadrants defined by the orientation of the double-couple. (**a**: After Aki and Richards, 1980.)

approximated as a *point* in space, hence the concept of a "point-source double-couple."

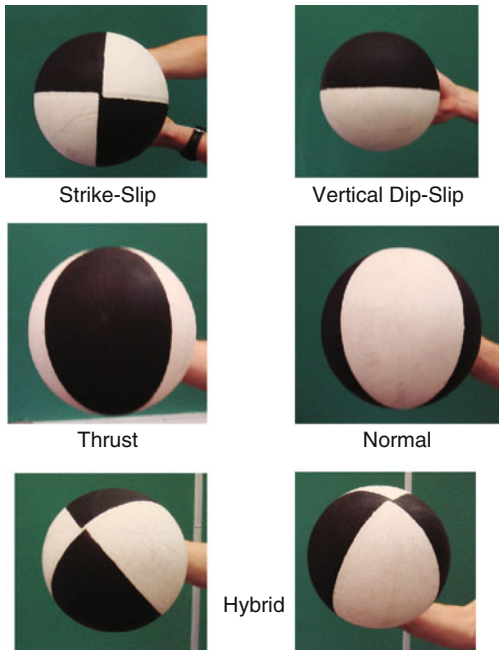
Focal mechanisms from P-wave first motions

Under the high-frequency approximation of geometrical optics, a most remarkable property of *P* waves is the conservation of the ana- or kataseismic character along the entire seismic ray, all the way to a receiving seismic station at the Earth's surface, where an anaseismic wave results in an initial *upward* motion of the ground, while a kataseismic one gives a *downward* first motion.

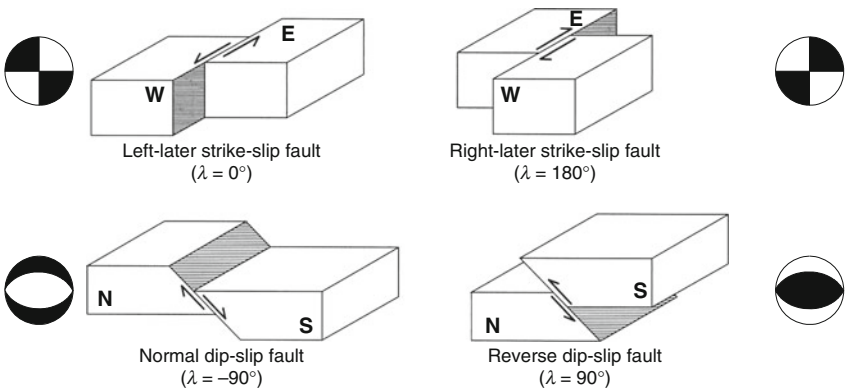
This property has been used extensively to obtain earthquake focal mechanisms by gathering first-motion *P*-wave data at large datasets of local and distant stations and backtracking this information along the relevant rays into a mapping of the focal sphere at the source. This amounts to resolving the orientation in space of the diagram on Figure 2c, known traditionally as a "beachball." Because of the difficulty of representing a full sphere on a planar figure (long known to world cartographers), and thanks to the symmetry of the beachball, it is convenient and sufficient to represent only a stereographic projection of the *lower focal hemisphere* separated at the horizontal plane and involving rays leaving down into the deep Earth, and eventually emerging at large distances. This constitutes the standard representation of earthquake focal mechanisms. Figure 3 illustrates examples of the most common types of mechanisms.

Note that a change of focal mechanism results in a mere *solid rotation* in space of the beachball pattern, but does not change its nature (Figure 4).

A common feature of the double-couple concept and of its beachball representation is their high level of symmetry. The two planes defining the quadrants on Figure 2b are conceptually interchangeable and as a result, there exists an inherent indeterminacy between two possible physical solutions obtained from any field of seismic data generated by a point source double-couple. For example, a left-lateral strike-slip earthquake on a vertical fault striking North–South is seismically indistinguishable from a right-lateral one on a fault striking East–West. This property, rooted in the symmetry of the double-couple, applies to all seismic waves, including *P* and *S* waves, surface waves, and the free oscillations of the Earth. The indeterminacy can be lifted only by considering a source extended in space, as opposed to a point source. In practice, this is done either by using field methods to recognize the orientation of the fault through its expression on the



Earthquake, Focal Mechanism, Figure 4 A basketball has been divided into four quadrants alternately painted black and white. By rotating the basketball in space, one can obtain a representation of all possible focal orientations of the double-couple shown in Figure 2b.This experiment demonstrates that earthquake focal geometries differ only by a solid rotation in space.



Earthquake, Focal Mechanism, Figure 3 Examples of focal geometries with corresponding beachball patterns. (Adapted from Stein and Wysession, 2003.)

ground, or by mapping the aftershocks of the event which are expected to occur along the direction of faulting, or by considering the so-called source-finiteness effects in the seismograms, which result from the interference of the elementary sources, distributed both in time and space, as the rupture propagates over the faulting area. In all cases, note again that the fault can no longer be represented as a point source.

Stress release

In another interpretation of focal mechanisms, one can expand the double-couple as a two-dimensional deviatoric and symmetric tensor

$$M_{ij} = M_0\left(\hat{d}_i\hat{n}_j + \hat{n}_i\hat{d}_j\right) \quad (1)$$

where $\hat{\mathbf{d}}$ and $\hat{\mathbf{n}}$ are the unit vectors along the direction of slip, and perpendicular to the fault, respectively. These components and the principal directions of the moment tensor are directly related to those of the stresses released during the earthquake.

In particular, the bisector $\mathbf{T} = \frac{1}{\sqrt{2}}\left(\hat{\mathbf{d}} + \hat{\mathbf{n}}\right)$ represents the axis of maximum tension and the direction of maximum positive amplitude of *P* waves; it plots at the center of the shaded quadrants on the beachball. The direction $\mathbf{P} = \frac{1}{\sqrt{2}}\left(\hat{\mathbf{d}} - \hat{\mathbf{n}}\right)$ is the axis of maximum compression (often and improperly called "pressure axis") and that of maximum negative amplitude of *P* waves; it plots at the center of the open quadrants. The direction $\mathbf{B} = \hat{\mathbf{d}} \times \hat{\mathbf{n}} = \mathbf{T} \times \mathbf{P}$ is the hinge of the fault planes; it is a direction where both *P* and *S* amplitudes vanish. For a given beachball, the **T, P, B** axes are independent of the choice between the two possible fault planes.

The interpretation of focal mechanisms in terms of stress release is particularly suited to the study of intraplate earthquakes, which express the release of stresses accumulated inside the plates by tectonic forces, while interplate events, which are controlled by the relative displacements of two of the Earth's plates at a common boundary, are more readily interpreted in terms of a slip vector on a fault plane.

Fundamental results

The most important application of focal mechanisms was the verification of the fundamental concepts of continental drift, seafloor spreading, and plate tectonics, in the mid-1960s. These ideas were derived using the spatial distribution of earthquake epicenters, but without the knowledge of the geometries of their ruptures. The latter could then be used as an independent verification of the concepts, following the development of the beachball model, and the deployment of the World-Wide Standardized Seismograph Network in the early 1960s. Sykes (1967) and Isacks et al. (1968) achieved a remarkable endorsement of the mechanisms predicted by plate motions (normal faulting expressing extension at the mid-oceanic ridges, underthrusting expressing convergence at the subduction zones), and most spectacularly, verified the polarity of strike-slip faulting at the oceanic transform faults, thus upholding the concept proposed by Wilson (1965).

Focal mechanisms inside subducting slabs were compiled by Isacks and Molnar (1971), who documented a universal mechanism of down-dip compression for events deeper than 450 km, expressing the difficulty of penetration by the slab of the lower mantle at the bottom of the transition zone. By contrast, a wide diversity of mechanisms is found in the upper parts of the slabs, where local parameters such as rate and steepness of subduction, as well as possible bending stresses, control the stress field accumulated inside the slab during the subduction process.

A most remarkable aspect of the focal mechanisms of deep earthquakes is the fact that, without exception, they can be modeled by a double-couple (e.g., using its beachball representation), even though the concept of brittle rupture should not apply at the relevant pressure and temperature conditions inside the slabs. In particular, modern analysis of major deep earthquakes (Kawakatsu, 1991; Okal, 1996) has ruled out the possibility of an isotropic (implosive) source even as a mere component of their mechanism, as initially envisioned by Bridgman (1945) and proposed by Gilbert and Dziewonski (1975). Deep events represent faulting on a planar dislocation in the framework of Figure 1, and differ from their shallow counterparts only in their usually higher level of stress drop (Antolik et al., 1999), but not in the geometrical or mechanical nature of their process. This observation supports the hypothesis that deep earthquakes may be induced by transformational faulting in volumes of metastable olivine persisting inside the slabs at greater depths than predicted by equilibrium thermodynamics (Kirby et al., 1996).

Modern focal solutions: inversion of the moment tensor

The double-couple used to represent a seismic source can be used, through its components given by Equation 1, as a forcing term in the wave equations expressing the fundamental law of dynamics (a variation of "$\mathbf{F} = m\,\mathbf{a}$"), to compute simulations of the Earth's response in space and time to the seismic disturbance. These are known as *synthetic seismograms*.

Conversely, and since the 1970s, inversion techniques have been used to derive the individual components of earthquake moment tensors directly from the waveforms of their recorded seismograms. Essentially, a best-fitting algorithm is used to express a large dataset of observed seismograms as a linear combination of synthetic seismograms computed for each individual component of the moment tensor. In addition, and for sufficiently large datasets, the inversion can resolve the best location in space of the source, and its result is known as a "centroid moment tensor" or CMT. These techniques, which can be applied on body waves, surface waves or

normal modes, as well as on regional phases in the near field, can be carried out automatically on digital data, and eliminate the occasional difficulty of picking a first motion polarity under noisy or emergent conditions. They have replaced the compilation of *P*-wave first motions as the primary source of earthquake focal mechanisms.

In particular, the Global CMT (*ex*–Harvard CMT) project, described initially by Dziewonski et al. (1981), has now inverted more than 30,000 earthquake sources since 1976, through a uniform, comprehensive procedure, into a catalog that has become the backbone of most modern seismotectonic studies.

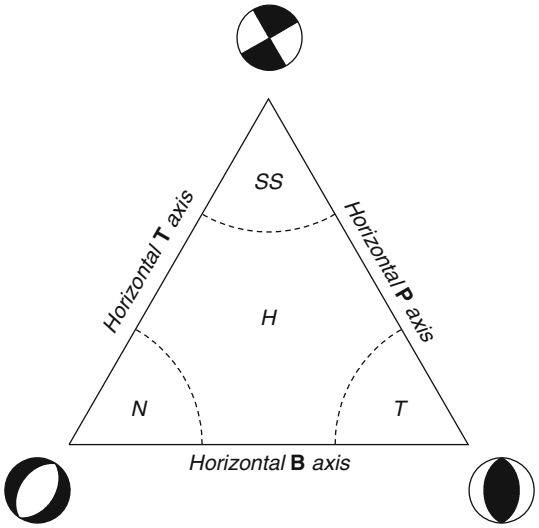
Evaluation tools for double-couple solutions

Because of the relative complexity of the double-couple source that cannot be represented by a vector, a number of applications have been developed to illustrate their properties in a user-friendly representation. Among them, Frohlich and Apperson (1992) have proposed to plot focal mechanisms in a ternary diagram whose apices are the "*pure*" mechanisms corresponding to vertical stress axes (**B**, strike-slip; **T**, thrust; or **P**, normal); using barycentric coordinates within the triangle, the position of the mechanism indicates at a glance the nature of faulting (Figure 5). Note that it remains independent of the azimuth ϕ of the fault strike.

In order to help compare different earthquakes, Kagan (1991) has offered an algorithm to quantify the proximity of two focal solutions given by their angles $(\phi_1, \delta_1, \lambda_1)$ and $(\phi_2, \delta_2, \lambda_2)$. It computes the angle ω of the minimum solid rotation bringing one of the beachballs onto the other. Because of their symmetry, the maximum value of ω is 120°.

Non-double-couple solutions

The double-couple is a four-dimensional mathematical entity which constitutes a subset (featuring a zero-eigenvalue) but not a sub-vector space, of the five-dimensional vector space of deviatoric (i.e., zero-trace), symmetric second-order tensors. Consequently, linear inversions are carried out in the full five-dimensional space. The quality of fit of the inverted solution to a double-couple is assessed through a so-called Compensated Linear Vector Dipole (CLVD) parameter ε, expressing the ratio of the intermediate eigenvalue of the moment tensor to its largest one (in absolute value). In principle, ε could range from -0.5 to 0.5, and should be zero for a perfect double-couple. The average value of $|\varepsilon|$ for the whole CMT catalog is 0.12, which constitutes a good verification of the concept of the double-couple, especially since it falls to 0.08 for earthquakes with moments $M_0 \geq 10^{26}$ dyn cm. Occasionally, larger values of $|\varepsilon|$ (which can reach 0.4) indicate a deviation from the model of a double-couple, which may result from a number of scenarios. For example, earthquakes with complex ruptures consisting of multiple events with differing geometries will feature an overall deviatoric moment tensor, which however cannot be described in terms of a lone double-couple. A recent example is the Samoa event of 29 September 2009 ($M_0 \approx 1.8 \times 10^{28}$ dyn cm; $\varepsilon = 0.37$), which was modeled as a main outer rise normal faulting event triggering a smaller underthrusting shock on the nearby interplate contact (Li et al., 2009).



Earthquake, Focal Mechanism, Figure 5 Ternary representation of focal mechanisms (Frohlich and Apperson, 1992). This approach uses barycentric coordinates with respect to end members with one vertical principal axis. Mechanisms close to apices are either predominantly strike-slip (*SS*), thrust (*T*) or normal (*N*). Hybrid mechanisms (*H*) plot in the center of the diagram. By contrast, the sides of the diagram represent geometries with one horizontal axis. This representation is useful when studying trends among large families of mechanisms, such as intraplate earthquakes, irrespective of their particular strike angles.

Other examples of non-double-couple solutions would include dyke injections during volcanic events (e.g., Tori-Shima Volcano, 13 June 1984; $\varepsilon = 0.33$; Kanamori et al., 1993), rupture on non-planar faults, again in a volcanic environment (Ekström, 1994), and certain cryoseismic events believed to involve calving at the front of glaciers (e.g., 15 August 2008, $\varepsilon = 0.33$; Nettles and Ekström, 2009).

Conclusion

Focal mechanisms provide a mathematical or illustrative representation of the geometry of the rupture process during an earthquake. Their compilation forms the basis of our interpretation of earthquakes in the framework of global tectonics.

Definition

Foreshocks. Smaller earthquakes preceding a large earthquake (the mainshock) in the same ruptured area.

Introduction

Earthquakes typically occur in sequences that may include foreshocks, the mainshock (the largest event or events), and *Earthquake, Aftershocks*. Earthquake sequences without a clear mainshock are called swarms.

Foreshocks are the most obvious premonitory phenomenon of earthquakes. They are thought to indicate earthquake nucleation and hence may have the potential for short-term earthquake prediction (Scholz, 2002). However, proof of the physical link between foreshores and earthquake nucleation is inconclusive, and earthquake prediction using foreshocks has not been reliable.

The problem begins with their recognition – foreshocks are earthquakes that are called foreshocks retrospectively, when a large event (the mainshock) followed. To be considered as foreshocks, these events need to occur within certain spatial and temporal windows, and these windows vary in different studies. Foreshocks are typically located within the mainshock's source area with a dimension roughly the length of the fault rupture, which is in the order of 100 km for a magnitude 7.0 earthquake. Temporally, most foreshocks occur a few days to hours before the mainshock (Jones and Molnar, 1979). In some cases, seismicity increases a few months or years before the mainshock. Some workers consider such increased seismicity foreshocks; others do not (Scholz, 2002). Depending on the choice of these spatial and temporal windows, a global survey shows that up to 70% of large earthquakes ($M \geq 7$) may be preceded by foreshocks (Jones and Molnar, 1979). While the percentage varies with different studies and in different regions, it is important to note that not all earthquakes are preceded by foreshocks.

Characteristics of foreshocks

Foreshocks, when they do occur, are typically few in comparison with aftershocks, sometimes consisting of only a few or a single event, hence are difficult for quantitative analysis. When considered collectively, they are shown to exhibit a temporal pattern similar to that of aftershocks (Jones and Molnar, 1979; Shaw, 1993). Most foreshocks occur within 10 days before the mainshock, and their numbers rapidly accelerate till the occurrence of the

mainshock. The collective time sequence of foreshocks seems to fit an inverse Omori's law:

$$n(t) = at^{-q}$$

where $n(t)$ is the number of foreshocks by time t before the origin of the mainshock, and a and q are constants, with q close to 1 (Kagan and Knopoff, 1978; Papazachos, 1975). Thus, the number of foreshocks tends to increase hyperbolically as the time approaches the origin of the mainshock. Some studies suggest that foreshocks may have lower b-values (see entry *Earthquake, Aftershocks*) relative to other earthquakes (Scholz, 2002).

It is not clear why some earthquakes have foreshocks while others do not. Studies of global and regional earthquake catalogs have found that neither the time sequences nor the largest magnitude of foreshocks correlate to the magnitude of the mainshock (Jones and Molnar, 1979), suggesting either the size of the mainshock is independent of the earthquake nucleation process, or foreshocks are not part of earthquake nucleation (Abercrombie and Mori, 1996). The incidence of foreshocks is found to decrease with increasing depth of the mainshock (Abercrombie and Mori, 1996). For earthquakes in California, more foreshocks are associated with strike-slip events than with thrust events (Abercrombie and Mori, 1996). This is opposite to the results from a study of global catalogs by Reasenberg (1999), who attribute the low rate of foreshocks for Californian thrust events to their relatively greater depths.

Causes of foreshocks

The causes of foreshocks remain uncertain. Some studies link foreshocks to earthquake nucleation (Scholz, 2002). Theoretically, fault ruptures only when slip has occurred over a fault patch of some critical radius. Ohnaka (1992) has proposed a theoretical model that attributes the generation of foreshock to failure of asperities loaded by accelerating premonitory creep. This model predicts numerous features found in foreshocks: their occurrence typically a few days before the mainshock, their accelerated rates as time approaches that of the mainshock, and their occurrence in the immediate vicinity of the hypocenter of the mainshock. However, not all foreshocks readily fit the nucleation model. Aside from the obvious problem that many earthquakes do not have foreshocks, the nucleation model has difficulties explaining foreshocks that occur away from the rupture plane or have significantly different focal mechanisms from that of the mainshock (Jones et al., 1982).

Others think that foreshocks are fundamentally the same as other earthquakes (Felzer et al., 2004; Helmstetter et al., 2003). In this view, foreshocks, the mainshock, and aftershocks are just different names for earthquakes within the same sequence of cascading ruptures triggered by a common mechanism.

Can foreshocks be used to predict earthquakes?

As the most obvious precursor of earthquakes, foreshocks are thought to be useful for short-term prediction of earthquakes, and successful predictions have been reported in numerous cases. The best example is perhaps the 1975 Haicheng earthquake (magnitude 7.3) in China, which was predicted largely based on foreshocks, more than 500 of which were recorded within 4 days before the mainshock (Jones et al., 1982). However, a recent investigation (Wang et al., 2006) has revealed that the role of foreshocks in this prediction was more psychological than scientific: the jolts and damages from increased seismicity in the preceding months stressed the minds of earthquake workers and the general public, and the intensified foreshocks in the last day before the mainshock prompted some local officials to order an evacuation. In other places where official orders were not issued, the increased seismicity caused many residents to evacuate voluntarily.

Aside from the problem that many earthquakes do not have foreshocks, short-term earthquake prediction using foreshocks is challenging in theory and in practice. For foreshocks to be a predictor, they must be an essential part of the physical process leading to the mainshock. Although this physical link between foreshocks and mainshock is suggested in the nucleation model, its validation in natural fault zones has not been conclusive. On the other hand, if foreshocks are fundamentally the same as other earthquakes (Felzer et al., 2004), then foreshocks cannot be predictors of mainshocks. In practice, we have yet to find any reliable ways to recognize foreshocks from background seismicity before the occurrence of the mainshock.

Nonetheless, there must be some symptoms associated with the stress buildup and physical property changes in and around the fault leading to a major rupture, and foreshocks are the most obvious symptoms known to us. Further studies of foreshocks will improve our understanding of the mechanics of earthquakes. A recent study of the foreshock sequences on East Pacific Rise transform faults (McGuire et al., 2005) suggests that foreshocks are linked to the mainshock through stress changes driven by aseismic slip transients or some fault preparation process, hence potentially can be useful for short-term earthquake prediction. On the other hand, by treating every earthquake as a potential foreshock that may be followed by a mainshock, statistical models based on the clustering properties of earthquake sequences can be developed to assess the real-time probability of damaging earthquakes, as has been done in California (Gerstenberger et al., 2005; Jones, 1985; Reasenberg and Jones, 1989).

Summary

Foreshocks are smaller earthquakes preceding a mainshock. They are thought to manifest the nucleation of the

mainshock, hence have the potential for short-term earthquake prediction. However, not all large earthquakes are preceded by foreshocks, and they are difficult to recognize from the background seismicity before the occurrence of the mainshock. Foreshocks may also be fundamentally the same as other earthquakes, if so they cannot be used as earthquake predictors.

Hypocenter determination

Definition

Earthquake location. Methods for determining the latitude, longitude, depth, and time of origin of a seismic event (earthquake, explosion, etc.) using the arrival times of seismic waves.

Introduction

Knowing the location of an earthquake (its latitude, longitude, depth, and origin time) is an essential starting point for the vast majority of quantitative seismological analyses. In the context of this article, earthquake location will be taken to mean determining the initiation point of fault rupture, that is, the hypocenter. After briefly tracing some of the early history of methods for the quantitative determination of earthquake locations, the focus of discussion turns to modern methods for single-event location and uncertainty estimation. The final section covers multiple-event location, with an emphasis on the substantial to – in some cases – profound improvement in relative location accuracy that can be achieved by combining waveform cross-correlation with relative location techniques.

Early history

John "Earthquake" Milne devised some of the first quantitatively based methods for earthquake location, known as the methods of circles, hyperbolas, and coordinates (Milne, 1886). For the method of circles, the difference in arrival time between later observing stations i ($i = 1, N$) and the first observing station 0, $t_i - t_0 = \mathrm{d}t_i$, is used to construct circles of radii $V\,\mathrm{d}t_i$, where V is the velocity of "shock" (i.e., seismic wave) propagation, and the center of the circle through station 0 that is roughly tangent to all the other circles defines the earthquake epicenter. The scale factor V is determined by trial and error. The commonly taught S minus P time location method (Bolt, 2006) is similar in concept. The method of hyperbolas is a variant on the method of circles, whereby differential times between pairs of stations are used to define hyperbolas of possible locations, and the intersection of hyperbolas defines the earthquake epicenter. The method of coordinates goes a step further by setting up a system of four equations (defined in Cartesian coordinates centered on the last-observing station) relating differential times to "shock" velocity and the (x,y,z) coordinates of the earthquake. With four equations and four unknowns, the solution is unique. These methods

were employed for many years, until slowly the method of Geiger (1910, 1912), discussed below, began to supplant it. Interestingly, Milne's methods have been revived recently for use in locating earthquakes in an early warning system (Satriano et al., 2008) and in tectonic (Zhou, 1994; Font et al., 2004) and volcanic (Sumiejski et al., 2009) settings.

Single-event location

The predominant method for earthquake location is based on what is commonly known as Geiger's method, which was developed early in the twentieth century (Geiger, 1910, 1912). This method involves deriving the least-squares (L2 norm) solution to a set of equations, for a trial hypocenter, of the form

$$r_i = \sum_{j=1}^{3} \frac{\partial T_i}{\partial x_j} \Delta x_j + \Delta t_o \tag{1}$$

where r_i is the residual at station i, defined as the observed arrival time of a seismic phase t_i minus the calculated arrival time given by the origin time t_o plus the calculated travel time T_i, the x_j's are the hypocenter coordinates, and Δ indicates the (unknown) parameter perturbations. The spatial derivatives $\partial T_i/\partial x_j$ have a simple relationship to the seismic velocity V and the ray direction at the source,

$$\frac{\partial T_i}{\partial x_j} = \frac{-1}{V} \frac{\mathrm{d}x_j}{\mathrm{d}s} \tag{2}$$

where s is the path length parameter. Equation 1 represents a nonlinear parameter estimation problem (Aster et al., 2005) so it is solved iteratively, and some convergence criteria must be defined. Mathematically, this problem can be expressed as

$$\mathbf{G}\Delta\mathbf{m} = \mathbf{r} \tag{3}$$

where the matrix $\mathbf{G}$ contains the partial derivatives, $\mathbf{\Delta m}$ is the vector of hypocenter perturbations (position and origin time), and $\mathbf{r}$ is the residual vector. Equation 3 is typically solved using iterative least squares, generally with some type of regularization (Aster et al., 2005). For a layered model, Geiger's method can be extended from this simple linearized form to a nonlinear form (Thurber, 1985), but that is of more theoretical than practical interest.

The seismic phases used for location vary depending in part on the epicentral distance domain – local (0–5°), regional (5–30°), and teleseismic (>30°) (note that these breakpoints are relatively standard ones, although that for the local–regional is somewhat more arbitrary). At local distances, first-arriving P and S phases are used almost to exclusion. At teleseismic distances, first-P and to a lesser degree first-S remain critically important, albeit with such complications as shadow zones and triplications, but a virtual cornucopia of other phases is also available. Among them, the depth phases (solid-surface reflections pP and sP and the water-surface reflections pwP and swP), which have travel-time derivatives for depth opposite in sign to the direct phases, have tremendous value in constraining event depth, although misidentification problems can be significant (Engdahl et al., 1998; Engdahl, 2006). The outer core reflection PcP has also proven quite useful (Schöffel and Das, 1999).

At regional distances, several factors combine to make the location situation complex. The mantle refractions Pn and Sn are the first-arriving body-wave phases, and their amplitudes can be small relative to crustal arrivals. Crustal thickness variations at a regional scale make accurate prediction of regional travel times difficult. These problems have an enormous impact on nuclear explosion monitoring efforts, where the goal is to be able to locate relatively small events often with only sparse regional data. The use of later arriving phases (crustal body-wave phases Pg, Sg, and PmP, and the surface-wave phase Lg) and also arrival azimuth is relatively common for this monitoring domain (Bratt and Bache, 1988). Arrival azimuth can be determined at high precision with a seismic array, or by a single three-component station with much lower precision.

There are some alternatives to Geiger's method, most of which fall into the general category of nonlinear optimization (Gill et al., 1981). One is the conceptually simple grid search approach (Rowlett and Forsyth, 1984; Sambridge and Kennett, 1986; Shearer, 1997; Lomax et al., 2000; Rodi, 2006). Others include the simplex method (Rabinowitz, 1988), genetic algorithms (Sambridge and Gallagher, 1993), and simulated annealing (Billings, 1994). Because these methods do not involve least squares and the calculation of derivatives (Equations 2 and 3), they are readily amenable to the use of the more robust L1 norm (Aster et al., 2005), and some can directly provide comprehensive uncertainty information, a topic we turn to next.

Location uncertainty

In some circumstances, knowing the uncertainty of a seismic event's location may be nearly as important as the location itself. The discussion of this topic can be separated into two parts: precision and accuracy. Precision is covered first, including a brief discussion of arrival-time estimation (phase picking). Accuracy is a far more subtle issue, with significant limitations on our ability to assess it thoroughly.

The standard approach for the evaluation of precision is the confidence ellipsoid (Flinn, 1965), which can be obtained from the model covariance matrix (Aster et al., 2005) for Equation 3,

$$\mathbf{C}_\mathrm{m} = \sigma_\mathrm{d}{}^2 (\mathbf{G}^\mathrm{T}\mathbf{G})^{-1} [(\mathbf{G}^\mathrm{T}\mathbf{G})^{-1}]^\mathrm{T} \tag{4}$$

where for now we assume that the data errors have a uniform standard deviation σ_d, often estimated from the data misfit, and are uncorrelated (independent). Given the desired confidence level p (e.g., 0.95), the corresponding confidence ellipsoid is obtained for $\mathbf{m}$ satisfying

$$(\mathbf{m}-\mathbf{m}^*)^{\mathrm{T}}\mathbf{C_m}^{-1}(\mathbf{m}-\mathbf{m}^*)=\kappa_p{}^2 \tag{5}$$

where $\mathbf{m}^*$ is the location solution and $\kappa_p{}^2$ is given by

$$\kappa_p{}^2=4\sigma_d{}^2\left[F_p(4,N-4)\right]/(N-4) \tag{6}$$

with F_p the F statistic at confidence level p and N the number of arrival-time data (Draper and Smith, 1981). Some limitations of this approach to uncertainty estimation are (1) that the misfit-based estimate of σ_d becomes unreliable for small numbers of observations (Evernden, 1969), (2) that it neglects the effects of velocity-model inaccuracy and correlated errors, and (3) that the linear approximation itself is inadequate in some circumstances.

Buland (1976) noted that data uncertainty estimated from either the misfit or a priori experience is generally too small due to the inaccuracy of the travel-time model. He suggested that the σ_d value should simply be increased to compensate for this problem. Jordan and Sverdrup (1981) developed an elegant statistical approach for making this compensation. Their philosophy is to replace the usual a posteriori estimate of the data variance, $s_d{}^2$, based on the data misfit for an individual earthquake,

$$s_d{}^2=||\mathbf{r}||^2/(N-4) \tag{7}$$

with an estimate based on a combination of a priori and a posteriori information:

$$s_d{}^2=\frac{Ks_0{}^2+\|\mathbf{r}\|^2}{(K+N-4)} \tag{8}$$

where the a priori variance estimate s_0 is given a relative weight of K. Thus, the a priori information is treated as contributing K observations to the estimate of $s_d{}^2$ and the data for the particular event contribute N observations. For self-consistency, given a large number of events, the mean of the estimated variances should approach s_0. Jordan and Sverdrup (1981) also show that the distribution of the estimated standard deviation needs to be consistent with the adopted value of K. In the limit of no prior information ($K = 0$), their estimate reverts to the standard formula (Flinn, 1965), whereas for infinite prior information ($K = \infty$), their estimate becomes equivalent to that of Evernden (1969).

One limitation of the Jordan and Sverdrup (1981) approach is that it assumes an uncorrelated, Gaussian error distribution with a constant data variance for all observations. Varying data uncertainty estimates can be incorporated simply by including a weighting matrix $\mathbf{W}$ in the standard linearized analysis (Aster et al., 2005):

$$\mathbf{WG}\Delta\mathbf{m}=\mathbf{Wr} \tag{9}$$

(e.g., Bolt, 1960) and then solving the weighted system as before. Weighting is generally done based on reported arrival-time reading precision (Engdahl et al., 1998), reported arrival quality (Buland, 1976), phase variance as a function of distance (Engdahl, 2006), residual size (Bolt, 1960), station distance (Klein, 1978), and/or azimuthal distribution of stations (Buland, 1976). However, the Gaussian data error assumption is generally inappropriate, as residual outliers are common in arrival-time data (Bolt, 1960; Buland, 1986). Discussions of correlated errors and their treatment can be found in Chang et al. (1983), Rodi and Myers (2007), and Bondár and McLaughlin (2009).

The "uniform reduction" method (Jeffreys, 1939) is effective for treating the situation of normally distributed errors plus a background of outliers. Bolt (1960) assumed a residual frequency distribution of the form

$$f(r)=as+\frac{(1\pm s)}{\sigma\sqrt{2\pi}}\exp\left(\pm\frac{(r\pm m)^2}{2\sigma^2}\right) \tag{10}$$

where a and s are constants and m and σ are the mean residual and its standard deviation. This corresponds to a residual weighting function of the form

$$w(r)=\left[1+\mu\exp\left(\pm\frac{(r\pm m)^2}{2\sigma^2}\right)\right]^{\pm1} \tag{11}$$

with $\mu=\sigma\,(2\pi)^{1/2}\,a\,s/(1-s)$.

It is important to point out that estimating the phase arrival time by itself is a difficult problem, particularly for S waves and other secondary phases. Many seismic networks use automated pickers, at least for preliminary locations. Simple auto-pickers use a threshold of the ratio of the short-term average (STA) to the long-term average (LTA) of the signal amplitude (Allen, 1978, 1982; Ruud and Husebye, 1992). There are a wide variety of other (generally more computationally demanding) approaches. Among these are energy analysis (Earle and Shearer, 1994), polarization analysis (Vidale, 1986; Cichowicz, 1993), autoregressive techniques (Maeda, 1985; Sleeman and Eck, 1999; Leonard and Kennett, 1999; Leonard, 2000), wavelet analysis (Zhang et al., 2003), or some combination (Wang and Teng, 1997; Diehl et al., 2009).

As noted above, constraints on event locations can be improved markedly via the inclusion of secondary arrivals. Gomberg et al. (1990) and Wilcock and Toomey (1991) examine the importance of even a single S arrival in reducing location uncertainty. A "chicken and egg" problem with the use of later phases is that their correct identification often requires knowledge of the event depth and distance. Recognizing this problem, Kennett et al. (1995) and Engdahl et al. (1998) included a phase re-association step in their location procedure. In their approach, catalog phase arrivals were reidentified after each relocation iteration using a statistically based association algorithm. This approach can be implemented by comparing probability density functions (PDF's) for relevant phases, centered on their theoretical relative travel times for a given hypocenter, to the observed phase arrivals. When PDF's overlap for a particular phase, the idea is to assign a phase identification in a probabilistic manner based on the relevant PDF values, making sure not to assign the same phase to two different arrivals.

The above discussion focuses almost exclusively on location precision. There are two general approaches for evaluating location accuracy: theoretical and empirical. Pavlis (1986) carried out a thorough theoretical analysis of both precision and accuracy aspects for local earthquakes. He identified and evaluated three sources of hypocenter error: (1) measurement errors, (2) velocity-model errors, and (3) nonlinearity. He treated the first via standard confidence ellipsoids, but the other two required the establishment of error bound estimates. Billings et al. (1994) explored aspects of (1) and (2) for the teleseismic case using a combination of Monte Carlo analysis and varying sets of observations, although their analyses involved real data, not synthetic data. One general conclusion of both these studies is that velocity-model-induced errors can be as significant as measurement errors.

"Ground truth" (GT) events provide a direct, empirical means to explore absolute location accuracy (also termed location bias). Having GT events allows one to evaluate location and uncertainty estimation strategies empirically that, for example, produce 95% confidence ellipses that overlap the true locations 95% of the time. This avenue of research has been motivated primarily by nuclear explosion monitoring needs (see *Seismic Monitoring of Nuclear Explosions*), but also is an important aspect of research on one-dimensional (1D) and three-dimensional (3D) earth models (see *Seismic Tomography*). See Bondár and McLaughlin (2009) and references therein for recent work on absolute location accuracy and Thurber and Engdahl (2000) for a review of the development of global 1D models.

The San Andreas Fault Observatory at Depth (SAFOD) provided a unique test of absolute location accuracy. One of SAFOD's goals (unfortunately not yet realized) was to penetrate the rupture zone of a magnitude ~2 repeating earthquake. This required determining a borehole trajectory that would pass within 100 m of the target event. Using data from a dense temporary array, permanent networks, deep borehole instruments, and active-source experiments, Thurber et al. (2004) carried out 3D tomography and used "virtual earthquakes" (receiver gathers of shots recorded on borehole instruments, effectively providing sources of known location at depth) to assess absolute location accuracy. Their work succeeded, as subsequent borehole recordings of target earthquake aftershocks showed the target event to lie within 100 m of the borehole.

Multiple-event location

There are two distinct but complementary aspects to this topic that will be discussed. One is the suite of methods used to infer the relative locations of events, including joint hypocenter determination (JHD), hypocentroidal decomposition (HDC), and double-difference (DD) methods. Note that local earthquake tomography takes multiple-event location a step further to determine seismic velocity structure simultaneously with the locations of many earthquakes (see *Seismic Tomography*). The other is the use of waveform cross-correlation (WCC) methods to determine differential times (DT's) and/or pick adjustments.

The use of catalog DT's for determining relative locations of earthquakes (or explosions) has been a fruitful field of work for many decades (e.g., Douglas, 1967). The precision of WCC DT's allows for spectacular relative location results to be achieved over a broad range of spatial scales when DT's from WCC are used in combination with joint location techniques. These and other studies have demonstrated the substantial improvement in the delineation of seismogenic features or in the accuracy of relative locations of GT events that is possible using multiple-event location methods in concert with high-precision arrival-time or differential-time data. WCC is covered first to streamline the subsequent discussion of the relative location techniques.

Waveform cross-correlation

For a pair of earthquakes that are located close to each other (relative to the predominant wavelength of the seismic signal from them) and have similar source mechanisms, the waveforms from them observed at a particular seismic station will be similar. The work by Poupinet et al. (1984) to use (frequency-domain) WCC on the coda of similar earthquakes ("doublets") to detect temporal changes in seismic velocity followed by the study of Fremont and Malone (1987) using the same WCC method to determine high-precision relative arrival times and earthquake locations at Mt. St. Helens ultimately led to an explosion in the use of WCC and location techniques in the 1990s and beyond.

The time-domain method for WCC is relatively simple, although computationally demanding for large sets of events. Windowed waveform segments spanning the time of the relevant arrival (P or S) for a pair of earthquakes at a particular station are cross-correlated over a range of lag times to find the time lag corresponding to the best alignment of the waveforms (i.e., the maximum CC value). Waveforms are typically filtered either with a simple bandpass filter or with coherency weighting (Rowe et al., 2002a). For very similar events (those with a high CC value), it can be worthwhile to apply a frequency-domain technique such as cross-spectral phase to determine the lag to a precision below the sample rate. This procedure takes advantage of the fact that, as an example, for two frequencies that are a factor of two different, the phase difference at the higher frequency should be exactly double that at the lower frequency. The lag is determined by calculating the phase difference as a function of frequency and fitting the result with a straight line through the origin at zero frequency.

Most of the studies using WCC adopt a threshold value (typically 0.7) below which DT's are discarded. This can result in good data being lost (correct lag value but low CC value – e.g., due to a noisy record) as well as bad data

being used (incorrect lag value but high CC value – e.g., due to a cycle slip). Du et al. (2004a) developed a procedure to provide independent lag estimates for verification of WCC results. They used the bispectrum (BS) method, which works in the third-order spectral domain, to check the reliability of the CC-determined time delay. They calculated two time delays with the BS method, one using the bandpass-filtered waveforms and the other with the raw data, and used them to verify (select or reject) the CC estimate computed with the filtered waveforms. This approach appears to be particularly effective in reducing cycle-slip errors.

Relative location

As noted above, the JHD method dates back to the work of Douglas (1967). In its basic form, the method takes the basic equation for earthquake location, Equation 1, adds a "station correction" term Δs_i, and sets up a large set of equations for a suite of events, $k = 1, K$:

$$r_{ik} = \sum_{j=1}^{3} \frac{\partial T_{ik}}{\partial x_{jk}} \Delta x_{jk} + \Delta t_{ok} + \Delta s_i \tag{12}$$

As noted by Wolfe (2002), JHD procedures assume that if the hypocentral separations among a set of earthquakes are small compared to the event-station distance and the scale length of heterogeneity, then the ray paths between the source region and a station are similar and the travel-time error introduced by an incorrect velocity model has a nearly constant value for a given station, thus justifying the linear term Δs_i. Pujol (2000) provides a review of JHD methods mostly aimed at local-scale studies. Pavlis (1992) presents a comprehensive analysis of relative location errors.

Wolfe (2002) thoroughly analyzed the HDC and DD methods. Her analysis shows that the solutions for both operators are similar, with the double-difference operator weighting fits to travel times on stations that record more earthquakes more heavily. The HDC method was introduced by Jordan and Sverdrup (1981). As the name indicates, it involves decomposing the system Equation 12 via projection operators into one involving just the locations of the events relative to the (unknown) average location (i.e., the hypocentroid). As Wolfe (2002) notes, the projection is in fact a travel-time differencing operation. The DD method of Waldhauser et al. (1999) and Waldhauser and Ellsworth (2000) constructs the event-pair difference equations directly, but it is distinguished from the original Jordan and Sverdrup (1981) method by evaluating the spatial derivatives at different points rather than assuming that they are constant and by including a separation-dependent weighting in order to reduce location-dependent path bias. Modern HDC methods also allow for spatially varying derivatives (Bergman and Engdahl, 2001), and the appropriateness of separation-dependent weighting has been subject to debate. The Markov-Chain Monte Carlo approach of Myers et al. (2007) takes a probabilistic approach that incorporates the probability of phase identification errors in the estimation of uncertainty.

Some examples of applications of WCC combined with relative location for microearthquakes at a local-scale include: Switzerland (Deichmann and Garcia-Fernandez, 1992), Kilauea volcano, Hawaii (Got et al., 1994; Rubin et al., 1998), California (Dodge et al., 1995; Shearer, 1997; Waldhauser et al., 1999; Waldhauser and Ellsworth, 2000; Schaff et al., 2002), Iceland (Slunga et al., 1995), the Soultz geothermal field, France (Rowe et al., 2002b), Mount Pinatubo, the Philippines (Battaglia et al., 2004), New Zealand (Du et al., 2004b), and Soufriere Hills volcano, Montserrat (Rowe et al., 2004). At a regional scale, Schaff and Richards (2004) determined relative locations for an earthquake sequence in China using WCC on Lg waves. For teleseismic data, WCC/relative location methods have been applied to body waves for nuclear explosions at the Balapan test site (Phillips et al., 2001; Thurber et al., 2001), to the aftershock sequences of the great Sumatra earthquakes (Pesicek et al., 2010), and to global seismicity (Waldhauser and Schaff, 2008).

Summary

Despite being one of the oldest quantitative problems in seismology, it is clear that there is still much to learn about earthquake location. The combination of WCC and high-precision relative location has brought new excitement to this rather old field of research. At the same time, the needs of nuclear explosion monitoring have motivated the careful study of absolute location capability and statistically consistent uncertainty estimation.

Richter scale

Definition

The *magnitude* of an earthquake is a number that characterizes the relative size or amount of elastic energy released by such an event (see *Earthquakes, Energy*). It is usually based on measurement of the maximum ground

motion recorded by a seismograph (sometimes for a particular wave type and frequency) and corrected for the decay of amplitudes with epicenter distance and source depth due to geometric spreading and attenuation during wave propagation (see *Propagation of Elastic Waves: Fundamentals*).

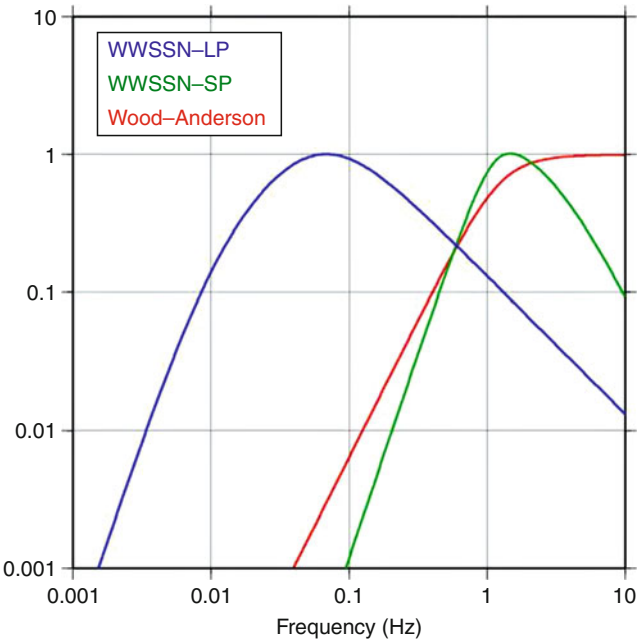
Original definition of earthquake magnitude

The first paper on earthquake magnitude was published by Charles F. Richter (1935), titled *An instrumental earthquake magnitude scale*. Therefore, often reference is made to the size or strength of earthquakes as measured on the *Richter scale*. Yet, this may be incorrect, especially for large earthquakes (magnitude saturation). Richter (1935, p. 1) wrote: "In the course of historical or statistical study of earthquakes in any given region it is frequently desirable to have a scale for rating these shocks in terms of their original energy, independently of the effects which may be produced at any particular point of observation." The term *magnitude* scale was recommended to Richter by H.O. Wood in distinction to the name *intensity* scale (see *Earthquakes, Intensity*), which classifies the severity of earthquakes mainly on the basis of felt shaking or damage manifestations at different localities.

Richter compared records of a standard type of short-period horizontal component Wood-Anderson (WA) torsion seismograph at different distances and azimuths from the earthquake source. All seismographs had an identical frequency response (red curve in Figure 1) and a static magnification of (said to be) 2800. Many stations in Southern California were equipped with WA seismometers. Figure 2 shows a typical record of a near earthquake. Plotting for each event the logarithm of the recorded maximum trace amplitudes A_{max} over the epicentral distance Δ (see *Earthquake, Location Techniques*) Richter derived an average attenuation law for a reference amplitude A_o up to $\Delta = 600$ km. He then corrected amplitudes measured at different stations by the $-\log A_o(\Delta)$ values. Thus measured amplitudes became comparable for a given event and differences of corrected amplitudes for different events indicative for difference in event size. In conclusion Richter (1935, p. 31) states:

> The magnitude of a shock is defined as the logarithm of the calculated maximum trace amplitude, expressed in microns, with which the standard short-period torsion seismometer ($T_o = 0.8$, $V = 2{,}800$, $h = 0.8$) would register that shock at an epicentral distance of 100 km.

Since then several other magnitude scales have been developed. They are based on different types of seismic waves (Bormann et al., 2002a; *Body Waves*; *Surface Waves*), recorded by seismographs with different frequency responses (e.g., those shown in Figure 1) and measured at different periods and source distances. Yet, all had to be mutually scaled so that at certain magnitudes they yield values in agreement with the above original definition.



Earthquake, Magnitude, Figure 1 Normalized amplitude–frequency responses of standard types of seismographs (or of their simulation filters) required for measuring several common types of magnitudes in agreement with recent IASPEI (2005) recommendations: Wood-Anderson seismograph and the short-period (SP) and long-period (LP) seismographs used in the former US World-Wide Standard Seismograph Network (WWSSN) (Seismic Instrumentation). (Reprint from IASPEI, 2005. With copyright granted by IASPEI.)

Local magnitude scales

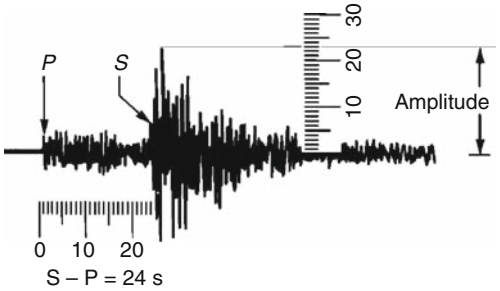
The *Richter scale* is termed M_L and applicable only to earthquakes recorded at local to near regional distances, typically less than 1,000 km distance. Its formula reads:

$$M_L = \log_{10} A_{max} - \log A_o(\Delta). \quad (1)$$

Figure 2 shows how the trace amplitude A_{max} on a WA record is measured and the distance Δ estimated via the arrival-time difference between the P- and S-waves. Figure 3 is a compilation of different $-\log A_o(\Delta)$ calibration curves for different seismotectonic regions of the world. The Richter values for Southern California form the dot-step curve. Tabulated Richter values and calibration formulas for the other curves are given by Bormann (2002).

Figure 3 illustrates that M_L calibration functions may strongly differ from region to region because of differences in crustal structure, thickness, age, heat flow and related wave propagation and attenuation properties. Therefore, in order to assure compatibility of M_L values measured in different regions one has to (a) investigate the regional amplitude- attenuation conditions, (b) derive regional calibration functions, and (c) scale them so as to yield for identical amplitudes measured at 100 km *epicentral* distance the same M_L as with the Richter $-\log A_o(\Delta)$

value at this distance. However, in order to assure a better comparison of earthquakes in regions having very different attenuation of waves within the first 100 km, Hutton and Boore (1987) recommend to define local scales such that M_L = 3 corresponds to 10 mm trace amplitude on a Wood-Anderson instrument at 17 km *hypocentral* distance rather than 1 mm at 100 km *epicentral* distance. Further, empirical measurements proved that the static magnification of the WA seismographs is not 2,800 but around 2,080 ± 60 (Uhrhammer and Collins, 1990).



Earthquake, Magnitude, Figure 2 Record of a short-period Wood-Anderson seismograph of a local earthquake. P marks the onset of the first arriving longitudinal wave, and S that of the shear wave. Note the long tail of scattered coda-waves following S. From the time difference S – P = 24 s follows a distance of about 190 km. The largest amplitude is A_{max} = 23 mm. With –logA_o(190 km) = 3.45 (Richter, 1958) Equation 1 yields M_L = 4.8. (Modified from Figure 1 in Bormann and Saul, 2009a. With copyright granted by Springer.)

Moreover, gain and response of modern seismographs may differ significantly from those of WA seismographs. Therefore, the Working Group on Magnitude Measurements of the International Association of Seismology and Physics of the Earth's Interior (IASPEI, 2005) recommends for crustal earthquakes in regions with attenuative properties similar to those of Southern California the following standard formula:

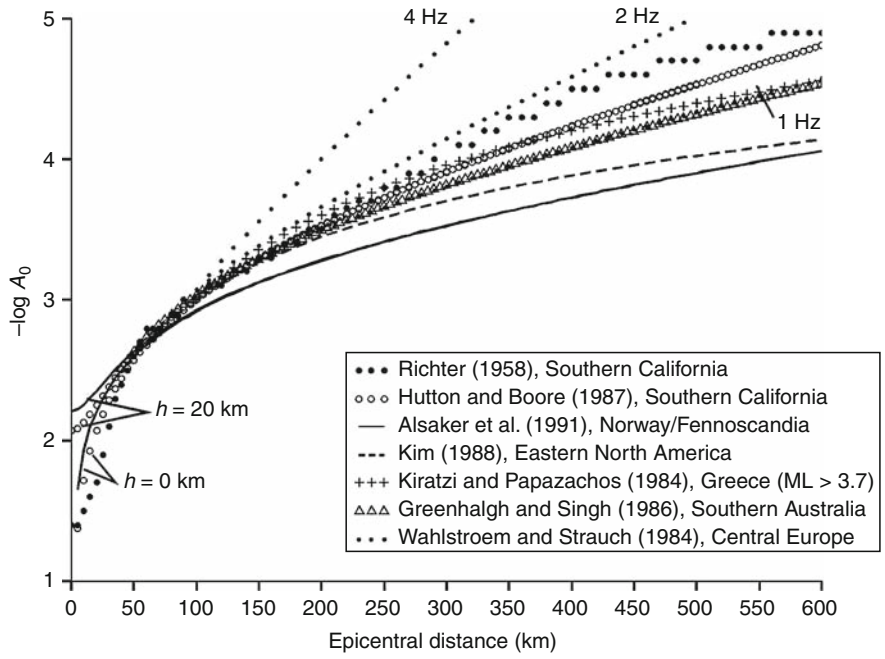
$$M_L = \log_{10} A_{max} + 1.11\log_{10} R + 0.00189 * R - 2.09 \quad (2)$$

where A_{max} = maximum trace amplitude in nm that is measured on the output from a horizontal-component instrument that is filtered so that the response of the seismograph/filter system replicates that of a Wood-Anderson standard seismograph but with a static magnification of 1, and R = hypocentral distance in km, typically less than 1,000 km.

For crustal earthquakes in regions with different attenuative properties and for measuring magnitudes with vertical-component seismographs, the standard equation is of the form:

$$M_L = \log_{10}(A_{max}) + C(R) + D \quad (3)$$

where A_{max} and R are defined as in Equation 2, except that A may be measured from a vertical-component instrument, and where $C(R)$ and D have been calibrated to adjust for the different regional attenuation and for any systematic differences between amplitudes measured on vertical



Earthquake, Magnitude, Figure 3 Calibration functions for M_L determination in different regions. (Reprint of Figure 3.12 in Bormann et al., 2002b. With copyright granted by IASPEI.)

instead of horizontal components. Besides M_L scales that measure A_{max}, typically of relatively weak motion, also M_L^{SM} scales have been developed, which are based on peak ground accelerations (e.g., Lee et al., 1990; Hatzidimitriou et al., 1993; *Earthquakes, Strong-Ground Motion*). Also the duration d of the event record or of its coda length c after the S onset can be used for estimating magnitude from locally recorded data (Bormann et al., 2002b). Further, there exist regression relationships which relate magnitude values to other observed parameter data such as (see *Earthquakes, Intensity*). But any such alternative local scale has to be developed individually for different seismic networks or regions because of regionally variable attenuation, scattering, signal-to-noise and other conditions. Also, for assuring the compatibility of their values these scales should be calibrated with amplitude-based M_L.

Teleseismic magnitude scales

Surface-wave magnitudes

Beno Gutenberg modified the Richter scale for application in the teleseismic range ($\Delta \geq 20°$; $1° = 111.22$ km) by using both body and surface waves. For shallow earthquakes the latter have by far the largest amplitudes in seismic records (Figure 4). The Gutenberg (1945a) formula for surface wave magnitude is

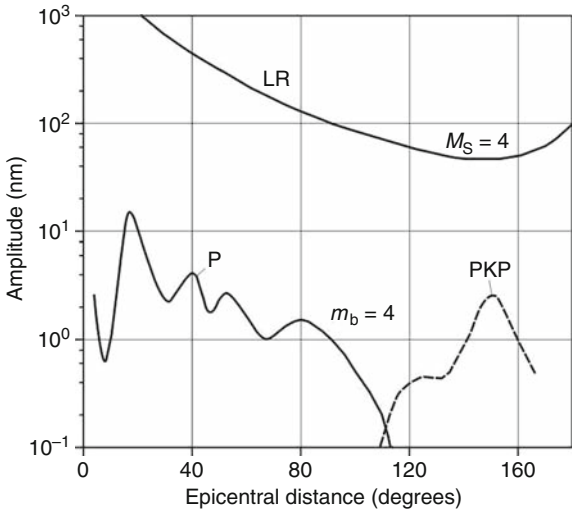
$$M_s = \log A_{Hmax} + 1.656 \log \Delta + 1.818 \quad (4)$$

with A_{Hmax} = vectorially combined maximum horizontal surface-waves displacement amplitude in micrometer measured at periods T around 20 s and the term 1.656 log Δ which compensates for the amplitude decay with distance in the range $20° \leq \Delta < 140°$. Equation 4 is best scaled for surface waves with oceanic travel paths.

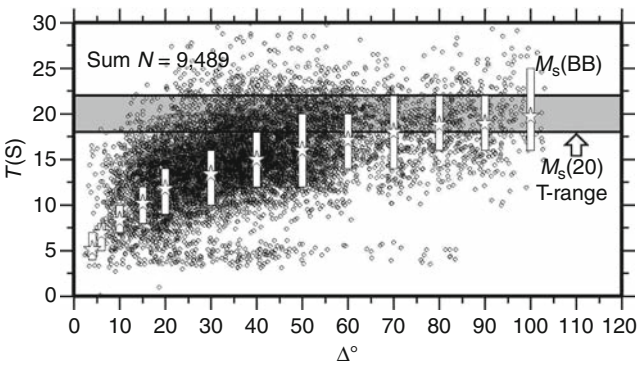
Later, a group of Czech and Russian seismologists investigated the propagation of surface waves with dominatingly continental travel paths, using records of seismographs of type Kirnos that are proportional to ground displacement in a wide range of periods. They found that surface waves may have their largest amplitudes in a much wider range of periods between about 3 and 30 s, as confirmed by Bormann et al. (2009); (see Figure 5). Moreover, estimates of M_s proved to be more stable in a wider range of epicentral distances between 2° and 160° if one measures instead of A_{max} the ratio $(A/T)_{max}$ (Vaněk et al.,1962). This ratio relates to ground velocity $V_{max} = 2\pi(A/T)_{max}$ and thus to the energy contained in the respective wave group. Therefore, these authors proposed a modified M_s formula, which is IASPEI standard for M_s determination since 1967:

$$M_s = \log (A/T)_{max} + 1.66 \log \Delta + 3.3. \quad (5)$$

National and global seismic networks and data centers run or initiated by the USA accepted Equation 5. However, with the introduction of the WWSSN they did not avail of medium- to long-period broadband displacement records that were standard equipment at first-rate stations over most of the Eurasian territory. Also, they continued



Earthquake, Magnitude, Figure 4 Amplitude decay with distance for short-period (1 Hz) P- and PKP-waves as well as long-period (≈20 s) Rayleigh surface waves LR radiated by an earthquake of magnitude 4. (Reprint of Figure 3.13 in Bormann et al., 2002a. With copyright granted by IASPEI.)



Earthquake, Magnitude, Figure 5 Variability with distance Δ of periods associated with $(A/T)_{max}$ in vertical component surface waves records. The gray shaded stripe marks the period range between 18 and 22 s, the light-gray columns mark the observed range of average periods as published by Vaněk et al. (1962), and the stars the average periods for different increments of the data cloud. (Reprint of Figure 8 by Bormann et al. 2009, p. 1874. With copyright granted by the Seismological Society of America.)

to measure A_{max} only at periods around 20 s rather than true $(A/T)_{max}$ in the whole surface-wave train. But then the use of Equation 5 results in significantly distance-dependent M_s estimates (see discussion in Bormann et al., 2009). Proposed new calibration functions for 20 s surface-waves, e.g., by von Seggern (1977), Herak and Herak (1993) and Rezapour and Pearce (1998) have not yet been accepted as global standards. In contrast, Kirnos-based M_s measurements in accordance with formula 5 have ever since been carried out in the former

Soviet Union and its allied countries, in the now Commonwealth of Independent States (CIS), and China.

Thus, two traditions of M_s measurements have been practiced for half a century, producing a host of valuable but not fully compatible data. Yet, the generic nomenclature M_s does not allow to discriminate between these two kinds of data. Moreover, M_s is measured by different agencies still in sometimes different ranges of source-depth, on different record components of different types of seismographs and sometimes even using different calibration functions, e.g., the International Data Centre (IDC) of the Comprehensive Test-Ban Treaty Organization (see *Seismology, Monitoring of CTBT*). This may result in procedure-dependent errors that have to be reduced by standardization of both nomenclature and procedures. This task is eased by the fact that modern digital broadband records allow to accurately synthesize records of classical seismographs, on which the original definition of magnitude scales often rests. Moreover, modern broadband records are mostly proportional to velocity and allow to measure $(A/T)_{max}$ directly and unambiguously on unfiltered traces. Therefore, IASPEI (2005) recommends for shallow earthquakes with source depth $h < 60$ km in future two surface-wave magnitude standards, namely, (a) a purely teleseismic one in the range $20° \leq \Delta \leq 160°$, termed $M_s(20)$, or when written in the International Seismological Format (ISF):

$$M_s\_20 = \log_{10}(A/T) + 1.66 \log_{10}\Delta + 0.3 \quad (6)$$

where A = vertical-component ground displacement in nanometer measured from the maximum surface-wave trace-amplitude having a period between 18 and 22 s on a waveform that has been filtered so as to replicate the record of the WWSSN-LP seismograph (Figure 1), and (b) another broadband (BB) surface-wave magnitude that is measured in a wider distance range of $2° \leq \Delta \leq 160°$, termed $M_s(BB)$, or in the ISF format:

$$Ms\_BB = \log_{10}(A/T)_{max} + 1.66 \log_{10}\Delta + 0.3 \quad (7)$$

where $(A/T)_{max} = (V_{max}/2\pi)$, with V_{max} = ground velocity in nm/s associated with the maximum trace-amplitude in the surface-wave train recorded on a vertical-component seismogram that is proportional to velocity, and where the period T is between 3 s $< T <$ 60 s. $M_s(BB)$ generally agrees well with $M_s(20)$, however, for weaker regional and local earthquakes it may yield up to about 0.5 magnitude units (m.u.) larger values than $M_s(20)$ (Bormann et al., 2009). Besides these two standard M_s there exist other surface-wave magnitude scales. E.g., Bonner et al. (2006) proposed a largely theory-based $M_s(V_{max})$ that requires multi-bandpass filtering and frequency-dependent attenuation corrections. Another scale, termed *Mm* (Okal and Talandier, 1989), uses very long-period surface-wave amplitudes with periods between 60 and 400 s, which penetrate into the earth mantle. *Mm* does not saturate (magnitude saturation) and thus is well suited for tsunami warning (e.g., Weinstein and Okal, 2005).

Body-wave magnitudes

Gutenberg (1945b, c) teleseismic magnitude scales for body-waves are applicable also to deep earthquakes down to source depths $h \approx 700$ km. Diagrams and tables with calibration values $Q(\Delta, h)$ for P, PP, and S waves (see *Seismogram Interpretation*), covering the distance range between about 5° and 170°, were published by Gutenberg and Richter (1956) (see also Bormann, 2002). Figure 6 shows the Q-values for vertical component P waves. It is the only classical body-wave scale which is still widely used. The general body-wave magnitude formula, applicable in the range $20° \leq \Delta \leq 100°$ reads, when A is measured in micrometer:

$$m_B = \log_{10}(A/T)_{max} + Q(\Delta, h). \quad (8)$$

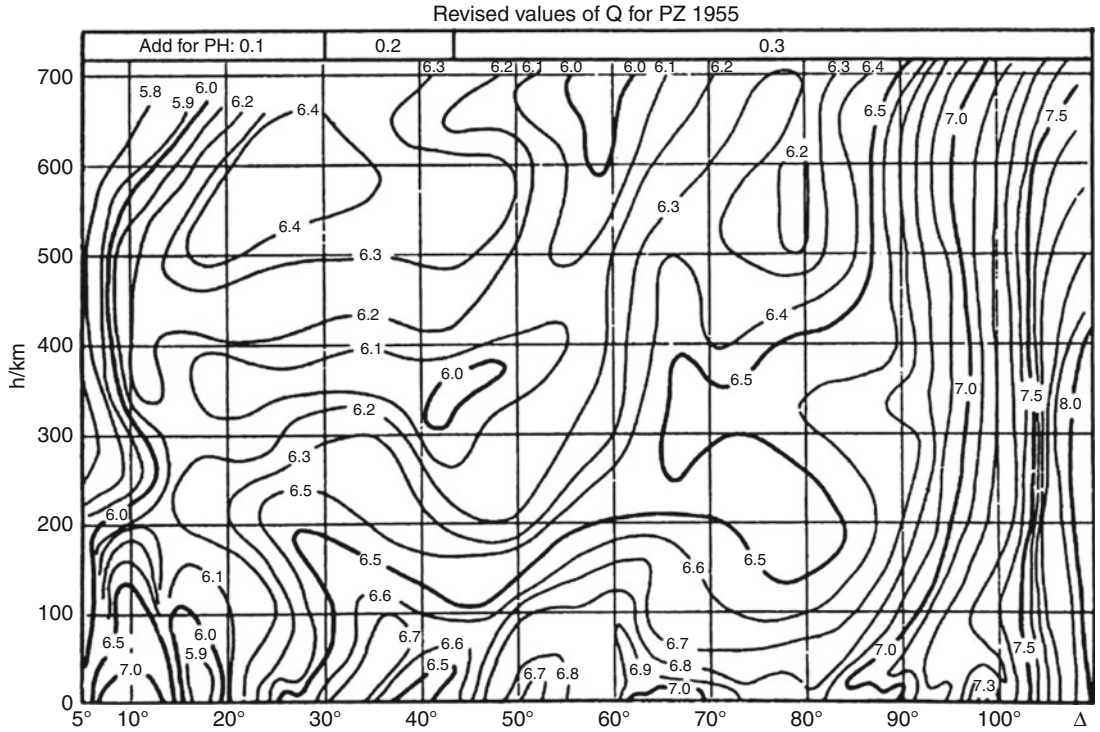
Gutenberg derived the Q-functions by analyzing mostly medium- to long-period body-wave amplitudes with periods 2 s $< T <$ 30 s (Abe, 1981). Therefore he did not account for frequency-dependent attenuation. Yet, the latter becomes significant for P-waves with $T <$ 4 s (Di Giacomo et al., 2008). Further, Gutenberg measured $(A/T)_{max}$ within the whole P-wave train and not within a fixed short time window after the P-wave onset. This was not taken into account when introducing with the WWSSN in the 1960s a short-period P-wave magnitude m_b. It measured A_{max} on narrow-band WWSSN-SP records (Figure 1) at periods < 3 s (mostly around 1 s) at fixed time-windows. The main advantage was the improved signal-to-noise ratio. It allowed teleseismic magnitudes to be determined down to $m_b \approx 4$. m_b became standard in all western countries, which discontinued to measure m_B. Yet, on average for values above 5.5, m_b tends to be smaller than other kinds of magnitudes (see Figure 7). Reasons are discussed in the section on *Magnitude saturation.*

Measurement procedures for m_b have been rather inconsistent, using different frequency responses, measuring the amplitudes within different time windows, applying different calibration functions (e.g., the IDC). The detrimental effect of such inconsistencies became strikingly evident after the great M_w9.3 Sumatra earthquake of 26 December 2004. The IDC reported $m_b = 5.7$, CENC 6.3, NEIC 7.0 and the German Regional Seismic Network (GRSN) 7.5. The IDC and CENC measured A_{max} within 5 s, the NEIC within 60 s, and the GRSN some 90 s after the first P onset. Such differences for the same event on a logarithmic scale are not tolerable and necessitate standardization of procedures. Broadband $m_B = 8.3$ was still larger than the largest m_b value.

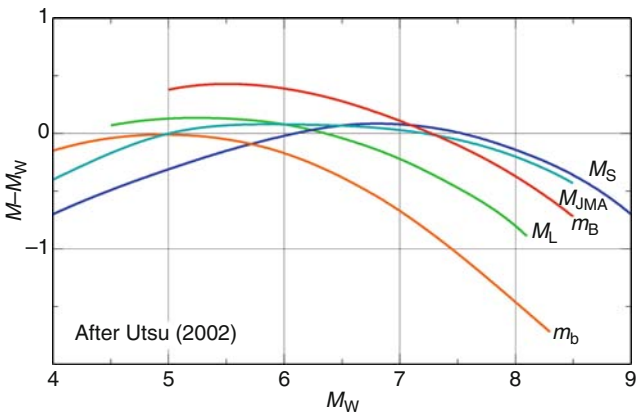
Based on such experience IASPEI (2005) proposes two complementary teleseismic body-wave magnitude standards:

$$m_b = \log_{10}(A/T) + Q(\Delta, h) - 3.0 \quad (9)$$

where: A = P-wave ground amplitude in nm, calculated from the maximum trace-amplitude in the entire P-phase train (time spanned by P, pP, sP, possibly PcP and



Earthquake, Magnitude, Figure 6 Calibration values $Q(\Delta, h)$ for vertical (Z) component P-wave amplitudes as a function of epicentral distance Δ in degree and source depth h in kilometer. They are used for the calculation of body-wave magnitudes m_B and m_b. (Figure redrawn from Gutenberg and Richter, 1956. Reprint of Figure 1a in Bormann, 2002. With copyright granted by IASPEI.)



Earthquake, Magnitude, Figure 7 Average relationships of different common types of magnitude scales with the moment magnitude M_w (non-saturating magnitude scales). M_{JMA} is determined by the Japanese Meteorological Agency. Modified from Figure 1 of Utsu (2002). Reproduction of Figure 4 in Bormann and Saul (2009a). With copyright granted by Springer.

their codas, and ending preferably before PP; *Seismogram Interpretation*); period $T < 3$ s, Δ in the range $20° \leq \Delta \leq 100°$ and h between 0 and 700 km. T and A are measured on the output of a vertical-component instrument that is filtered so that the frequency response of the seismograph/filter system replicates that of a WWSSN-SP seismograph (Figure 1). This new definition of m_b yields for great earthquakes significantly larger values than common procedures. None the less, short-period m_b should – at least for $m_b > 5.5$ – be complemented by broadband $m_B(BB)$, which reads in ISF format:

$$m_B\text{-}BB = \log_{10}(A/T)_{max} + Q(\Delta, h) - 3.0, \qquad (10)$$

where: $(A/T)_{max} = (V_{max}/2\pi)$, with V_{max} = ground velocity in nm/s associated with the maximum trace-amplitude in the entire P-phase train (see m_b) as recorded on a vertical-component seismogram that is proportional to velocity at least in the period-range 0.2 s $< T <$ 30 s; $Q(\Delta, h)$, Δ and h ranges are as for m_b.

Besides these two body-wave standards there exist several other broadband P-wave magnitudes. Most of them aim at fast estimates of the moment magnitude M_w (non-saturating magnitude scales).

Relationships between magnitude scales and released seismic energy E_s

There is no "true" single magnitude parameter which can sufficiently reliable and complete characterize both size and shaking strength of earthquakes and thus related *Seismic hazard*. Depending on the measured kinematic parameters and their frequency range the magnitudes

relate to different geometric, kinematic, or dynamic aspects of the (see *Earthquake Rupture: Inverse Problem*). Accordingly, the scales discussed so far do not scale 1:1, agree in some value ranges but differ in others. Although Figure 7 hints to sometimes nonlinear relationships, the most important ones are reasonably linear within the range of data scatter, e.g., that of Gutenberg and Richter (1956)

$$m_B = 0.63M_s + 2.5. \quad (11)$$

Equation 11 is well reproduced by the new standards $m_B(BB)$ and $M_s(BB)$ (Bormann et al., 2009) but differs strongly from the $m_b - M_s(20)$ relationship (Gordon, 1971):

$$m_b = 0.47M_s(20) + 2.79. \quad (12)$$

Despite the shortcomings of narrow-band m_b and $M_s(20)$ they are particularly useful for discriminating earthquakes and Nuclear Explosions.

Gutenberg and Richter (1956) published also a semi-empirical relationship between m_B and seismic energy E_s:

$$\log E_s = 2.4m_B - 1.2 (\text{with } E_s \text{ in units of Joule}). \quad (13)$$

When inserting Equation 11 into Equation 13 one gets

$$\log E_s = 1.5M_s + 4.8. \quad (14)$$

M_s in all these formulas means $M_s(20)$. But, 20 s displacement amplitudes are not very representative for the radiated seismic energy, especially not for smaller earthquakes. Another relationship has been derived by Kanamori et al. (1993) between M_L and $\log E_s$ for Southern California, valid in the range $1.5 < M_L < 6.0$:

$$\log E_s = 1.96M_L + 2.05. \quad (15)$$

But any such relationship allows only rough estimates of E_s within about an order of magnitude. This uncertainty can nowadays be reduced, down to a factor of about 3–5, by integrating squared velocity broadband records with good signal-to-noise ratio in the teleseismic range and thus measuring directly (see *Earthquakes, Energy*).

Magnitude "saturation"

Magnitude saturation is a widely but not uniquely used term in seismological literature. Originally, one assumed that classical magnitudes do not increase further beyond some value of a reference magnitude of earthquake size such as M_w (non-saturating magnitude scales) (e.g., Geller, 1976; Kanamori, 1983). However, such a complete saturation is not supported by Figures 7 and 8 and recently published data (e.g., Bormann et al., 2009). We therefore may speak of magnitude "saturation," or more correct underestimation of earthquake size, also if one magnitude Mx increases slowly with respect to increases in M_w (see Figure 7). Such saturation may occur when the earthquake rupture duration is much longer than the periods at which A_{max} or $(A/T)_{max}$ are measured.

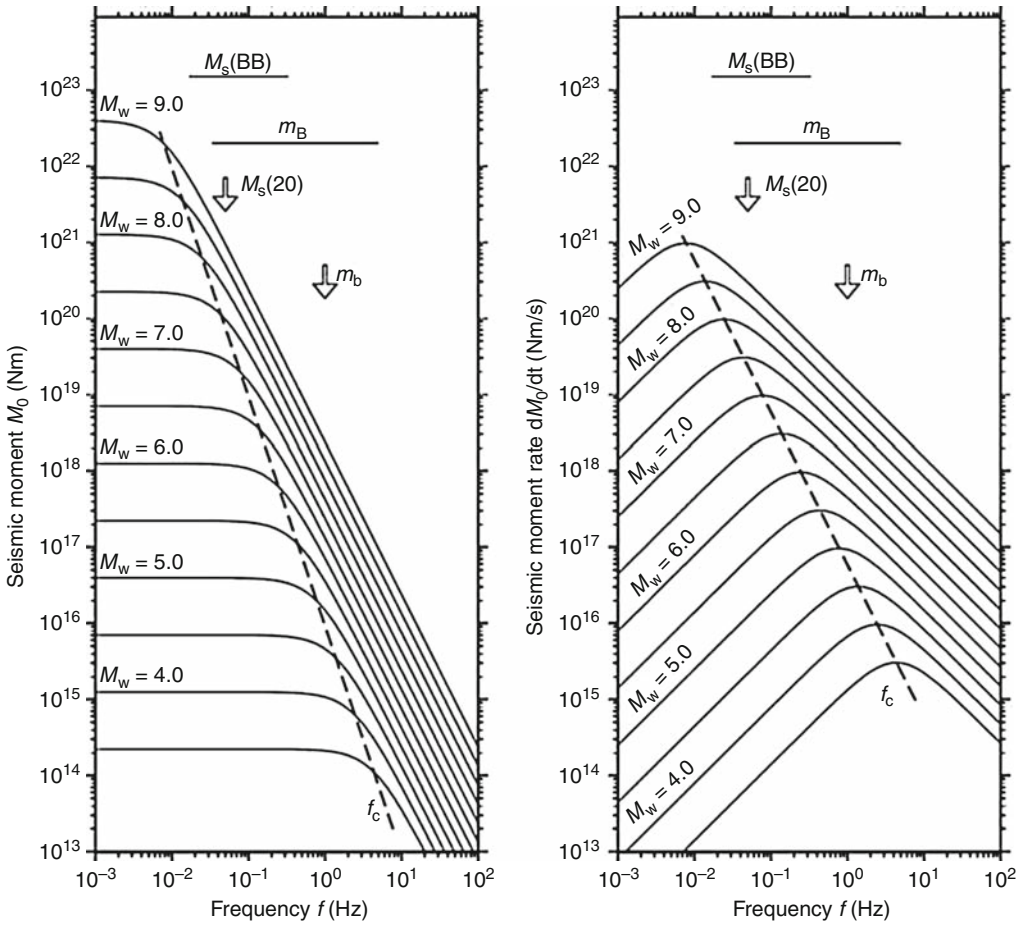
This is also illustrated by Figure 8, calculated for a common ω^{-2} source model (Aki, 1967), assuming an average rupture velocity, stress drop in the source volume and ratio E_S/M_0. For details see Bormann et al. (2009). The spectra have been plotted together with the periods, respectively period ranges, at which m_b, $m_B(BB)$, $M_s(20)$ and $M_s(BB)$ are measured. The left panel is scaled to $M_0 = \mu\ D\ F$ (where F = rupture area, D = average displacement over the fault and μ = average rigidity of the rock material in the source volume) and the right panel to the time derivative of M_0 (moment rate), which is proportional to far-field ground motion velocity. M_0 can only be estimated correctly when displacement amplitudes are measured at frequencies less than the corner frequency f_c (left panel) and seismic energy, which is proportional to the squared ground motion velocity, only when velocity spectral amplitudes are measured sufficiently wide around f_c. Accordingly, m_b measured around 1 Hz necessarily begins (on average) to underestimate both M_0 and E_s for $M_w > 5$ to 5.5, in contrast to the broadband magnitudes, which are more closely related to M_0 and E_s up to M_w 7.5–8. The spectral reasons for underestimating earthquake size or energy release may be aggravated by too short a measurement time window, which was rather common for m_b. Figure 9 illustrates both the spectral and time-window component of magnitude saturation.

Non-saturating magnitude scales

Kanamori (1977) , Purcaru and Berckhemer (1978) and Hanks and Kanamori (1979) proposed a non-saturating magnitude scale for very large earthquakes, based on M_0 data. Kanamori termed it M_w. For converting M_0 into M_w Kanamori (1977) replaced in Equation 14 M_s by M_w and assumed an average ratio $E_s/M_0 = 5 \times 10^{-5} = \text{constant}$. This led to a relationship, which reads in the IASPEI (2005) recommended standard form with M_0 in units of Nm:

$$M_w = (2/3)(\log_{10} M_0 - 9.1). \quad (16)$$

M_0 calculations are nowadays routine at major seismological centers, either by measuring the displacement amplitude u_0 on the long-period asymptote (plateau) of the wave spectrum, which is proportional to M_0 after correcting for the source radiation and wave propagation effects (as done in Figure 8), or by fitting long-period synthetic seismograms for different source models best to long-period filtered real seismic records, using wavelengths that are larger than the rupture length (Dziewonski et al., 1981). However, if this condition is not fulfilled, as sometimes in routine computations, then also M_w may be underestimated, e.g., for the great 2004 Sumatra earthquake values between 8.2 and 9.3 were reported. The last value resulted from using either extremely long-period free oscillation data (Stein and Okal, 2005) or from multiple CMT source analysis (Tsai et al., 2005). For all major earthquakes with $M_w > 5.5$ the Global Centroid Moment Tensor (GCMT) project publishes moment tensor and

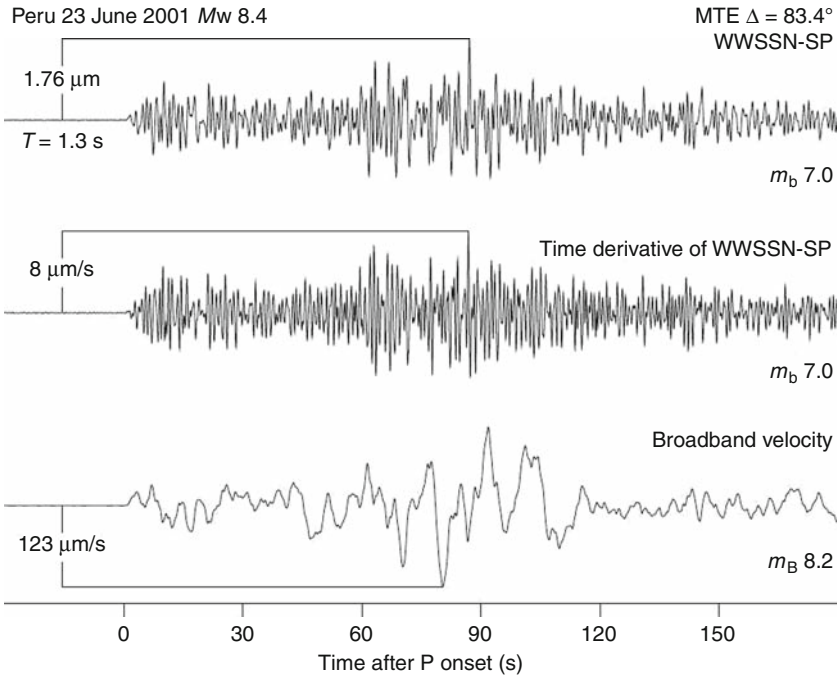


Earthquake, Magnitude, Figure 8 "Source spectra" of ground displacement amplitudes *A* for an "average" seismic shear source as a function of frequency *f*, scaled to M_0 and M_w. *Right*: The same as left, but for ground motion velocity amplitudes *V*, scaled to seismic moment rate and M_w. The maximum of seismic energy $Es \sim V^2$ is radiated around f_c. The open arrows point to the center frequencies on the abscissa at which m_b and $M_s(20)$ are measured. The horizontal bars mark the frequency range within which V_{max} of P- and Rayleigh-waves for *mB*(BB) and M_s(BB) should be measured. (Courtesy of Di Giacomo. Reproduced from Figure 1 of Bormann et al., 2009, p. 1870. With copyright granted by the Seismological Society of America.)

M_w solutions usually within a few hours after the event (http://www.globalcmt.org/CMTsearch.html). Regional centers, such as the Swiss Earthquake Sercice, may provide – with larger time delay – such data down to $M_w \approx 3.0$ when dense quality networks close to the source are available (Braunmiller et al., 2002).

Besides calculation of M_w via direct measurements of M_0 there exist several methods of fast M_w proxy estimates, e.g., M_{wp} in the context of tsunami early warning (Tsuboi et al., 1999). M_{wp} scales nearly 1:1 with broadband m_B (Bormann and Saul, 2009a) but also tends to underestimate very great and (see *Slow Earthquake*). More advanced fast and non-saturating versions of broadband P-wave magnitudes are M_{wpd} by Lomax and Michelini (2009), the (unspecified) *M* by Hara (2007), and m_{Bc}, a modified "cumulative" m_B procedure for great multiple-rupture earthquakes (Bormann and Saul, 2009b). All these procedures account additionally for rupture duration, estimated in real time. Another very perspective promising new method for rapid non-saturating moment tensor and M_w estimates uses very long-period W-phase observations between the P-wave and S-wave arrivals (Kanamori and Rivera, 2008).

However, both M_0 and M_w are only long-period or quasi-static measures of earthquake size and thus of the tectonic earthquake effect. More relevant for assessing seismic hazard in terms of the earthquake potential for causing shaking damage are estimates of the amount of released seismic energy E_s and of the corner frequency f_c. These two parameters largely control the relative amount of radiated high-frequency velocity amplitudes. This necessitates, complementary M_w, also an energy-scaled magnitude M_e, which better relates to the kinematics and dynamics of the earthquake rupture, such as rupture velocity and stress drop. Velocity-broadband records allow nowadays to estimate (see *Earthquakes, Energy*) directly by



Earthquake, Magnitude, Figure 9 Plot of vertical-component P-wave records of an M_w8.4 Peru earthquake at station MTE at $\Delta = 83.4°$. It illustrates the difference between broadband *mB* and short-period m_b for large earthquakes. *Top trace*: m_b based on measuring A_{max} and the related period T from the simulated WWSSN_SP record. *Second trace*: Time derivative of the top trace for making $V_{max} = 8$ µm/s for m_b comparable with $V_{max} = 123$ µm/s on the *bottom trace*. The latter yields $m_B = 8.2$, in contrast to IASPEI standard $m_b = 7.0$, or 6.4, when A_{max} is measured within the first 5 s. (Copy of Figure 1 in Bormann and Saul, 2008, p. 699. With copyright granted by the Seismological Society of America.)

integrating squared velocity amplitudes over a wide range of periods around the peak of the velocity spectrum (see Figure 8) and correcting them for wave propagation effects. Comparing so determined E_s values for hundreds of shallow earthquakes with their NEIC M_s magnitudes in the range $5.5 < M_s < 8.5$ Choy and Boatwright (1995) found

$$log\, E_s = 1.5M_s + 4.4. \quad (17)$$

Equation 17 differs from Equation 14 that was used for deriving the M_w relationship 16 only in the constant. Replacing in Equation 17 M_s by M_e and resolving it for M_e yields

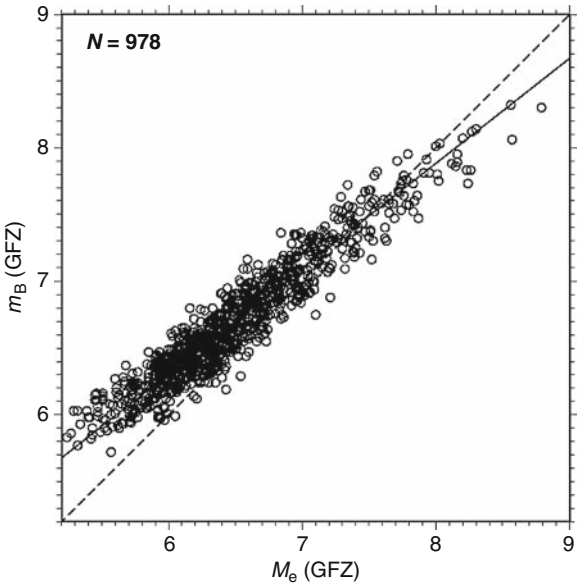
$$M_e = (2/3)(\log E_s - 4.4). \quad (18)$$

Di Giacomo et al. (2010b) showed that their $M_e(GFZ)$ and the related M_w(GCMT) agree on average in the range $5.5 < M_w < 9$ within 0.1 m.u., with a standard deviation SD = 0.25. The respective deviations between M_w(GCMT) and $M_e(NEIC)$ are larger. The reason is that $M_e(NEIC)$ is calculated from E_s values to which theoretically derived source mechanism corrections have been applied. In contrast, $M_e(GFZ)$ follows the tradition of classical magnitudes with no such corrections made to measured A_{max} or V_{max}. The pros and cons of such corrections and of their size under real Earth conditions of wave radiation and propagation are still a matter of debate and require further research.

M_e and M_w may differ for the same earthquakes up to about 1 m.u. This is mainly due to the fact that earthquake stress drop and the related ratio E_s/M_0 are not constant but may vary more than two to three orders. Examples of striking differences in M_e and M_w have been published, e.g., by Choy and Kirby (2004) and by Di Giacomo et al. (2010a). Suitable seismotectonic setting provided, $M_e << M_w$ may be indicative for high tsunamigenic potential, and vice versa, $M_e >> M_w$ for high shaking damage potential (see also Figure 11 and related discussion).

Relationship between M_w, M_e, and classical magnitudes

Scordilis (2006) published global regression relationships, based on many thousands of NEIC and ISC (International Seismological Centre) m_b and M_s values, with M_w values of the US Geological Survey and of Harward. First regression relationships between IASPEI standard magnitudes with non-saturating M_w, M_e, and m_{Bc} have been derived by Bormann and Saul (2008, 2009a, b) and by Bormann et al. (2009). From the classical magnitudes, M_s relates for strong earthquakes best with M_w, tends to be smaller, however, for $M_w < 6.2$–6.5 and > 7.8–8.5 (see Figure 7; Scordilis, 2006; Ekström and Dziewonski, 1988). Yet,



Earthquake, Magnitude, Figure 10 Relationship between automatically determined values of m_B and M_e according to procedures developed at the GFZ German Research Centre for Geosciences by Bormann and Saul (2008) and Di Giacomo et al. (2010). The *broken line* is the 1:1 and the solid line the orthogonal regression relation $m_B = 0.79M_e + 1.58$. (Courtesy of D. Di Giacomo and J. Saul.)

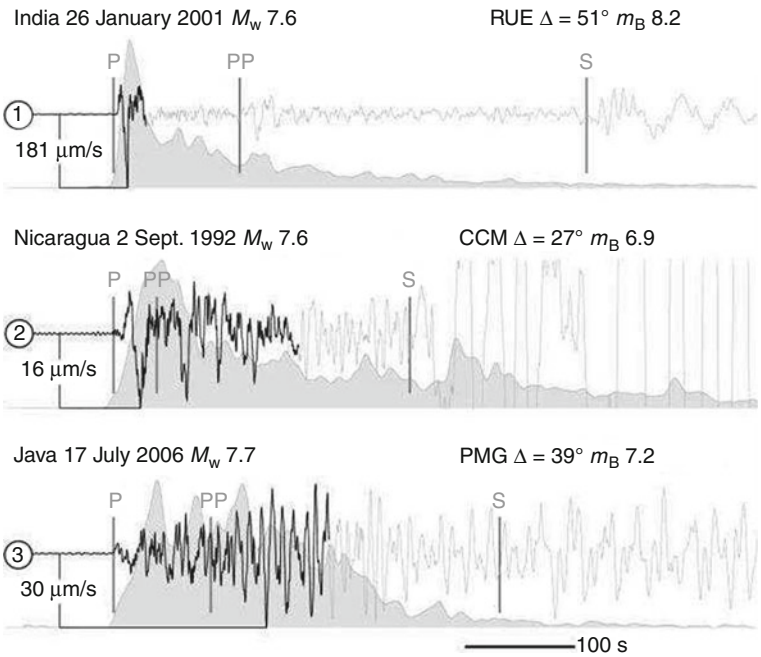
$M_s(BB)$ reduces to half the systematic underestimation of M_w by $M_s(20)$ towards smaller magnitudes (Bormann et al., 2009). The $M_s(20)$ bias had been predicted already theoretically by Kanamori and Anderson (1975).

The first magnitude-energy Equation 13 had been defined with m_B. Automatically determined $m_B(GFZ)$, which agrees with IASPEI standard $m_B(BB)$, correlates very well with $M_e(GFZ)$ (Figure 10), allowing estimates of M_e via simple m_B measurements with a SD = ±0.18 m.u. Both magnitudes are based on ground motion velocity and therefore reflect – when compared with M_w – in a similar way differences in source properties.

Figure 11 presents three records of equal M_w (within 0.1 m.u.), however very different rupture durations and m_B values. The Indian intra-plate Budj earthquake had the shortest rupture duration of about 30 s, the most impulsive waveform and largest m_B = 8.2, 0.6 m.u. larger than M_w. This event caused tremendous shaking damage. In contrast, the two very slow Nicaragua and Java earthquakes with rupture durations around 200 s were (see *Tsunami*) earthquakes. Their m_B values were 0.5 and 0.7 m.u. smaller than M_w. Both earthquakes were not or only weakly felt at the relatively nearby coasts.

Summary and conclusions

The aim and historical development of magnitude scales have been sketched, systematic inconsistencies between



Earthquake, Magnitude, Figure 11 Velocity broadband records of three earthquakes with similar M_w but exceptionally different rupture durations, m_B values and earthquake effects. The rupture duration D is estimated from the envelope of high-frequency P-wave radiation (*gray shaded area*). D corresponds approximately to the time window from the P-wave onset until the envelop amplitude drops to 40% of its maximum value (*black record trace*). (Copy of Figure 2 in Bormann and Saul, 2008, p. 700. With copyright granted by the Seismological Society of America.)

current measurement procedures and their sometimes detrimental effects been outlined, the need for international standardization highlighted, and the recently proposed IASPEI standard procedures introduced. Reduction of magnitude errors due to incompatible measurement practices is a precondition for improving the usefulness of magnitude data for a more realistic quick assessment of differences in source physics and associated actual earthquake risk. No single magnitude value can describe the peculiarity of individual earthquakes both in terms of their tectonic size and shaking strength sufficiently reliable. A multi-magnitude documentation in earthquake catalogs and a deeper understanding of the physics behind different magnitude data is indispensable also for upgrading procedures aimed at improved medium- to long-term seismic hazards assessment.

EARTHQUAKES AND CRUSTAL DEFORMATION

Robert McCaffrey
Department of Geology, Portland State University, Portland, OR, USA

Definition

The term earthquake is commonly used only to describe sudden slip on a fault within the Earth that produces seismic waves in the frequency bands that we can either feel or observe with seismometers. However, other sources that produce deformation of the Earth's surface do not generate seismic waves but are instead observable with sensitive geodetic instruments that measure the crustal deformation directly. Because of the great advances over the past few decades in observing and understanding them, in this chapter we broaden the definition of earthquake to include these "quiet" sources of Earth deformation. Other chapters deal with some of these sources in more detail.

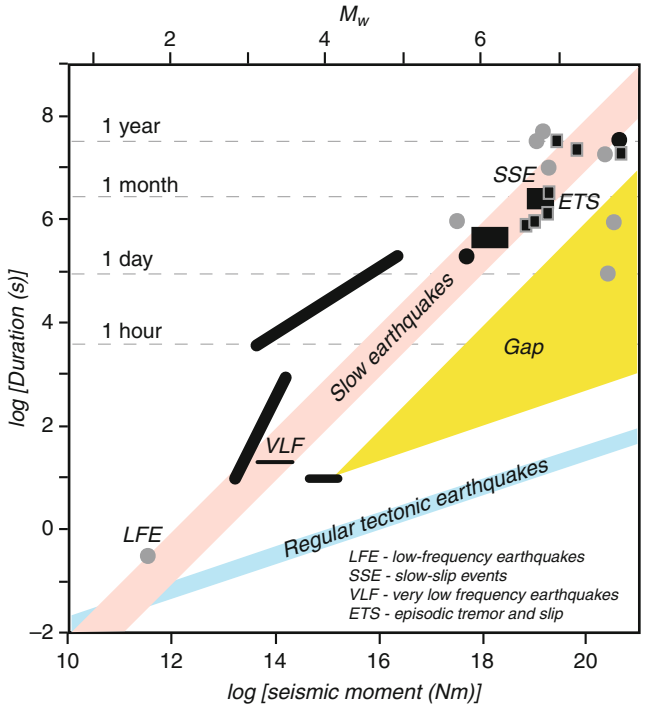
With this enhanced definition, earthquakes encompass a wide range of phenomena. The most common type we often think of is rapid slip within the Earth. The motion across a fault is typically of a shearing type but seismic disturbances can include volumetric or planar expansion in some settings, most notably near volcanoes. The classes of "earthquakes" now observed can be categorized by a rate of slip from very fast, kilometers per second, to slow, millimeters per year, covering ~12 orders of magnitude in slip rate. Figure 1, taken from Ide et al. (2007), shows the classes of earthquakes broken down by rate of the deformation. Because of the varying speeds of the motions, different types of instrumentation are required to cover specific bands.

Types of earthquakes and related phenomena defined

Here the types of earthquakes that produce crustal deformation are briefly defined. Many of them are described in detail in other chapters.

Tectonic earthquakes – Tectonic earthquakes are those that occur in response to plate motions or other predominantly shearing sources. They result primarily from the stick-slip behavior of faults. (Deep earthquakes occur by other mechanisms but are not discussed here as they do not visibly deform the crust.) As stress builds up across a fault surface, friction on the fault prevents the surface from sliding until the strength (some maximum shear stress) of the fault is exceeded. Then the two sides of the fault snap back (see elastic rebound below), releasing some or all of the elastic strain built up. This slip occurs at several kilometers per second, releasing high-frequency seismic waves. These are by far the most common type of earthquakes and the most destructive.

Tectonic tremors – These are a new type of seismic disturbance first recognized in Japan in 2002 (Obara, 2002). Originally they were called non-volcanic tremors



Earthquakes and Crustal Deformation, Figure 1 Durations and moments of various types of crustal deformation events, modified from Ide et al. (2007). *Black and gray circles* and *elongated bars* show silent earthquakes, afterslip and slowslip events from Italy, Nankai, Kilauea, San Andreas, and Sanriku (Ide et al., 2007). *Squares* are slowslip events from New Zealand (McCaffrey et al., 2008) and Guererro, Mexico (Larson et al., 2007). These follow a scaling relation of $\sim M_o/t$. Typical scaling relation for regular shallow interplate earthquakes is shown by the blue line. See Ide et al. (2007) for additional information.

due to some similarities to volcanic tremors. Whereas tectonic earthquakes are due to finite duration slip (on the order of seconds to minutes) on the fault, tectonic tremors appear as low amplitude, non-harmonic background disturbances lasting days to weeks. They are comprised in part of very small earthquakes but most of the signals are incoherent. Often, but not always, they accompany slow-slip events and are thought to be some aspect of the same process (Rubenstein et al., 2010).

Volcanic earthquakes – Volcanic earthquakes are similar to tectonic earthquakes in that they are due to the failure of rock along faults. However, their size is limited due to the relatively small fault surface area available near volcanoes.

Volcanic tremors – These earth disturbances are likely caused by fluid (water or magma) moving inside the earth. The signals are harmonic and can last a long time (relative to tectonic earthquakes) but are generally of low amplitude and generate little crustal deformation.

Slow earthquakes – Some earthquakes occur at slip speeds that are slower than typical tectonic earthquakes but fast enough to excite seismic waves. They occur when slip is in materials of low rigidity such as accretionary prisms of subduction zones. In such cases, they can produce tsunamis that are larger than expected for the earthquake's magnitude. Examples are earthquakes in Nicaragua (Kanamori and Kikuchi, 1993) and New Zealand (Doser and Webb, 2003).

Low-frequency earthquakes – Such earthquakes, called LFEs, have been observed in volcanic settings and more recently associated with tectonic tremors at subduction zones. As the name indicates they generate much lower frequencies than normal tectonic earthquakes. In both settings the low frequencies may be attributable to fluid interactions (Shelly et al., 2006).

Slow-slip events – In this class of events, called SSEs, the rupture speed is on the order of a few millimeters per day. Thus the rupture propagates at 11 orders of magnitude slower than a tectonic earthquake but only about 10 times faster than tectonic creep at plate motion rates. At these slow-slip speeds, seismic waves are not generated and slow-slip events are not detected by seismometers. To date, SSEs have been detected by geodetic instruments at subduction zones, Kilauea and on the San Andreas fault.

Post-seismic slip events – Another type of crustal motion that is often observed following large tectonic earthquakes is due to afterslip, thought to arise from continued slip on the fault at slow speeds. Afterslip can in small part be explained by aftershocks but the majority of the slip occurs without producing seismic waves. Such slip can last years and produce as much total slip as the main earthquake itself. The afterslip events often decay in accordance with Omori's Law.

Mantle relaxation – Following large earthquakes, the redistribution of the stress in the crust and mantle can cause the mantle to flow in a viscous manner, which then produces a long-period deformation of the crust above. This signal can often be confused with post-seismic slip.

Induced earthquakes – Earthquakes are induced by the activities of humans that modify the stress at shallow depths in the Earth. Examples of such activities are mining, drilling, and water impoundment behind dams. Induced earthquakes tend to be of significant hazard because they are very shallow and close to infrastructures (see *Artificial Water Reservoir Triggered Earthquakes*).

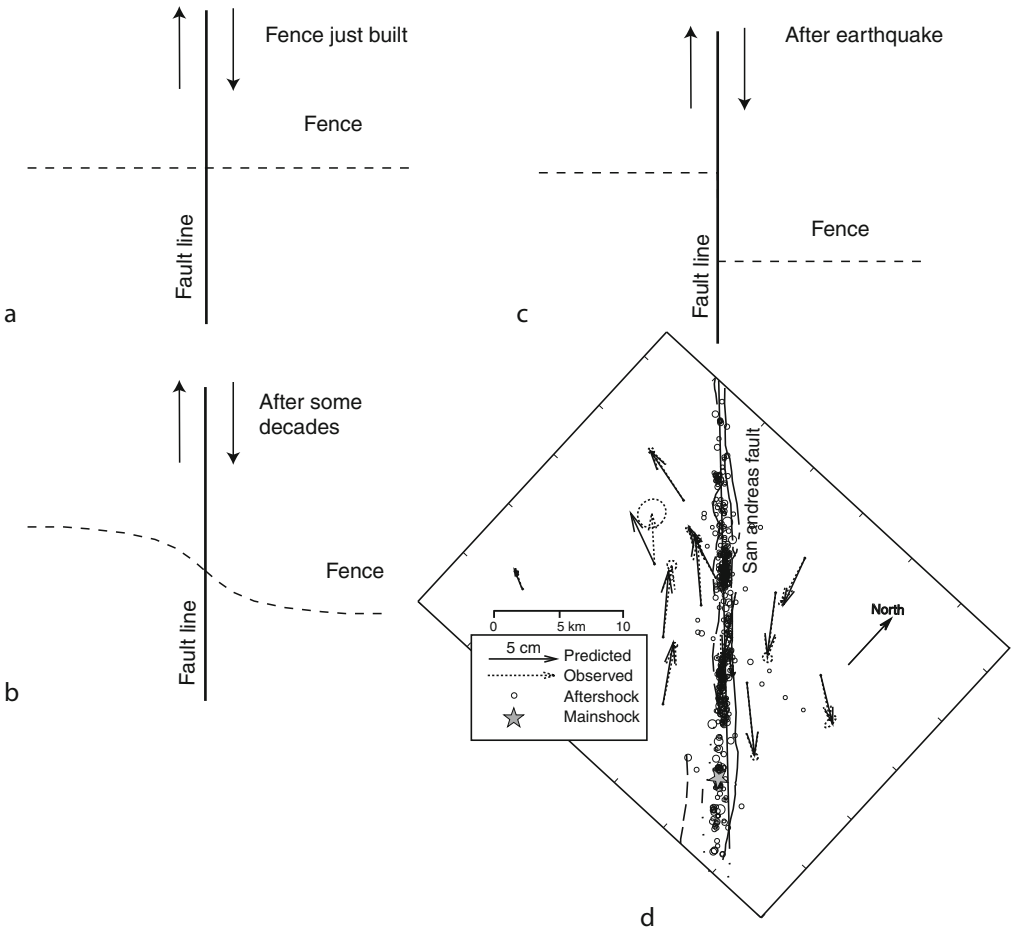
Fault morphology – Most deformation of the crust is accommodated by faulting. Crustal faults are the lasting expressions of past earthquakes and provide a means via geologic investigations to characterize the earthquakes. Compilations of estimates of slip rates and fault lengths are used to calculate long-term (Holocene, for example) deformation rates in continental regions.

Elastic rebound theory

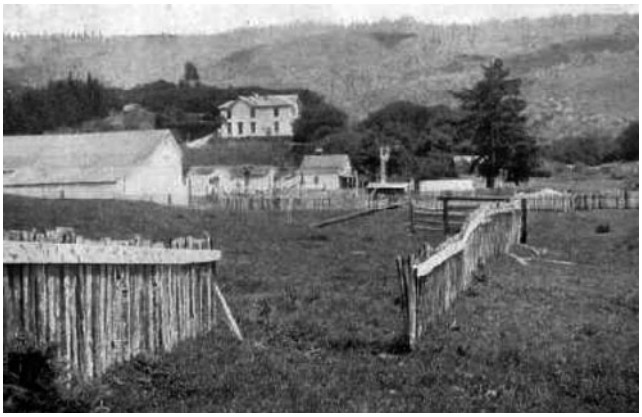
Large earthquakes, as noted above, are caused by slip on crustal faults and exhibit stages of strain build-up and release known as the earthquake cycle. A simple form of this cycle is elastic rebound. The concept of elastic

rebound as relating to the earthquake cycle was first introduced by Harry Reid (Reid, 1910) following earthquake observations in Sumatra and California. (See the interesting, in-depth description of the history of elastic rebound by Segall, 2010.) In this description, the crustal blocks adjacent to a fault are stuck together by friction on the fault surface and their relative movement causes strain in the blocks (Figure 2a and b). The material comprising the upper crust is thought to be linearly elastic, so the strain increases over time in a steady fashion as long as the blocks move at the same speed. At some point, the stress on the fault reaches its strength, and the fault slips suddenly in an earthquake (Figure 2c). The strain accumulated over decades to centuries is relieved in a matter of seconds. The slip on the fault causes the stored strain energy in the crust to be converted to kinetic energy which in turn is emitted as seismic waves and heat and the stress on the fault drops to a lower level. The use of the word "rebound" in this case refers to the idea that any feature on the surface, such as a fence crossing the fault, will return to its original shape (i.e., free of strain) after the earthquake (Figures 2 and 3). The earthquake in a broader sense produces permanent strain on a regional scale by displacing the crustal blocks along the fault (and offsetting the fence). Many observations of earthquake deformations have validated the elastic rebound model – the example of the 2004 Parkfield, California, earthquake rebound is shown in Figure 2d (Barbot et al., 2009).

We have discovered in the past few years that elastic rebound pertains not only to earthquakes of the type Reid observed, but also to earthquake afterslip (Heki et al., 1997) and so-called "slowslip events" (Dragert et al., 2001). In these phenomena, illustrated by GPS time series shown in Figure 4, slip on faults can occur at much slower rates than it does during earthquakes. In these time series showing the position of a point on the ground, the steady motion of the linear earthquake cycle is interrupted not only by earthquakes (abrupt offsets in Figure 4a) but also by afterslip that decays with time. In slowslip events, the linear site motion is interrupted for weeks to months



Earthquakes and Crustal Deformation, Figure 2 Illustration of the elastic rebound effect. The fence originally built in a *straight line* across the fault (**a**) is deformed by the strain around the fault in the period leading up to an earthquake (**b**). In (**c**) the earthquake has offset the fence but also straightened it again by the release of the strain. (**d**) Measured and modeled co-seismic offsets near Parkfield CA resulting from the 2004 M6 earthquake (Redrawn with permission from Barbot et al., 2009).



Earthquakes and Crustal Deformation, Figure 3 Picture taken in Marin County shows a fence that was offset about 10 ft along the trace of the San Andreas fault by the 1906 earthquake (Photo attributed to G.K. Gilbert; http://americahurrah.com/USGS/26.htm).

(Figure 4b) in Cascadia and New Zealand, for example. The spatial pattern of the slip and our knowledge of the rebound cycle guide our interpretation of these anomalous signals as slip on the fault surface.

The simple picture of elastic rebound theory is a good conceptual view of the earthquake cycle but in detail we see that it is much more complex. As more and better observations are made we see that the earthquake cycle includes time-dependent deformations on many time scales. These are discussed next.

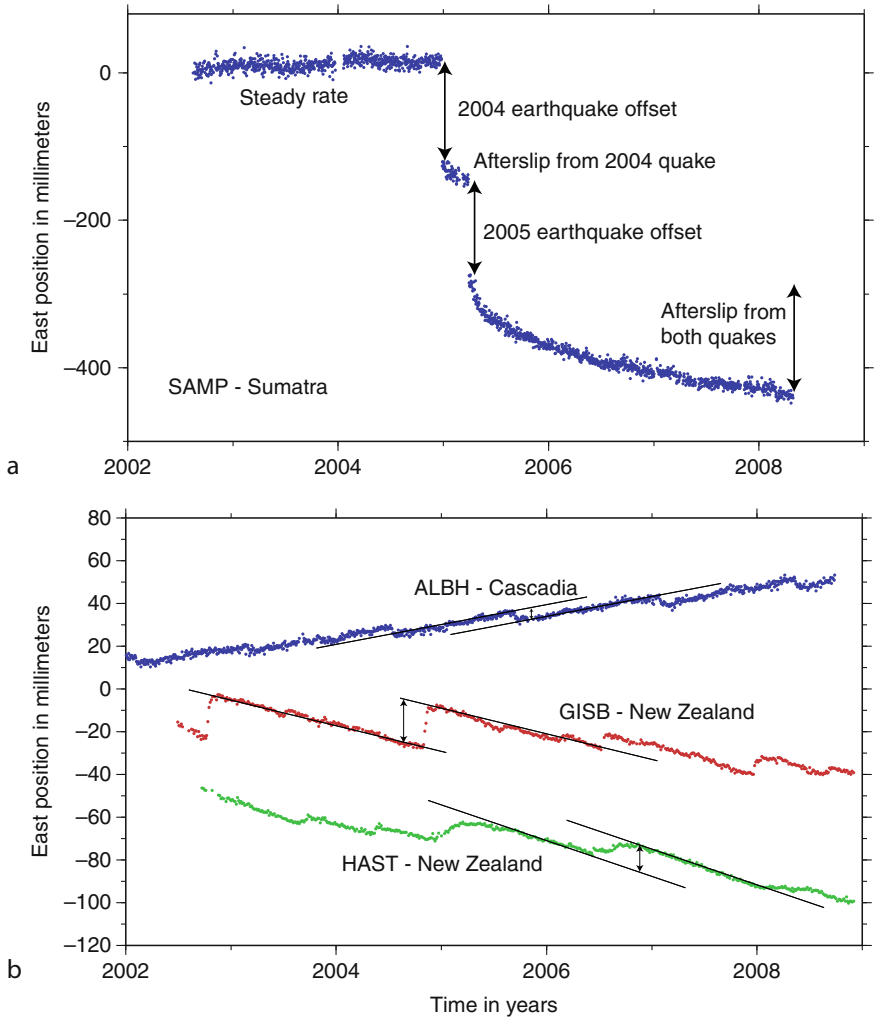
Pre-seismic crustal deformation

The deformation of the Earth's surface leading up to earthquakes has been of great interest to scientists for a long time due to the quest to identify precursors for prediction purposes. Such deformation can be grouped into long-term and short-term signals. For the long-term, the Earth deforms in the vicinity of faults largely in roughly the elastic rebound manner described above. Mapping out the temporal changes in crustal strain near faults is being used extensively to identify which parts of the fault are being loaded, or being subject to stress increases. In a simple sense, the parts of the fault being loaded may help delineate the future rupture region but the details are far from clear. For example, the current rate of loading of the Cascadia subduction thrust is inferred from the results of 15 years of GPS observations by McCaffrey et al. (2007) (Figure 5) and has the important implications for how close to populated regions the rupture may come during a large subduction earthquake. Such studies have been conducted for most subduction zones and continental transform faults globally and the relationship of such loading to seismic slip is just starting to be understood.

A now common approach to understanding the crustal deformation between earthquakes (also called the *interseismic* phase) is through the use of block models (Matsu'ura et al., 1986; McCaffrey, 2002; and many others). This method uses the idea that the crust or lithosphere is comprised of discrete entities (blocks) that are bounded on their lateral sides by other blocks and at their base by a stress-free region (asthenosphere). The lateral boundaries between the blocks are described by their frictional properties (i.e., a stuck fault). The blocks themselves rotate on the Earth's surface and so the motion can be described by an angular velocity (Euler pole) with its origin at the center of the Earth. Frictional interactions with adjacent blocks cause elastic strains to build in the blocks. Hence, new GPS observations contain information about both the angular velocities of the blocks (and slip rates of their bounding faults) and the frictional properties of the bounding faults. A recent example of this is the January 2010 M 7.0 Haiti earthquake – block modeling by Manaker et al. (2008) had shown that a M ~7.2 was possible for the Enriquillo Fault in Haiti (of course such modeling does not tell when such an event will occur).

Another approach to understanding crustal deformation is to assume that at some depth below the surface, the deformation field is continuous and that the surface faulting is only a vague reflection of that motion (England and McKenzie, 1982), in a similar fashion that floating ice blocks may show the general, but not specific, flow pattern of the water beneath. In this case, the surface faulting can be related to the continuous deformation field only in a statistical manner and the deformation field cannot be used to predict slip on unknown faults. On the other hand, the continuous deformation approach can be more readily related to the forces driving deformation through an assumption that the deformation is controlled by a viscous, rather than elastic, Earth. (The assumption of a viscous medium is required to relate our observations of deformation rates to forces.) For example, Jones et al. (1996) relate crustal deformation in the western USA to gravitational forces arising from spatial variations in crustal thickness acting on a viscous medium.

Short-term crustal deformation around faults leading up to earthquakes is much more elusive. To date there have been few or no convincing cases of isolated changes in deformation in the days to months prior to a large earthquake. Mogi (1985) shows evidence for accelerated uplift at tide gages in the 5 years preceding the 1983 Sea of Japan earthquake (see also Scholz, 2002). This evidence must be considered less certain than it was a few years ago before we knew of slowslip events. Although no SSEs have been observed in the past 10 years on modern GPS equipment in the vicinity of the 1983 earthquake, we cannot rule out that the pre-earthquake uplift was due to slowslip on the fault that subsequently ruptured (or some other fault) rather than a useful precursory change prior to the quake. (Because many SSEs have occurred without triggering tectonic earthquakes, we know that slowslip events are NOT short-term precursors to earthquakes.)

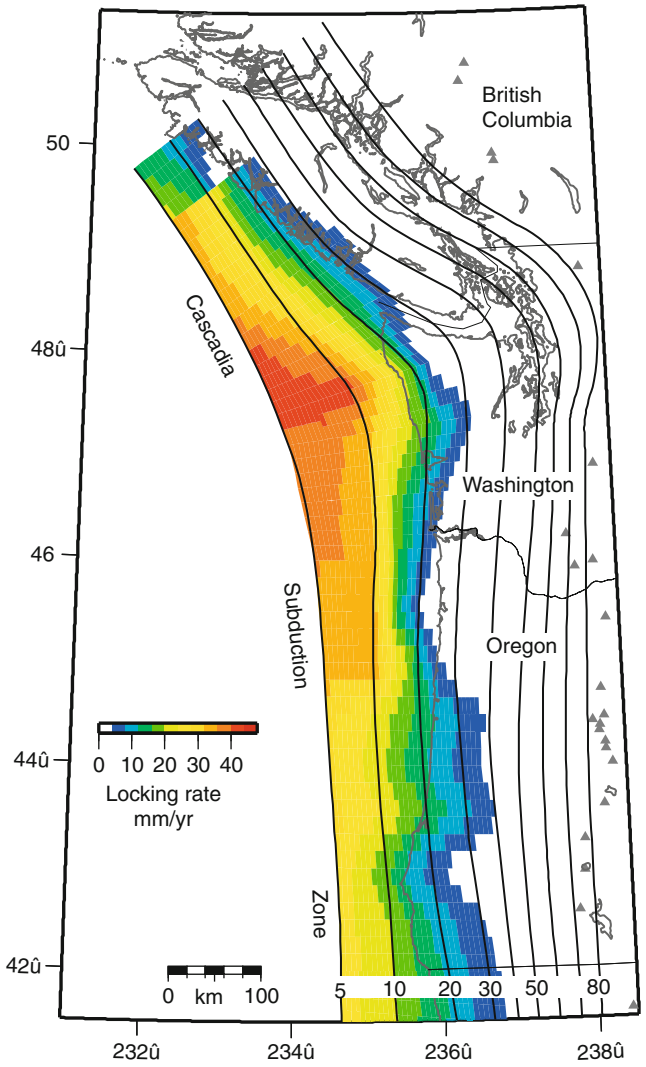


Earthquakes and Crustal Deformation, Figure 4 (**a**) The east position of continuous GPS site SAMP in northern Sumatra leading up to and following the December 2004 and March 2005 great earthquakes at the Sumatra subduction zone. The earthquakes each caused large sudden offsets of about 100 mm. The afterslip, which decays in a logarithmic fashion, produced over 100 mm of additional motion in the 3 years following the earthquakes. (**b**) GPS time series from Cascadia and New Zealand showing the geodetic signature of "slowslip" events. These events produce offsets of the time series but, unlike earthquakes, the offsets occur over weeks to months, rather than minutes. The *solid lines* show the linear trends (steady site velocities) between the slip events.

Co-seismic crustal deformation

The term co-seismic refers to the time right around the earthquake when the fault rupture is still propagating and seismic waves are being generated. Generally this amounts to a few seconds for a magnitude 6–7 earthquake and a minute or more for $M > 8$. The 2005 M9.3 Sumatra earthquake is thought to have ruptured for about 5 min – this is the time it takes to rupture such a long fault (∼1,300 km) at typical rupture speeds (∼ 3–4 km/s). Earthquakes generate both dynamic displacements, those that propagate but return to their original positions after the waves pass, and static displacements that are permanent. Seismometers can record the dynamic motions within their pass band but cannot measure the static displacement which requires geodetic instrumentation. Both the dynamic and static displacements induce stress changes in the crust and mantle that can lead to other forms of crustal deformation, such as triggered earthquakes, afterslip, slowslip and mantle relaxation. While GPS observations can measure the passing waves for very large earthquakes (as can seismographs), we are more concerned here with the static displacements.

The static displacements from a large earthquake provide much information on the faulting process and can be measured by comparing the position of ground points before and after the earthquake (Figure 2d). However, because the points are moving constantly due to tectonic plate motions and fault-induced elastic and anelastic strain, as discussed above, it is not always easy to know where the points were just prior to the earthquake.



Earthquakes and Crustal Deformation, Figure 5 Frictional loading of the Cascadia subduction zone inferred from crustal deformation of the coastal regions measured with 15 years of GPS observations (McCaffrey et al., 2007). The locking rate is the rate at which the subducting plate pushes the base of the overriding plate landward. This rate, integrated over time, provides an estimate, according to elastic rebound theory, of how much slip might occur in a large strain-relieving earthquake. Contours are of the depth to the plate boundary interface, in kilometers.

Consequently, in many active regions of the world, GPS data are collected continuously (called continuous GPS, or cGPS) which provide a direct measure of the pre-quake position. However, such observatories are expensive and generally not sufficiently dense to characterize the earthquake details when one happens. The geodetic characterizations of most earthquakes are now based on a combination of cGPS and survey-mode GPS, where measurements are made intermittently.

Simple physical representations of the Earth have been quite successful in characterizing the slip during large earthquakes based on the observed static displacements. (Seismic waves are also used to estimate the slip distributions of earthquakes – see *Earthquakes, Source Theory*). The most commonly used structure and source representation is the elastic, half-space dislocation (see Segall, 2010). The popularity of this method owes to the simplicity of the algorithm published by Okada (1992, 1995) for use in three dimensions and its success in reproducing the observations. More times than not, the geodetic and seismologic representations of an earthquake source agree within the levels of accuracy. In fact, when they do not agree, the blame is often placed on the complexity of the source rather than on the techniques.

Such studies of the distributions of slip on the fault during earthquakes have shown us just how complex the slip can be. It remains enigmatic why the earthquake slip distributions (fault unloading) are so much more heterogeneous that the loading distribution (as estimated from interseismic studies as discussed above). This is one of the challenges facing us if we want to use contemporary fault loading measurements to understand the real earthquake hazards.

Post-seismic crustal deformation

Unlike pre-seismic deformation, many striking examples of post-seismic deformation have been documented for large- and moderate-magnitude earthquakes. The mechanisms of this deformation are most likely either continued slowslip on the fault or adjustment of the viscous mantle or lower crust to the changes in stress brought about by the earthquake.

It has been known for a long time that large, shallow earthquakes produce aftershocks that decay with time (t) in a $1/t$ fashion. This aftershock decay was explained by the changes in friction on the fault as the slip rate decayed, known as Omori's Law. Continued slip on faults after large earthquakes sometimes shows a similar decay and this decay follows Omori's Law as well (though the total slip is many times greater than what can be explained by aftershocks alone). The first clear example of significant afterslip was for the 1994 Japan Trench earthquake observed by Heki et al. (1997) where the relatively aseismic afterslip exceeded the co-seismic slip magnitude in the year following the earthquake. The 2004 Parkfield earthquake was followed by aseismic afterslip that was about three times the co-seismic slip (Johanson et al., 2006).

We now describe the magnitude of an earthquake or any other slip event with the moment-magnitude scale. For a slip event on a fault, the moment M_o is defined as the average slip magnitude times the area of that slip times the rigidity modulus of the rocks around the fault, and the magnitude is $M_w = 2/3 \log(M_o) - 9.5$ (Hanks and Kanamori, 1979). Hence moment can be based on either seismic or geodetic measures of the slip and area and these

can be compared. By making such comparisons we now understand that aseismic afterslip (or slowslip) contributes as much or more to the total slip budget on some faults as do earthquakes. This discovery has positive implications for earthquake hazards in the sense that seismic events of a given size may be less frequent than previously estimated.

Observational advances and new discoveries

Our knowledge of the existence of the various types of earthquakes and their structures and our understanding of them rely on our ability to detect them and explain the observations. In the past 20 years, great advances in instrumentation have led directly to the detection of some new types of deformation sources. They, along with new analytical algorithms, have greatly advanced our understanding of earthquakes and crustal deformation. Here, we describe some of these new methods and the important discoveries that they have allowed.

Possibly the greatest advance in the past couple of decades has been in the use of remote sensing in earthquake and crustal deformation studies. These new methods include the Global Positioning System (GPS), Interferometric Synthetic Aperture Radar (InSAR), and Light Detection and Ranging (LIDAR). The first two of these allow us to measure displacements of the Earth's surface using information obtained from satellites orbiting the Earth. With repeated measurements we can watch the temporal variations in surface deformation with great accuracy. LIDAR is allowing unprecedented resolution of the topography of the Earth's surface beneath the biological layer and has delineated geologic structures (faults) in regions that are too remote or forest-covered to find otherwise.

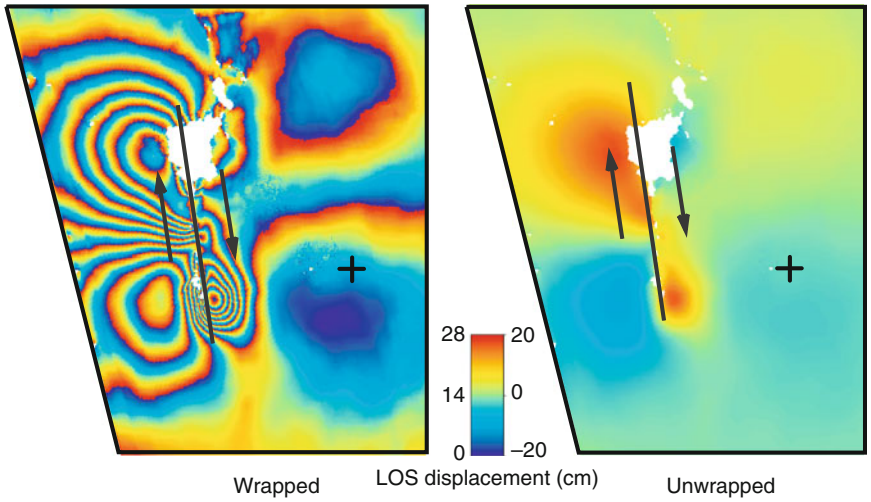
GPS, in particular when used in the differential mode, has resulted in the detection of the large, slow movements along faults – slowslip, post-seismic, afterslip, and mantle relaxation described above. Today, thousands of GPS instruments operate continuously at sites around the globe providing daily estimates of the site's three-dimensional position, which can be combined to form the equivalent of a displacement seismogram. The positional accuracy achieved for any given day is on the order of a few millimeters. The signal can also be sampled at a smaller time interval, such as seconds, to record the passing seismic waves in addition to the total static displacement produced by the earthquake. Such a resampling is possible only for very large earthquakes where the ground motions exceed a few millimeters. However, the greatest contribution of GPS has been in the discovery of crustal deformation sources that do not produce seismic waves.

The knowledge that fault movement could occur at rates somewhere between fast slip (km/s) and creep (mm/year) has been with us for years – such motions were observed on strain meters near the San Andreas fault in California (e.g., Linde et al., 1996). However, these slip events were very small compared to sizes of earthquakes on the fault. As described above, the observation by Heki et al. (1997) that post-seismic slip exceeded the slip during the earthquake itself was remarkable as it changed our ideas about how often earthquakes should occur on a given fault. In other words, we could no longer expect that the total slip on a fault in a given time period would be accompanied by earthquakes, an idea that held its roots in elastic rebound theory. Instead, some large portion of fault could slip without earthquake shaking.

As remarkable as that discovery was, in 1999 Dragert et al. (2001) recorded in the Western Canadia Deformation Array (continuous GPS network) a very slow deformation of the ground that looked just like a $M \sim 6.7$ earthquake, except that it occurred over 2 weeks time instead of just a few seconds. The maximum surface displacement was only 5 mm and at the time no seismic waves were detected. The slow surface deformation was interpreted by them to be due to slip on the Cascadia subduction fault directly beneath the GPS network. The slip on the fault was very slow, amounting to only 2 cm over the 2 weeks – this was 12 orders of magnitude slower than slip during a normal earthquake ($\sim$3 km/s).

Around the same time, Obara (2002) discovered the presence of low-level incoherent but intermittent seismic signals, called *tectonic tremor* above, coming from the subduction fault beneath Japan. Importantly, these signals appeared to originate on the fault just below the deepest slip extent from recent large earthquakes. Initial suggestions were that the tremor coincided in space and time with slowslip (Rogers and Dragert, 2003) but additional studies of both phenomena have not born that out. Further detailed studies of tectonic tremor requiring new seismological techniques revealed that it is likely in part due to numerous small thrust earthquakes of very low frequencies, called low-frequency earthquakes (LFE), on the subduction thrust boundary (Shelly et al., 2006). However, when they occur together, the total slip that can be accounted for with these small quakes is far less than what is seen in the slowslip events. Hence, it appears that the majority of the slowslip is indeed seismically silent.

While GPS provides a fine temporal sampling of the deformation, it is generally sparse in the spatial dimension because continuous GPS installations are expensive. The use of differential satellite interferometry (InSAR) has helped fill in the spatial gaps in pictures of the deformation of the Earth's surface by earthquakes and volcanoes. The InSAR method uses the interference patterns between two or more radar images of the ground that have been obtained from satellites. Comparing the images allows estimation of the displacement of the ground in the direction of the satellite (the LOS or line-of-sight component). The method relies on the ground surface changing at long wavelengths only, so that the images have strong correlation (coherence) and can be matched. InSAR provides a scalar observation of the deformation but at high spatial density (Figure 6) whereas GPS provides a vector of the deformation at high temporal sampling. Many studies use GPS and InSAR together to characterize the



Earthquakes and Crustal Deformation, Figure 6 Interferogram showing the ground deformation observed during the December 2003 M6.6 Bam, Iran, earthquake (http://neic.usgs.gov/neis/eq_depot/2003/eq_031226/). On *left*, the "wrapped" image shows line-of-sight (LOS) displacements by the phase of the difference in distance to the satellite; on the *right* the image has been "unwrapped," that is, converted to distance changes. In both cases the four-lobe displacement field of the strike-slip earthquake is evident. (Image with permission from Funning et al. [2005].)

deformation, taking advantage of the strengths of both types of observations.

The LIDAR method is extremely useful in detecting faults that intersect the ground surface. Because it uses shorter wavelengths than radar, it allows us to see finer features. Very often, faults produce only subtle lineations on the ground surface, which can now be detected at the sub-meter level. While LIDAR does not give details of the fault, like the slip rate, it can pinpoint targets for additional field study. An example of the utility of the LIDAR method is the delineation of the Seattle Fault in northwestern Washington state (Haugerud et al., 2003). This fault, which crosses the highly populated Puget Sound region, produced a large earthquake about 1,100 years ago. The fault scarp is large and obvious in some places but subtle and covered in forests in others.

The advance of the new geodetic techniques has had such a positive impact on geophysics that major organizational steps have been taken to utilize them. The consortium of universities called UNAVCO (University Navstar Consortium; unavco.org) was developed to support the global research community in the use of geodetic tools. In several countries, permanent dense geodetic networks and similar consortia have been established to monitor earthquakes and their associated phenomena.

Perspectives

Our ideas about earthquakes sensu strictu have undergone drastic changes in the past few years. Elastic rebound theory, while still a sensible conceptual model, does not cover the large range of observed phenomena that make up the earthquake cycle. A clear challenge that still faces us is to tie together the various deformation processes we observe throughout the cycle into a comprehensive earthquake theory. Some of the more important goals are to understand the observations we make in terms of future earthquake risk. For example, although we can measure current loading of faults quite well by its elastic strain near the fault, we do not know what it means for the slip distribution in future events. Geodetic methods of measuring crustal deformation have a short history relative to the times between large earthquakes, so geologic methods including paleoseismology (see *Paleoseismology*) and LIDAR that extend the observation history are crucial. Continued study and understanding of the aseismic slip events and tectonic tremor on faults may pay big dividends toward delineating the parts of the faults that are prone to seismic slip during large destructive earthquakes. The acquisition of deformation data at high resolution in both time and space will assist greatly in understanding processes operating at depth within the Earth.

EARTHQUAKES, EARLY AND STRONG MOTION WARNING

Richard M. Allen
Berkeley Seismological Laboratory, Department of Earth and Planetary Science, University of California, Berkeley, CA, USA

Synopsis

Strong motion earthquake warning (also known as earthquake early warning) is the rapid detection of an earthquake underway, the estimation of the ground shaking likely to result, and the issuance of an alert to people in the region where the ground shaking is likely to be hazardous. The last decade has seen rapid development of methodologies for early warning, which include the use of strong motion observations close to the epicenter to provide warnings at greater distances, the use of P-wave observations across a network to locate the event and map the distribution of likely strong ground motion, and the use of a P-wave detection at a single station to estimate the likely shaking intensity at the same station. These approaches have been listed in the order of increasing warning time, but the additional warning time comes at the expense of certainty. The earlier a warning is provided the greater the likelihood of false and missed alarms and the greater the uncertainty in the estimated shaking intensity. Typical warning times range from a few seconds to tens of seconds; the upper limit is about 1 min. Identified applications include personal protective measures where individuals move to a safe-zone within a few feet; automated mechanical response including stopping trains and isolating sensitive and hazardous machinery and chemicals; and situation awareness by large organizations that can help prevent cascading failures and be available before shaking disrupts communications. Large-scale public warning systems are currently operational in

Mexico and Japan, and smaller systems are used in Romania, Turkey, and Taiwan. Testing is underway by seismic networks in many other countries; however, implementation will require significant financial, political, and sociological hurdles to be crossed.

Introduction

Strong motion earthquake warning, more commonly referred to as earthquake early warning (EEW), is the rapid detection of an earthquake underway, estimation of the intensity of ground shaking likely to result, and issuance of a warning in the area likely to experience damaging strong motion. It provides high-probability warnings of shaking likely to occur within seconds to tens of seconds. The ability to provide warnings is relatively new and due to recent scientific development of methodologies to rapidly estimate the size of earthquakes underway, coupled with modern engineering of rapid communications to collect seismic data and distribute warnings, and a political will to operate state-of-the-art geophysical networks for the purpose of both scientific discovery and societal benefit.

EEW is one of three categories of earthquake warnings. Long-term warnings provide relatively low probabilities of earthquakes over long time periods, typically decades, and are usually referred to as earthquake forecasts. On these long timescales, earthquake likelihood can be estimated based on historic earthquake recurrence intervals and plate motion rates, linked together with deformation models incorporating fault geometries. For example, the probability of an $M > 6.7$ earthquake on the Hayward-Rodgers Creek fault that crosses the UC Berkeley campus is estimated to be 31% over 30 years (Working Group on California Earthquake Probabilities, 2007). These forecasts are also translated into estimates of ground shaking intensity that can be used to define building codes designed to prevent new buildings from collapse in the forecast of earthquakes.

The other end-member is earthquake prediction. The term prediction usually means a high probability of a large, damaging earthquake over a short time interval. For example, predicting an $M > 7$ earthquake on the Hayward Fault next week (Allen, 1976). Earthquake prediction is currently not possible, as we have not been able to identify a precursory signal that consistently occurs before earthquakes, and most seismologists agree that prediction will not be possible in the near future. EEW is intermediary in that it is possible to provide warning before shaking is felt, however, the warnings are only a few seconds to tens of seconds.

Uses of early warning

Uses of EEW that have been identified to date fall into three broad categories (Allen et al., 2009d): personal protection, automated mechanical actions, and situation awareness. The first use that people think about when introduced to early warning is personal protection. For most people, given that there will only be a few to a few tens of seconds of warning, the appropriate action is to move to a "safe-zone" within a few meters of your current location – under a sturdy table, away from falling hazards including windows, bookshelves, etc. These safe-zones need to be identified ahead of time in the locations that people spend most of their time, that is, in their homes and offices or workplaces. In most cases there is not sufficient time to evacuate buildings, and EEW is no substitute for building standards that prevent building collapse. It currently takes schoolchildren in Japan and Mexico ~5 s to get under their desks in response to audible warnings. Outdoors, people should move away from buildings, masonry walls, and other falling hazards including broken glass, street signs, etc. In hazardous work sites including construction sites, manufacturing and chemical facilities, the same principle applies: move to predefined safe-zones.

The second category is automated mechanical control. Within the transportation sector, implemented warning systems are currently used to slow and stop trains, stop airplanes from landing by issuing a go-around command, and to bring traffic to a halt. They could also be used to turn metering or tollbooth lights to red at the entrance to vulnerable road bridges, tunnels, and overpasses. Within buildings, warnings are now used to stop elevators at the next floor and open the doors, open emergency exit doors and window blinds, and turn on lights. Industrial facilities use the warning to place machinery or product into a safe mode. For example, a chip manufacturer in Japan places sensitive micro-robots into a hold mode to reduce damage, and isolates hazardous chemical systems to minimize any resulting leaks. In Japan, engineers are also experimenting with using warnings within automated structural control systems that change the mechanical properties of the building to better withstand the expected shaking. This is an area where there are a myriad of possible applications, most of which are very specific to individual users.

Finally, situation awareness is very important to organizations with responsibilities for large infrastructures and/or people. These include government agencies, utility, and transportation companies. While these groups may take early warning actions, they also have a need to rapidly understand why part or all of their system is failing. For example, an electrical power grid may start to fail in one area, and operators need to rapidly understand why it is failing in order to reduce cascading failures throughout the system. EEW can provide this information more rapidly than any of the existing post-earthquake information systems. EEW also has the advantage that much of the data needed to map out the likely shaking is collected before significant shaking has occurred. This means that the information can be transmitted across data-networks and out to users before strong shaking has the opportunity to disrupt communications.

One of the main concerns expressed in response to the early warning concept is panic: will people panic when they receive the warning and injure themselves or others as a result. Social scientists have long studied this issue

and find that it is not the source of concern that many seismologists think it is (Quarantelli, 1956; Goltz, 2002). The experience that we now have from public warnings in Mexico and Japan provides no evidence that warnings result in panic (Espinosa Aranda et al., 2009; Kamigaichi et al., 2009). There is no evidence for traffic accidents resulting from warnings and no evidence of public stampedes. Implementation of EEW does require an educational campaign to educate people about what EEW can do and help them identify the appropriate actions in their locations (Kamigaichi et al., 2009).

Approaches to early warning

All EEW methodologies must use just a few seconds of data to detect an earthquake underway and rapidly assess its intensity. There is generally a trade-off between the amount of warning time and the accuracy or certainty of the warnings. Greater certainty requires more data from one or more stations, but waiting for that data reduces the warning time. The challenge when building an early warning system is to determine whether additional accuracy is worth the increasing delay.

Strong-motion-based warning. The first warning methodologies used this approach. When strong ground shaking is observed at one location, close to the earthquake epicenter, the shaking intensity at greater distances can be estimated using ground motion prediction equations and a warning transmitted ahead of the ground shaking. This approach is called front detection and is used in Mexico City where the earthquake source zone is ~300 km from the city. Figure 1 shows the time at which peak ground shaking was observed at all available stations recording nine $M \geq 6$ earthquakes. A strong-motion-based warning would be possible at some point between 10 s and 20 s after the origin time for these events, depending on the proximity of the closest station(s). By 20 s, the onset of strong shaking is ~60 km from the epicenter meaning that warnings based on peak-shaking observations near the epicenter are only available at distances greater than ~60 km. The region within ~60 km of the epicenter would get no warning and is referred to as the "blind zone."

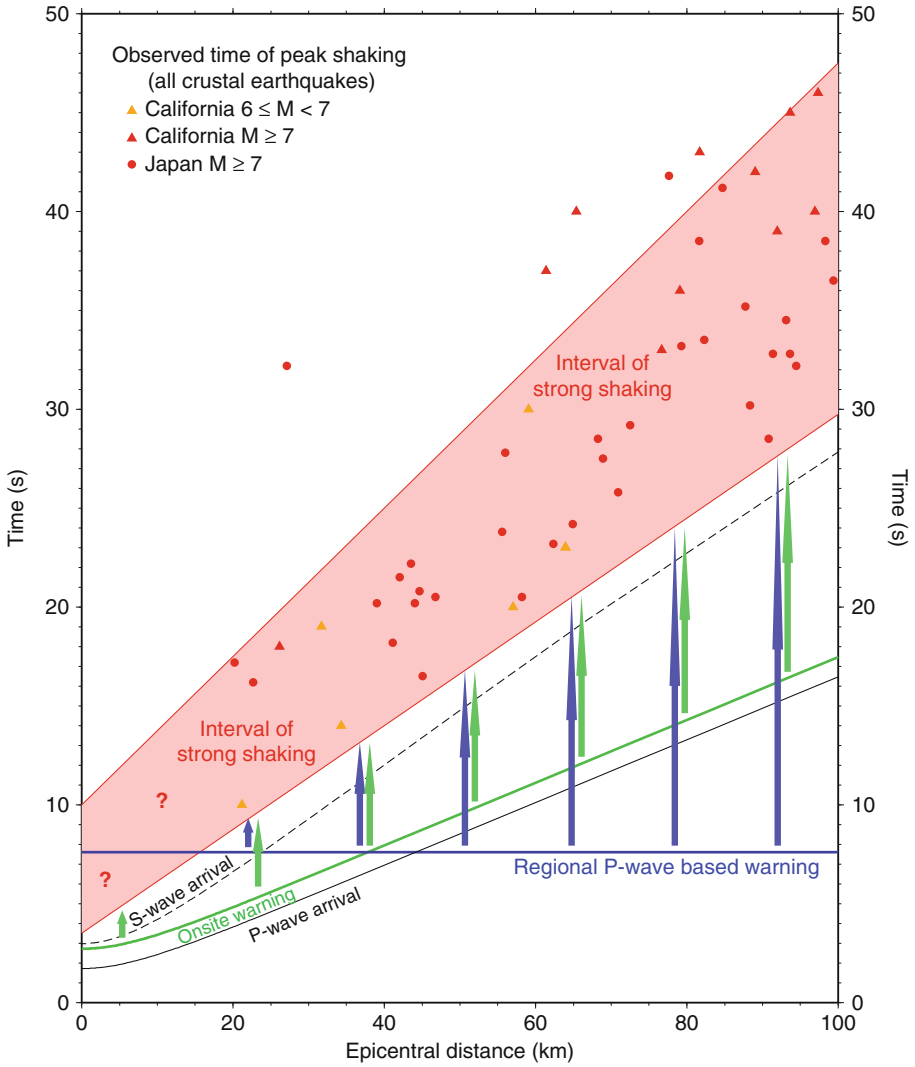
P-wave based warning. To reduce the size of the blind zone, P-wave based methodologies are used. These approaches use a few seconds of the P-wave to estimate either the magnitude or the peak-shaking amplitude. In order to estimate the magnitude, a variety of parameters have been developed that are measures of the frequency content (Nakamura, 1988; Allen and Kanamori, 2003; Kanamori, 2005) or the amplitude (Kamigaichi, 2004; Wu and Kanamori, 2005b; Zollo et al., 2006; Cua and Heaton, 2007; Wurman et al., 2007; Böse et al., 2008; Wu and Kanamori, 2008b; Köhler et al., 2009). In order to estimate magnitude, amplitude-based parameters need to be corrected for epicentral distance. However, the frequency-based parameters have been found to be insensitive to epicentral distance provided the observations are made within ~100 km of the epicenter. For all of these parameters empirical scaling relations between the observation and earthquake magnitude have been developed so that magnitude (plus or minus some uncertainty) can be estimated from an observation at one or more stations.

Regional warning. When a regional network is available, P-wave based estimates of magnitude can be combined with an estimate of the earthquake location to then map the distribution of strong ground motion using ground motion prediction equations. In their simplest form these maps are a "bulls-eye" centered on the epicenter. Corrections can also be made for site amplification effects. Examples of this approach include ElarmS (Allen, 2007; Wurman et al., 2007; Allen et al., 2009a; Brown et al., 2009), Presto (Zollo et al., 2009), the Virtual Seismologist (Cua and Heaton, 2007; Cua et al., 2009), and the NIED approach in Japan (Horiuchi et al., 2005).

When using a regional network, P-wave observations at multiple stations can be combined in order to verify that an earthquake is underway and improve the accuracy of the magnitude estimate. Generally, the more stations used, the better the accuracy of the warnings and the fewer false alarms. The time at which a warning is available therefore depends on the number of station detections required and the number of seconds of P-wave data required at each station. Figure 1 illustrates the amount of warning time available using this approach. The horizontal blue line at 7.6 s represents the time at which a warning is available for a particular scenario (Figure 1). In this case, the size of the blind zone is ~15 km and the amount of warning time increases linearly with distance beyond 15 km. There would be ~9 s warning at 50 km and ~22 s warning at 100 km.

Onsite warning. Onsite warning provides the most rapid approach to earthquake warning by removing the need for communications. The delay in issuing a warning is minimized by using a seismic station at the location where the warning is needed. Onsite methodologies are intended to estimate the intensity of ground shaking at the same location that the P-wave is detected (Odaka et al., 2003; Wu and Kanamori, 2005a, b; Nakamura and Saita, 2007a, b; Wu et al., 2007; Wu and Kanamori, 2008a, b; Böse et al., 2009a, b). The challenge with onsite warning is to provide enough accuracy that the warnings are useful. The character of P-wave arrivals is variable at different locations for the same earthquake due to variability in source radiation and also local site effects. Using a single station (or several stations within a few hundred meters) does not allow for averaging of this variability as in the case of regional methodologies. However, the onsite approach is faster.

Figure 1 illustrates the best-case scenario for onsite warning in which the warning is available using 1 s of P-wave data and the earthquake is at a sufficient depth that there is more than 1 s between the P-wave arrival and the onset of peak shaking at the epicenter. This means that there is no blind zone and a warning is available at the epicenter. The warning time increases with distance as the



Earthquakes, Early and Strong Motion Warning, Figure 1 Plot showing the time of observed peak shaking for large magnitude events and illustrating the time at which warnings could be available using various methods. The time of peak shaking was determined for all available stations in nine M $\geq$ 6 earthquakes from California (triangles, magnitudes 6.0, 6.5, 6.7, 7.1, 7.1, and 7.5) and Japan (circles, magnitudes 7.0, 7.1, and 7.3) and is plotted as a function of epicentral distance. All events are crustal earthquakes with epicentral depths of 21 km or less. The *red* shaded region illustrates the approximate interval of strong shaking when most of the peak-shaking observations are made. Note that there are few observations close to the epicenter due to the stations spacing of networks in California and Japan. The P-wave (*solid black line*) and S-wave (*dashed black line*) arrival times for a 10 km depth earthquake are also shown. The *blue line* and *arrows* illustrate available warning times for a regional P-wave based warning system. The horizontal line is the time at which a warning is available. It assumes that the required number of stations for a warning have detected a P-wave once the P-wave front reaches 25 km (at 4.6 s), that 1 s of P-wave is required to estimate magnitude (available at 5.6 s), and that an additional 2 s is needed for communications. The purpose-built seismic network in Japan provides data to the network centers within 1 s, and we assume that an additional 1 s is required to get the warning out to users. This means that the warning reaches users at 7.6 s after the origin time. The onset of strong shaking has reached ~15 km from the epicenter at this time. The available warning time increases linearly (shown by *blue arrows*) from 0 s at 15 km to ~22 s at 100 km. The *green line* and *arrows* illustrate the available warning time using the onsite P-wave based warning approach. It is assumes that 1 s of P-wave data is needed and the time of warning (*green line*) is therefore 1 s after the P-wave arrival. As shown, it is possible to provide a warning at the epicenter if the earthquake is more than ~10 km deep meaning there could be no blind zone. The warning time then increases with distance as the time between the P-wave arrival and peak shaking increases. Warning times (*green arrows*) range from ~2 s at 10 km to ~12 s at 100 km.

time-separation of the P-wave and peak shaking increases. Typical warning times are ~2 s at 10 km, ~7 s at 50 km, and ~12 s at 100 km. The onsite approach provides the most warning close to the epicenter. However, for locations at greater distances, regional warning provides more warning time that onsite warning as alerts are transmitted electronically ahead of ground motion. In the scenarios shown in Figure 1, the crossover when the regional method provides more warning than onsite is at ~35 km.

Implementations of early warning

There are currently two large-scale implementations of early warning in Mexico and Japan (Figure 2). The first public system started to provide warnings to Mexico City in 1993. It was built following the 1985 M8.1 earthquake that killed 10,000 people in the city. The system uses a line of seismometers deployed near the coastline to detect offshore earthquakes and transmit the warning 300 km to the city ahead of strong shaking (Espinosa Aranda et al., 1995). The offset between the source region and the city allows the use of a front detection approach and still provides more than 60 s of warning time. These warnings are broadcast by 58 radio stations and 6 TV channels in the city. There are also more than 250 users who receive the warning through dedicated radio links including schools and universities, emergency and civil protection agencies, government buildings, and the subway system.

Japan Railways first began to experiment with early warning in the 1960s. These systems became increasingly sophisticated including the first P-wave based application of UrEDAS in the 1980s (Nakamura, 1988). With the growth of computerized communication systems in the 1990s automated remote sensing of earthquakes expanded. Following the 1995 Kobe earthquake that killed 6,000 people, Japan installed dense seismic networks across the entire country (Okada et al., 2004). This network led to the development and implementation of a nationwide regional warning system that became operational in 2007 and is operated by the Japan Meteorological Agency (JMA). These warnings are now broadcast by the majority of TV and radio stations in Japan, through the government operated J-Alert system that issues warnings to municipalities (many of which relay the warning to loudspeaker systems in public spaces), by cell phone companies, and by a myriad of private providers and purpose-built consumer devices (Kamigaichi et al., 2009). The various Japanese systems use both onsite and regional warning systems. In the 2004 M_w7.2 Niigata earthquake the emergency brakes of one of the bullet trains were triggered by the onsite UrEDAS system (Nakamura and Saita, 2007a), and the regional warning system operated by JMA has issued warnings for multiple earthquakes including the 2008 M_w7.2 Iwate-Miyagi Nairiku earthquake (Kamigaichi et al., 2009).

Smaller scale and user-specific warning systems have also been implemented in various locations around the world. In Bucharest, warnings are provided to a nuclear research facility (Ionescu et al., 2007). Istanbul has warning systems for a power plant and a large banking building, and a more general use warning system has also been implemented in the last few years using a new strong motion network (Alcik et al., 2009). In Taipei, a test warning system provided warnings to the rail system, the university, and a hospital (Wu and Teng, 2002). Finally, in the US, a temporary warning system was implemented following the 1989 Loma Prieta earthquake (Bakun et al., 1994).

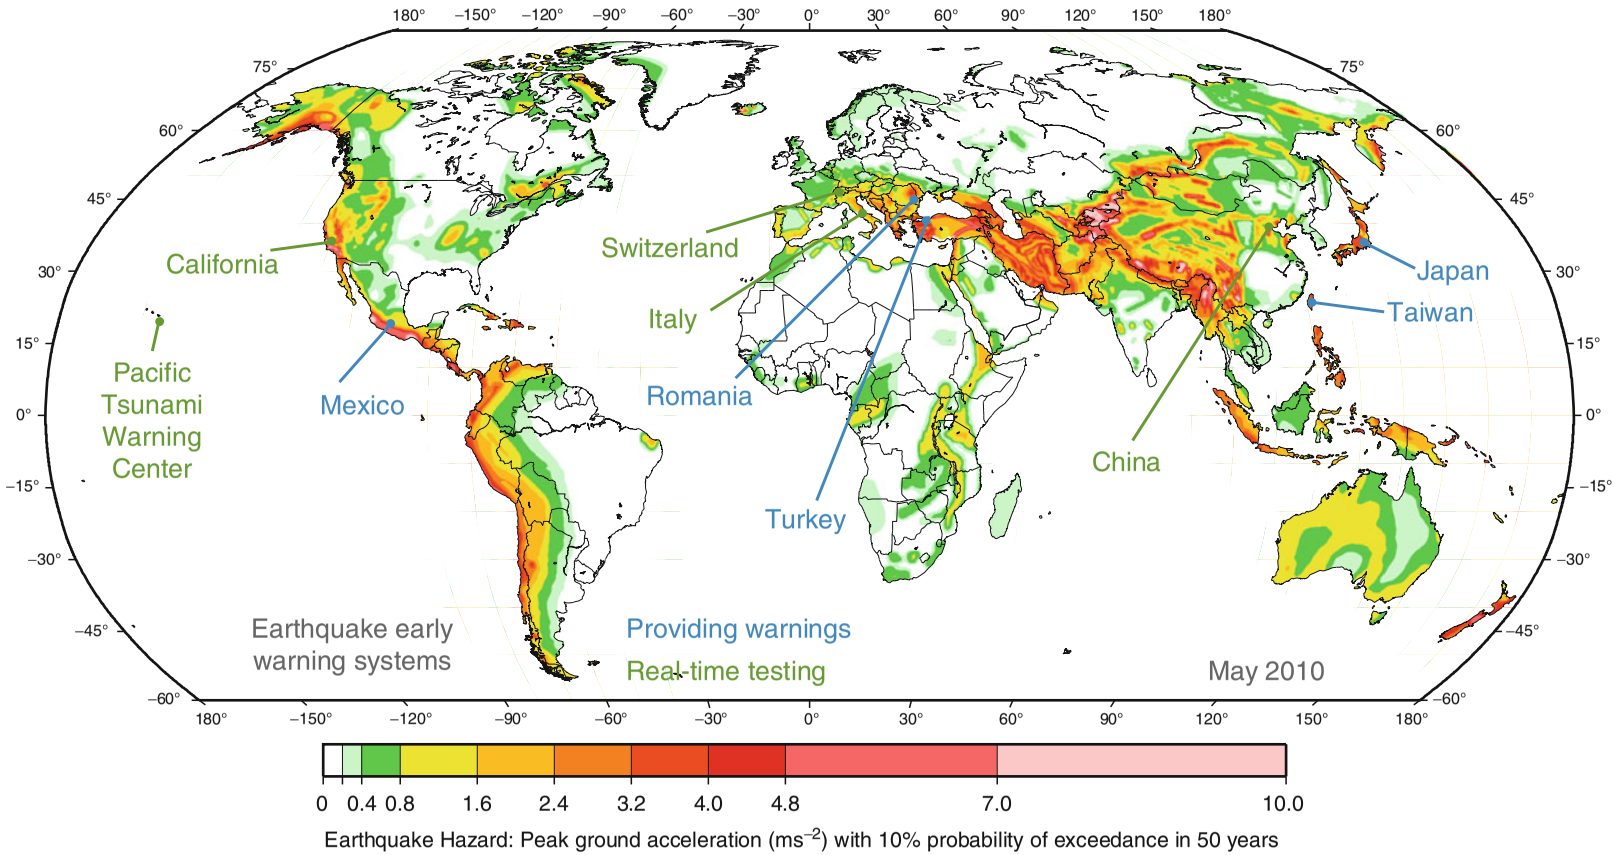
Testing of early warning methodologies is now underway on an increasing number of regional seismic networks around the world. This includes networks in California, China, Italy, at the Pacific Tsunami Warning Center, and in Switzerland (Figure 2). In many of these cases the technical feasibility of providing warnings has been demonstrated. Whether these test systems will transition to implementation of public warning systems will therefore be largely determined by financial, political, and sociological factors.

Summary

The last decade has seen rapid development of earthquake early warning methodologies (e.g., Gasparini et al., 2007; Allen et al., 2009b, c) by multiple research groups around the world. A range of methodologies has been developed that generate warnings based on observations of strong shaking near the epicenter, estimation of shaking hazard maps using P-wave detections across a network, and single-station detections of P-waves to estimate hazard at the same location. Warning times typically range from a few seconds to tens of seconds with an upper limit of around 1 min. With all these methodologies there is a trade-off between the accuracy of the warning and the amount of warning time. The challenge is to identify the optimal threshold at which to provide a warning.

There are now several implementations of public warning systems around the world, most notably in Mexico and Japan. These provide insight to the potential uses of earthquake alerts, which fall into three categories. Personal protection is about actions of individuals to protect themselves. For individuals it is important to identify "safe-zones" at home and work. These are spaces that are reachable within a few seconds where they will be protected from falling hazards. Automated mechanical control can be used to further reduce the impacts of earthquakes. This category includes slowing trains, opening elevators at the nearest floor, and isolating sensitive or hazardous machinery or chemicals. Finally, early warning can provide situational awareness information to large organizations that may be used to limit cascading failures and initiate response. This information could be available before much of the shaking, and therefore increases the likelihood that the information can be transmitted before communications are lost.

While 5 years ago there were many technical questions about the feasibility of earthquake early warning, today the primary hurdles to implementation are financial,



Earthquakes, Early and Strong Motion Warning, Figure 2 Map of seismic hazard around the world (*pink* represents the greatest hazard) showing regions where earthquake early warnings are currently being provided (*blue* labels) and the regions where real-time testing on existing seismic networks is underway (*green* labels) (after Giardini, 1999).

political, and sociological. The existing public warning systems in Mexico and Japan were built following major destructive earthquakes. The challenge for the hazard mitigation communities in other countries is to generate the necessary will to implement these systems before the next earthquake.

Definition and calculation

During the earthquake process, the strain energy W available for rupture is divided into fracture energy E_G, thermal energy E_H, and radiated seismic energy E_S. The stress conditions around the fault and the rheological and elastic characteristics of the Earth materials being ruptured determine the partitioning of the overall energy budget involved in the earthquake source process. In particular, E_G and E_H are the energies dissipated mechanically and as frictional heat during faulting, respectively, and E_S is the energy fraction that goes into elastic seismic waves energy. The latter being of great importance for seismologists in evaluating an earthquake's shaking potential, in the following the relationship between the strain energy and radiated seismic energy is outlined.

After Knopoff (1958), the change in strain energy before and after an earthquake can be obtained from:

$$\Delta W = S\bar{D}\bar{\sigma}, \tag{1}$$

where S = fault area, $\bar{D}$ = average displacement over the fault, and $\bar{\sigma} = (\sigma_0 + \sigma_1)/2$ is the mean stress (with σ_0 being the initial stress and σ_1 the final one). This energy represents the total work associated to the earthquake rupture process. The small energy fraction converted to E_S is (e.g., Wyss and Molnar, 1972):

$$E_S = \frac{1}{2}\left(\sigma_0 + \sigma_1 - 2\sigma_f\right) \cdot S\bar{D}, \tag{2}$$

where σ_f is the average frictional stress during faulting. It is also useful to relate E_S and ΔW via the radiation efficiency $\eta_R = E_S/(E_S + E_G)$ (see, e.g., Wyss, 1970; Husseini, 1977):

$$E_S = \eta_R \Delta W. \tag{3}$$

The radiation efficiency η_R, spanning between 0 and 1, expresses the amount of work dissipated mechanically, therefore if an earthquake is effective in radiating E_S then η_R approaches 1 (that is to say about all the energy budget is converted into the seismic waves energy), whereas if η_R is very small or = 0 then the energy is dissipated and no E_S is radiated.

Assuming that the final stress σ_1 and the frictional stress σ_f are identical (that is to say the stress drop $\Delta\sigma = \sigma_0 - \sigma_1$ is complete, Orowan, 1960), it has been shown by Kanamori (1977) that a measure of ΔW can be obtained considering another important physical parameter of the seismic source, that is the seismic moment M_0:

$$\Delta W = \left(\frac{\Delta\sigma}{2\mu}\right) M_0, \tag{4}$$

with $M_0 = \mu S\bar{D}$ (where μ = rigidity of the medium in the source area). M_0 is a measure of the overall static displacement caused by the fault rupture. It is a well determined seismological parameter (normally within a factor of 2) since it must be calculated from long and/or very long periods (usually >100 s for large earthquakes) of the recorded seismograms (Dziewonski et al., 1981), which are less affected than the short periods by the small-scale Earth heterogeneities along the path from the source to the receivers.

By assuming that the stress drop is complete and nearly constant (between some 20 and 60 bars = $2–6\cdot10^7$ dyn/cm^2 = 2–6 MPa) for very large earthquakes and that $\mu = 3–6\cdot10^{11}$ dyn/cm^2 = $3–6\cdot10^4$ MPa in the source area under average crust-upper mantle conditions, Kanamori (1977) showed that the ratio

$$E_S/M_0 = 5 \times 10^{-5} = \text{constant}. \tag{5}$$

Therefore, under these conditions (adopted also for introducing the moment magnitude *Mw*, see *Earthquake, Magnitude*), one could easily have an indirect estimation of E_S from known M_0.

However, M_0 and E_S are two distinct physical parameters. Indeed, M_0 is a static parameter that is not sensible to the details of the rupture history and does not bring any direct information about the frequency content radiated by the seismic source, whereas E_S depends on the dynamic characteristics of the seismic source and, being related to velocity, it is more important than M_0 for evaluating the earthquake damage potential over frequencies of

engineering interest (between about 0.1 and 10 Hz). Therefore, direct and independent measurements of E_S are fundamentals in seismic source studies, also considering that many authors pointed out how the assumption of constant stress drop may not be fulfilled (see, e.g., Purcaru and Berckhemer, 1978). Indeed, E_S is sensible to the stress conditions during the fault rupture, as shown by the following formulation (e.g., Rudnicki and Freund, 1981):

$$E_S = \int_{-\infty}^{\infty} \int_S \left[-\sigma_{ij}\ \gamma_j\ \dot{u}_i\right] dS dt, \tag{6}$$

where $\dot{u}_i$ = particle velocity, σ_{ij} = stress change associated with the fault displacement u_i, γ_j = unit vector normal to the surface S and pointing outward from the source, and t = time. This definition holds in the far field, that is, the radius of the surface S is much larger than the dimension of the earthquake source. It can be shown that Equation 6 is equivalent to another one often used in seismology and proposed by Haskell (1964):

$$E_S = \int_{-\infty}^{\infty} \int_S \rho\left[\alpha\, \dot{u}_\alpha{}^2 + \beta\, \dot{u}_\beta{}^2\right] dS dt, \tag{7}$$

where ρ = density, α and β = P- and S-wave velocities in the medium, $\dot{u}_\alpha$ and $\dot{u}_\beta$ = far-field velocity records of P- and S-waves, respectively. Thus, it would be straightforward to compute E_S by analyzing the recorded waveforms. However, with respect to the determination of M_0, for computing E_S it must be considered not only the low-frequency part but especially the high-frequency content of the seismograms, which is more sensible to the fine heterogeneities of the Earth structure. Since the seismic recordings must be corrected for the energy loss due to the geometrical spreading and anelastic attenuation of body waves during their travel from the seismic source to the receivers (see *Propagation of Elastic Waves: Fundamentals*), it follows that the computation of E_S is more difficult and less stable than M_0. However, thanks to the worldwide deployment of high-quality digital broadband seismic station networks in the past few decades, much progress has been done and the calculation of E_S has started on a routine basis. Here a brief description of some techniques to calculate E_S is reported.

Since the correction for the high frequencies (above 1–2 Hz) is difficult to perform, many approaches to compute E_S use teleseismic recordings (usually between 30° and 90° epicentral distance Δ, although some procedure for rapid response purposes uses also recordings down to 20° or 25°, see Newmann and Okal, 1998; Di Giacomo et al., 2010a) for global earthquakes (magnitude above ~5) so that the effects of the Earth filter can be reasonably modeled by assuming an average 1-D layered structure. Moreover, since the P-waves are less affected by attenuation than S-waves, for which the correction for propagation effects at frequencies $f > 0.5$ Hz may be difficult on a routine basis, the analysis is often performed (1) by considering the P-wave train of the seismograms and (2) in the frequency domain by exploiting the Parseval's identity:

$$\int_{-\infty}^{\infty} |\hat{s}(\omega)|^2 d\omega = 2\pi \int_{-\infty}^{\infty} |s(t)|^2 dt, \tag{8}$$

where $\hat{s}(\omega)$ is the Fourier transform of the time signal $s(t)$ and $\omega = 2\pi f$ the angular frequency.

Currently E_S determinations at the USGS are obtained from the approach proposed by Boatwright and Choy (1986) and are available at the SOPAR database (http://neic.usgs.gov/neis/sopar/). This method calculates the energy flux ε^* from the velocity spectrum of P-waves $|\dot{u}(\omega)|$ as:

$$\varepsilon^* = \frac{\rho\alpha}{\pi} \int_0^{\infty} |\dot{u}(\omega)|^2 e^{\left(\omega t_\alpha^*(\omega)\right)} d\omega, \tag{9}$$

where the symbol * indicates that the energy flux is corrected for anelastic attenuation by the function $t_\alpha^*(\omega)$ (Choy and Cormier, 1986). Then, the computation of the average E_S is obtained from:

$$E_S = 4\pi \langle F \rangle^2 \frac{\sum R_i^2 \varepsilon_i^*}{\sum F_i^2}, \tag{10}$$

where $\langle F \rangle$ = is the average radiation pattern coefficient for P-waves over the focal sphere, ε_i^* the energy flux at a given station i, R_i the geometrical spreading, and F_i the specific radiation pattern for the station i (Aki and Richards, 1980).

Other authors calculate E_S from integration of the moment rate spectral function (an average theoretical curve is shown in Figure 8 of the entry *Earthquake Magnitude*). The moment rate spectrum $\left|\hat{\dot{M}}(f)\right|$ can be obtained from the teleseismic P-waves spectrum $|\hat{u}(f)|$ as (e.g., Houston and Kanamori, 1986):

$$\left|\hat{\dot{M}}(f)\right| = \frac{4\pi\rho\alpha^3 R_E e^{(\pi f t^*)} |\hat{u}(f)|}{g(\Delta) R(\theta,\varphi) C \left|\hat{I}(f)\right|}, \tag{11}$$

where, R_E is the Earth radius, g(Δ) the geometrical spreading factor, $R(\theta,\phi)$ the radiation pattern, C the free surface coefficient, and $\left|\hat{I}(f)\right|$ the instrument response. Recalling that E_S is proportional to velocity, and, therefore, to the derivative of the function obtained from Equation 11, E_S is obtained from integration over frequency f as (see, e.g., Venkataraman and Kanamori, 2004):

$$\begin{aligned} E_S &= \left[\frac{8\pi}{15\rho\alpha^5} + \frac{8\pi}{10\rho\beta^5}\right] \int_0^{\infty} f^2 \left|\hat{\dot{M}}(f)\right|^2 df \\ &= \left[\frac{2}{15\pi\rho\alpha^5} + \frac{1}{10\pi\rho\beta^5}\right] \int_0^{\infty} \left|\hat{\ddot{M}}(f)\right|^2 df, \end{aligned} \tag{12}$$

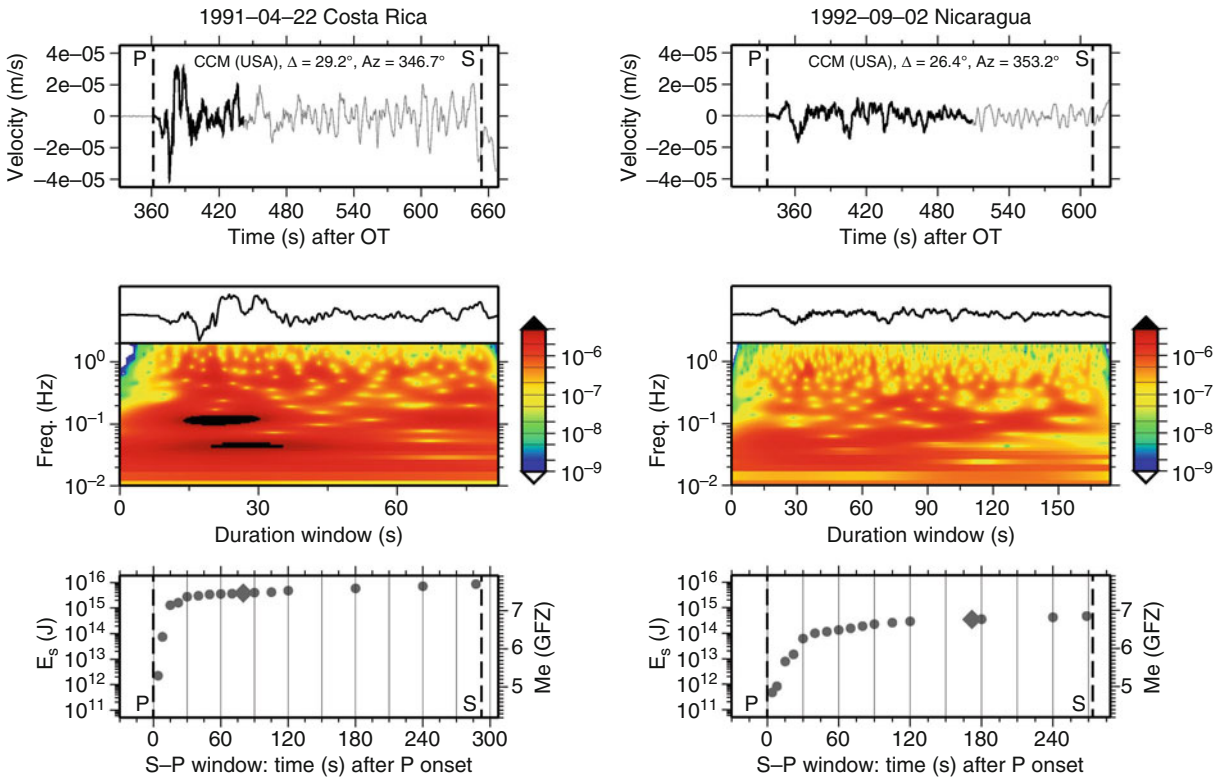
which holds for point sources, that is, sources smaller than the analyzed wavelengths (see *Earthquakes, Source Theory*) and neglecting directivity effects.

In sum, the calculation of E_S requires, after correction for propagation effects, to integrate the squared velocity spectrum recorded at seismic stations over a broad frequency range. Correction for the propagation effects is one of the most challenging tasks in seismological practice, since – in contrast to seismic moment determination (see *Earthquake, Magnitude*) – the high-frequency part of the source spectrum must also be considered. Correcting frequencies >1 Hz requires detailed knowledge of the Earth fine structure and attenuation properties, also below the seismic station, which is often not available. Consequently, E_S determinations from local and/or regional recordings are more problematic and are, anyway, more reliable only in areas with a high density of seismic stations (like California and Japan, see, e.g., the recent works by Izutani and Kanamori, 2001; Venkataraman et al., 2002; Boatwright et al., 2002; Oth et al., 2010) where a better knowledge of the local Earth structure is available.

Summary and outlook

The energy budget involved in the earthquake process is partitioned in different forms. In seismology it is of great importance to quantify two macroscopic parameters of the source, namely the seismic moment M_0 and the radiated seismic energy E_S. While the former (and the related magnitude *Mw*, see *Earthquake, Magnitude*) is a static measure of the seismic source and fundamental for the tsunami potential evaluation of an earthquake, the latter (and the related magnitude *Me*) represents the fraction of the strain energy converted in elastic seismic waves energy and fundamental for the evaluation of the shaking potential.

However, only since the early 1990s procedures to calculate E_S can be implemented on a routine basis at regional and global seismological centers. The approach of Boatwright and Choy (1986) allowed systematic and direct measurements of E_S from digital data, and later Choy and Boatwright (1995) demonstrated the importance of such measurements showing the significant variability of E_S for a given value of M_0. Therefore, the indirect



Earthquakes, Energy, Figure 1 *Upper panels*: *S-P* time windows (see *Body Waves*) of the vertical component velocity seismograms recorded at station CCM for the 1991 Costa Rica (*left*) and the 1992 Nicaragua earthquake (*right*). Vertical broken lines mark the theoretical arrival times of the *P* and *S* phases. *Middle panels*: time-frequency analysis via the *S-transform* (Stockwell et al., 1996) calculated over the *P*-wave duration window (black record traces in the upper panels that are also shown enlarged just above each middle panel); the color scales represent the amplitude of the *S-transform* in m/s. *Lower panels*: E_S and *Me* values as a function of time for different cumulative *P*-wave windows. The diamonds mark the end of the *P*-wave groups (see *black* record traces in the *upper panels*) that have been used for the single station E_S-*Me* estimates.

measurement of E_S, based on the assumptions leading to Equation 5, may be affected by large errors.

Of course, a better picture of the source characteristics can be obtained and help end users in the evaluation of the tsunami and shaking potential of an earthquake by complementing the information provided by direct measurements of E_S and M_0 and their related magnitudes. To this regard it is remarkable the case of two earthquakes that occurred about 500 km apart from each other in Central America, namely the 1991 Costa Rica earthquake and the 1992 Nicaragua earthquake. Both had the same moment magnitude $Mw = 7.6$ (i.e., about the same M_0). Because of their small difference in epicenter location, one can assume very similar propagation paths to teleseismic stations. However, the broadband waveforms of both earthquakes, recorded at identical stations, differ strongly. As an example, Figure 1 illustrates the *P*-wave windows, their time-frequency analysis performed with the *S-transform* (Stockwell et al., 1996), and the corresponding E_S-*Me* (see Di Giacomo et al., 2010a, b) values at station CCM for both earthquakes. The 1991 Costa Rica earthquake has much larger amplitudes, especially at higher frequencies, than the 1992 Nicaragua event. Such large differences can be only ascribed to significant differences in the medium-to-high-frequency parts of the source spectra of these two earthquakes with about the same M_0. Accordingly, E_S (and the corresponding *Me*) for the Costa Rica earthquake is much larger than for the Nicaragua earthquake. The latter caused a damaging *Tsunami* with 8 m run-up height, in contrast to severe damages caused by strong ground shaking of *intensity* I = X in the epicentral area of the Costa Rica earthquake (see *Earthquakes, Intensity*). This shows that M_0 alone (and a single type of magnitude as *Mw*) may not describe accurately enough the kind of seismic hazard and damage potential posed by a given earthquake and that a combined use of M_0 and E_S (and a multiple magnitude approach, see *Earthquake, Magnitude*) is preferable.

Thus, for improving seismic hazard assessment, future studies must focus on combining in a systematic way E_S and M_0 determinations in order to fully harness the information provided by these two important physical parameters of the seismic source.

Macroseismic intensity

Definition

The *intensity*, or *macroseismic intensity*, represents a classification of the severity of ground-motion shaking during an earthquake on the basis of observed effects at a given place. The word "macroseismic" refers to perceptible effects of earthquakes as opposed to instrumental observations. Intensity data are not only a surprisingly good measure of ground motion (Atkinson and Wald, 2007) but are also capable of constraining the magnitude of an event with the same order of uncertainty as individual instrumental magnitude readings (Johnston, 1996). Intensity data of an earthquake are usually presented in the form of a map showing for each intensity point either a corresponding color code or symbol. Contour lines in such maps separating intensities of different degrees are called isoseismals. The epicentral intensity I_0 is usually the largest observed intensity near to the epicenter or the barycenter of the highest intensity values. It can only be given for onshore events.

Macroseismic scales and intensity assignment

Earthquake intensities are defined in macroseismic scales. Since the early twentieth century, they usually contain 12 intensity degrees with the prominent exception of the 7° Japanese Meteorological Agency (JMA) scale (later upgraded to 10°). Earthquakes generate different intensities at different places, generally decreasing with distance from the epicenter. The epicentral intensity can be used in combination with the hypocentral depth as a classification of earthquake strength – with restrictions for large earthquakes ($M \geq 7$) with extensive fault planes.

Although not a physical parameter as such, intensity is a measure of strength of shaking, which can be related to physical ground-shaking parameters. It is a shorthand description of common observations from an earthquake, for example, instead of writing "the event was felt indoors by most, outdoors by few, and china and glasses clattered together", one summarizes "intensity 5".

Intensity is an integer quantity. Uncertain intensity assignments can be expressed as, for example, 8–9 (meaning either 8 or 9), being used in numerical procedures as 8.5, without claim of precision. A macroseismic scale defines each intensity degree with a series of diagnostics. Each diagnostic describes typical effects of ground vibrations related to different sensors. For the lower intensities, these main sensors are people and objects indoors, whereas for higher intensities they are buildings, which suffer progressively more severe damage with increased intensities. The type of building, for example, masonry or reinforced concrete, its condition and workmanship, as well as the level of earthquake-resistant design influence its strength considerably.

The most recent scale in general use, the European Macroseismic Scale (EMS-98), fully considers the varying strength of buildings in the form of six vulnerability classes, five damage grades for both masonry and reinforced concrete structures, as well as differentiating structural and nonstructural damage (Grünthal, 1998). Another element of the EMS-98 associated with the diagnostics is the relative frequency with quantitative definitions of the qualitative terms "few, many, most." It is the only intensity scale supplemented by comprehensive guidelines and background materials, and this contributes, together with the other mentioned elements, to a reduction of the subjectivity, which often is associated with intensity assignments.

The EMS-98 is easily adaptable for use to the building stock anywhere in the world. Table 1 gives the short form of the EMS-98 as a very simplified and generalized description. The long, full version should be used for intensity assignments.

The EMS-98 should be the basis for intensity evaluation in European countries and has also been applied in a number of countries outside Europe. Some South European countries, like Italy, still deploy Sieberg's (1932) Mercalli–Cancani–Sieberg scale (MCS). The basic intensity scale used in North America is the Modified Mercalli scale MMI. This scale has also been applied in countries elsewhere. In China, the China Seismic Intensity Scale (CSIS) has been used since 1999. This scale is strongly related to the test version of the EMS-98, that is, the EMS-92. While all these scales have 12 intensity degrees, the 1996 version of the JMA scale, introduced after the 1995 Great Hanshin earthquake, has been upgraded from originally 7° to 10°.

History of intensity scales

Historically, the use of intensities is important because it does not require instrumental measurements of earthquakes. In the last quarter of the nineteenth century, that is, before the establishment of instrumental seismology, the macroseismic intensity became a widespread parameter. The first internationally introduced scale was the 10° Rossi–Forel scale of 1883, which in some countries

Earthquakes, Intensity, Table 1 Short form of the EMS-98

EMS intensity	Definition	Description of typical observed effects (abstracted)
I	Not felt	Not felt.
II	Scarcely felt	Felt only by very few individuals at rest in houses.
III	Weak	Felt indoors by a few people. People at rest feel a swaying or light trembling.
IV	Largely observed	Felt indoors by many people, outdoors by very few. A few people are awakened. Windows, doors, and dishes rattle.
V	Strong	Felt indoors by most, outdoors by few. Many sleeping people awake. A few are frightened. Buildings tremble throughout. Hanging objects swing considerably. Small objects are shifted. Doors and windows swing open or shut.
VI	Slightly damaging	Many people are frightened and run outdoors. Some objects fall. Many houses suffer slight nonstructural damage like hairline cracks and fall of small pieces of plaster.
VII	Damaging	Most people are frightened and run outdoors. Furniture is shifted and objects fall from shelves in large numbers. Many well-built ordinary buildings suffer moderate damage: small cracks in walls, fall of plaster, parts of chimneys fall down; older buildings may show large cracks in walls and failure of fill-in walls.
VIII	Heavily damaging	Many people find it difficult to stand. Many houses have large cracks in walls. A few well-built ordinary buildings show serious failure of walls, while weak older structures may collapse.
IX	Destructive	General panic. Many weak constructions collapse. Even well-built ordinary buildings show very heavy damage: serious failure of walls and partial structural failure.
X	Very destructive	Many ordinary well-built buildings collapse.
XI	Devastating	Most ordinary well-built buildings collapse, even some with good earthquake-resistant design are destroyed.
XII	Completely devastating	Almost all buildings are destroyed.

persisted up to the 1960s. This points to the relevance of knowing the different scales that have been used in different countries during different time periods. Here, only a short summary can be given. For a comprehensive compilation, see Musson et al. (2010) and Musson and Cecić (2002).

A later popular scale is Mercalli's version from 1902. The first 12° scale is the one by Cancani (1904) with the focus on associating peak ground acceleration with single intensities. Based on the macroseismic observations from the 1911 $M_L = 6.1$ Central European earthquake, Sieberg (1912) provided a completely revised 12° version with descriptions of the intensity degrees given in great detail. This scale, which overwhelmingly influenced all modern intensity scales, later became known as the Mercalli–Cancani–Sieberg scale. Sieberg's (1923) minor revision of this scale was translated into English and published by Wood and Neumann (1931) in a largely condensed form, at the cost of clarity. The title is also inappropriate: the Modified Mercalli scale, MM-31. Sieberg's (1932) further revised version, with some major innovations, the MCS scale, is still in use in southern Europe. The MM-31 scale was completely overhauled in 1956 by Richter (1958). He refrained from associating his name with the new version to avoid confusion with the "Richter" magnitude scale M_L, and it was to be known as the Modified Mercalli scale of 1956 (MM-56).

Today's macroseismic evaluation procedures at the USGS rely basically on the MM-31 scale, but in a newly edited and almost undocumented version, that is, lacking differentiations in the terminology used, and in which extra rules and conventions are being applied (see Musson et al., 2010; Musson and Cecić, 2002). Intensity data sets are often given only as MM or MMI.

In Europe, Medvedev, Sponheuer and Kárník developed the MSK scale (Medvedev et al., 1964), introduced as MSK-64, on the basis of the MCS, the Russian GEOFIAN scale, and the MM-56. It is more systematically arranged than the forerunners and was widely adopted in Europe.

In 1988, the European Seismological Commission (ESC) launched the updating of the MSK scale to bring it in line with modern earthquake-resistant building types and engineering requirements. After the new scale had been constructed it was obvious that it contained so many new elements with respect to the MSK scale that it should bear a new name, and so EMS-92 and EMS-98 were established.

An aspect connected with the history of intensity scales is the decline of interest in macroseismology in the middle of the twentieth century when instrumental monitoring was progressing. However, the 1970s saw a revival of the subject since intensity assignments are fundamental for parametrizing historical seismicity and developing intensity-based ground-motion models essential in seismic hazard (see *Seismic Hazard*) and risk assessments.

Conversion of intensity scales

The conversion between intensity scales is, due to their integer nature, not possible in the way scalar parameters like different magnitude types can be converted. Ideally, conversions between intensities according to different scales should be avoided and the original data should be

Earthquakes, Intensity, Table 2 Conversion from the JMA-96 scale to the EMS-98 (After Musson et al. [2010])

JMA-96	EMS-98
0	1
1	2 or 3
2	4
3	4 or 5
4	5
5 Lower	6
5 Upper	7
6 Lower	8
6 Upper	9 or 10
7	11

reassessed using one scale. This is frequently not possible. Therefore, conversion diagrams have been developed in which the intensities according to different scales are represented as a series of "intensity ranges." One scale, taken as a standard with equally large ranges, is, as it is perceived by different authors, compared with other scales with different ranges for the intensities. Musson et al. (2010) elaborate in more detail on this issue and present tables suggesting direct numerical correspondence. Among the 12° scales, Musson et al. (2010) conclude equality between EMS-98 and MCS, MMI, and MSK for the intensities 1–10. For intensities 11 and 12, the definitions in MCS, MSK, and MMI relate to phenomena, such as surface faulting, which do not represent strength of shaking, or to a saturation of classification criteria in the scale where, for example, total damage refers to total damage to buildings without antiseismic design. Therefore, the intensities 11 and 12 do not have an equivalent in the EMS-98. The relation of the JMA-96 (JMA, 1996) scale with the EMS-98 is given in Table 2.

Macroseismic surveys

After an earthquake is felt, there are several ways to gather macroseismic data. The main source of data collection is questionnaires designed according to the diagnostics of the intensity-degree definitions. Questionnaires are especially used to compile data for the vast majority of observations in the range of intensities ≤ 6, although many questionnaires are designed for diagnostics up to intensity 7 or 8. Information on earthquake damages to buildings and other constructions need to be collected in the field. Special forms are in use in several high seismicity countries to optimize this procedure with respect to certain intensity scales and the building stock in a region.

Printed questionnaires used in the past have today been almost entirely replaced by internet web-based versions. The "Did You Feel It" (DYFI) program by the USGS (Wald et al., 1999a) is the basis of similar current activities worldwide. Musson (2006) describes the DYFI procedure for EMS-98 intensities in detail. The idea of such DYFI programs is that persons who have observed an earthquake use an internet web-site to report the macroseismic effects through answering a multiple-choice questionnaire. Such DYFI programs are often not restricted to a certain country but can be applied internationally. They have been remarkably successful since their inception. In the U.S. alone, more than ¾ million domestic responses have been compiled in the first 7 years since the start of the program in 2000 (Atkinson and Wald, 2007). This vast amount of macroseismic information proves to be very useful as an essential new source of ground-motion data (see *Earthquakes, Strong-Ground Motion*).

Intensity attenuation and focal depth

The rate of decay of shaking strength with distance from the epicenter, that is the intensity attenuation, is strongly dependent upon the focal depth h and to a lesser extent on the regionally dependent absorption of energy. Assuming a logarithmic proportionality between intensity and ground acceleration after Cancani (1904), an isotropic intensity-attenuation model results (Kövesligethy, 1906), rewritten by Jánosi (1907) as

$$I_0 - I_i = 3\log\left(\frac{r}{h}\right) + 3\alpha \log e(r-h) \tag{1}$$

with $r = \sqrt{R^2 + h^2}$, where R is the radius of the isoseismal intensity, I_i, I_0 the epicentral intensity, and e is Euler's constant. The same structure as Equation 1. results for a logarithmic proportionality between intensity and seismic energy density (Howell and Schultz, 1975; *Earthquakes, Energy*).

The first and, for a long time, the most important use of intensity attenuation was focused on depth determinations. For this purpose, graphical schemes by Sponheuer (1960) were frequently used in the pre-computer era. In the case of good macroseismic data, the calculated depths coincide very well with instrumental depth determinations, at least for shallow (5–25 km) events with small source dimensions (Musson, 1993). Intensity-attenuation relations of the type of Equation 1. were determined from a few mean isoseismal radii. Only within the last few years have modern statistical procedures been applied, which rely directly on a huge amount of intensity data points. One of these relations based on Central European data after Stromeyer and Grünthal (2009) reads

$$I_* - I = 2.95\log\left(\frac{r}{h}\right) + 0.0025(r-h) \tag{2}$$

where I is the intensity at epicentral distance r and I_* is any estimate of the intensity at $r = 0$, but not necessarily epicentral intensity I_0. Gomez Capera (2006) compiled 15 intensity-attenuation relations of this type.

Conversion of intensities to magnitudes

Intensity data give surprisingly robust measures of earthquake magnitudes (see *Earthquake, Magnitude*). This important fact qualifies the macroseismic method to be used for magnitude determinations of historical earthquakes occurred in early or pre-instrumental times. Seismic hazard analysis greatly benefits from long-term

earthquake catalogues. There are three ways of macroseismic magnitude determinations based on the following: (1) the epicentral intensity, (2) the areas affected by certain intensity levels, and (3) the entire field of intensity data points. These ways are described below.

1. A few years after the introduction of the earthquake magnitude, the first empirical relation with the epicentral intensity I_0 was given (Gutenberg and Richter, 1942). The maximum or epicentral intensity is in most cases the only information at hand for historical earthquakes. I_0 is strongly affected by the focal depth h. Therefore, h should be taken into consideration or the seismogenic depth in an area should be narrowly constrained at the conversion to magnitude. A modern relation based on well constrained moment magnitude M_w, I_0, and h of European earthquakes given by Grünthal et al. (2009) reads

$$M_w = 0.667I_0 + 0.30\log(h) - 0.10 \quad (3)$$

or omitting h

$$M_w = 0.682I_0 + 0.16 \quad (4)$$

These relations are valid for the ranges $5 < I_0 < 9.5$, $3.0 < M_w < 6.4$, and $5 \leq h[\text{km}] < 22$.

2. For earthquakes with known total felt area or known area enclosed by one or more of the n preferably outer isoseismals (An), the magnitude can be determined as a function of $\log An$. Johnston (1996) derived regression relations for MMI isoseismal areas for stable continental regions to predict seismic moments M_0 according to a functional regression form proposed by Frankel (1994)

$$\log M_0 = a + b\log An + c\sqrt{An} \quad (5)$$

From the published relations for different isoseismal areas, the coefficients for the areas of intensity 3 and 4 read

	a	b	c
A3	17.59	1.020	0.00139
A4	18.10	0.971	0.00194

The uncertainties in the derived moment magnitudes can be halved by applying weighted averaging of a suite of isoseismal areas. The uncertainties are then in the range of $\pm 0.15 \ldots 0.23M_w$ units.

3. The most advanced methods to derive magnitude from macroseismic data use the intensity data points of an event to make a joint determination of epicenter location (see *Earthquake, Location Techniques*) and magnitude. These methods need a well-calibrated intensity-attenuation model valid for a certain region. The most important methods of this type are by Bakun and Wentworth (1997), originally developed for Californian earthquakes $(4.4 < M_w < 6.9)$, and by Gasperini et al. (1999) for Italian earthquakes with $M_s \geq 5.5$. The latter additionally provides the fault azimuth, essentially derived from the direction of maximum elongation of the highest intensity data points. An adaption of the Bakun and Wentworth (1997) method to the intensity attenuation in France was made by Bakun and Scotti (2006).

Magnitudes derived from macroseismic data should be indicated as such, for example, as $M_w(I_0)$ or $M_0(An)$.

Intensity-attenuation models

Rapid post-earthquake information in the form of shake maps and earthquake early warnings, and other quantitative scientific studies like intensity-based seismic hazard and risk assessments, require well-established models of intensity attenuation with distance. The macroseismic data accumulated by the "Did You Feel It" (DYFI) program (Wald et al., 1999a) represent a vast new source of engineering seismology data. The DYFI intensity data "make up in quantity what they may lack in quality... They are also robust and of surprisingly high utility" (Atkinson and Wald, 2007). Their regression equation reads as:

$$MMI = C_1 + C_2(M_w - 6) + C_2(M_w - 6)^2 + C_4\log R + C_5R + C_6B + C_7M_w\log R \quad (6)$$

where C_1 through C_7 are determined constants, $R = \sqrt{D^2 + h^2}$ where D is rupture distance and h effective depth. $B = log(R/R_t)$ where R_t is the transition distance in the attenuation shape. The values in Table 3 are yielded for California and Central and Eastern U.S. (Atkinson and Wald, 2007).

In recent years, intensity-attenuation models have especially been derived for regions where shake map programs (see *Earthquakes, Shake Map*) and early warning systems exist or are under development.

Relation of intensities to recorded strong ground motion

Attempts to express the strength of an earthquake and its observed effects in the form of physical parameters date

Earthquakes, Intensity, Table 3 Coefficients of equation 6

Coefficient	California	Central and Eastern U.S.
C_1	12.27(±0.24)	11.72(±0.36)
C_2	2.270	2.36

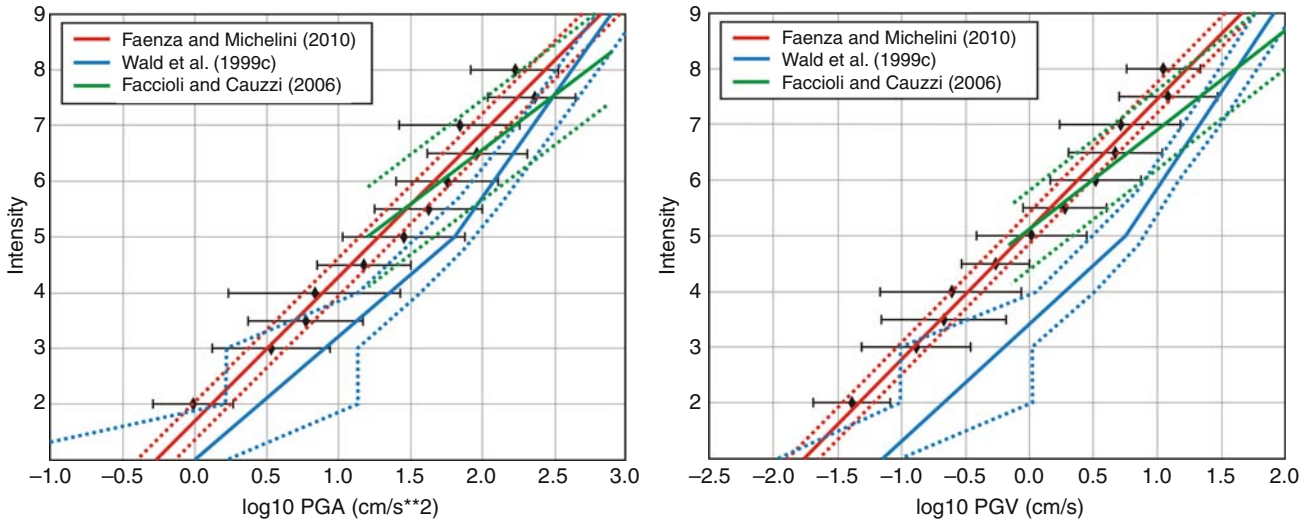
h	14.0	17.0
R_t	30.0	80.0



Earthquakes, Intensity, Figure 1 Relations between intensity versus PGA (*left*) and PGV (*right*) after Wald et al. (1999c), Faccioli and Cauzzi (2006), and Faenza and Michelini (2010). Although MMI values and MCS values are used in these studies, the relations are given in a common scheme according to their de facto equivalence (Musson et al., 2010). (Redrawn after Faenza and Michelini [2010].)

back to the last quarter of the nineteenth century (cf. summary in Grünthal, 1984). Omori (1900) and Cancani (1904) were the first who related intensity degrees to peak ground acceleration (PGA) (see *Earthquakes, Strong-Ground Motion*). Kövesligethy (1906) and Jánosi (1907) invented a functional form that is still used today – a linear regression between intensity I and the logarithm of Cancani's PGA $(I = a + b\log(PGA))$. Grünthal (1984) compiled 30 published relations of intensity to peak ground motion, which showed a larger scatter in PGA compared to peak ground velocity (PGV).

For the implementation of the USGS Shake Map (see *Earthquakes, Shake Map*) software package (Wald et al., 1999b), representing shaking through maps of PGA, PGV, and ground-motion shaking intensity, it was necessary to derive "instrumental intensity" by converting peak ground motion to MMI intensity values (Wald et al., 1999c; Figure 1). In Europe, notably Italy, well-established relations for MCS intensities have recently been developed by Faenza and Michelini (2010) and references therein. Their orthogonal relations (Figure 1) read:

$$I = 1.68 + 2.58\log PGA\,[\mathrm{cm/s^2}] \tag{7}$$

$$I = 5.11 + 2.35\log PGV\,[\mathrm{cm/s}] \tag{8}$$

The densest network to generate shake maps in terms of instrumental intensity exists in Japan. Here, the instrumental intensity according to the JMA scale (I_{JMA}) is computed from Fourier acceleration spectra multiplied with different filter functions (Kuwata and Takada, 2002; Karim and Yamazaki, 2002). Empirical relationships between I_{JMA} and different ground-motion parameters are given by Karim and Yamazuki (2002). Their relation between I_{JMA} and PGA was derived as

$$I_{JMA} = 1.58 + 1.38\log SI + 0.59\log \mathrm{PGA} + 0.02M \tag{9}$$

where SI is the "spectrum intensity" ($\mathrm{cm/s^2}$) introduced by Housner (1961) as the integral over the velocity response spectrum in the period range from 0.1 to 2.5 s, and PGA is in $\mathrm{cm/s^2}$. However, correspondence between "instrumental intensity" and the wording of the macroseismic scale cannot be taken for granted.

Conclusions

Macroseismic intensity is a robust measure of perceptible and potentially damaging ground motion and is essential in engineering seismology. Modern developments of macroseismic scales, defining intensity degrees with persons and buildings as sensors, fully consider the range of vulnerability of buildings and differentiate structural and nonstructural damage patterns. Intensity provides the principal means by which one can parameterize historical or pre-instrumental earthquakes, that is, to determine their location, magnitude, and focal depth. Good quality macroseismic data enables a similar range of uncertainty in the derived focal parameters as standard instrumental seismology. The increased relevance of the parameter macroseismic intensity is strongly related to the enhanced needs in reliable seismic hazard and risk assessments. With the internet-based platforms Shake Map and "Did You Feel It?" the macroseismic intensity has become omnipresent.

Definition and introduction

Prompt Assessment of Global Earthquakes for Response (PAGER) is an automated system that produces content concerning the impact of significant earthquakes around the world within approximately 30 min of any magnitude 5.5 or larger event. PAGER rapidly assesses earthquake impacts by comparing populations exposed to estimates of shaking intensity, and models of economic and fatality losses based on past earthquakes in each country or region of the world. The main purpose of the PAGER system is to inform emergency responders, government and aid agencies, and the media to the scope of the potential disaster. Earthquake alerts – which were formerly sent based on event magnitude and location, or population exposure to shaking – are generated based on the estimated range of fatalities and/or economic losses.

The U.S. Geological Survey's National Earthquake Information Center (NEIC), located in Golden, Colorado, locates over 30,000 earthquakes a year. Tragically, about 25 of these cause significant damage, injuries, or fatalities. The U.S. Geological Survey (USGS) often detects earthquakes well before eyewitness reports are available. The USGS must then decide rapidly whether Federal and international agencies should be alerted to a potentially damaging event. In the past, the USGS primarily relied on the experience and intuition of its on-duty seismologists to estimate the impact of an event. To quantify and improve the accuracy of the assessment, the USGS has developed PAGER, an automated system to rapidly estimate the shaking distribution, the number of people and settlements exposed to severe shaking, and an estimate of the range of possible fatalities and economic losses. The estimated losses, in turn trigger the appropriate color-coded alert (green, yellow, orange, red), which determines suggested levels of response, whether no-response-needed, or local/regional, national, or international response, respectively.

In addition to direct alert notifications, PAGER provides important supplementary information, including comments describing the dominant types of vulnerable buildings in the region, exposure, and any fatality reports from a previous nearby earthquake, and a summary of regionally specific information concerning the potential for secondary hazards, such as earthquake-induced landslides, tsunami, and liquefaction. A map provides quick visual overviews of shaking levels and population densities, and a table summarizes the predicted shaking intensity at nearby cities and towns. This impact summary information is available on the USGS earthquake web site [http://earthquake.usgs.gov/pager/] and as a printable, one-page report with an accompanying description such as that shown on the following pages.

Fundamental to such a system, the USGS operates the robust computational and communication infrastructure necessary for earthquake response. PAGER results are generally available within 30 min of a significant earthquake, shortly after the determination of its location and magnitude. However, information on the extent of shaking will be uncertain in the minutes and hours following an earthquake and typically improves as additional sensor data and reported intensities are acquired and incorporated into models of the earthquake's source. Users of PAGER should account for the inherent uncertainty in shaking and loss estimations, and always seek the most current PAGER release on the USGS web site for any earthquake.

The PAGER process

In general, the shaking-related impact of an earthquake is controlled by the distribution and severity of shaking, the population exposed at each shaking intensity level, and how vulnerable that population is to building damage at each intensity level. Population vulnerability is dominated by the degree of seismic resistance of the local building stock. The PAGER system takes all these factors into account. At the heart of PAGER are the timely and accurate earthquake location and magnitude determinations that the USGS has been producing for decades. PAGER uses these earthquake parameters to calculate estimates of ground shaking by using the methodology and software developed for ShakeMap (http://earthquake.usgs.gov/shakemap/). The ShakeMap system produces maps of regional ground shaking using a site-specific ground-motion amplification map, seismic wave attenuation equations, and reported or recorded intensities and ground motions (Wald et al., 2005). The number of people exposed to each shaking intensity levels is then calculated by combining the maps of estimated ground shaking with a comprehensive worldwide population database (Landscan, from Oak Ridge National Lab).

Next, based on the population exposed to each intensity level of shaking, the PAGER system estimates total losses based on country-specific models developed from economic and casualty data collected from past earthquakes (Jaiswal et al., 2009). To calibrate the loss models, the USGS has generated an atlas of approximately 6,000 ShakeMaps for significant global earthquakes that have occurred during the last 40 years (Allen et al., 2009). The calibration of loss methodologies relies on this atlas and on fatality and damage data collected by the NEIC. Finally, the alert level, determined by estimated ranges of fatalities and economic loss are produced, with the higher of the two levels setting the overall alert level. The alert level determines which users are actively notified, and, at the same time, all PAGER information and content is automatically distributed to the Web on the USGS Earthquake web pages, as part of the earthquake summary information, for immediate consumption.

USGS science for a changing world

Summary Alert Red

GSN USAID FROM THE AMERICAN PEOPLE

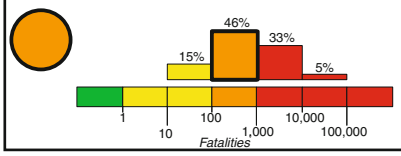
M 8.8, OFFSHORE MAULE, CHILE

Origin Time: Sat 2010-02-27 06:34:14 UTC (03:34:14 local)
Location: 35.91°S 72.73°W Depth: 35 km

PAGER Version 5

Created: 6 days, 10 hours after earthquake

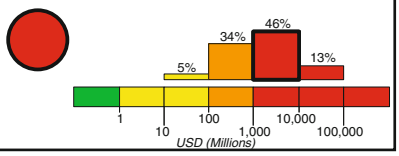
Estimated Fatalities



Red alert level for economic losses. Widespread damage is likely and the disaster is potentially widespread. Past events with this alert level have required a national or international level response.

Orange alert level for fatalities. Significant casualties are likely.

Estimated Economic Losses



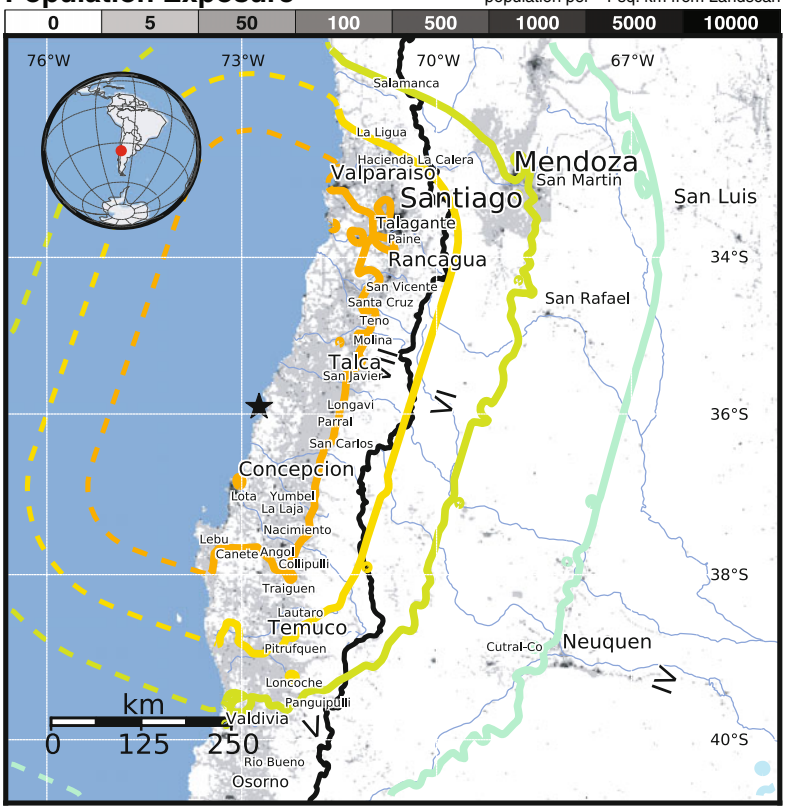
Estimated Population Exposed to Earthquake Shaking

ESTIMATED POPULATION EXPOSURE (k = x1000)		- -*	0*	1,101k*	2,795k*	967k*	9,169k	3,585k	0	0
ESTIMATED MODIFIED MERCALLI INTENSITY		I	II-III	IV	V	VI	VII	VIII	IX	X+
PERCEIVED SHAKING		Not felt	Weak	Light	Moderate	Strong	Very Strong	Severe	Violent	Extreme
POTENTIAL DAMAGE	Resistant Structures	none	none	none	V. Light	Light	Moderate	Moderate/Heavy	Heavy	V. Heavy
	Vulnerable Structures	none	none	none	Light	Moderate	Moderate/Heavy	Heavy	V. Heavy	V. Heavy

*Estimated exposure only includes population within the map area.

Population Exposure

population per ~1 sq. km from Landscan



Structures:
Overall, the population in this region resides in structures that are vulnerable to earthquake shaking, though some resistant structures exist. The predominant vulnerable building types are low-rise reinforced/confined masonry and adobe block construction.

Historical Earthquakes:
On May 22, 1960 (UTC), a magnitude 9.5 earthquake 273 km South of this one struck Valdivia, Chile, with estimated population exposures of 216,000 at intensity IX and 230,000 at intensity VIII, resulting in a reported 3,263 deaths from the earthquake and tsunami. Recent earthquakes in this area have caused tsunamis, landslides, and liquefaction that may have contributed to losses.

Selected City Exposure

from GeoNames.org

Earthquakes, PAGER, Figure 1 Example of the PAGER summary product showing the color-coded impact scale indicated the alert levels (*top*), the total population exposed per color-coded intensity level (*center, near top*), a map of the population density and contoured intensity level (*lower left*), summary statements on country-specific structures and historical earthquakes, and selected cities with population and intensity level (*lower right*).

The PAGER earthquake impact scale

PAGER employs a new earthquake impact scale (EIS, Wald et al., 2010) that is based on two complementary criteria. One, based on the estimated cost of damage, is most suitable for domestic events; the other, based on estimated ranges of fatalities, is generally more appropriate for global events, particularly in developing countries. Simple thresholds, derived from the systematic analysis of past earthquake impact and associated response levels, turn out to be quite effective in communicating predicted impact and response needed after an event, characterized by alerts of green (little or no impact), yellow (regional impact and response), orange (national-scale impact and response), and red (international response). Corresponding fatality thresholds for yellow, orange, and red alert levels are 1, 100, and 1,000, respectively. For damage impact, yellow, orange, and red thresholds are triggered by estimated losses reaching $1 million, $100 million, and $1 billion, respectively. The rationale for a dual approach to earthquake alerting stems from the recognition that relatively high fatalities, injuries, and homelessness dominate in countries where local building practices typically lend themselves to high collapse and casualty rates, and it is these impacts that lend to prioritization for international response. In contrast, it is often financial and overall societal impacts that trigger the level of response in regions or countries where prevalent earthquake resistant construction practices greatly reduce building collapse and resulting fatalities.

Since PAGER calculations are available well in advance of ground-truth observations or news accounts, PAGER information can play a primary alerting role for domestic as well as international earthquake disasters. An example of the PAGER summary product, or *onePAGER*, is shown on the following pages for a recent destructive earthquake in early 2010 near central Chile that killed approximately 300 people. This earthquake reached an orange-alert level based on both projected fatalities and economic losses. The alert level is based on the median loss estimate; the uncertainty in the alert level can be gauged by the histogram showing the percent likelihood that adjacent alert levels (or loss/fatality ranges) occur. Accompanying text clarifies the nature of the alert based on experience from past earthquakes and provides context on the total economic losses in terms of the percent of the gross domestic product (GDP) of the country affected.

Though PAGER uses simple and intuitive color-coded alerting criteria, it preserves the necessary uncertainty measures by which one can gauge the likelihood for the alert to be over- or underestimated. Utilizing the earthquake impact scale, PAGER's rapid loss estimates can adequately recommend alert levels and suggest appropriate response protocols, despite their uncertainties; demanding or awaiting observations or loss estimates with a high level of accuracy may increase the losses. Over the past 38 years (1973–2010), there would have been approx. 17,792 green (not shown in Figure 1), 568 yellow, 52 orange, and 49 red alerts. This frequency equates to approximately 15 yellow, 1–2 orange, and 1–2 red alerts per year.

Ongoing PAGER developments

USGS is improving the PAGER system to include more comprehensive loss-estimate methodologies that take into account detailed building inventories that account for subcountry level regional variations, more complete population demographics (including time of day population shifts), and better tools to compute building damage (e.g., Jaiswal et al., 2010). Such data sets are very difficult and time consuming to acquire, and are effectively unavailable in many areas of the globe. In particular, more detailed within-country building inventories are key for describing the dominant vulnerable structures that contribute to casualties in the region. Knowledge of the main collapse "culprits" is vital for response, public safety, recovery, and long-term mitigation. Related USGS developments under the auspices of the PAGER Project include rapid determination of fault geometry, size, and rupture characteristics; refined global estimates of seismic soil-amplification patterns; ShakeMap enhancements; ground-motion and loss-uncertainty analyses; and earthquake-induced landslide and liquefaction probability mapping.

EARTHQUAKES, SHAKE MAP

David J. Wald
U.S. Geological Survey, Denver Federal Center, Lakewood, CO, USA

Definition and introduction

ShakeMap® is an open-source software program employed to automatically produce a suite of maps and

products that portray the geographical extent and severity of potentially damaging shaking following an earthquake. ShakeMap's primary purpose is to provide post-earthquake situational awareness for emergency management and response as well as damage loss estimation. The availability of ShakeMaps immediately after a significant earthquake is critical for the identification of areas likely to be most damaged. Principal users include first responders, utility companies, response and aid agencies, scientists and engineers, and the media. Maps are made publicly available via the Internet within several minutes of an earthquake's occurrence. ShakeMap is widely deployed in seismically active, well-instrumented portions of the USA, internationally in Italy, Iceland, Greece, Romania, Switzerland, among other countries, and the U.S. Geological Survey (USGS) global system provides approximate maps for all events of magnitude 5.5 and larger worldwide.

Making a ShakeMap entails deriving a detailed description of the shaking over a large region with a variable distribution of seismic stations; this requires intelligently guided interpolation of measured ground motions unless the recordings are extremely abundant (as in Japan, for instance). In the ShakeMap algorithms, empirically based ground-motion estimates, modified by simple geologically based, frequency- and amplitude-dependent site-correction factors provide useful first-order shaking constraints to guide interpolation in areas that are not well instrumented. Thus, essential elements of a ShakeMap system (Wald et al., 2005) include: (1) near-real time peak ground motion and/or intensity observations; (2) a ground-motion, site-amplification map for the region; (3) the ShakeMap algorithms, which combine and guide interpolation of ground-motion observations with built-in shaking estimates to produce the suite of shaking-hazard maps; and (4) mechanisms for automatically transferring ShakeMap products to users, including via web pages and through internet-based product feeds.

Historical context

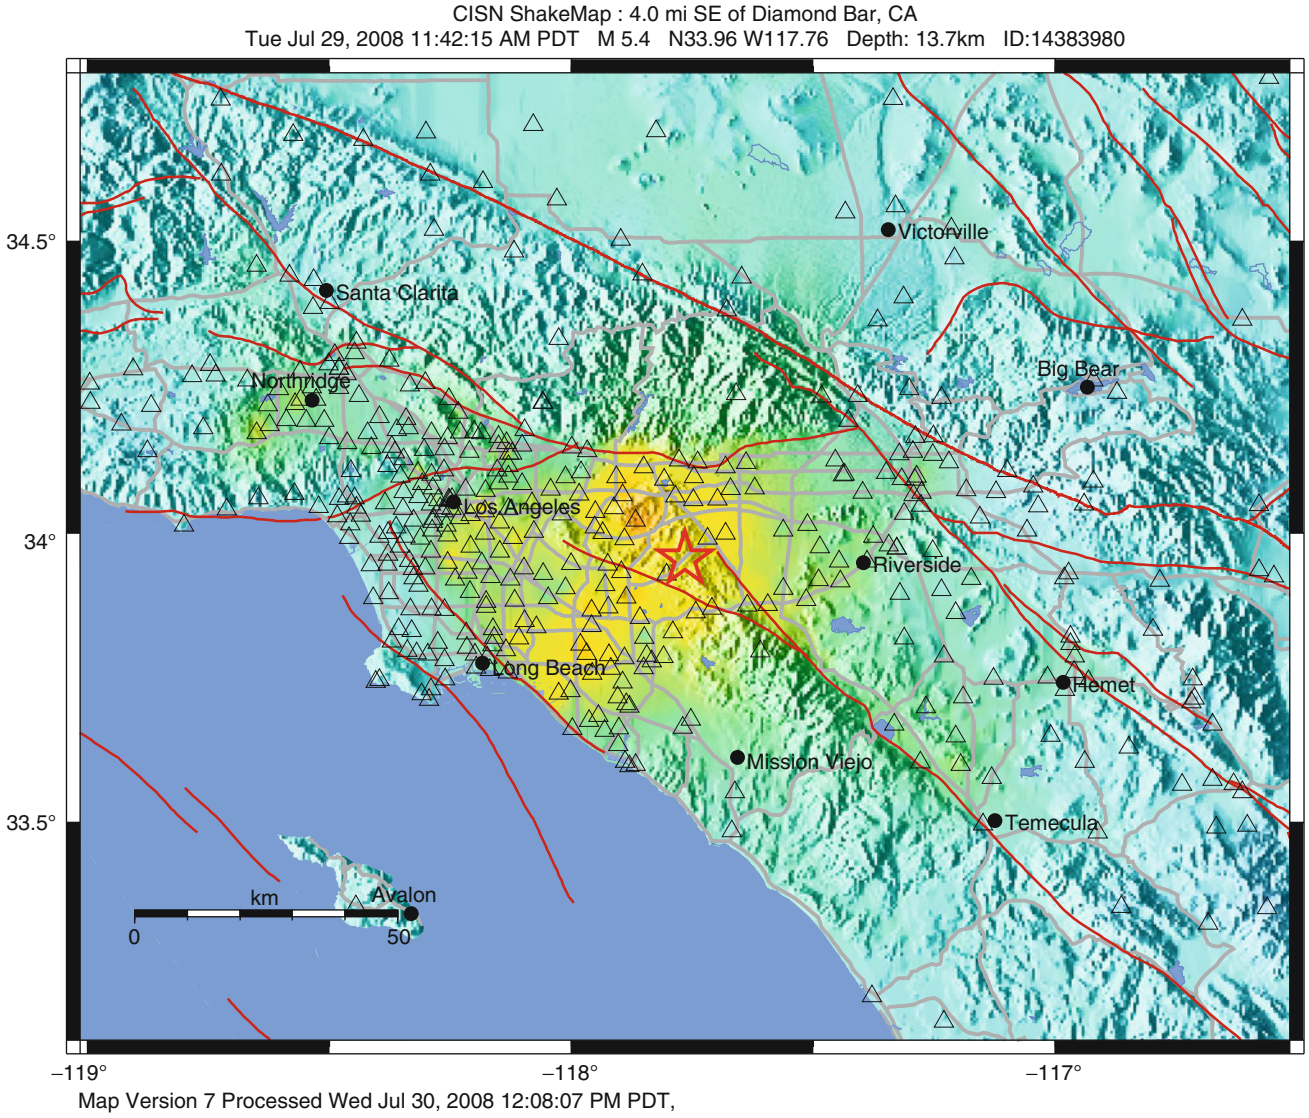
The most common information available immediately following a damaging earthquake has traditionally been its magnitude and the location of its epicenter. However, the damage pattern is not a simple function of these two parameters alone, and more detailed information is necessary to properly evaluate the situation. ShakeMap fills this role, and it has proven to be a useful, descriptive display for rapidly assessing the scope and extent of shaking and potential damage potential damage, following an earthquake. Because large earthquakes happen over a fault surface, not at a single point, the location of the earthquake (the epicenter) tells us only where the earthquake started, not necessarily where the shaking was the greatest. For a large earthquake, damage can occur hundreds of miles from the epicenter. Other factors, such as rupture direction, underground earth structure, and shallow geology, influence the amount of shaking in a particular area. For example, although emergency responders identified many areas of heavy damage soon after both the 1994 Northridge and the 1989 Loma Prieta, California, earthquakes, additional regions of severe damage were only belatedly discovered. A ShakeMap displays the distribution of ground shaking within minutes after an earthquake so that emergency managers can properly deploy resources to those locations with the greatest damage.

Part of the strategy for generating rapid-response ground-motion maps was to determine the best format for reliable presentation of the maps, given the diverse audiences. In an effort to simplify and maximize the flow of information to the public, ShakeMap was designed to produce not only peak-ground acceleration and velocity maps, but also an instrumentally derived, estimated Modified Mercalli Intensity map. The color-coded instrumental intensity map makes it easier to relate the recorded ground motions to the felt experience and damage distribution. ShakeMap was first developed for earthquakes in Southern California as part of the TriNet Project, a joint effort by the USGS, the California Institute of Technology, and the California Geological Survey (Wald et al., 1999b). Following the Northridge earthquake, older analog instruments were replaced with a modern seismic network employing near-real time digital communications. A by-product of that new network, ShakeMap was made possible by advances in telecommunications and computer-processing speed, as well as research that improved empirical ground-motion predictions and the relations among recorded ground motions and shaking intensities. A prototype ShakeMap system was first deployed in Southern California in 1997; refinements to the ShakeMap system continue today.

Related systems and uses

ShakeMap has facilitated the development and implementation of additional post-earthquake analyses and tools. Separate map layers are generated, each comprised of the spatial distribution of a specific peak ground-motion parameter (specifically acceleration, velocity, or response-spectral acceleration) as well as a layer for instrumentally derived seismic intensities. In addition to maps, ShakeMap produces an equally spaced grid containing the value of each parameter, as well as geographic information system (GIS) files and a host of other products for intended uses and users. Peak ground and spectral acceleration are fundamental parameters for earthquake-engineering and loss-estimation analyses; grids of shaking values can be combined with building inventory or lifeline databases to rapidly produce maps of estimated damage.

One such commonly used loss-modeling approach, both for post-earthquake response and pre-earthquake mitigation, is the Federal Emergency Management Agency's (FEMA) Hazards U.S. (HAZUS) software. FEMA routinely uses HAZUS to compute earthquake



Perceived shaking	Not felt	Weak	Light	Moderate	Strong	Very strong	Severe	Violent	Extreme
Potential damage	none	none	none	Very light	Light	Moderate	Moderate/Heavy	Heavy	Very Heavy

Instrumental intensity	I	II-III	IV	V	VI	VII	VIII	IX	X+

Earthquakes, Shake Map, Figure 1 ShakeMap for the magnitude 5.4 Diamond Bar, Los Angeles, California earthquake in July 2008 made by the California Integrated Seismic Network (CISN). Triangles indicate locations of seismic stations contributing to the map. Due to radiation pattern and site amplification, the strongest shaking is not at the epicenter; amplification due to the Los Angeles basin is particularly apparent at large distances southwest of the epicenter. Shaking variations in areas without stations are calculated from mapped soil variations and their amplification properties.

losses based on ShakeMap input within the USA. A secondary system for ShakeMap, ShakeCast (short for ShakeMap Broadcast), is a fully automated system for delivering specific ShakeMap products to critical users and for triggering established post-earthquake response protocols (Lin and Wald, 2008). ShakeCast allows utility and transportation agencies, businesses, and other large organizations to control and optimize the earthquake

information they receive. With ShakeCast, users can automatically determine the shaking value at their facilities, set thresholds for notification of different degrees of damage for each facility, and then automatically notify (via pager, cell phone, or email) specified operators, inspectors, or responders within their organizations who are responsible for those particular facilities so they can prioritize response. Having deployed ShakeCast, the California Department of Transportation (Caltrans) can prioritize inspection of thousands of bridges and overpasses statewide, an otherwise potentially overwhelming task.

Another secondary system, also developed primarily as a by-product of the USGS global implementation of ShakeMap, is called PAGER (Prompt Assessment of Global Earthquakes for Response). PAGER combines shaking intensity with exposed populations to rapidly and automatically estimate economic and human impacts worldwide. Unlike regional ShakeMap systems that rely on dense instrumentation, the global ShakeMap system relies primarily on the predictive aspects of the ShakeMap system; it incorporates site amplifications based on approximate soil conditions derived from topographic slope and utilizes macroseismic intensity data, if available, from near-real time, Internet-based data collection systems such as the USGS "Did You Feel It?" system (Wald et al., 1999a).

Outlook

Though developed primarily for post-earthquake, near-real time situational awareness, ShakeMap algorithms, which incorporate empirical ground-motion estimation capabilities, are widely used for other purposes. One side-benefit of the built-in ability to estimate ground motions for a specified earthquake is for generating hypothetical earthquake ground-motion maps. Such "Scenario ShakeMaps" are highly useful for response planning and long-term earthquake mitigation since portraying the overall pattern of shaking for potential future events is highly useful for earthquake drills and loss assessments. Calibration of earthquake loss models is facilitated by running ShakeMaps for historical earthquakes, which has been done for significant earthquakes around the globe from 1970 to 2008 (the ShakeMap Atlas; Allen et al., 2009). Some of these historic ShakeMap events have constraints from ground motion, intensity, and fault extent; others are purely predictive. Nonetheless, such historic ShakeMaps can be used for loss calibration or for better scientific understanding of the nature of past earthquakes. Ongoing refinements and the addition of earlier past or more recent events will continue. In addition, refinements to ShakeMap algorithms, products, formats, and associated tools are ongoing, and ShakeMap systems are being deployed and operated in numerous countries. At the time of this article, systems operate or are in development in countries including the USA, Italy, Iceland, Switzerland, Greece, Romania, China, and Indonesia.

EARTHQUAKES, SOURCE THEORY

Raul Madariaga
Laboratoire de Géologie, Ecole Normale Supérieure, Paris, France

Definition

Seismic moment. A measure of the size of an earthquake. In the simplest situation it represents the moment of the couples of forces that make up a dipolar source. In more general cases it is a 3 by 3 symmetric tensor of elementary force couples. For planar faults it is the product of rigidity by slip times the source area.

Seismic radiation. The seismic waves emitted by an earthquake. For point sources these are spherical P and S waves emitted by the point source.

Seismic spectrum. Fourier transform of the seismic waves in the far field from the source. In general, when it is not noted otherwise, it refers to the amplitude of the Fourier transform of the far-field displacement.

Kinematic earthquake model. A model of slip history of rupture on a fault determined from near and far-field observations. In kinematic models, the propagation of rupture is arbitrarily specified.

Dynamic earthquake model. A model of rupture propagation on an earthquake fault based on fracture mechanics.

Introduction

Earthquake source theory studies the dynamics of seismic sources in the Earth. The simplest possible model of a seismic source is that of a point source buried in an elastic medium. A proper understanding of the exact nature of seismic source took more than 50 years since the first

efforts by Nakano and colleagues in the 1920s in Japan. Earthquakes were initially modeled as simple explosions, then as point forces and, finally, as the result of fast transformational strains inside a sphere. In the early 1950s, it was recognized that P waves radiated by earthquakes presented a spatial distribution similar to that produced by single couples of forces, but it was very soon recognized that this type of source could not explain S wave radiation. The next level of complexity was to introduce a double couple source, a source without resultant force or moment. The physical origin of the double couple model was established in the early 1960s. Soon after that, finite source models derived from dislocation theory were introduced as a simple way to model observations of seismic radiation. Dislocation models present some severe mechanical problems that we will discuss later. They were soon replaced by more mechanically sound models based on dynamic shear cracks. These are the two kinds of models that are currently being used to model earthquakes over a broad range of frequencies and length scales.

Point source models

The radiation from a point force or Green function is the fundamental solution of the equation of elastodynamics. With few rare exceptions, seismic sources are due to fast internal deformation in the earth, for instance, faulting or fast phase changes on localized volumes. For a seismic source to be of internal origin, it has to have zero net force and zero net moment. It is not difficult to imagine seismic sources that satisfy these two conditions. The simplest such source is an explosion or implosion, but they do not produce shear waves, at least in uniform media. The next group of possible sources is dipoles, quadrupoles, or combinations thereof. Experimental observation has shown that simple dipoles are not good models of seismic sources. It is possible, however, to combine three orthogonal linear dipoles in order to form a general seismic source. These three dipoles represent the principal directions of a symmetric tensor of rank 2 that we call the seismic moment tensor:

$$\mathbf{M} = \begin{bmatrix} \mathrm{Mxx} & \mathrm{Mxy} & \mathrm{Mxz} \\ \mathrm{Mxy} & \mathrm{Myy} & \mathrm{Myz} \\ \mathrm{Mxz} & \mathrm{Myz} & \mathrm{Mzz} \end{bmatrix} \tag{1}$$

This moment tensor has a structure that is identical to that of a stress tensor, but it is not of elastic origin. The off-diagonal elements of the moment represent the torque produced by two point forces of direction i separated by an infinitesimal distance in direction j. The diagonal terms represent linear dipoles, two opposite forces separated by a very small distance.

Radiation produced by a point moment tensor source located at point $\mathbf{r}_0$:

$$\mathbf{M}(\mathbf{r}, t) = \mathbf{M}_0(t)\delta(\mathbf{r} - \mathbf{r}_0) \tag{2}$$

form a set of Green functions. In a homogeneous, linear elastic medium, these Green functions are well known and contain both near-field and far-field terms. The most important are the far-field terms, the radiation observed at large distance from the source. These are:

$$u_i^{\mathrm{P}}(\mathbf{r}, t) = \frac{1}{4\pi\rho\alpha^3}\frac{1}{R}\sum_{jk} R_{ijk}^{\mathrm{P}}\dot{M}_{jk}(t - R/\alpha) \tag{3a}$$

for P waves, and

$$u_i^{\mathrm{S}}(\mathbf{r}, t) = \frac{1}{4\pi\rho\beta^3}\frac{1}{R}\sum_{jk} R_{ijk}^{\mathrm{S}}\dot{M}_{jk}(t - R/\beta) \tag{3b}$$

for S waves. Here R is the distance from the source to the observer. R^{P} and R^{S} are the radiation patterns of P and S waves, respectively; $\rho, \alpha,$ and β denote the density and the P and S wave speeds of the elastic medium. The radiation patterns are different for every element of the moment tensor with its own set of symmetries and nodal planes. We observe that the far-field signal carried by both P and S waves is the time derivative of the seismic moment components, so that far-field seismic waves are proportional to the moment rate of the source.

Very often in seismology, it is assumed that the geometry of the source can be separated from its time variation, so that the moment tensor can be written in the simpler form:

$$\mathbf{M}_0(t) = \mathbf{M}_0\Omega(t) \tag{4}$$

where, $\mathbf{M}_0$ is a time-invariant tensor that describes the geometry of the source and $\Omega(t)$is the time variation of the moment, the source time function determined by seismologists, often called also the scalar seismic moment rate. In this case, we can now write a simpler form of Equation 3:

$$u_i^c(\mathbf{r}, t) = \frac{1}{4\pi\rho c^3}\frac{1}{R}R^{\mathrm{c}}(\theta, \phi)\dot{\Omega}(t - R/c) \tag{5}$$

where, c stands for either the P or the S wave velocity. For P waves, u^c is the radial component; for S waves, it is the appropriate transverse component for SH or SV waves. We observe that the signal emitted by the source in the far field is the derivative of the scalar moment time function $\Omega(t)$. The term $R^{\mathrm{c}}(\theta, \phi)$is the radiation pattern, a function of the takeoff angle of the ray at the source.

With small modifications designed to take into account smooth variations of elastic wave speeds in the earth, these expressions are widely used to generate synthetic seismograms in the far field. The main changes that are needed are the use of travel time instead of R/c in the waveform (Equation 5), and a more accurate geometrical spreading to replace the $1/R$ term. The complete expressions are given by Aki and Richards (2002). In most work with local earthquakes, the approximation (Equation 5) is frequently used with a simple correction for free surface response.

What does a seismic moment represent? A number of mechanical interpretations are possible. In the previous sections, we introduced it as a simple mechanical model of double couples and linear dipoles. Other authors (Backus and Mulcahy, 1976) have explained them in terms of the

distribution of inelastic stresses (sometimes called stress "glut"). Let us first notice that a very general distribution of force of internal origin must necessarily derive from a symmetrical seismic moment density of the form

$$\mathbf{f}(r,t) = \nabla \bullet \mathbf{M}_0(\mathbf{r},t) \tag{6}$$

where, $\mathbf{M}_0$ is the moment tensor density per unit volume. It is not difficult to prove that such a force distribution has neither net force nor torque. The moment tensor represents a stress tensor due to internal stresses as proposed by Eshelby (1957). From the moment tensor one can define the associated inelastic strain by

$$\mathbf{M}_0 = \lambda\theta_I\mathbf{I} + 2\mu\boldsymbol{\varepsilon}_I \tag{7}$$

where, $\mathbf{I}$ is the identity matrix in 3D, λ and μ are the elastic constants. $\boldsymbol{\varepsilon}_I$ represents the inelastic strain at the source. This is the strain that would occur in the body in the absence of elastic forces. We can now define ε_I for a fault segment. Let the source be reduced to a 2D fault element of area dS and thickness h. Then the inelastic strain that occurs across the fault element dS is approximately ½ D/h, the ratio of the displacement discontinuity or slip, D across the fault by the thickness of the fault. Thus $\varepsilon_I h \to D/2$ as h decreases to zero fault width. For a planar moment distribution we get a 2D seismic moment distribution

$$dm_0 = \mu\, D\, dS \tag{8}$$

That is, the moment density of a shear fault is just the product of the elastic constant by slip, a classical result obtained by Burridge and Knopoff (1964) using a different argument based on the representation theorem.

Seismic radiation in the spectral domain. In seismically active areas the waves radiated by earthquakes become quite complex because of multipathing, scattering, attenuation, site response, etc., so that the actually observed seismogram resembles the source time function $\Omega(t)$only at long periods. Complexities in wave propagation affect much less the spectral amplitudes in the Fourier transformed domain. Radiation from a simple point moment tensor source can be obtained from Equation 5 by straightforward Fourier transformation:

$$u_i^c(\mathbf{r},\omega) = \frac{1}{4\pi\rho c^3}\frac{1}{R}R^{\mathrm{c}}(\theta,\phi)\,\tilde{\Omega}(\omega)\exp(-i\omega R/c) \tag{9}$$

where, $\tilde{\Omega}(\omega)$ is the Fourier transform of the source time function, $\Omega(t)$.

From the scaling of moment with earthquake size, Aki (1967), and from spectral observations, Brune (1970) concluded that the seismic spectra decayed as ω^{-2} at high frequencies. A simple model of the spectral amplitude is:

$$\Omega(\omega) = \frac{M_0}{1+\omega^2/\omega_0^2} \tag{10}$$

where, ω_0 is the corner frequency of the earthquake, the intersection between the low and high frequency asymptotes of expression (11). This is the so-called omega-squared model of seismic radiation. In this model, seismic sources are characterized by only two independent scalar parameters: the seismic moment and the corner frequency. As mentioned earlier, not all earthquakes have displacement spectra as simple as this, but the omega-squared model is a simple starting point for understanding seismic radiation.

Finite source models

Earthquakes are due to the fast propagation of slip on a fault, or fault system, at speeds of the order of that of shear waves. There is evidence that a few events have propagated at speeds faster than that of shear waves, but these are exceptional events. For most others, the speed of rupture propagation is close to that of Rayleigh waves on the fault. Traditionally, finite source earthquake models are either kinematic or dynamic. In the first class the distribution of seismic moment and rupture time are specified in order to satisfy certain observational constraints on the source. The most common way is to specify the rupture process based on simple models of rupture propagation, for instance, at constant speed and then determining the distribution of moment (slip) on the fault from the waveforms observed in different seismic stations. As the data has improved kinematic inversion methods have become increasingly sophisticated, but the basic problem of how does a rupture grow cannot be determined from basic kinematic principles. The alternative is to use dynamic models where rupture is computed numerically from the specification of the stresses that prevail on the fault and the friction law that acts on the fault surface.

Kinematic models

One of the most widely used kinematic models was introduced by Haskell (1964). In this model a uniform displacement discontinuity spreads at constant rupture velocity inside a rectangular fault. At low frequencies, for wavelengths longer than the size of the fault, this model is a reasonable approximation to the rupture of a strike slip fault. In Haskell's model at time $t = 0$, a line dislocation of width W appears suddenly and propagates along the fault length at a constant rupture velocity v until a region of length L of the fault has been broken. As the dislocation moves it leaves behind a zone of constant slip D. Assuming that the fault lies on a plane of coordinates (x, y), the slip function can be written as

$$D(x,y,t) = D\,s(t-x/v) \quad \text{for} \quad -W < y < W \text{ and } 0 < x < L \tag{11}$$

where, $s(t)$ is the source time function that, in the simplest version of Haskell's model, is invariant with position on the fault. The most important feature of this model is the

propagation of rupture implicit in the time delay of rupture x/v, where v is the rupture velocity. An obvious unphysical feature of this model is that rupture appears instantaneously in the y-direction; the other is that near the borders of the fault slip suddenly jumps from D to zero. This violates material continuity and produces very strong unphysical stress concentrations. In spite of these two shortcomings, Haskell's model gives a simple, first-order approximation to seismic slip, fault finiteness, and finite rupture speed. The seismic moment of Haskell's model is just $M_0 = \mu DLW$. This model has been extensively used to invert for seismic source parameters both in the near and far field from seismic and geodetic data. Some of the limitations of Haskell's model can be improved by admitting that slip is variable on the fault, so that D in Equation 11 is no longer assumed to be constant but a function of position on the fault. Slip can be tapered as suggested by dynamic models of rupture. Rupture speed can also be made variable.

Dynamical fault models

The most frequently used source models are dynamic models, based on some basic concepts of fracture mechanics introduced by seismologists in the middle 1960s. The simplest of these dynamic models is a circular shear crack. This model was introduced by several authors in order to relate fault slip to stress drop inside a fault. A natural approach to model earthquakes was to use well-known results from fracture mechanics. Among dynamic models we consider here a circular shear crack, assuming that rupture starts from a point and then propagates self-similarly until it finally stops at a certain source radius. This model was carefully studied in the 1970s and a complete understanding of it is available without the need of getting into the details of the numerical modeling of earthquake sources.

Kostrov's self-similar circular crack. The simplest model of how an earthquake starts is a circular-shaped rupture front that starts from a point and spreads at constant rupture speed v without ever stopping. Slip on this fault is driven by stress drop inside the fault. The solution for slip across the fault, found by Kostrov (1964), is surprisingly simple:

$$D(r,t) = C(v)\frac{\Delta\sigma}{\mu}\sqrt{v^2t^2 - r^2} \tag{12}$$

where, r is the radius of the fault measured from the point of rupture initiation, vt is the instantaneous radius of the rupture at time t, $\Delta\sigma$ is the constant stress drop inside the rupture zone, μ is the elastic shear modulus, and $C(v)$ is a very slowly varying function of the rupture velocity. For most practical purposes $C \sim 1$. Inside the fault, for $r < vt$, the stress change produced by the slip function is constant and equal to $\Delta\sigma$. Thus for constant stress drop, slip inside the fault scales with the "ratio of stress drop over rigidity 'times' the instantaneous radius of the fault." As rupture propagates, displacement around the fault scales with the instantaneous radius of the rupture zone. The dynamic model (Equation 12) describes rupture propagation, but it has no mechanism to stop the rupture.

A finite fault model can be developed from Equation 12 by assuming that rupture suddenly stops after the fault has grown to a certain fixed radius. This simple dynamic model was proposed by Madariaga (1976). The circular crack problem is posed in terms of stresses not of slip, but the rupture process is fixed in advance so that rupture does not develop spontaneously. This is the only unrealistic feature of this model and it is the reason it was qualified as quasidynamic, that is, rupture is kinematically defined, but slip is computed solving the elastodynamic equations.

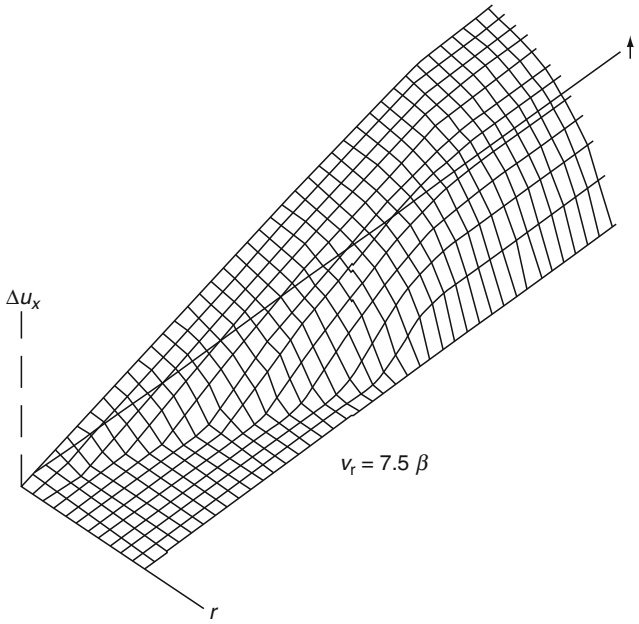
The static circular shear crack. We start by a quick study of a simple circular crack from which we derive some of the most fundamental properties of dynamic source models. Let us consider a static circular ("penny shaped") crack of radius a lying on the x, y plane. Assuming that the fault is loaded by an initial shear stress σ_0 and that the stress drop $\Delta\sigma$ is uniform inside the fault, slip on the fault is given by

$$D(r) = \frac{24}{7\pi}\frac{\Delta\sigma}{\mu}\sqrt{a^2 - r^2} \tag{13}$$

where, r is the radial distance from the center of the fault, a is the radius of the shear crack, and μ is the elastic rigidity of the medium surrounding the crack. Slip in this model has the typical elliptical shape that we associate with cracks. The taper of slip near the edges of the crack is the hallmark of dynamic source models. The slip distribution near the edges has a parabolic shape that is closely related to stress concentrations outside the fault zone (see Madariaga and Olsen, 2002).

From Equation 13 we can determine the scalar seismic moment for a circular fault, $M_0 = 16/7\ \Delta\sigma\ a^3$, so that the moment is the product of the stress drop times the cube of the fault size. This simple relation is the basis of the seismic scaling law proposed by Aki (1967). The circular crack model has been used to quantify numerous small earthquakes for which the moment was estimated from the amplitude of seismic waves, and the source radius was estimated from corner frequencies, aftershock distribution, etc.; the result is that for shallow earthquakes in crustal seismogenic zones like the San Andreas fault, or the North Anatolian fault in Turkey, stress drops are of the order of 1–10 MPa. For deeper events in subduction zones, stress drops can reach several tens of MPa. Thus, in earthquakes, stresses do not change much, at most a couple of orders of magnitude, while source radius varies over several orders of magnitude from meters to 100 km or more. It is only in this sense that the usual assertion "stress drop in earthquakes is constant" should be taken; it actually changes but much less than the other parameters in the scaling law.

The quasi-dynamic circular crack. There are no simple analytical solutions like Equation 13 for finite dynamic cracks. We are forced to use numerical solutions that are actually very simple to obtain using either finite difference or boundary integral equation techniques. The full solution to the circular crack problem is shown in Figure 1. Initially, until the sudden arrest of rupture at the final radius a, the slip distribution can be accurately computed using



Earthquakes, Source Theory, Figure 1 Slip distribution as a function of time and position for Madariaga's (1976) quasi-dynamic circular crack model.

Kostrov's self-similar solution (Equation 12). The stopping of rupture generates strong healing waves that propagate inward from the rim of the fault. These waves are of three types: P, S, and Rayleigh waves. Soon after the passage of the Rayleigh waves, slip rate inside the fault decreases to zero and the fault heals. After healing, we assume that frictional forces are sufficiently strong that no slip will occur until the fault is reloaded. As observed in Figure 1, it is clear that slip and rise time are functions of position on the fault, the rise time being much longer near the center where slip is also larger than near the edges of the fault where slip is clamped. Finally, let us note that the slip after healing is very similar to that of a static circular crack, except that there is a slight overshoot of slip with respect to the static solution (Equation 13). The overshoot is of course a function of the rupture speed, but its maximum value is of the order of 15% for a rupture speed of 0.75.

Future work

Seismic observations have steadily improved in the last 20 years due to the wide availability of digital, continuously recording accelerograms that can be integrated to obtain velocity and band limited displacement fields near active faults. Additional information about rupture is provided by field studies of faulting associated with earthquakes and from geodetic observations. Modeling and inversion of such data has been usually done using kinematic models derived from the original Haskell model. This approach gives solutions that are very nonunique because the rupture process (the rupture velocity) is difficult to estimate. Rupture velocity actually controls seismic radiation, so that poor velocity control leads to poor seismic inversions. There is hope that dynamic models, where rupture is inverted as part of the inversion process will provide better estimates of the stress field around major fault zones along with some essential parameters like the friction law that controls rupture propagation.

Definition

Strong-ground motion. An earthquake-induced ground motion capable of damaging man-made environment.

Introduction

Earthquake ground motion is a natural phenomenon associated with a sudden release of energy due to a fault rupture. Strong-motion seismology deals with seismic waves radiated by large earthquakes. More precisely, it is concerned with measurement, interpretation and prediction of strong shaking generated by damaging earthquakes.

Because of the engineering need for estimates of future strong-ground motion, the scope of strong-motion seismology encompasses seismic source theory and all other aspects of seismology that can provide insights helpful in making the best possible earthquake ground-shaking scenarios given the limited observational data.

Accumulated data have been providing very important knowledge about rupture processes of earthquakes, propagation paths and site effects on ground motion, and the relation between ground motion, damage, and other earthquake related phenomena (e.g., landslides earthquake induced).

The most important goals of strong-motion seismology are the improvement of the physical understanding of the processes controlling strong-ground motion and the reliable assessment of seismic hazard.

To assess the hazard for engineering design applications and due to the limited availability of strong-ground motion records, it has become increasingly common to compute broadband synthetic seismograms that allow us to perform realistic waveform modeling for different seismotectonic environments. The modeling has to take simultaneously into account the properties (e.g., dimensions, directivity, and near-field effects) of the radiating source, lateral heterogeneities along the path, and local site effects.

The joint use of reliable synthetic signals and observations can be fruitfully used for design purposes. In fact, even if recently strong-motion records in near-fault, soft soils, or basin conditions have been obtained, their number is still very limited to be statistically significant for seismic engineering applications.

The lack of a representative set of observations is due to the low frequency of large earthquakes and to the difficulty of providing a proper instrumental coverage of all the areas prone to strong shaking. Despite of the growing strong-motion registration networks, the existing database is still not complete with respect to the possible scenario earthquakes, and the lack of completeness will last for many years if not centuries. The variability of ground motion, due to different causes, e.g., spatial variability, source parameter variability, azimuthal variability (Strasser and Bommer, 2009), show how the current available strong-motion data still represent only a small sample of all physically possible ground motion. The mathematical modeling, with different degrees of complexity, based on probabilistic concepts cannot fill in the gap due to the lack of knowledge about the physical process behind an earthquake (Panza et al., 2004). Therefore, to resort to broadband synthetic seismogram is a fundamental step: where no records are available, synthetic signals can be used to estimate the ground motion without having to wait for a strong earthquake to occur.

Description of strong-ground motion

A seismic record of ground acceleration, due to a damaging shaking, is usually defined a strong-motion datum. There is not a quantitative rule, but it is generally assumed that damaging earthquakes are those of magnitude 5 and above. The threshold to be exceeded in terms of peaks acceleration for ground motion to be considered strong motion is quite blurred. The strongest recorded earthquake motions have peaks between 1 and 3 g, but these are very rare events. Usually, damages are caused by ground motion, which exceeds the threshold of 0.1 g, but Bolt and Abrahamson (2003) lower this limit to 0.05 g.

Due to the importance of strong motion for earthquake engineering, a number of different parameters have come into use to represent various characteristics of strong motion. Actually, the most appropriate way to describe or specify the characteristics of ground motion for the purpose of seismic design is still an open problem. A large number of parameters have been proposed for measuring the capacity of earthquakes to damage structures. However, to account for the complex characteristics of earthquake-induced strong-ground motion in the engineering analysis and design, the need arose for a more inclusive definition of the existing parameters and for the introduction of new ones. In fact, the adoption of inadequate parameters can lead to the definition of unrealistic design earthquakes and consequently to the unreliable evaluation of the seismic risk.

The parameters fundamentally involved in the evaluation of the level of severity associated with strong motion are, for engineering purposes, the frequency content, the amplitude, and the effective duration.

Beginning about the 1960s, the most used ground-motion parameter for quantification of ground motion was the peak ground acceleration (PGA), as the inertia forces depend directly on acceleration. PGA is simply obtained from unprocessed accelerograms. However, PGA is a poor indicator of damage, since, as observed, time histories with the same PGA could be very different in their frequency content, strong-motion duration, and energy level. In fact, PGA may be associated with high frequency pulses, which do not produce significant damage to the buildings as most of the impulse is absorbed by the inertia of the structure with little deformation. On the other hand, a more moderate acceleration may be associated with a long-duration pulse of low frequency (acceleration pulse), which gives rise to a significant deformation of the structure. The peak ground velocity (PGV) is another useful parameter for the characterization of ground-motion amplitude. The velocity is less sensitive to the higher-frequency components of the ground motion, so the PGV should be more useful than the PGA in characterizing the damaging potential of ground motion. For design purposes, the peak ground displacement (PGD),

generally associated with the lower-frequency components of an earthquake ground motion, has been recognized as useful parameter, mostly for the design of seismically isolated structures.

The response spectrum, firstly proposed by Benioff (1934), defined as the maximum response of a damped harmonic system to input motion (Anderson, 2003), is a parameter widely used for engineering purposes.

Another ground-motion parameter, very important for engineers, is the duration of shaking (Villaverde, 2009). Duration can impact structures and response of soils: structures that can stand one or two large oscillations may collapse under prolonged motions, and while a second of shaking of sandy soil can be tolerated, repeated oscillations can induce liquefaction (Jennings, 2003). But there is not a unique definition of duration, as clearly evidenced in Bommer and Martinez-Pereira (1998), where 30 definitions of strong-motion duration are reported. The available definitions can be classified in three different groups, or as a combination of them (Montejo and Kowalsky, 2008): (1) "bracketed" durations (Bolt, 1969), in which the duration is defined to be the time interval between the first and the last exceedances of a threshold of acceleration; (2) "significant" durations that define the duration of strong motion as the time interval during which a given percentage of the total energy of the record is released; and (3) frequency-dependent durations, in which the duration of strong-ground motion is analyzed separately in several narrow-frequency bands (Bolt, 1969; Trifunac and Westermo, 1977). The following two examples of duration measurement show the limits of this parameter. A way to estimate duration is to measure the interval of time within which acceleration exceeds some threshold, usually 0.05 g (bracketed duration, Bolt, 1969); another measure is the interval of time in which 90% of the integral of the acceleration-squared is recorded. These two estimations yield opposite results as the distance from the source increases. Peak ground motions decrease, as a rule, with increasing distance from the source (for exceptions, see e.g., Panza and Suhadolc, 1989; Fah and Panza, 1994), but energy becomes dispersed, so the time that is necessary to wait for the arrival of the 90% of the total energy in the seismogram increases (Anderson, 2003).

Several equations, commonly referred to as attenuation relations or ground-motion prediction equations (GMPE), have been proposed over the years from strong-ground motion observations and theoretical studies. These mathematical expressions give ground-motion intensity measures as a function of earthquake magnitude and distance. They may be determined empirically, by a regression of recorded ground motion, or theoretically, using seismological models to generate synthetic ground motions that account for the source, site, and path effects. Theoretical attenuation relations between various source parameters are used to estimate source parameters for earthquakes that have not yet occurred, or for which parameters of interest are unknown (e.g., Geller, 1976; Oth et al., 2007; Somerville et al., 1997). The other approach uses empirical relations between source parameters compiled for a huge number of earthquakes (e.g., Wells and Coppersmith, 1994). In the past few years, the availability of additional strong-motion data has allowed the incorporation of additional parameters, such as type of fault, fault orientation; further recent relationships have increasingly become more refined, although, at the same time, more complicated. Attenuation relations are usually grouped into three sets (Panza et al., 2004): shallow crustal earthquakes in active tectonic regions, shallow crustal earthquakes in stable tectonic regions, and subduction zone earthquakes. These relations can differ in the assumed functional form, the data selection criteria, the number and definition of independent variables, and the statistical treatment of the data. A review can be found in Douglas (2003), where the complete procedure that needs to be followed to derive equations for the estimation of ground motion from recorded strong-motion data is outlined as well. As the coefficients of the attenuation relations are determined empirically by means of regression analysis, they are quite sensitive to the used data set, an example of the dependence of attenuation relations on the procedure followed in the data processing is given by Parvez et al. (2001) for the Himalayas. The Izmit, Turkey, earthquake of August 17, 1999 and the Chi Chi, Taiwan, September 20, 2000, did show the inadequacy of the existing database: as explained in Anderson (2007), the GMPEs available at that moment underestimated the peak accelerations for those events. The discrepancies could be due to a wide variety of factors, so these examples suggest that a large amount of data and a deep physical understanding of the processes involved in seismic events are needed to improve the quality of GMPEs (Anderson, 2007). A common main source of error can be mathematical shortcomings that arise when attenuation relations are used in geologically complex areas (e.g., Peresan et al., 2010).

As stressed earlier by Aki: "a major goal of strong-motion seismology is to be able to synthesize strong-motion seismograms suitable for use in engineering analysis" (Anderson, 2003, p. 942). The use of computational modeling has the aim to simulate the wave generation and propagation process in complex media. The formulation of physical-mathematical models aimed to represent the effective complexity of the phenomenon and their resolution is a complicated affair. With the exception of a very limited number of simple situations, the physical-mathematical approach does not lead to closed form solutions, i.e., fully analytical, so it is necessary to employ numerical procedures, more or less complex, or approximated theories (Bolt, 1999).

Earthquake source effects on strong-ground motion: near-field effects

Source effects on far-field seismograms are discussed by Aki and Richards (1980, Chap. 14). Seismic data used in earthquake engineering are occasionally collected in the

near-field, but the question where the near-field ends and the far-field begins is gradational and will not be addressed here.

Near-fault ground motions often contain large long-period pulses (Somerville, 2002). There are two causes for these pulses: one is constructive interference of the dynamic shaking due to rupture directivity effects, the other is due to the movement of the ground associated with the permanent offset of the ground. For keeping these two causes separated, the terms "directivity pulse" and "fling step" have been introduced (Bolt and Abrahamson, 2003).

Large earthquakes are produced by rupture that starts at a point and travels with a velocity that is generally only slightly smaller than the shear-wave velocity in the medium. Therefore, when rupture is towards the station, the propagation causes most of the seismic energy to arrive in a single large pulse occurring at the beginning of the record. Forward-directivity effects occur when the rupture front propagates towards the recording site and the slip direction on the fault is aligned with the site. Backward-directivity effects, occurring when the rupture front propagates away from the recording site, generates opposite effects, i.e., longer-duration motions, lower amplitudes, and longer periods. This phenomenon has been first explained by H. Benioff in 1955, when analyzing the records of the 1952 Kern County, California, earthquake. The conditions for generating forward-rupture directivity effects are readily met in strike-slip faulting, where the rupture propagates horizontally along the strike either unilaterally or bilaterally, and the fault slip direction is oriented horizontally in the direction along the strike of the fault. As described by Bolt and Abrahamson (2003), for strike-slip earthquakes, the rupture directivity is observed on the fault normal component, and the static displacement fling step is observed on the fault parallel component. The conditions required for forward directivity are also met in dip-slip faulting, including both reverse and normal faults. The alignment of both the rupture direction and the slip direction updip on the fault plane produces rupture directivity effects at sites located around the surface exposure of the fault (or its updip projection if it does not break the surface). Consequently, it is generally the case that all sites located near the surface exposure of a dip-slip-fault experience forward-rupture directivity when an earthquake occurs on that fault.

For dip-slip earthquakes, the separation of the effects (rupture directivity and fling step) on the fault components is more complicated: the rupture-directivity effect will be strongest on the fault normal component at a location direct updip from the hypocenter, and the fling-step will also be observed on the horizontal component perpendicular to the strike of the fault, i.e., directivity-pulse effects and fling-step effects occur on the same component for dip-slip faults. The horizontal records of the 1966 Parkfield and 1971 San Fernando, California, earthquakes were the first to be discussed (Bolt, 1975) as examples of near-fault velocity pulses. The pulses from both directivity and fling-step may attenuate differently. Hisada and Bielak (2003) investigated the combined effects of fling-step and rupture directivity by paying special attention to the contribution of static and dynamic Green's functions. Fling effects are found to be stemmed mainly from the static Green's function. They are dominant in the vicinity of the surface fault and negligible for buried faults since the static Green's function decreases rapidly, as $(1/r^2)$, with the distance from the fault. When the observation point is above the buried fault, the fling step disappears because the slip dislocation of the fault cannot fling the ground, due to the presence of a continuous medium above the fault itself. Directivity effects derive mainly from the dynamic Green's function and attenuate as $(1/r)$ to $(1/\sqrt{r})$, more slowly than the fling. The combination of both the effects of rupture directivity and fling-step results in inclined directions, with respect to the fault plane, of maximum velocities, and displacements.

The destructive potential of near-fault ground motions was manifested in the 1994 Northridge and 1995 Kobe earthquakes. In each of these earthquakes, peak ground velocities as high as 175 cm/s were recorded. The period of the near-fault pulses recorded in both of these earthquakes lies in the range from 1 to 2 s, comparable with the natural periods of structures, such as bridges and buildings, many of which were indeed severely damaged.

Near-fault recordings from recent earthquakes indicate that this pulse is a narrow band pulse whose period increases with magnitude. This magnitude dependence of the pulse period causes the response spectrum to have a peak whose period increases with magnitude, such that the near-fault ground motions from moderate-magnitude earthquakes may exceed those of larger earthquakes at intermediate periods (around 1 s).

Wave-propagation effects

Wave propagation in heterogeneous media is addressed in another chapter herein (see *Propagation of Elastic Waves: Fundamentals*), so, here we limit the analysis to site effects due to their impact on strong-ground motion.

Ground motion can be highly amplified, or deamplified, by local effects. The essential aspects of site effects on strong-ground motion are widely addressed in literature (see e.g., Kawase, 2003). The pioneering works where site effects are well-recognized date back to 1930s and are due to Sezawa and Ishimoto (Kawase, 2003), but a first comment on the effect of near-surface conditions on shaking intensity during the 1906 San Francisco earthquake dates back to 1910: "Experience shows that the damage done by destructive earthquakes is much greater on alluvial soil than on solid rock" (Reid, 1910). Almost all recent destructive earthquakes have shown the relevance of site effects in the amplification of the seismic ground motion. The classical example of such a situation is the September 19, 1985 earthquake that, in Mexico City, about 400 km far away from the epicenter, caused a large victims toll (about 8,000), destroyed or heavily damaged hundreds of buildings, and caused few billion dollars damage (Fah et al., 1994; Anderson et al., 1986).

The presence of lacustrine sediments is the cause of the large ground motion, up to 40 times larger than that of firm ground (Chàvez-Garcìa and Salazar, 2002). The modeling of wave propagation in basins, and more generally in complex 2D and 3D regions, using numerical methods, such as finite difference (FDM), finite element (FEM), spectral element method (SEM), boundary integral equation, and boundary element method (BIEM and BEM) is an active field of research (see e.g., Aagaard et al., 2001; Bielak et al., 1991; Bouchon and Sánchez-Sesma, 2007; Graves, 1996; Komatitsch and Tromp, 1999, 2002a, 2002b; Komatitsch and vilotte, 1998; Komatitsch et al., 2004; Oprsal and Zahradnik, 1999, 2002; Pitarka, 1999; Yoshimura et al., 2003). These methods differ in accuracy with respect to different structural features of the complex heterogeneous models and considerably in the computational efficiency. For comparison of several modeling methods, we refer to the review paper by Takenaka et al. (1998), but the most recent review of the computational- and numerical-modeling methods can be found in the book edited by Wu and Maupin (2007). Very recently, a new analytical approach has been developed and validated performing simulations in the area of the Kanto basin, Japan (La Mura et al., 2010). It is generally observed that at stations throughout the basin larger amplitudes and longer durations of ground shaking are observed, but the pattern can be very complicated. The amplification patterns depend not only on the site conditions, but also on the characteristics of the incoming wavefield and, therefore, on the source and the wave propagation path. Clear examples are given in Field (2000).

Last but not least, we mention the liquefaction phenomenon, largely observed, for example, during the Niigata earthquake, Japan, on June the 16th, 1964 (Youd, 2003; Bardet, 2003). Liquefaction of water-saturated sands is believed to occur when the pore pressure, increased by the strong-ground motion, reaches the effective confining pressure. The likelihood that an earthquake will liquefy a site depends on many site characteristics (e.g., mean grain size, percentage of fine-grained sediment, porosity and level of saturation) and on the regional geology, which influences the amplification and attenuation of strong-motion amplitude. Ground-motion modeling may help in defining a priori the liquefaction potential (e.g., Nunziata et al., 2008).

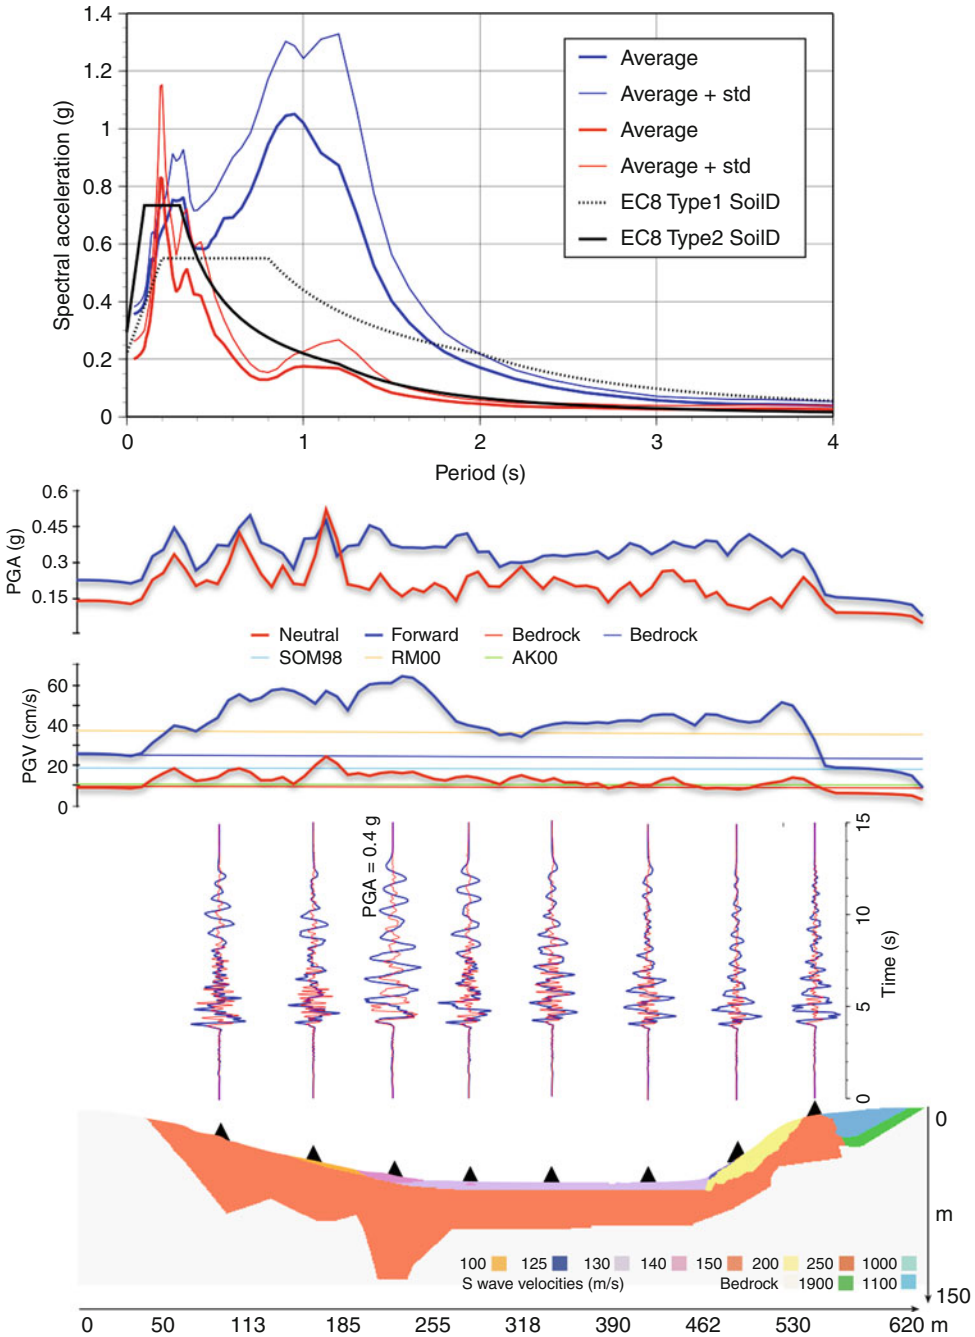
Strong-ground motion modeling

Due to the destructive potential of earthquakes, a goal is to develop methodologies for modeling strong-ground motions from seismic sources related to active faults and subduction zones with high probability of earthquake occurrence. Confidence in such modeling relies on the theoretical part of strong-motion seismology and on the calibration of the techniques against the empirical data.

One of the most common methods to simulate broadband strong-ground motion is the use of records from small earthquakes occurred in the vicinity of the source area of a large earthquake. This kind of modeling of the strong motion is known as empirical Green's function method, and it has been proposed by Hartzell in 1978 and largely reviewed and applied through the years (see e.g., Irikura, 1986; Dan et al., 1990). The empirical Green's function method has been applied in simulating strong-ground motions from a large event, even using observed records of just one or two small events. The records are used as the empirical Green's functions over the fault plane of the large event by correcting only attenuation effects due to difference in distance from each subfault to the site. The advantage of this approach relies in the fact that the seismograms contain all the complexities of wave propagation. On the other hand, the serious disadvantage is that the empirical Green's functions may not be available for the desired source-station path and may originate by an earthquake with a focal mechanism and/or depth different from the desired one.

Very recently, a procedure, called "recipe of strong-motion prediction," has been developed to the aim of obtaining ground-motion time histories from specific earthquakes (Irikura et al., 2004). Such a recipe is based on source characteristics obtained from the waveform inversion using strong-motion data. The idea is to follow a procedure, outlined as a recipe, for characterizing the source model estimating three kinds of source parameters: outer-, inner-, and extra-fault parameters. The outer are to outline the overall properties of the target earthquake, such as entire source area and seismic moment; the inner are parameters characterizing stress heterogeneity inside the fault area; the extra parameters are considered to complete the source model, such as the starting point and propagation pattern of the rupture.

The theoretical approach to the simulation of strong motion, based on the computation of synthetic seismograms, has experienced an impressive growth in the last decades. A description of both analytical and numerical methods can be found, e.g., in Anderson (2003), Bolt and Abrahamson (2003), Bielak et al. (2003). Hybrid techniques, obtained combining analytical and numerical methods, e.g., modal summation method and finite difference (Panza et al., 2001), wave number method and finite difference (Zahradnik and Moczo, 1996), finite element and boundary integral method (Bielak et al., 1991), have been developed and a review of these methods dating back to 1980 can be found in Moczo et al. (1997). Numerical-modeling methods for anelastic wave propagation, that take into consideration the earthquake source, propagation path, and local site effects, have become available for the estimation of the site responses and, more generally, for addressing the problem of solving the wave equation in 3D models. Then simulations based on finite difference (see e.g., Sato et al., 1998) or, more recently, finite element (see e.g., Bielak et al., 2003) and Spectral Element Method (SEM) (see e.g., Komatitsch and Tromp, 2002a, b; Komatitsch et al., 2004) have been largely used in order to simulate strong-ground motion in 3D structures. A very recent development (La Mura et al., 2010) extended the very efficient analytical modal summation (Panza et al., 2001) to 3D anelastic structures.



Earthquakes, Strong-Ground Motion, Figure 1 From *bottom* to *top*: local geotechnical model schematizing the surface geology along the Warth bridge. *Black triangles* show the sites of the abutments and of the piers along the section. Transverse acceleration time series computed at the eight pier sites. The amplitude of the signals is normalized with respect to the maximum one (0.4 g). *Blue* and *red* curves correspond to the case of forward and neutral directivity, respectively. Peak Ground Velocities (*PGV*) calculated along the profile, for forward (*blue curves*) and neutral (*red curves*) directivity, for a unilateral rupture and for the bedrock case (*BED*), that can be compared with the regression analysis for PGV made using a database of near-fault, forward-directivity motions, proposed by: Somerville (1998) -SOM98- *azure* curve, Alavi and Krawinkler (2000) -AK00- *orange* curve and Rodriguez-Marek (2000) -RM00- *green* curve, for a magnitude equal to 5.5. Peak Ground Accelerations (*PGA*) calculated along the profile, for forward (*blue curves*) and neutral (*red curves*) directivity, for a unilateral rupture. Average Response Spectra Accelerations (*ARSA*) and ARSA + one standard deviation computed for the eight sites; *blue* and *red curves* correspond to the case of forward and neutral directivity, respectively. The *black lines* correspond to the two (Type 1 and 2) Design Spectra suggested by EC-8 (EN, 1998) for a 5.5 magnitude earthquake and for a soil of class D.

Strong-motion simulation: an example

In this section, an example of simulation of strong ground motion is discussed. The determination of the seismic ground motion due to an earthquake with a given magnitude and epicentral distance from the site has been done following a theoretical approach. In order to perform an accurate and realistic estimate of ground shaking scenario, it is necessary to make a parametric study that takes into account the complex combination of the source and propagation parameters, in realistic geological structures.

The realistic modeling of ground motion requires the simultaneous knowledge of the geotechnical, lithological, geophysical parameters, and topography of the medium on one side, and tectonic, historical, paleoseismological, seismotectonic models on the other, for the best possible definition of the probable seismic source.

To deal both with realistic source and structural models, including topographical features, a hybrid method, that combines modal summation and the finite difference technique (e.g., Panza et al., 2001) and optimizes the use of the advantages of both methods, has been used. Wave propagation is treated by means of the modal-summation technique from the source to the vicinity of the local, heterogeneous structure that has to be modeled in detail. A laterally homogeneous, anelastic structural model is adopted that represents the average crustal properties of the region. The generated wavefield is then introduced in the grid that defines the heterogeneous area and it is propagated according to the finite differences scheme. With this approach, source, path, and site effects are all taken into account simultaneously.

An example of seismic-input computation is illustrated. The computations are performed for the Warth bridge, freeway A2, 63 km south of Vienna (Austria), a location where no seismic records are available (see Romanelli et al., 2003, 2004). The information about the possible seismic input is limited to an estimate of the macroseismic intensity, in the range from VI to VIII (MSK), the value of the magnitude, M, of the nearest largest recorded event, M = 5.5 and the most probable focal depth of strong earthquakes, in the range from 6 to 11 km.

The synthetic time signals are calculated for the three components of motion and the working magnitude is 5.5 (seismic moment equal to 1.8×10^{17} Nm). The study of possible directivity effects in the direction of the Warth bridge (see cross section in Figure 1) has been performed with the method developed by Gusev (2010), based on the modeling of a Haskell-type seismic source (Haskell, 1964; Haskell, 1966), where a stochastic component allows to build a spectrum (amplitude and phase) of the source function that takes into account both the rupture process and directivity effects. The near-source effect is shown in Figure 1, where the acceleration time series at the eight sites are plotted in the case of forward (blue curves) and neutral (red curves) directivity for a unilateral rupture. In the figure are also reported the Peak Ground Velocities (PGV) and Peak Ground Accelerations (PGA) along the profile, for neutral (N) and forward (F) directivity, calculated for a unilateral rupture, both for the bedrock case and taking into account the local site conditions. The curves can be compared with the regression analysis for PGV made using a database of near-fault, forward-directivity motions proposed by Somerville (1998), Alavi and Krawinkler (2000) and Rodriguez-Marek (2000). From the results it is evident the strong influence of the rupture and site effects on the ground-motion characteristics, in terms of amplitude and duration. The accelerograms exhibit the greatest peaks in the frequency range, from 1 to 6 Hz, and reach considerable peak values, around 0.4 g.

The analysis of the computed strong-ground motion can be carried out in the time domain (broadband ground-motion time series) and other domains (e.g., Fourier and response spectra). The results show that lateral heterogeneities and source effects can produce strong spatial variations (e.g., more than doubling the amplitudes) in the ground motion (also in terms of differential motion) even over distances of a few tens of meters. In other words, considering that an increment of one intensity degree in the MCS scale roughly corresponds to a doubling of the PGA (Cancani, 1904), a general result of the modeling is that a difference greater than one unit in the seismic intensity can be experienced at sites as close as a few tens of meters.

Conclusions

Solution to earthquake engineering problems, either design or estimation of seismic hazard, are today very different than they were before a strong interaction between seismologists and engineers. Today the differences between strong motion and weak motion have been softened, due to progress in instrumentation and the awareness that both kinds of motions are useful to the understanding of the nature of earthquakes. Today it is unthinkable to study seismic-rupture processes and seismic-wave generation of large earthquakes without near-source strong-motion data; however, while waiting for the enlargement of the strong-motion data set, a very useful approach is the development and use of modeling tools based, on one hand, on the theoretical knowledge of the physics of the seismic source and of wave propagation and, on the other hand, exploiting the rich database about the geotechnical, geological, tectonic, seismotectonic, and historical information already available. With these efforts, the prediction of strong motions through physical modeling is adequate and desirable.

EARTHQUAKES, VOLCANOGENIC

J. W. Neuberg
Institute of Geophysics and Tectonics, School of Earth and Environment, University of Leeds, Leeds, UK

Definition

Volcano-tectonic earthquakes. "Conventional" double-couple earthquakes of shallow tectonic origin, occurring in a volcanic setting, and comprising primary (*P*) and secondary (*S)* waves as well as surface waves.
Rock-fall events. High-frequency (above 2 Hz), "cigar-shaped" signals caused by the surface impact of solid, crystallized lava dome material, consisting mainly of surface waves.
Low-frequency earthquakes. Earthquakes with low-frequency content (0.5–2 Hz), generated at the interface between a magmatic fluid and solid rock, causing parts of the volcanic plumbing system such as conduits, dykes, and cracks to resonate.
Volcanic tremor. Either unstructured, random background noise on a volcano caused by magma movement, or merging swarms of low-frequency earthquakes that retain all characteristics of the single events.
Very-long-period earthquakes. Seismic transients with periods between tens of seconds and several minutes, caused by magma/gas movement in the shallow plumbing system.

Volcano seismology

Introduction

Volcano seismicity covers a large variety of seismic signals caused by the complex interaction of magmatic and hydrothermal fluids with solid rock within the volcanic edifice leading to stress changes, brittle failure of rock, pressure variations, magma fracturing, and fragmentation. Volcano seismology has the aim to identify and separate different seismic signals and attribute them to physical processes, a task that helps volcanologists to understand the dynamics of the magmatic systems.

The interpretation of different volcanogenic seismic signals and the development of conceptual and numerical models are at the core of any attempt to forecast volcanic eruptions. While volcano seismology emerged from earthquake seismology, it has evolved into a separate discipline in its own right, dealing with a large complexity of seismic source processes in a volcanic environment.

Crucial for the interpretation of seismic signals is the examination of their frequency content by Fourier or frequency analysis by which the signal is decomposed into harmonic waves and contributions of single frequencies are compared with each other. This decomposition is called a frequency spectrum, and its repeated application in consecutive time windows is referred to as a spectrogram. It turns out that different volcanogenic signals can be easily identified and separated by their frequency content; hence, we will make frequent use of this methodology in the following sections where the characteristics and the possible origin and source mechanism of different volcanogenic signals are described. Single event types are classified according to their source mechanism rather than using a phenomenological classification according to their waveform. A summary of the three main types of volcanogenic signals and their respective frequency spectra are shown in Figure 1, while volcanic tremor and very-long-period transients are depicted in Figures 3–5, respectively.

Volcano-tectonic earthquakes

Volcanoes are often located in tectonically active areas such as subduction zones, where earthquakes are generated merely by changes in the regional stress field due to the continuous movement of the tectonic plates. When magmatic and hydrothermal processes occur at the same location and time, the local stress field is further modulated and impacted upon by these processes. It is this complex interaction between the regional stress field and local stress modulation by volcanic processes such as dyke intrusion and (de)pressurization of the volcanic plumbing system that leads to the generation of volcano-tectonic earthquakes, referred to in the following as VTs for brevity. These stress changes can be created directly by magma emplacement, or indirectly by temperature changes or pressure changes as a result of magma–water interaction in a hydrothermal system.

Assuming that the pressure modulation through a magmatic body produces only a localized effect on the overall stress field impacting only on close distance of a few hundreds meters from the magmatic source, the earthquake location in itself indicates the emplacement of fresh magma (or its withdrawal). Hence, the locations of VT earthquakes over a certain time period are an indicator of changes in the system rather than providing a picture of a so-called magma chamber. VTs are generated by *stress changes*, as a consequence of *magma movement*. In this way, Battaglia et al. (2005) traced the rising magma dyke through time at Piton de la Fournaise, La Reunion.

Being generated by brittle fracture of rocks along a fault plane, VTs have all the characteristics of local earthquakes: containing a clear primary (P) wave, followed by the secondary (S) wave, both in the frequency range of 1–20 Hz (see Figure 1a). If the recordings of several seismic stations are available, the hypocenter of the event can be located using standard seismological tools, as well as other seismic source parameters which can be obtained by the fault plane solution. Typical VTs range in magnitude Mb between 1 and 3.

Rock-fall events

This event type is produced by the impact of falling rock fragments on the surface of the volcanic edifice, and therefore, is typical for dome-building eruptions involving highly viscous magma. There is a continuum between small rock avalanches to highly energetic, so-called pyroclastic

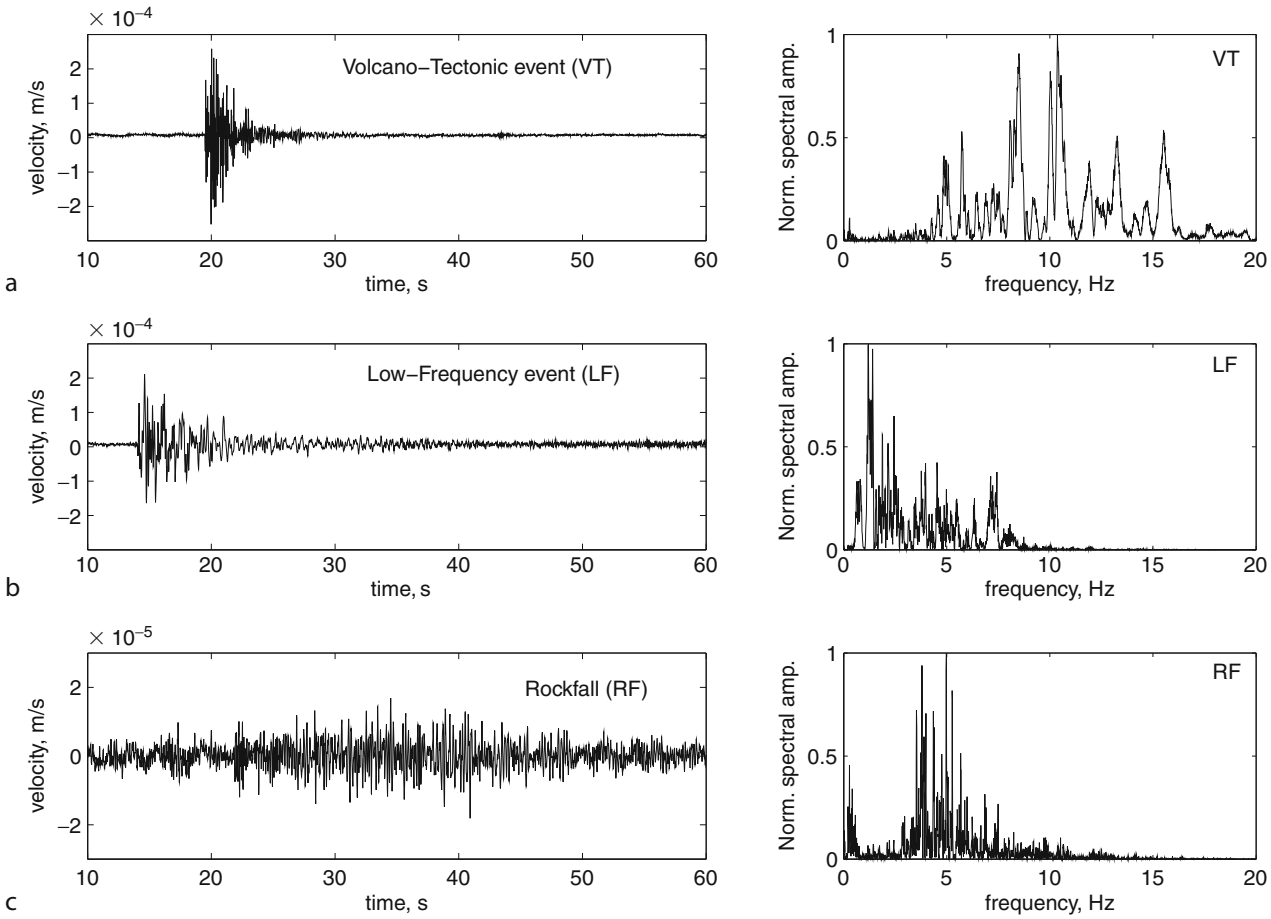
flows, which are a mixture of hot gas and rock fragments, ranging from huge boulders to fine volcanic ash particles. The impact that generates the seismic signal depends on rock size, impact angle, and the property of the surface.

The signal, a typical example of which is depicted in Figure 1c, has a "cigar-shaped" waveform, increasing in amplitude as more and more rocks form a rock avalanche, gaining speed and momentum. Secondary phases can be identified in the waveform as the flow reaches a change in topography slope converting its kinetic energy into a seismic signal. The frequency content is very high, containing mostly surface waves. The end of the "cigar" is reached once the material involved in the flow has settled. Rock-fall signals occur sometimes as secondary events in connection with low-frequency events that are able to cause significant seismic shaking of a dome structure (see below) or volcanic explosions resulting in a shower of volcanic ejecta and collapsing eruption columns. Another signal with a similar waveform is caused by so-called *lahars*, high-density mudflows that can keep big boulders in suspension. These mudflows occur often after heavy rainfall or through melting icecaps that cover parts of the volcano. While rock-fall events are seismologically the least interesting signals on a volcano, they can often be used as a proxy for magmatic extrusion rate, assuming that the lava disintegrates and falls off the dome at the same rate as it is extruded.

Low-frequency earthquakes

Low-frequency earthquakes, depicted in Figure 1b and in the following referred to as LF, proved to be pivotal to modern volcano seismology. Several examples have been quoted where these events have been successfully used to forecast volcanic eruptions (e.g., Chouet, 1996). Their occurrence alone has been used as an indicative tool even though a full understanding of their source mechanism had not been achieved. On Galeras volcano, Colombia, the occurrence of a few low-frequency earthquakes played a major role in the heated scientific and public debate regarding whether lives could have been saved had their occurrence been recognized as a warning sign for an imminent volcanic eruption (Gil Cruz and Chouet, 1997).

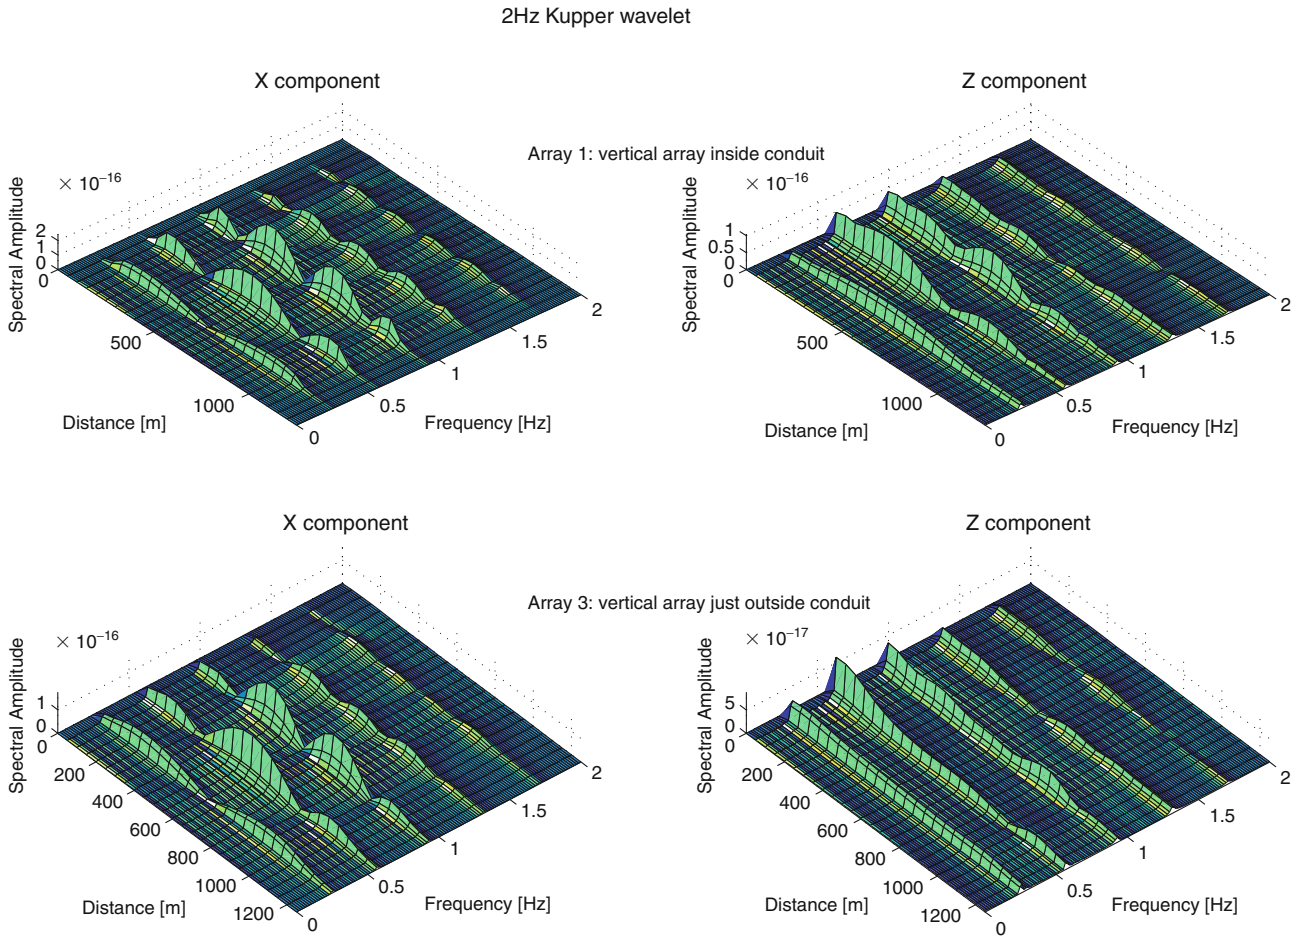
Low-frequency earthquakes occupy a spectral range of approximately 0.2–10 Hz and form a spectral



Earthquakes, Volcanogenic, Figure 1 Different event types in time and frequency domain, recorded on Soufriere Hills volcano on Montserrat; (**a**) volcano-tectonic earthquake (VT), (**b**) low-frequency earthquake, and (**c**) rock-fall event.

continuum between two end-members of seismic categories: *long-period events* and so-called *hybrid events*, which are similar to long-period events but carry in addition a high-frequency onset. On Soufriere Hills volcano in Montserrat, it has been demonstrated that the amount of high-frequency energy observed in the seismic signal can vary from station to station, and also at one station from event to event. Therefore, long-period and hybrid earthquakes have been grouped together under a more generic term as *low-frequency earthquakes* (Neuberg et al., 2000). These events have been observed on many, mostly dome-building volcanoes, and have been empirically associated with the pressurization of the volcanic system (Lahr et al., 1994; Neuberg et al., 1998).

Very different from tectonic events, low-frequency earthquakes originate from a boundary between a fluid, such as gas or magma contained in conduits, dykes, or cracks, and the solid surrounding rock (e.g., Ferrazzini and Aki, 1987; Chouet, 1988; Neuberg et al., 2000). Most of the seismic energy is trapped in the fluid-filled plumbing system – conduit, dyke or crack – and resonates within this system while only a small part can escape and propagate through the volcanic edifice and is recorded at the surface. Hence, low-frequency earthquakes are generated by resonating interface waves – hence the term *conduit resonance* – however, these interface waves must not be confused with acoustic waves in the fluid, often referred to as organ pipe modes. Acoustic and interface waves differ in one important aspect: Interface waves are dispersive; hence, the velocity varies with wavelength, and it is the slow moving part of the wave field that explains the low-frequency character (Ferrazzini and Aki, 1987). Figure 2 shows the horizontal and vertical seismic component of a synthetic, resonating interface wave for a two-dimensional dyke model. The single overtones, or modes, are separated by frequency in the depth–frequency plot. The low-frequency seismic wave can be considered as the superposition of these modes. The frequency content



Earthquakes, Volcanogenic, Figure 2 Eigen modes of a low-frequency earthquake source: spectral amplitude distribution for horizontal (X) and vertical (Z) component inside (*above*) and outside (*below*) the conduit for single frequencies. The superposition of the frequency contributions represents the source signal inside the conduit and outside. Note that the vertical component is affected by the interaction with the free surface, while the horizontal component is not.

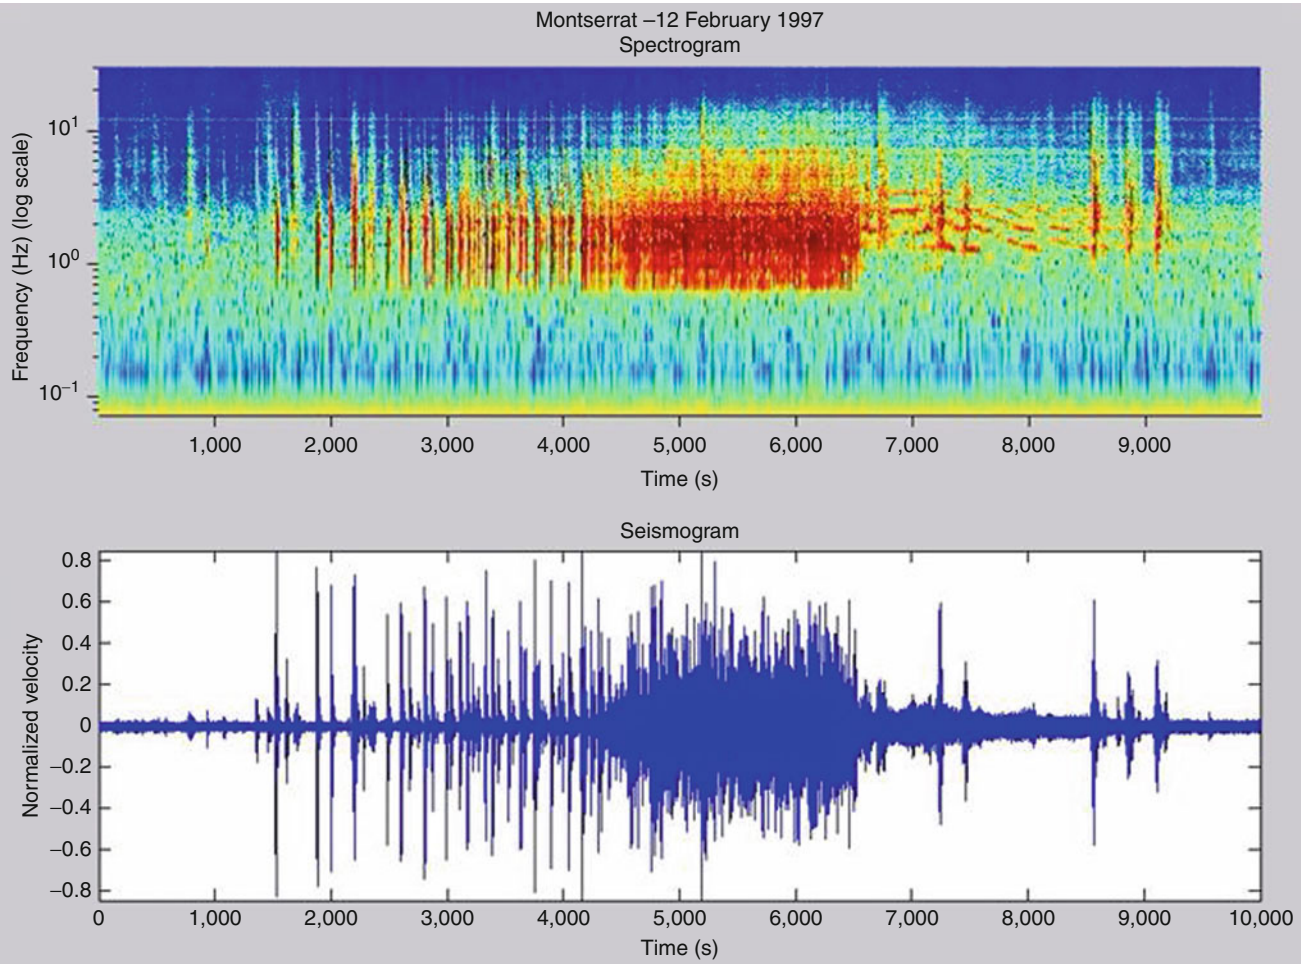
is controlled by the interface wave velocity which, in turn, is determined by the rigidity μ of the surrounding rock, the bulk modulus of the fluid κ, the wavelength of the interface wave, and the width of the fluid-filled container.

Low-frequency earthquakes are observed on many volcanoes, and most observations include one or several of the following characteristics: (1) LFs occur in swarms, (2) the waveforms are very similar, (3) their occurrence is highly regular, (4) with increasing occurrence, the LF swarms merge into continuous tremor, and most importantly, (5) major dome collapses or other eruptive phases are preceded by LF swarms (Miller et al., 1998; Aspinall et al., 1998; Hellweg, 2003). The highly periodic occurrence of LFs in swarms of similar waveform can be seismologically interpreted as a stationary seismic source with a repetitive non-destructible source mechanism (Green and Neuberg, 2006). The other exciting aspect is their potential as a forecasting tool for volcanic eruptions or dome collapses. Both Galeras volcano in Colombia and Soufriere Hills volcano in Montserrat are examples where LF swarms occurred before such events; however, the occurrence of the earthquakes does not guarantee a volcanic event. This demonstrates that the mere occurrence of LFs is not yet a reliable forecasting tool unless the actual trigger mechanism is understood and a direct link between the seismogram and source mechanism can be made.

Several trigger mechanisms for LFs have been proposed, including magma–water interaction (Zimanowski, 1998), stick-slip motion of magma plugs (Goto, 1999; Iverson et al., 2006), magma flow instabilities (Julian, 1994), periodic release of gas–ash mixtures into open cracks (Molina et al., 2004), and repeated, brittle fracturing of magma in glass-transition (Neuberg et al., 2006).

Volcanic tremor

As indicated in the previous section, one definition of volcanic tremor is the superposition of low-frequency earthquakes as they merge in time. Figure 3 depicts an



Earthquakes, Volcanogenic, Figure 3 Seismic low-frequency earthquake swarms merging into tremor: spectrogram (*upper part*) and seismogram (*lower part*). Note the *lines* in the spectrogram toward the end of the signal, representing a highly periodic repeated excitation of identical events. The spectral distance between the lines corresponds to the excitation frequency.

example in time and frequency domain from Soufriere Hills volcano in Montserrat where single LF earthquakes merge into tremor. If the highly periodic occurrence, or trigger mechanism, is maintained, the tremor signal exhibits a spectral signature of integer harmonic spectral lines (see Figure 3) if the time window from which the spectral slice is computed is long enough to cover several events. The distance between the spectral lines is inversely related to the time separation between LFs of the same waveform, origin, and time history. As the frequency of occurrence increases, the distance between spectral lines will increase as well. In this way, one can measure the inter-event time, or event rate, by using the separation of spectral lines, even though the single events have merged in time into a continuous tremor signal. For this type of volcanic tremor, it has been shown that the spectral signature of the tremor signal is identical to the low-frequency earthquakes of which it is composed (Latter, 1981).

Another definition of volcanic tremor is more general and refers to the background noise caused by magmatic processes. Figure 4 shows an example from Piton de la Fournaise, La Reunion, where volcanic tremor is produced by lava extruding from fissures. The onset and end of the tremor signal are remarkably sharp and coincide with the start and finish of the eruption. The spectrum of the signal is "white"; hence, it is composed of a large number of frequencies and does not have any spectral structure. The origin of the tremor is due to pressure fluctuations during turbulent magma flow (Julian, 1994). Another tremor source of this kind can be attributed to hydrothermal activity or degassing. While such a tremor signal does not have any distinct seismic phases (like *P* and *S* wave arrival) that could be used to determine the source location on the base of relative travel times, the relative amplitudes of the signal can be utilized to obtain an approximate location of the tremor source.

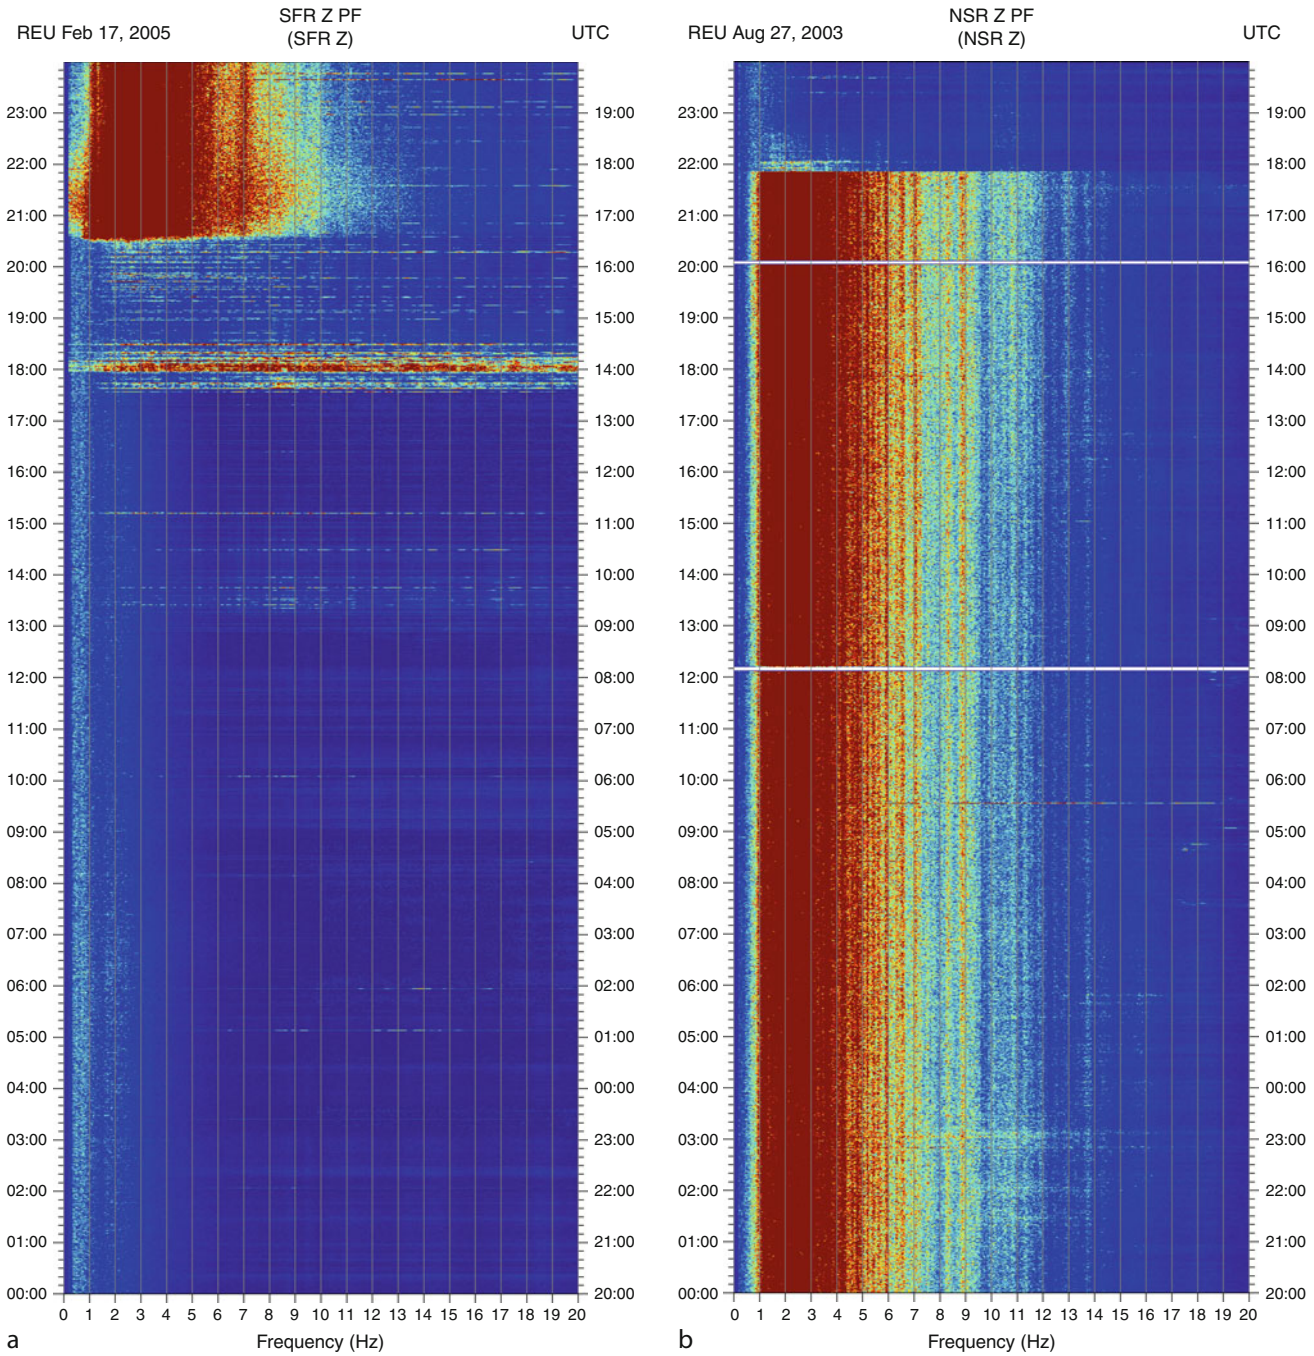
Very-long-period earthquakes

With the availability of broadband seismic sensors, seismology opened a new window to very-long-period signals caused by transients of pressure variations in the volcanic edifice with periods ranging from tens of seconds to several minutes (Neuberg et al., 1994; Wielandt and Forbriger, 1999). Measurements in this frequency range close the gap between classic seismology and ground deformation as determined by strain-, tilt-meters, and GPS. However, while ground deformation can be measured directly as ground *displacement*, a seismometer detects the ground *velocity*, or the temporal change of the displacement, due to its electromagnetic measurement principle, reacting to the *change* of the magnetic flux by inducing an electric current. The advantage of such a system lies in the high sensitivity of the detection system; the disadvantage is that several data processing steps are necessary to retrieve the ground displacement, if this is the quantity required for modeling or further interpretation. For short-period signals, this does not pose any problem as the instrument response is constant in this narrow (high-) frequency band; hence, the seismogram has only to be integrated to convert ground velocity into displacement. However, for a broadband seismometer, the instrument response is highly frequency dependent and lower frequencies are treated by the seismometer in a different way than high frequencies. In order to retrieve the ground displacement from the measured ground velocity, the effect of the instrument response has to be taken into account and, if possible, to be removed. This is in addition to the integration step in the data processing sequence.

Modern broadband seismometers have a "flat" frequency response typically in the range between 50 and 0.008 Hz, expressed in periods, between 0.02 and 120 s. Figure 5 shows the effect of the removal of the instrument response in an example from Stromboli volcano. The seismic record of a Strombolian eruption shows an ultra-long-period transient in the vertical direction, caused by an ascending magma/gas plug with an eruptive, high-frequency seismic signature superimposed. In order to represent the long-period part of the signal properly, the original velocity seismogram has to be corrected for the instrument response as well as integrated. This processing sequence is shown in Figure 5, where the velocity seismogram is converted to displacement by integration (Figure 5a), and where finally, after the instrument response has been successfully removed, the seismogram (Figure 5d) represents the true ground displacement at the location of the seismic sensor. The comparison between corrected and uncorrected displacement demonstrates the importance of this processing steps. An interpretation or model of the uncorrected trace (Figure 5a) would comprise an upward movement of the volcanic edifice prior to the Strombolian eruption followed by a deflation and slow recovery of the edifice. The corrected trace offers a much simpler interpretation (Neuberg and Luckett, 1996): The edifice inflates while the magma plug is ascending, and once the gas is released through, the eruption deflates to its original level. This example demonstrates that each seismic sensor, and indeed each recording instrument, has to be considered a *filter* that affects and modifies the original physical signal in a certain way, often introducing a frequency-dependent change in amplitude and phase. To correct for these effects is absolutely essential when dealing with ultra-long-period seismic signals.

Volcano seismology in a wider volcanological context

Volcanogenic earthquakes have been the first signals to be used to monitor and assess volcanic activity, and are today still at the core of any volcano monitoring program. However, if combined with other observations and integrated into wider conceptual and numerical volcanological models, their potential as a forecasting tool increases even further. In the following section, we give a few examples

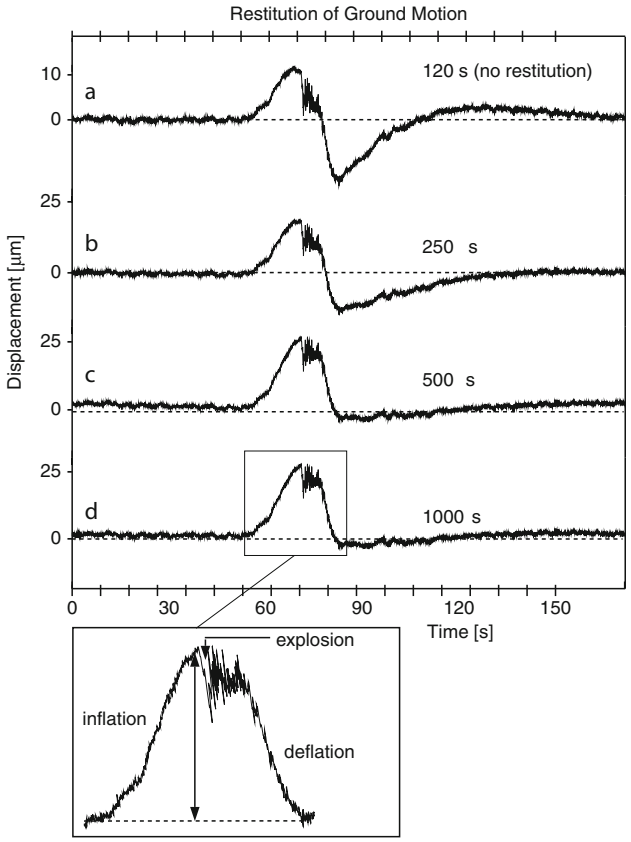


Earthquakes, Volcanogenic, Figure 4 Spectrograms of continuous tremor at Piton de la Fournaise, La Reunion. (**a**) Onset of tremor is preceded by a short swarm of VT events, (**b**) continuous tremor during lava extrusion, note the extremely sharp end of the tremor signal when magma extrusion stops.

how volcanogenic earthquakes have been used to assess several aspects of volcanic activity.

Estimation of magma ascent rate

A very exciting example from Montserrat has been reported by Voight et al. (1998), where a radial tilt signal recorded on Chances Peak, an old dome structure adjacent to the active lava dome of Soufriere Hills volcano, correlated perfectly with the cyclic occurrence of seismic swarms. Neuberg et al. (2006) reinvestigated this correlation and found that seismic activity, in this case, low-frequency earthquake swarms, commences when the tilt



Earthquakes, Volcanogenic, Figure 5 Very-long-period signal from Stromboli volcano after removal of instrument response. (**a**) through (**d**) indicate the period limit to which the spectral energy has been included in the restitution. While the trace in (**a**) contains only spectral components up to 120 s period, the true ground displacement is reconstructed by including all spectral components to a period of 500 s (**c**) or even 1,000 s (**d**). The final result in the lowermost trace shows the ground displacement associated with the rising gas slug, the Strombolian explosion as well as the deflation after the explosion.

signal goes through an inflection point (Figure 6). Furthermore, low-frequency seismicity ceases when the tilt signal goes through a second turning point. The tilt, which is the rotation of the volcano's flank, is caused by a combination of a pressure buildup in a shallow magma reservoir and the shear stress acting across the conduit wall by the motion of viscous magma at shallow depth (Green et al., 2006). Hence, the cyclic occurrence of LF swarms can be directly related to the magma ascent rate: As the pressure in the magma has reached a certain threshold, magma starts to move causing low-frequency seismicity by either a stick-slip motion (Iverson et al., 2006) or by magma rupture (Neuberg et al., 2006). This causes the turning point in the tilt behavior; however, the ground deformation (tilt) still increases to its maximum where the magma ascent rate peaks. At this point, the magma ascent slows down as gas bubble diffusion cannot keep up with the pressure drop, caused by the magma movement. This can be clearly seen in both the tilt signal and the seismicity rate depicted in the inset of Figure 6. At the second turning point, magma ascent rate has become so low or even stopped completely that no further LF seismicity is produced. This gives gas diffusion a chance to catch up, leading to a renewed pressurization of the system again, and a new cycle has started.

This example demonstrates how LF seismicity can be interpreted following a conceptual model that allows to estimate the changes in magma ascent rates on the base of seismicity, even if no tilt signal is available. Using such a model, Hammer and Neuberg (2009) found an accelerating seismicity rate in consecutive LF swarms on Montserrat – as a proxy for an accelerated magma ascent – which led to a dome collapse in 1997.

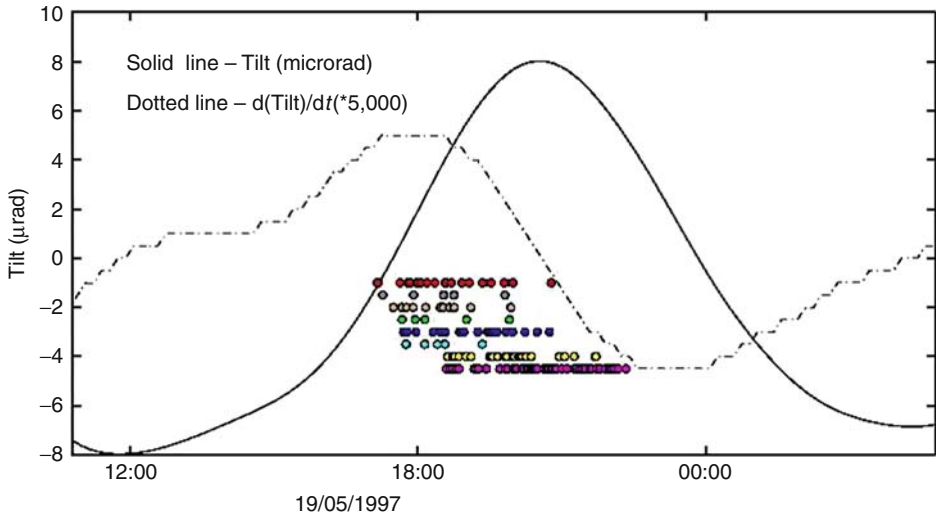
Combining seismicity with infrasonic signals

A second example of a combined interpretation uses infrasonic acoustic signals with seismicity. The monitoring of infrasonic signals on active volcanoes has become routine in the last 10 years and turned out extremely helpful for open volcanic systems.

See Johnson (2003) for an overview on infrasonic monitoring techniques. Compared to seismic waves, infrasonic signals are less affected by the medium (steam and air) through which they propagate, and the relative timing between the two types of signals can be used to dissect a complex volcanic event such as a dome collapse, that can last for several hours and exhibit distinct phases. Green and Neuberg (2005) modeled a partial dome collapse at Montserrat in 2004 and used the relative timing between seismic and infrasonic pulses to separate several distinct explosions during the collapse. Furthermore, they identified a plume forming degassing event as the underlying cause of the collapse. A further application of a combined interpretation can be found in Ripepe et al. (2002) where relative timing between infrasound and seismic signal revealed the relative height of a magma column on Stromboli volcano from where an explosion occurred.

Detection of lahars and pyroclastic flows

Pyroclastic flows, lava flows, and lahars often escape direct visual observation, but the fast determination of their location can be crucial in terms of risk mitigation. As pointed out above, the seismic signals produced by such events lack any clear seismic phase that could be used for a classic travel-time-based location procedure. Jolly et al. (2002) devised a method based on a relative seismic amplitude estimation across a seismic monitoring network, that allowed to follow the path of a flow in near real-time. The basic idea is to determine the location of the seismic surface source by assuming that the amplitudes of the surface waves caused by the flow decay by the inverse of the distance to a seismic station and by inelastic attenuation. They performed a so-called grid search inversion



Earthquakes, Volcanogenic, Figure 6 Correlation between tilt and seismicity on Soufriere Hills volcano, Montserrat. The low-frequency seismicity is sorted in different event "families." The different colors indicate different families of similar seismic waveform which implies that each family has a common source mechanism and origin. It commences and ceases at the inflection points of the tilt signal (*solid line*), equivalent to the maximum and minimum of its time derivative (*dotted line*).

across the volcanic edifice to locate the flow. Through this technique, they were able to resolve fine details of the flow propagation such as a "piling-effect" that occurred when the front of the pyroclastic flow came to a halt while the rest of the flow piled up behind it, causing the seismic source travelling backup-hill!

On Piton de la Fournaise, a similar method is used to detect the source of basaltic lava flows, which are responsible for the generation of a tremor signal. In this way, the observatory staff is able to inform the authorities in near real-time about the source location of the lava flow.

Detecting stress changes in volcanic settings

Recent advances have made it possible to detect temporal variations in properties of seismic signals that are caused by stress changes in the medium that they penetrate. These changes can be seen in directional variations of the wave speed (also referred to as anisotropy), energy loss, and seismic source parameters (fault plane solution) of volcano-tectonic events.

Gerst and Savage (2004) detected a change in anisotropy at Mt Ruapehu, New Zealand, which coincided with the eruptive activity in 1995 and 1996. They interpreted these changes to be caused by changes in the stress due to magmatic activity that altered the orientation and volume of cracks in the volcanic edifice. Using newly developed noise correlation techniques, Brenguier et al. (2008) observed at Piton de la Fournaise, La Reunion, similar changes in seismic velocity caused by the pressurization of the volcanic edifice due to ascending magma. Roman et al. (2006) found systematic variations in the orientation of the main pressure axis, which was derived from fault plane solutions of volcano-tectonic events on Soufriere Hills volcano on Montserrat. They identified distinct episodes in the eruptive history of Soufriere Hills volcano, where the regional stress field was superimposed by local stress perturbations that caused the pressure axis determined from VT fault plane solutions to swing around by 90°. Again, these stress changes were interpreted as caused by ascending magma, and indeed, these episodes preceded in some cases the restart of dome growth and magma extrusion. While the methods mentioned in this section do not necessarily utilize only volcanogenic earthquakes, they employ seismological tools to monitor the stress perturbations caused by volcanic activity, and therefore, could lead to new methods of volcanic forecasting.

Summary and conclusions

Monitoring and interpretation of volcanogenic earthquakes are core tasks of any volcano observatory. The separation into different event types allows us to attribute seismic activity to certain volcanic processes. While some event types are directly caused by brittle failure during magma ascent, or by extrusion of magma at the surface, other seismic signals provide us with indirect evidence of changes caused by the volcanic-magmatic system. Volcano seismology emerged from classic earthquake seismology as a separate discipline focusing on the special character of seismo-volcanic source processes. This development is ongoing, and classic seismic techniques such as the determination of seismic moment tensors will be applied in the future to the wider variety of seismo-volcanic sources which can be significantly different from usual earthquake sources acting on a single fault plane. With the availability of seismic broadband sensors, volcano seismology overlaps with high-frequency acoustic

emissions on one side of the seismic spectrum and with deformation signals on the low-frequency end. Multidisciplinary approaches combining seismology with other signals recorded on volcanoes will lead to more detailed insights into volcanic processes.

ELECTRICAL PROPERTIES OF ROCKS

Takashi Yoshino
Institute for Study of the Earth's Interior, Okayama University, Misasa, Tottori, Japan

Definition

Electrical conduction. The movement of electrons or electrically charged particles through a medium.
Electrolyte. Any substance containing free ions that make the substance electrically conductive. The most typical electrolyte is an ionic solution.
Fermi level. The highest energy of occupied states in a solid at 0 K. The Fermi level in conductors lies in the conduction band, in insulators it lies in the valence band, and in semiconductors it falls in the gap between the conduction band and the valence band.
Stern layer. One of two electrically charged layers of electrolyte ions; the layer of ions immediately adjacent to the surface, and the layer in the neighborhood of a negatively charged surface.

Introduction

The interpretation of electromagnetic data obtained from the electromagnetic (EM) induction method requires knowledge of electrical properties of rocks comprising the Earth's interior. The electrical properties of rocks are widely used in electrical conductivity (resistivity) and induced polarization methods to identify zones of ore deposits and to probe the thermal and compositional structure of the Earth's interior. For example, electrical resistivity measurements were first used in the 1960s to prospect for sulfide ore deposits. Furthermore, the use of EM induction techniques to determine the electrical conductivity of the crust and mantle can provide useful information regarding the processes in the Earth's interior independent from seismological studies. This results from the fact that electrical conductivity is sensitive to small amounts of accessory phases, such as fluid, melt and metal in rocks, and small amounts of hydrogen and ferric irons in rock-forming minerals.

The bulk electrical properties of rocks depend on complex combinations of various electrical components consisting of solids (silicates, oxides, and metal), pores filled with air or liquid, and interfaces between solids and liquids. Thus, rocks are composites of a wide variety of minerals occasionally containing fluids and molten material. Since the 1960s, many studies have investigated the electrical properties of rocks and rock-forming minerals as a function of frequency, temperature, pressure, oxygen fugacity, water content, applied electric field, and other variables. Recent developments of analytical techniques and improvements in the resolution of electromagnetic observations have led to an increase in interest with regard to the electrical properties of rocks at depth within the Earth. The high pressures and temperatures within the Earth's interior are difficult to replicate in the laboratory, but experimental results are required to predict the electrical properties in these environments. Within the last two decades, many efforts have been made to measure physical properties of high-pressure phases to obtain knowledge of temperature, composition, and water content in the Earth's mantle. As a result, the maximum range of pressure where the electric conductance can be measured currently covers the pressure conditions at the core–mantle boundary (2,900 km depth).

Definition of electrical conductivity (resistivity)

When an electric potential difference V is applied across a material, the electrical current I in the material is proportional to the voltage across it according to Ohm's law, $V = IR$, where R is the electrical resistance, which depends on the intrinsic resistivity ρ of the material and on the geometry (length l and area A through which the current passes):

$$R = \rho l / A \tag{1}$$

The electrical conductivity σ is the inverse of the resistivity. The current density J can be expressed as $J = E/\rho = E\sigma$. Conductivity has one of the widest ranges for material property, from 10^{7} S/m (metals) to 10^{-20} S/m (good electrical insulators). Semiconductors have conductivities in the range of 10^{-6} to 10^{4} S/m.

Electrical conduction

An electrolytic process can be considered as a dominant mechanism for electron charge transport in shallower crustal rocks, which contain pores and cracks filled with electrolyte fluids. At high saturation conditions, conduction currents in electrolytes primarily arise from the flow of ions in the electric field. The conductivity of an electrolyte is controlled by the solute concentration, ionic charge, and other physical parameters, such as temperature and pressure. Fluid saturated rocks contain interfaces between the minerals and the fluid leading to surface conductivity, which can be considered as an additional fluid electrical conductivity in the vicinity of the charged surface. The concentration of ions increases with increasing proximity to the charged surfaces as a result of attractive electrostatic forces, which are induced by the surface charge. This high concentration layer is called the electrochemical double layer (DL), and it is composed of the Stern layer in contact with solids, and a diffusive layer in contact with fluids. Higher concentrations of ions in the Stern layer lead to higher conductivity. The significant influence of surface conductivity on bulk electrical properties appears to be the same for porous samples saturated with dilute electrolytes and low porosity samples where the thickness of the DL is the same as the width of a crack. A mixed conduction process of electrolyte and surface conductivity is most likely to appear in low saturation conditions.

As pressure and temperature increase, the electrical conduction in rock-forming minerals is likely to control

the bulk electrical conductivity of rocks. This is achieved by a decrease in the effect of rock open space and interface effects. Solids can be classified in terms of their conductivity as conductors, semiconductors, or insulators. The classification for solid materials can be visualized in terms of band theory, and is strongly correlated with the interatomic spacing in the solid. The electron energy level in a solid is often expressed in relation to the Fermi energy. In metals, the electrons occupy states up to the Fermi level. Conduction occurs by promoting electrons into the conduction band that starts at the Fermi level. The promotion energy is negligibly small so that at any temperature, electrons can be found in the conduction band. The number of electrons participating in electrical conduction is extremely low. In semiconductors and insulators, the valence band is filled, and no more electrons can be added, following Pauli's principle. In insulators, there is a large energy gap between the valence and conduction bands, so that a large quantity of energy is needed to promote an electron to the conduction band. Semiconductors can be divided into intrinsic or extrinsic conductors. Intrinsic conduction means that electrical conductivity is pure, and does not depend on impurities. In extrinsic semiconductors, the conductivity depends on the concentration of impurities. Electronic conduction through extrinsic semiconductors takes place through electrons and electron holes. The electrical conductivity of semiconductors can be enhanced by doping to produce n (negative)-type or p (positive)-type semiconductors.

Silicates and oxides usually are insulators at ordinary temperatures. Since the large energy gap of an insulator could be overcome by heat, the silicate minerals can behave as a semiconductor at high temperatures corresponding to conditions of the Earth's interior. Mobility of lattice defects and a small amount of impurity, such as hydrogen and ferric iron, enhances electrical conduction of silicate minerals at high temperatures. The conductivity of ionic-bonded crystals is proportional to the number and mobility of charge carriers. It is known from the Nernst–Einstein equation that electrical conductivity σ depends on the number N of electric charge carriers per unit volume:

$$\sigma = Nze\mu \tag{2}$$

where z is the charge number, e is the charge of electron and μ is mobility.

The dependence of conductivity on temperature is similar to other thermally activated processes:

$$\sigma = A\exp(-\Delta H/2kT) \tag{3}$$

where A is a pre-exponential constant, ΔH is an activation enthalpy, k is the Boltzmann constant and T is the absolute temperature. Plotting log normal σ versus reciprocal temperature ($1/T$) produces a straight-line slope ($H/2\ k$) from which the band gap energy can be determined. In addition to this dependence, extrinsic semiconductors rely on the thermal promotion of electrons from donor levels or holes to acceptor levels. The dependence on temperature also is exponential, but it eventually saturates at high temperatures, where all the donors are emptied or all the acceptors are filled. This means that at low temperatures, extrinsic semiconductors have higher conductivities than intrinsic semiconductors. At high temperatures, both impurity levels and valence electrons are ionized, but since the impurities are very low in number and they are exhausted, eventually the behavior is dominated by the intrinsic type of conductivity. The activation enthalpy (H) also can be defined as a function of pressure (P) as follows:

$$\Delta H = \Delta E + P\Delta V \tag{4}$$

where ΔE is the activation energy and ΔV is the activation volume.

Ionic (intrinsic) conduction can occur at high temperatures through the creation of cation vacancies. In the ferromagnesian mantle minerals (silicates and oxides), the charge carriers are generally vacancies in magnesium sites. The activation enthalpy of ionic conduction usually is higher than 2 eV. For this reason, extremely high temperatures are needed to observe the ionic conduction. Proton conduction is a type of ionic conduction. Because the proton is an extremely small ion, but massive compared with an electron, the proton is the only ion which is expected to be highly mobile in solids. The energy barrier for the transportation of charge carriers for proton conduction is relatively low because of its small bonding energy and small ionic radius. The activation enthalpy of proton conduction usually is less than 1 eV, and tends to decrease with an increasing number of hydrogen atoms in minerals at very low concentrations. The proton conduction is a dominant conduction mechanism at low temperatures.

The most dominant conduction mechanism for the ferromagnesian minerals, such as olivine, is hopping (small polaron) conduction. Hopping conduction occurs through charge transfer between neighboring ions of different valences. A ferrous ion (Fe^{2+}) generally substitutes an Mg ion in an Mg site. However, a certain proportion of ferric ions, which have an electron hole, depend on oxygen fugacity, temperature, pressure, and crystal structure. Transfer of an electron hole between ferrous and ferric iron sites carries an electric charge, which is the hopping conduction. If only electron holes migrate in crystals, the energy barriers for the migration would be low. However, presence of an electric hole significantly affects the local structure of the ionic crystals. The presence of ferric iron generates an extra positive charge, which repulses cations and attracts anions. This complex of the local strains is called "small polaron." The migration of electron holes is associated with migration of small polarons. A relatively large activation enthalpy is needed to move a small polaron. The hopping conduction of common ferromagnesian silicates has relatively large activation enthalpy (>1 eV). The activation enthalpy for hopping conduction decreases with increasing iron concentration. The conductivity of ferromagnesian minerals also is

controlled by the oxidation state of iron. A variation of the oxygen fugacity from an oxidizing to a reducing environment decreases the conductivity, due to the reduction of Fe^{3+} to Fe^{2+}. Moreover, at the same oxygen buffer, the conductivity tends to increase with increasing iron content in minerals.

Dielectric behavior

A dielectric is an electrical insulator that can be made to exhibit an electric dipole structure. When a dielectric is placed in an electric field, electric charges do not flow through the material, but only slightly shift from their average equilibrium positions, causing dielectric polarization. In this instant, positive charges are displaced along the field and negative charges shift in the opposite direction. This creates an internal electric field, which partly compensates the external field inside the dielectric. The term dielectric is commonly used for the electrically insulating material between the metallic plates of a capacitor. When two parallel plates of area A, separated by a small distance l, are charged by $+Q$, $-Q$, an electric field develops between the plates:

$$E = Q/A\varepsilon\varepsilon_0 \tag{5}$$

where ε_0 is called the vacuum permittivity and ε the relative permittivity, or dielectric constant ($\varepsilon = 1$ for vacuum). In terms of the voltage between the plates, $V = El = Q/C$. The constant $C = A\varepsilon\varepsilon_0/l$ is called the capacitance of the plates.

Polarization of dielectric materials in an electric field can be categorized by three types: electronic, ionic, and orientation polarizations. Since electrons have much smaller mass than ions, they respond more rapidly to a changing electric field. For electric fields that oscillate at very high frequencies, electronic polarization can occur. At smaller frequencies, the relative displacement of positive and negative ions also can take place. Orientation of permanent dipoles, which require the rotation of a molecule, can occur only if the oscillation is relatively slow (MHz range or slower). The time needed by the specific polarization to take place is called the relaxation time.

Most rock-forming minerals have characteristics of capacitors requiring dielectrics of high ε that can function at high frequencies (small relaxation times). Some ore minerals are ferroelectric minerals exhibiting permanent polarization in the absence of an electric field. This is due to the asymmetric location of positive and negative charges within the unit cell. Two possible arrangements of this asymmetry result in two distinct polarizations. In a piezoelectric material, like quartz, an applied mechanical stress causes electric polarization by the relative displacement of anions and cations.

Impedance spectroscopy

Electrical properties of rocks have strong frequency dependence. Impedance spectroscopy (IS) is a very useful and versatile electrochemical tool to characterize electrical properties of any material and its interfaces. The basis of IS is the analysis of the impedance (resistance of alternating current) of the observed system with regard to the applied frequency and exciting signal. This analysis provides quantitative information about the conductance, the dielectric coefficient, the static properties of the interfaces of a system, and its dynamic change due to adsorption or charge-transfer phenomena. IS usually uses alternating current with low amplitude, and measurements can be made with cells with two electrodes on the sample faces.

A common way to describe the complex impedance is to use the R (resistor)–C (capacitor) circuit elements in series and parallel, indicating a relaxation process. When the system has a distribution of relaxation time differing in time constants, the system represents a combination of R–C circuits (Cole and Cole, 1941). The R–C parallel circuit generally has been used to determine the electrical conductivity of minerals, based on the assumption that the system has a single relaxation process. In the complex impedance plane, the magnitude and direction of a planar vector can be defined by an impedance:

$$Z(\omega) = Z' + jZ'' \tag{6}$$

where $Z(\omega)$ is impedance as a function of frequency for alternating current, and Z' and Z'' are real and imaginary parts of impedance, respectively. The phase angle (θ) in a complex impedance plane can be obtained from $\theta = \tan^{-1}(Z''/Z')$. When the phase angle is 0°, the sample resistance for the R–C parallel circuit equals the real part of impedance.

Various frequency dispersive polarization processes should be accounted for in mixed media, such as rocks. Roberts and Tyburczy (1991) observed three impedance arcs in the complex impedance plane from the frequency-dependent electrical measurements (10^{-4} to 10^4 Hz) of polycrystalline olivine compacts at atmospheric pressure. The authors interpreted these impedance arcs as grain interior (first arc), grain boundary (second arc) and electrode reaction mechanism (third arc) from high to low frequency, respectively. At high pressures, pores, cracks, or grain boundaries in a sample are tightly closed. Under these conditions, the conduction along grain boundaries disappears in the impedance spectra. If electrodes reacted with a sample, the electrode reaction part may appear on the lower frequency side. The next step is to consider the complex impedance spectra for the system with a fluid/melt phase. In the absence of an interconnected fluid/melt, the impedance spectra contain three components similar to the polycrystalline process. If an interconnected fluid/melt phase does exist, it forms an electrical pathway in parallel with the solid matrix. The resultant impedance spectra show only the single arc if the electrode reaction is negligible.

Electrical conductivity of liquid-bearing rocks

The effective conductivity of liquid-bearing rocks is very sensitive to the pore geometry in rocks. The enormous

contrast in conductivity between silicates and liquids implies that electrical currents flow almost totally through the pore liquid within rocks. Archie (1942) proposed an empirical equation that relates the bulk conductivity σ_r to the conductivity of a pore saturating fluid σ_f. The rocks were assumed to exhibit interconnected porosity, and no disturbance due to the presence of reactive minerals was considered. The ratio σ_f/σ_r is known as the formation factor F. Archie's law forms the basis for resistivity log interpretation:

$$F = \frac{\sigma_f}{\sigma_r} = C\phi^{-n}, \tag{7}$$

where C and n are constants. Archie's law is not a geometrical model. There are various theoretical models for estimating the bulk conductivity of liquid-bearing rocks from the conductivity of liquid and solid phases. A frequently used model to predict the maximum effective bulk conductivity of an interconnected two-phase mixture is the Hashin and Shtrikman (HS) upper bound (Hashin and Shtrikman, 1962). This upper bound is representative for liquid phases distributed along grain boundaries and filling triple junctions of spherical grains. The opposite case representing isolated spheres of liquids in solid grains is known as the HS lower bound.

Electrical conductivity of crustal rocks

The shallower zone of the upper crust consists of a sequence of sedimentary rocks along with fractured crystalline rocks. Because these rocks contain pores and cracks that are filled with fluid electrolytes, they are moderately good conductors of electricity. As well as electrolyte conductivity, surface conductivity caused by electrochemical reactions between the fluid electrolyte and the mineral surface contribute additionally to the bulk conductivity. This zone has conductivities varying from about $10^{-0.5}$ S/m in recent sediments to 10^{-3} S/m or more in weathered crystalline rocks. As pressure increases, the rock conductivity decreases due to the reduction of porosity. Remarkable changes in electrical properties often occur at mid-crustal depths, probably caused by the development of incipient fractures. If the fractures are filled with fluid electrolytes, electrical conductivity would largely be enhanced compared to the surrounding dry crystalline rocks. Secular changes in electrical conductivity might be used in predicting earthquakes (Varotsos and Alexopoulos, 1984).

Lower crustal rocks mainly consist of crystalline igneous or metamorphic rocks, which are thought to be much denser, and which have little pore space for water collection. Since the main rock-forming minerals are highly insulating at crustal temperatures, electrical conductivity in such rocks should be expected to have lower values than the upper crust. However, magnetotelluric (MT) and deep geomagnetic soundings (GDS) have revealed an unexpectedly high conductivity anomaly in the lower crust (Shankland and Ander, 1983). A very small portion of well-conducting material may cause enhanced conductivity of the whole rock mass, provided that the material fills interconnected pore space, or covers grain surfaces. To generate a conductive layer, an indispensable interconnectivity of the well-conducting phase must be established and maintained over large distances under deep crustal conditions.

There are two popular candidates (water and graphite) to explain the high conductivity anomaly. Geophysicists traditionally have considered aqueous fluids as the likely origin of this anomaly (Hyndman and Hyndman, 1968). This is because in active tectonic environments, aqueous fluid can be supplied *via* metamorphic dehydration, igneous activity, and introduction of fluids derived from dehydration of subducting plates. However, in stable craton, fluids would be gravitationally driven but also would be able to gain access only to the upper 10 km or so of the crust. Below this depth the crust would be "dry." The discovery of grain-boundary films on minerals in high-grade rocks (Frost et al., 1989) has led to a very reasonable alternative to aqueous fluids as a cause for conductivity anomalies. Duba and Shankland (1982) used the upper bound formula to calculate the absolute amount of well-ordered graphite required to enhance the conductivity of dry rocks. They found that a volume fraction of carbon of only 5×10^{-6}% could cause a conductivity of 0.1 S/m, if well interconnected. However, high wetting angles of CO_2-quartz systems cannot establish along grain boundaries to form a connecting graphite film upon reduction with CO_2. Although both water and graphite can produce high conducting layers at deeper levels of the crust, any a priori preference for only one of them appears inadequate in view of the great and obvious diversities of geological situations.

Electrical conductivity of mantle rocks

Upper mantle

Upper mantle rocks are composed of olivine, orthopyroxene, clinopyroxene, and aluminous phases, such as plagiocase, spinel, and garnet. These variations in mineral proprtion are dependent on pressure. Olivine is the most abundant mineral in the upper mantle, extending to 410 km depth. Elecrical conduction behavior of dry olivine shows weak anisotropy (a factor of 2–3), oxygen fugacity dependence, and a change of conduction mechanism from hopping (small polaron) to ionic conduction at high temperatures. The conductivity data of mantle peridotites are not significantly different from measurements made on olivine single crystals and polycrystals, even though the rocks contain large amounts of pyroxene (Duba and Constable, 1993). The conductivity values of olivine at high temperatures corresponding to the upper mantle condition usually are consistent with those obtained from electromagnetic observations.

The conductivity of the high-conductive layer at the top of the asthenosphere (60–100 km depth for oceanic plates) is too high to be explained by the conductivity of ordinary

anhydrous olivine. One possibility is that partial melting occurs in this region, and the melt forms an anisotropic, interconnected conductive path in the partially molten peridotites. Another possibility is that olivine in the region contains considerable amounts of hydrogen inside crystal structures, and thus electrical conductivity is substantially elevated by proton conduction (Karato, 1990). Wang et al. (2006) reported large effects of water on electrical conductivity of olivine, and concluded that 10^{-2} wt.% water is enough to explain the high conductivity anomaly of oceanic asthenosphere. On the other hand, Yoshino et al. (2006) reported that the electrical conductivity of single crystal hydrous olivine is nearly isotropic and distinctly lower than the observed conductivity. Thus, hydration of olivine cannot account for the geophysical observations, which instead may be explained by the presence of partial melt with basaltic composition elongated in the direction of plate motion. Because electrical conductivities of molten carbonates are three orders of magnitude higher than those of molten silicate and five orders of magnitude higher than those of hydrated olivine, high conductivities in the asthenosphere may be explained by the presence of very small amounts of carbonate melt in peridotite (Gaillard et al., 2008).

Mantle transition zone

Wadsleyite and ringwoodite, which are high-pressure polymorphs of olivine, are the main constituent minerals in the mantle transition zone (410–660 km depth). Xu et al. (1998a) reported that electrical conductivities of wadsleyite and ringwoodite are similar, and two orders of magnitude higher than that of olivine. The laboratory-based model obtained from previous studies showed a single large conductivity jump at the 410 km discontinuity. However, recent electromagnetic observations (Kelbert et al., 2009) did not show such a distinct conductivity jump at this depth. In addition, their conductivity values are too high to explain the conductivity–depth profiles in the transition zone obtained by the semi-global electromagnetic induction studies (Shimizu et al., 2010). This inconsistency would be caused by a significant amount of water in their samples.

The Earth's mantle transition zone also has been considered as a large water storage area because wadsleyite and ringwoodite can aquire significant amounts of water in their crystal structures. Therefore, the effect of water on electrical conductivity was investigated to determine the water content in this region. Huang et al. (2005) were the first to report water content dependence on electrical conductivity of their minerals, but without separation of the effect of hopping conduction, and estimated 0.1–0.2 wt.% water in the mantle transition zone. Later, Yoshino et al. (2008a) distinguished hopping and proton conductions of their minerals and showed that contribution of proton conduction becomes smaller at higher temperatures. They demonstrated that three moderate conductivity jumps – at the 410 km depth for the olivine–wadsleyite transition, 520 km for the wadsleyite–ringwoodite transition, and 660 km for the post-spinel transition – are consistent with those obtained from electromagnetic observations, even if the minerals are dry.

Lower mantle

The lower mantle extends from 660 to 2,890 km depth (24–136 GPa), and is mainly composed of Mg-rich silicate perovksite (Mg-Pv) and ferropericlase (FP), with a small amount of Ca perovskite. Mg-Pv is thought to be the major phase in the Earth's lower mantle, and is assumed to store much of the aluminum and iron of the lower mantle. Mg-Pv is likely to control the bulk rock conductivity of the lower mantle (Yoshino et al., 2008b). Conductivity measurements of Mg-Pv at the conditions of the uppermost lower mantle show slightly higher conductivity and lower activation enthalpies than ringwoodite. If Mg-Pv contains significant amounts of Al_2O_3, the electrical conductivity is higher than that of aluminum-free perovskite (Xu et al., 1998b). The conduction mechanism in Mg-Pv changes from hopping conduction to ionic condution with increasing temperature. Last decade, two important discoveries in the lower mantle provided new insights to interpret lower mantle structure. One is the discovery of post-perovskite, and the other is the discovery of iron spin transition (Murakami et al., 2004; Badro et al., 2003). The transition pressure of $MgSiO_3$ perovskite to post-perovskite (125 GPa) is consistent with the depth of the velocity increase at the D″ seismic discontinuity (2,700 km depth). Only one conductivity measurement of silicate post-perovskite showed extremely high conductivity ($>10^2$ S/m) in comparison with that of silicate perovskite, as well as almost no temperature dependence under the conditions of the D″ layer (Ohta et al., 2008). Electrical conductivity of Mg-Pv and FP decreases with increasing pressure due to the high-spin to low-spin transition of iron in these minerals.

Electrical structure of the Earth's mantle

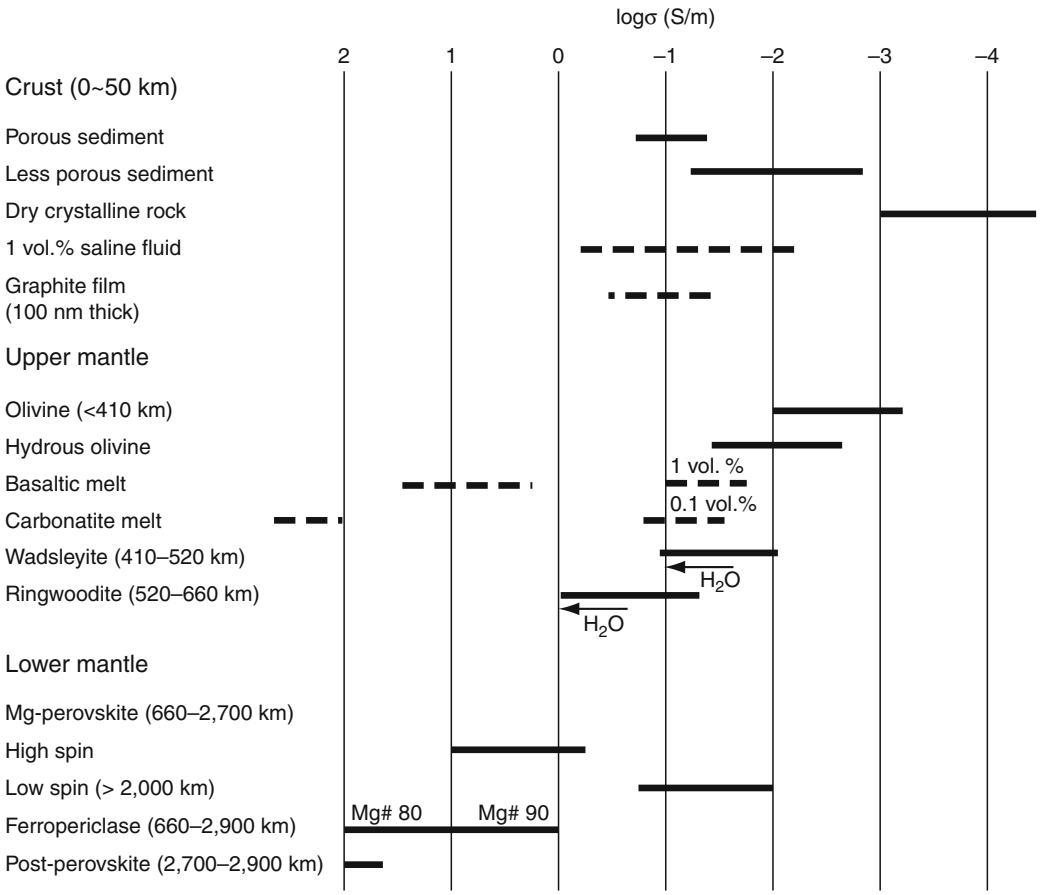
Electrical conductivity of mantle rocks tends to be similar to that of the most dominant phases, unless small amounts of conductive phases establish interconnection. The main mantle constituent minerals with higher-pressure stability fields generally have higher conductivity. A phase transformation affects electrical properties due to a change in atomic arrangement (crystal structure), as well as the nature of chemical bonding. Phase transitions would yield the conductivity jumps at certain depths where seismic velocity suddenly changes. Thus, electrical conductivity measurements of the main mantle minerals to depths of up to the core–mantle boundary indicate that the Earth's mantle is zoned electrically. This tendency can well explain the geophysically observed electrical conductivity structure in the mantle.

Conductivity generally increases with increasing depth up to the top of the lower mantle, from 10^{-3}–10^{-2} to 1 S/m. This increase is considered to represent both the

semiconductive behavior of the constituent minerals at high temperatures because mantle temperature adiabatically increases with depth, and also pressure-induced phase transformations of dominant mantle minerals. The high conductivity anomaly in the mantle would be caused by a thermal anomaly, relatively high concentrations of water and iron in mantle minerals, or presence of partial melt. Local variations of electrical conductivity are large at shallow depths, and become smaller with increasing depth. In the lower mantle, there is no phase transition down to the D″ seismic discontinuity. Because activation enthalpy for small polaron and ionic conductions is smaller for mantle minerals with higher-pressure stability fields, temperature dependence decreases as pressure increases. For this reason, a uniform electrical conductivity is expected to exist in the lower mantle. However, the high to low spin transition of iron in silicate perovskite, discovered recently would yield lower conductivity in the deeper part of the lower mantle. On the other hand, the D″ layer composed of post-perovskite might be an abnormal highly conductive layer. Thus, there should be huge conductivity jump at the D″ discontinuity.

Conclusions

The electrical conductivity of rocks within the Earth shows an ultimate variation that exceeds eight orders of magnitude (Figure 1). The electrical conductivity measurements of rocks as a function of temperature, pressure, oxygen fugacity, and impurity concentrations can constrain thermal and compositional structure in the solid Earth. At shallower depths, electrolytes filled with cracks or grain boundaries control the conductivity of rocks, whereas the conductivity of the mantle rocks is mainly controlled by semiconductive behavior of the constituent minerals. In the last 2 decades, development of measurement techniques for electrical properties of rocks and minerals under high pressure and high temperature conditions has improved our understanding of the electrical structure of the Earth's deep interior up to the core–mantle boundary. Although some discrepancies of data among laboratories have remained due to the difficulty of the electrical conductivity measurement at high pressures, it is not doubtful that the Earth's mantle is electrically zoned, and the conductivity generally increases with depth. Further improvement of experimental techniques will provide us



Electrical Properties of Rocks, Figure 1 Range of electrical conductivity of representative Earth's constituent materials at the corresponding temperature conditions.

accurate reference conductivity–depth model up to depth of the core–mantle boundary and more detailed knowledge of chemical composition and thermal distribution in the present Earth's interior by comparison with the results of the electromagnetic surveys.

ELECTRICAL RESISTIVITY SURVEYS AND DATA INTERPRETATION

Meng Heng Loke
Geotomo Software Sdn. Bhd., Gelugor, Penang, Malaysia

Definition

Electrical survey. Mapping the subsurface resistivity by injecting an electric current into the ground.

Electrode. Commonly a metal rod through which current is injected into the ground, or is used to measure the induced voltage on the ground surface.

Least-squares resistivity inversion. Finding the subsurface resistivity model that minimizes the sum of squares of the differences between the measured and calculated apparent resistivity values.

Introduction

Electrical resistivity surveys map the subsurface structure by making electrical measurements near the ground surface. An electric current is injected into the ground through two electrodes and the voltage difference is measured between two other electrodes (Figure 1a). The true subsurface resistivity can be estimated by making the measurements of potential difference at different positions of the current and potential electrodes, converting these values into apparent resistivity and then inverting the data set. The ground resistivity is related to various geological parameters such as the mineral and fluid content, porosity, and degree of water saturation in the rock (see *Electrical Properties of Rocks*). Over the past 20 years, the resistivity method has undergone rapid developments in the instrumentation, field survey

techniques, and data interpretation. It has now become one of the standard geophysical exploration techniques widely used in environmental, engineering, hydrogeological, and mining investigations.

The basic data from a resistivity survey are the positions of the current and potential electrodes, the current (I) injected into the ground and the resulting voltage difference (ΔV) between the potential electrodes (Figure 1a). The current and voltage measurements are then converted into apparent resistivity (ρ_a) by using the following formula

$$\rho_a = k\frac{\Delta V}{I}, \tag{1}$$

where k is the geometric factor that depends on the configuration of the current and potential electrodes (Koefoed, 1979). Over the years, various electrode configurations (or arrays) have been developed. Figure 1 shows the arrangements for some commonly used arrays. A discussion on the merits of the different arrays is given by Dahlin and Zhou (2004). Determining the true subsurface resistivity from the apparent resistivity values is the data inversion problem.

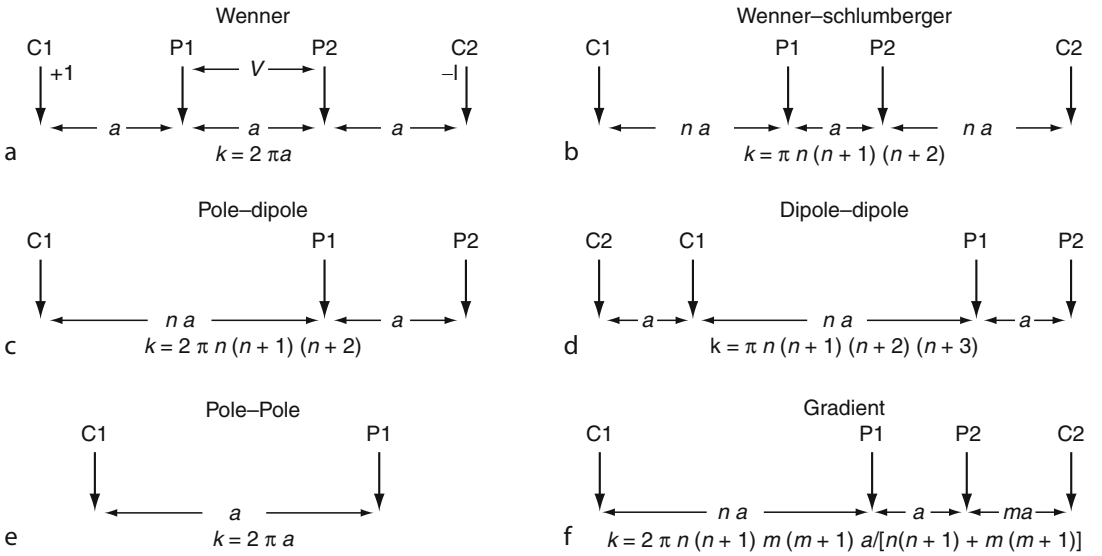
Traditional profiling and sounding surveys

The resistivity survey method has its origin in the 1920s due to the work of the Schlumberger brothers. Traditionally resistivity surveys were divided into profiling and sounding surveys. The distances between the electrodes are kept fixed in a profiling survey, such as in the Wenner survey (Figure 1a), and the four electrodes are moved along the survey line. The data interpretation for profiling surveys was mainly qualitative. The second type of survey is the vertical sounding method, such as the Schlumberger survey (Figure 1b), where the center point of the electrodes array remains fixed but the spacing between the electrodes is increased to obtain information about the deeper sections of the subsurface. The Schlumberger array is usually used for sounding surveys. Apparent resistivity plotted as a function of the current electrode spacing gives information about the subsurface resistivity variations. A sample sounding curve is shown in Figure 2.

Quantitative data interpretation for sounding surveys uses a one-dimensional (1-D) earth model with a series of horizontal layers (Figure 3a). A major advance in automatic data modeling was made in the 1970s with the development of the linear filter method (Ghosh, 1971) that greatly reduced the computer time required to calculate the apparent resistivity values. This made it practical to carry out automatic inversion of resistivity-sounding data even on relatively slow early microcomputers (Koefoed, 1979). One commonly used method for 1-D data inversion is the damped least-squares method (see *Inverse Theory, Linear*) (Inman, 1975) that is based on the following equation

$$\left(\mathbf{J}^{\mathbf{T}}\mathbf{J} + \lambda\mathbf{I}\right)\Delta\mathbf{q} = \mathbf{J}^{\mathbf{T}}\Delta\mathbf{g}, \tag{2}$$

where the discrepancy vector $\Delta\mathbf{g}$ contains the difference between the logarithms of the measured and the calculated apparent resistivity values and $\Delta\mathbf{q}$ is a vector consisting of the deviation of the estimated model parameters from the true model. Here, the model parameters are the logarithms of the resistivity and thickness of the model layers. $\mathbf{J}$ is the Jacobian matrix of partial derivatives of apparent



Electrical Resistivity Surveys and Data Interpretation, Figure 1 Common arrays used in resistivity surveys and their geometric factors. The current is injected into the ground through the C1 and C2 electrodes while the voltage difference is measured between the P1 and P2 electrodes. For the arrays with less than four electrodes, the remaining electrodes are placed at sufficiently large distances so that they do not affect the measurements.

Electrical Resistivity Surveys and Data Interpretation, Figure 3 The three different models used in the interpretation of resistivity measurements.

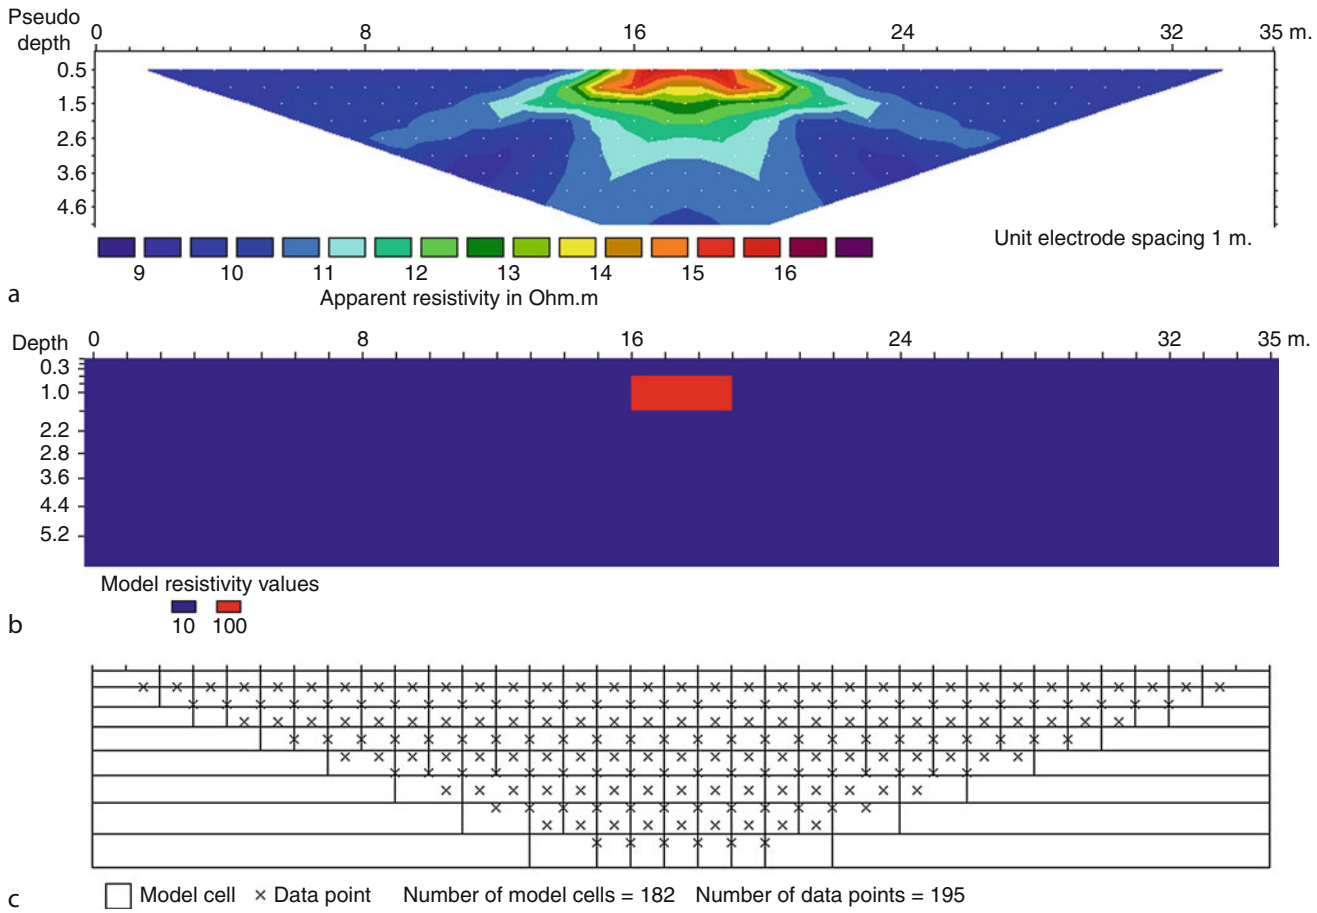
resistivity with respect to the model parameters. λ is a damping or regularization factor (Marquardt, 1963) that stabilizes the ill-condition Jacobian matrix usually encountered for geophysical problems (see *Inverse Theory, Singular Value Decomposition*). Starting from an initial model (such as a homogeneous earth model), this method iteratively refines the model so as to reduce the data misfit to a desired level (usually less than 5%). Figure 2 also shows an example of a 1-D interpretation model.

The resistivity sounding method has been used for many years, particularly in groundwater exploration. It gives useful results for geological situations (such as the water-table) where the 1-D model is approximately true. The greatest limitation of this method is that it does not take into account lateral changes in the subsurface resistivity. Such changes are probably the rule rather than the exception. The failure to include the effect of lateral changes can result in errors in the interpreted resistivity and thickness of the layers. The offset Wenner method was introduced by Barker (1978) to reduce the effect of lateral variations on the sounding data. However, to obtain a more accurate picture of the subsurface resistivity distribution, a two-dimensional (2-D) survey and interpretation model is required.

Two-dimensional resistivity imaging surveys

In recent years, development of the multielectrode resistivity meter system (see *Instrumentation, Electrical Resistivity*) has made 2-D surveys a practical tool for mapping moderately complex geological environments. The apparent resistivity measurements from the survey are commonly plotted in the form of a pseudosection (Figure 4a). The horizontal position of a data point is the average of the locations of the electrodes in the array used to make the measurement. The vertical position of the plotting point is commonly set at the median depth of investigation (Edwards, 1977) of the array. The pseudosection is a useful method to present the data in a pictorial form and as an initial guide for further quantitative interpretation. One useful practical application of the pseudosection is in identifying bad apparent resistivity measurements that usually appear as points with unusually high or low values. The pseudosection gives a distorted picture of the subsurface because the shapes of the contours depend on the type of array used as well as the true subsurface resistivity. Figure 4a shows an example of a Wenner-array pseudosection where the real structure is a rectangular block model (Figure 4b) in a homogenous medium. An inversion of the data set using a 2-D model is necessary to obtain an accurate picture of the subsurface resistivity.

A 2-D model that consists of a large number of rectangular cells is commonly used to interpret the data (Loke and Barker, 1996a). Figure 4c shows an example of a 2-D model where the distribution of the data points in the pseudosection is used as a guide in setting the arrangement of the model cells. The resistivity of the cells is allowed to vary in the vertical and the horizontal direction, but the size and position of the cells are fixed. An inversion scheme is used to determine the resistivity of the cells that will produce a response that agrees with the measured values. The finite-difference (see *Numerical Methods, Finite Difference*) or finite-element method (see *Numerical Methods, Finite Element*) is used to calculate the apparent resistivity values for the 2-D model. A non-linear optimization method is then used to automatically change the resistivity of the model cells to minimize the difference



Electrical Resistivity Surveys and Data Interpretation, Figure 4 (**a**) Example of an apparent resistivity pseudosection (Wenner array). (**b**) The actual structure with a high resistivity block in a homogenous medium. (**c**) Example of a 2-D model showing the arrangement of the model cells.

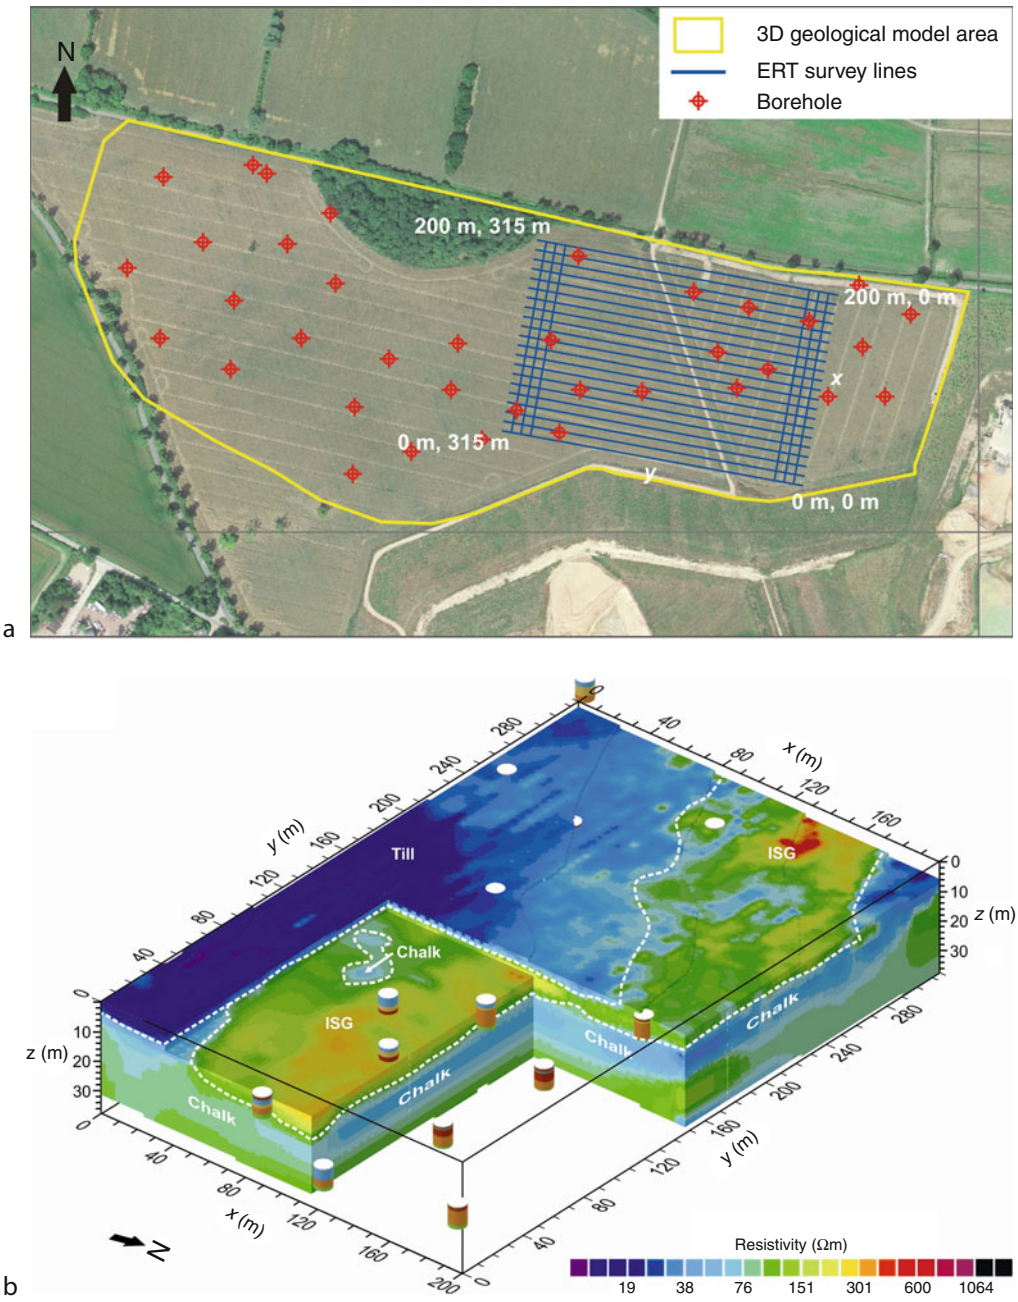
between the measured and calculated apparent resistivity values. The inversion problem is frequently ill-posed due to incomplete, inconsistent and noisy data. Smoothness or other constraints (e.g., in Equation 2) are usually incorporated to stabilize the inversion procedure such that numerical artifacts are avoided. As an example, the following equation includes a model smoothness constraint to the least-squares optimization method,

$$\left(\mathbf{J}^{\mathrm{T}}\mathbf{J}+\lambda\mathbf{F}\right)\Delta\mathbf{q}_k=\mathbf{J}^{\mathrm{T}}\Delta\mathbf{g}_k-\lambda\mathbf{F}\mathbf{q}_{k-1},\ \text{where}\quad \mathbf{F}=\alpha_x\mathbf{C}_x^{\mathrm{T}}\mathbf{C}_x+\alpha_z\mathbf{C}_z^{\mathrm{T}}\mathbf{C}_z. \tag{3}$$



Electrical Resistivity Surveys and Data Interpretation, Figure 6 (**a**) Map showing the survey grid of the BGS survey at Ingham, Suffolk (Aerial Photography © UKP/Getmapping License No. UKP 2010/01). (**b**) 3-D resistivity inversion model with cut-outs, annotation and borehole logs. The target of the survey is the Ingham sand and gravel (ISG) deposits. Details on the boreholes are available in Chambers et al. (2007). Reproduced with permission of the British Geological Survey and Tarmac Ltd.

Here, $\mathbf{C}_x$ and $\mathbf{C}_z$ are the roughness filter matrices in the horizontal (x) and vertical (z) directions, and α_x and α_z are the respective relative weights of the roughness filters. k represents the iteration number. One common form of the roughness filter is the first-order difference matrix (deGroot-Hedlin and Constable, 1990), but the elements of the matrices can be modified to introduce other desired characteristics into the inversion model (Pellerin and Wannamaker, 2005; Farquharson, 2008). The method can also be modified to produce "blocky" models for regions that are piecewise constant and separated by sharp boundaries (Loke et al., 2003). The laterally constrained inversion method (Auken and Christiansen, 2004) that includes sharp boundaries has been successfully used in areas with a layered subsurface structure. A number of microcomputer based software is now available that can automatically carry out the inversion of a 2-D survey data set in seconds.

Figure 5a shows an example of a measured apparent resistivity pseudosection from a groundwater survey (Acworth, 1987) using the Wenner array. The resistivity model after inversion and the calculated apparent resistivity pseudosection for this model are shown in Figure 5c and 5b, respectively. The model obtained after inversion has a prominent low resistivity fracture zone in the bedrock (approximately between the 180 and 230 m marks and below a depth of 20 m). A borehole that was placed at the 175 m mark had yields that were lower than expected, possibly because it lies at the edge of the fracture zone. The placement of the well was partly based on EM profiling data. The shallow low resistivity anomaly with values of less than 40 Ω·m in the overburden had probably shifted the EM anomaly to the left of the fracture zone.

Three-dimensional resistivity imaging surveys

Since all geological structures are three-dimensional (3-D) in nature, a 3-D resistivity survey and interpretation model (Figure 3c) should give the most accurate results. Although it has not reached the same level of usage as 2-D surveys, it is now more widely used in very complex areas such as in many environmental (Dahlin et al., 2002; Chambers et al., 2006; Rucker et al., 2010) and mineral (White et al., 2001; Bingham et al., 2006) exploration surveys. Much of the early 3-D surveys used the pole-pole array over relatively small grids (up to about 20 by 20 electrodes) with measurements in different directions (Park and Van, 1991; Li and Oldenburg, 1992). The use of other arrays, such as the pole-dipole and Wenner–Schlumberger, is now becoming more common in 3-D surveys that involve thousands of electrode positions (White et al., 2001; Chambers et al., 2006). A true 3-D survey requires placing of electrodes in the form of a 2-D grid. However, a cost-effective strategy is usually followed wherein 3-D data sets are collated from independent parallel 2-D survey lines with possibly a few crosslines. This strategy greatly reduces the cost of a 3-D survey and also allows for 2-D inversions of each individual line. The data interpretation techniques used for 2-D surveys can be extended to 3-D surveys (Loke and Barker, 1996b). Fast computer software that takes minutes to hours to invert a 3-D data set (depending on the size of the data set) on multicore PCs is now available (Rucker et al., 2010). Other non-linear optimization methods such as neural networks, simulated annealing and conjugate gradient techniques have also been used for resistivity data inversion (Pellerin and Wannamaker, 2005).

Figure 6 shows an example of such a 3-D survey at Ingham, Suffolk by the British Geological Survey (Chambers et al., 2007) to map sand and gravel deposits. Most of the survey lines are in an approximately east–west direction with a few crosslines near the edges (Figure 6a). The area has a fairly complex geology with Chalk bedrock overlain by the fluvial Ingham sand and gravel, glacial sand, and clayey till (Figure 6b). The till has the lowest resistivity values of below 50 Ω·m while the sand and gravel is generally between 100 to 1,000 Ω·m. The Chalk shows a distinct increase of resistivity with depth due to weathering.

The data inversion methods have been adapted for other types of surveys such as induced polarization (IP) surveys (White et al., 2001), measurements across boreholes (Wilkinson et al., 2008), surveys in water covered areas (Loke and Lane, 2005), and for cylindrical geometries (Chambers et al., 2003; al Hagrey et al., 2004). The least-squares optimization method has also been modified for time-lapse surveys so as to minimize temporal changes in the model resistivity values (Loke, 2001; Kim et al., 2009).

Summary

The electrical resistivity survey method has undergone tremendous changes over the past 20 years. While traditional resistivity profiling and sounding surveys are still widely used, 2-D imaging survey is now the method of choice for most areas as this can accurately map moderately complex structures. The field equipment and computer interpretation software are widely available. 3-D surveys now play an increasingly important role in very complex areas. In many cases the 3-D data set is collated from a series of parallel 2-D survey lines to reduce the survey cost.

Acknowledgments

I would like to thank the British Geological Survey and Tarmac Ltd for permission to use the figures for the Ingham survey.

eGY. Electronic Geophysical Year. An international science year (2007–2008) celebrating the IGY+50 anniversary that focused on increasing access to scientific data and information for all people.

Introduction and concept

Sharing scientific data and information for the common good has long been at the heart of good scientific practice. For the geosciences, this culminated in the outstandingly successful International Geophysical Year, 1957–1958 (IGY). During IGY, in addition to the initiation of much new research, scientists and member countries worked together to emplace a large number of geophysical observatories around the globe, and establish a network of

World Data Centers for archiving data and for making data available without restrictions.

The Electronic Geophysical Year, 2007–2008 (*e*GY), was conceived in the conviction that the benefits of this "Information Commons" are even greater today than they were 50 years ago. Modern information and communications technologies endow us with capabilities for sharing data and information that are unprecedented, provide impressive and timely opportunities for Earth and space science, and require international coordination to avoid replication of effort and a multiplicity of standards.

> The eGY VISION. We can achieve a major step forward in Earth and space science capability, knowledge, and usage throughout the world for the benefit of humanity by accelerating the adoption of modern, visionary practices for managing and sharing data and information.

History

In 1999, the International Union of Geodesy and Geophysics (IUGG) called on its Scientific Associations to propose activities to mark the 50-year anniversary of IGY. The International Association of Geomagnetism and Aeronomy (IAGA) responded through a resolution passed at the IUGG General Assembly in Sapporo in 2003 to lead an Electronic Geophysical Year.

*e*GY began on July 1, 2007 and ended on December 31, 2008, exactly 50 years after the start and end of IGY. Support for *e*GY came from IAGA, IUGG, NASA, the United States National Science Foundation, United States Geological Survey, and the Laboratory for Atmospheric and Space Physics (LASP) of the University of Colorado. In-kind contributions came from the American Geophysical Union (AGU), the National Centre for Atmospheric Research in Boulder, and the volunteer labor of *e*GY participants.

Scope

*e*GY focused the international science community to achieve a step increase in making past, present, and future geoscientific data (including information and services) rapidly, conveniently, and openly available. The themes of eGY were electronic data location and access, data release and permission, data preservation and rescue, data integration and knowledge discovery, capacity building in developing countries (mainly improving Internet connectivity), and education and outreach. Promoting the development of virtual observatories (VOs) and similar user-community systems for providing open access to data and services was a central feature of *e*GY.

Operations

Working groups were established to focus effort on each of the eGY theme areas. National eGY groups were particularly active in Canada, China, India, Japan, Russia, and the UK. A Web site (www.egy.org) served not only as a means of networking among eGY participants, but was developed as, and remains, an information resource for data and information practice and policy.

Presentations, theme sessions, Town Hall meetings, workshops, and demonstrations of VO technology and working systems were organized at international conferences run by AGU, The Asia Oceania Geophysics Society (AOGS), ICSU's Committees on Data for Science and Technology (CODATA), the Committee on Space Research (COSPAR), the European Geosciences Union (EGU), IAGA, and IUGG. Virtual Observatories in Geosciences (VOiG) Conference was held in Denver in June 2007, with selected papers published in the April 2008 issue of Earth Science Informatics (http://www.springerlink.com/content/1865–0473).

In 2008, an Earth and Space Science Informatics Summit was held in Rome to establish a better understanding and cooperation among the various geoinformatics and space science informatics initiatives and programs that are growing up rapidly worldwide. A report is available at http://egy.org/files/ESI_Summit_Report_final.pdf.

One of the first actions of eGY was to establish a declaration for an Earth and Space Science Information Commons. It states

> *The Electronic Geophysical Year (eGY) joins with the International Council for Science, the World Summit on the Information Society, and many other bodies in recognizing that knowledge is the common wealth of humanity. We have a shared responsibility to create and implement strategies to realize the full potential of digital information for present and future generations. In the 21st century and beyond, access to digital information and new technologies for information integration and knowledge discovery will influence the free and productive development of societies around the world. Providing ready and open access to the vast and growing collections of cross-disciplinary digital information is the key to understanding and responding to complex Earth system phenomena that influence human survival.*

and includes eight articles addressing the major aspects of an Earth and space science information commons (mirroring the eGY themes).

Achievements

Principal legacies of eGY are (1) stronger awareness of the role that informatics plays in modern research, (2) adoption of virtual observatories and similar systems for accessing data, information, and services, and (3) an expanding infrastructure at the international and national levels. As with the IGY, the mission of eGY is being carried forward through existing and newly formed national and international organizations.

Advances in which the eGY effort played a role include:

- Establishment of the Earth & Space Science Informatics Division in EGU
- Establishment of a COSPAR's Panel for Informatics
- Establishment of an IUGG Union Commission for Data & Information
- Strengthening of AGU's Earth & Space Science Informatics Special Focus Group

- IUGG readmission as a member of CODATA and support for a CODATA delegate
- Drafting of implementation guidelines for GEOSS's (GEOSS = the Global Earth Observing System of Systems) data and information policy
- Formation of an International Polar Year (IPY) Data Policy and Management Subcommittee under ICSU, WMO, and CODATA as a CODATA Task Group
- Contributions to development of the IPY Data and Information Service (IPYDIS, http://ipydis.org) and the Polar Information Commons (http://polarcommons.org)
- Formation of a CODATA Task Group: eGY Earth & Space Science Data Interoperability
- ICSU/SCID and SCCID: eGY membership of SCID to review data policy and representation on ICSU's Strategic Coordinating Committee for Information and Data
- eGY-Africa as a contribution to IUGG's Geoscience in Africa initiative

ENERGY BUDGET OF THE EARTH

Jean-Claude Mareschal[1], Claude Jaupart[2]
[1]Centre GEOTOP-UQAM, University of Québec at Montréal, Montréal, QC, Canada
[2]Institut de Physique du Globe, Paris, France

Definition

The Earth is a physical system with an energy budget where the outgoing energy must be balanced against all the sources of energy. The planet is not in equilibrium: the difference between the energy flowing out of the Earth and the internal heat production is accounted for by the secular cooling of the mantle and core.

Total heat loss of the earth

The main constraint on the total heat loss of the Earth comes from many heat flux measurements that have been made both on continents and oceans. Because the continents and the oceans have different thermal structures and because the heat flux data are affected by different biases in each region, it is necessary to analyze separately the continental and the oceanic heat losses (Jaupart et al., 2007).

Continental heat flow

There are more than 18,000 reported heat flux measurements on the continents and their margins. This number includes many additions by individual researchers to the data in the compilation by Pollack et al. (1993). The measurements are very unevenly distributed geographically with the majority of the data coming from Eurasia and North America. Two large continents, Antarctica and Greenland, are almost unsampled. The raw average of all continental heat flux values is 79.7 mW m^{-2}. This value is biased because the data set includes many data from the USA that were collected for geothermal exploration in anomalously hot regions. The bias is made evident when data from the USA and the rest of the world are analyzed separately: the average is 112.4 mW m^{-2} for the USA versus 65.7 mW m^{-2} for the rest of the world. One way to remove the bias is by area-weighting, that is, estimating the average over sufficiently large windows (1° × 1°), and then taking the average of all the windows. It yields an average heat flux for all the continents of 63 mW m^{-2} (Table 1). Multiplying by the continental surface area of 210×10^6 km^2 gives 13.5 TW for the heat loss through the continents. An alternative method to calculate continental heat loss is to bin the data by "age," determine the average heat flux for each age group, and integrate the

Energy Budget of the Earth, Table 1 Continental heat flux statistics[a]

	$\mu(Q)$ mW m^{-2}	$\sigma(Q)$ mW m^{-2}	$N(Q)$
World			
All values	79.7	162	14,123
Averages 1° × 1°	65.3	82.4	3,024
Averages 2° × 2°	64.0	57.5	1,562
Averages 3° × 3°	63.3	35.2	979
USA			
All values	112.4	288	4,243
Averages 1° × 1°	84	183	532
Averages 2° × 2°	78.3	131.0	221
Averages 3° × 3°	73.5	51.7	128
Without USA			
All values	65.7	40.4	9,880
Averages 1° × 1°	61.1	30.6	2,516
Averages 2° × 2°	61.6	31.6	1,359
Averages 3° × 3°	61.3	31.3	889

[a]μ is the mean, σ is the standard deviation, and N is the number of values

product of heat flux times the areal age distribution for continental crust (Pollack et al., 1993). It gives about the same value for the heat loss as the area weighted average.

Oceanic heat flow

There are more than 20,000 heat flux measurements reported in the oceans but these data are not directly used to calculate the total heat loss through the oceans. The oceanic heat loss is calculated from a model of cooling of the seafloor. The measurements are used to determine the parameters of this model. The cooling model of the seafloor is a direct consequence of the seafloor spreading hypothesis. It assumes that seafloor forms at mid-oceanic ridges and cools as it moves away from the ridge. The surface heat flux is calculated by solving the heat conduction equation with fixed surface temperature. For a cooling half-space model, heat flux q decreases with seafloor age τ as (Lister, 1977):

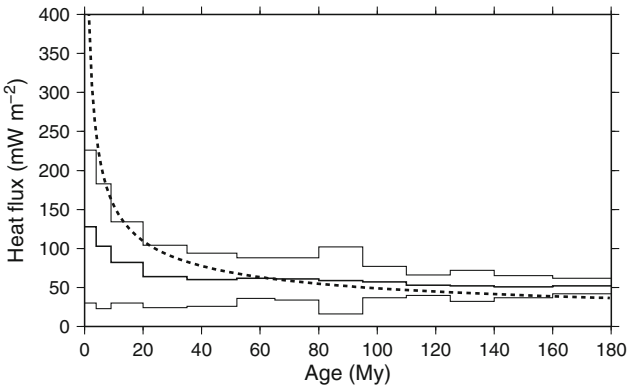
$$q(\tau) = C_Q \tau^{-1/2}$$

where C_Q depends on the temperature of the magma ascending at the seafloor, and on the thermal properties (thermal diffusivity and conductivity) of the cooling lithosphere.

In order to compare the oceanic heat flux measurements with the model, data have been binned by age. Figure 1 shows that the observed heat flux is systematically less than predicted for seafloor ages <60 My, and that heat flux is approximately constant and higher than predicted for ages >80 My.

Young seafloor

Only the heat that is conducted through the seafloor can be measured. Near the mid-oceanic ridges, where there are large open fractures in the shallow crust, much heat is transported by the movement of hydrothermal fluids. This convective component of the heat flux accounts for the difference between the observations and the predictions of the cooling model. At depth, fractures are sealed by the confining pressure and cooling is by conduction only. In regions of the seafloor that are well sealed by sediments, the heat flux observations do fit the cooling model and can be used to determine the constant C_Q. With the additional constraint being $q(\tau \to \infty) \to 0$ (Harris and Chapman, 2004), the value of C_Q ranges between 470 and 510 mW m^{-2} My$^{1/2}$.



Energy Budget of the Earth, Figure 1 Observed and predicted oceanic heat flux as a function of seafloor age. The *dotted line* is the predicted heat flux for the half-space cooling model. The average observed heat flux (±1 SD) within different age groups is shown by *continuous (thin) lines*. Data from Stein and Stein (1994).

Old seafloor

For ages greater than 80 My, the heat flux levels off and is higher than calculated for a half-space cooling model. The common interpretation is that cooling of the mantle triggers the onset of small-scale convection, which maintains a constant temperature or heat flux at fixed depth below the seafloor. Experiments designated to measure the heat flux on seafloor older than 100 My have shown that it is almost constant and equal to 48 mW m^{-2}.

Bathymetry

One consequence of the cooling of the seafloor is that the average density of a rock column increases because of thermal contraction:

$$\Delta\rho_m = -\alpha\rho_m \Delta T$$

where α is the thermal expansion coefficient, ρ_m is mantle density, and ΔT is the temperature difference at time τ. The change in bathymetry can be calculated from the isostatic balance condition:

$$\begin{aligned}\Delta h &= \frac{1}{(\rho_m - \rho_w)} \int_0^d \Delta\rho_m(z,\tau)dz \\ &= \frac{-\alpha\rho_m}{(\rho_m - \rho_w)} \int_0^d \Delta T(z,\tau)dz \\ &= \frac{\alpha}{C_p(\rho_m - \rho_w)} \int_0^\tau [q(0,\tau) - q(d,\tau)]d\tau\end{aligned}$$

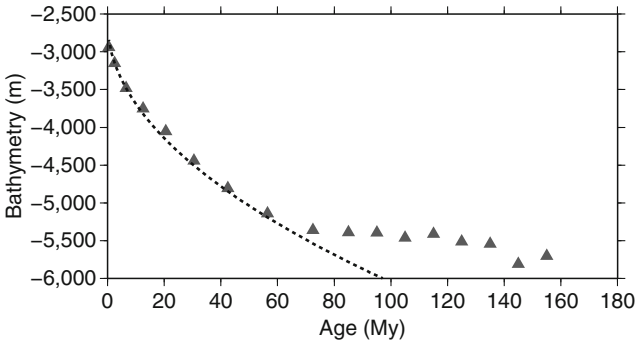
where C_p is the specific heat of the lithospheric rocks and ρ_w density of seawater. For a half-space, $d \to \infty$ and $q(d, \tau) \to 0$, we have:

$$\Delta h = \frac{\alpha}{C_p(\rho_m - \rho_w)} \int_0^\tau q(\tau)d\tau$$

It gives:

$$h = h_0 + \frac{2\alpha}{C_p(\rho_m - \rho_w)} C_Q \tau^{1/2} = h_0 + C_H \tau^{1/2}$$

The bathymetry of the seafloor fits very well the half-space cooling model for ages less than 80 My. For greater ages, the bathymetry becomes flat, confirming that heat supplied at the base balances the heat loss at the surface of the plate (Figure 2). The constant C_H is related to C_Q and, with standard values for the physical properties



Energy Budget of the Earth, Figure 2 Worldwide average seafloor bathymetry as a function of age (*triangle*), and predicted bathymetry for a cooling half-space (*dotted line*). Bathymetry data from Crosby and McKenzie (2009).

of the mantle ($\alpha = 3.1 \times 10^{-5}$ K^{-1}, $C_p = 1{,}170$ J kg^{-1} K^{-1}, $\rho_m = 3{,}330$ kg m^{-3}, and $\rho_w = 1{,}000$ kg m^{-3}), we obtain $C_H/C_Q = 704$ m^3 W^{-1} My^{-1}. Measurements of the depth to the basement on old seafloor have been used to determine a value of 345 m My$^{-1/2}$ for C_H, which translates as 480 mW m^{-2} My$^{1/2}$ for C_Q (Carlson and Johnson, 1994). This is within the range obtained from the heat flux data set.

Age distribution of the seafloor

In order to determine the total oceanic heat loss, we have to integrate the heat flux times the areal distribution of seafloor ages. The distribution of seafloor ages has been very well determined from studies of the marine magnetic anomalies (Müller et al., 2008). There are few ages higher than 180 My and the areal distribution appears to decrease linearly with age τ, such that the areal distribution can be approximated by:

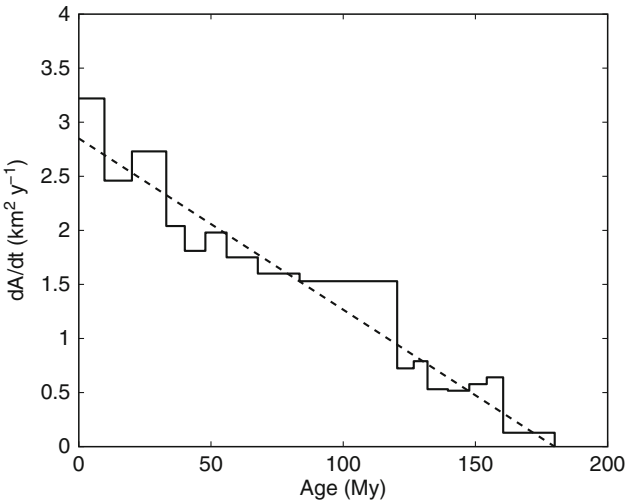
$$C_A(1 - \tau/180) \tag{1}$$

where τ is age in My (Figure 3). In order to account for the total area covered by the oceans including the marginal basins (300×10^6 km^2), the accretion rate $C_A = 3.4$ km^2 y^{-1}.

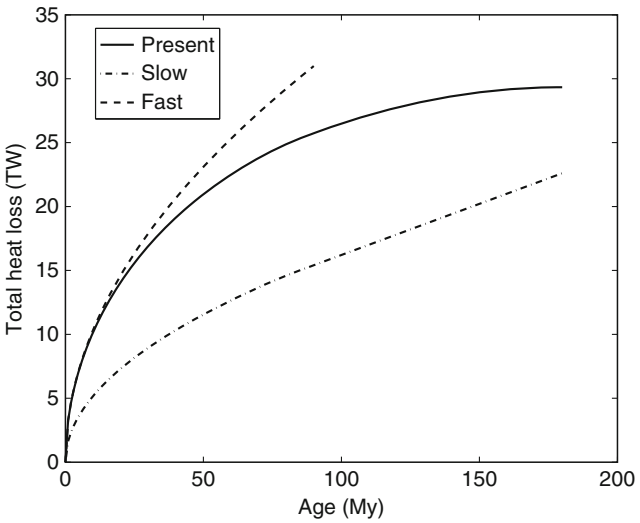
Integrating separately seafloor younger and older than 80 My gives:

$$\begin{aligned} Q_{80-} &= \int_0^{80} C_Q \tau^{-1/2} C_A(1 - \tau/180) d\tau \\ &= 24.3 \text{ TW} \\ Q_{80+} &= q_{80} \int_{80}^{180} C_A(1 - \tau/180) d\tau \\ &= 4.4 \text{ TW} Q_{\text{oceans}} = 29 \pm 1 \text{ TW} \end{aligned} \tag{2}$$

The cumulative heat loss as a function of age depends strongly on the age distribution (Figure 4). With a lower accretion rate and a rectangular age distribution, the oceanic heat loss could be as low as 22 TW.



Energy Budget of the Earth, Figure 3 Age distribution of the seafloor, not including the marginal basins: distribution from isochrons (*solid line*); best fit to the distribution (*dashed line*). Data from Cogné and Humler (2004).



Energy Budget of the Earth, Figure 4 Cumulative total heat loss of the seafloor for three different distributions of the seafloor age: the present triangular distribution, triangular distribution with twice the present spreading rate and oldest seafloor 90 My, rectangular distribution with oldest seafloor 180 My and spreading rate half of present. The total oceanic area is 300×10^6 km^2, and $C_Q = 490$ mW m^{-2} My$^{1/2}$; for ages >80 My, heat flux is 48 mW m^{-2}.

Hot spots

Hot spots bring additional heat to the oceanic plates. This heat is not accounted for by the plate cooling model and should be added to the oceanic heat loss. The extra heat flux is barely detectable, but the heat that has been put in the plate can be estimated from the volume of the swell of the seafloor: it amounts to 2–4 TW. The resulting value

for the total energy loss at the Earth's surface, 46 TW, is not much different from the first estimates by Williams and von Herzen (1974) (Table 2).

Energy budget of the mantle

The total heat loss at the Earth surface includes continental heat losses 14 TW, cooling of the sea floor, 29 TW, and heat from the hot spots, 3 TW. Part of this heat comes from radioactive heat production in the continental crust, which has been estimated by multiple and extensive sampling (Rudnick and Fountain, 1995; Rudnick and Gao, 2003; Jaupart and Mareschal, 2003). It is estimated to be 7 TW. This leaves 39 TW for the mantle, either by cooling of the seafloor or by conduction through the continental lithosphere. Three main components balance the mantle energy loss: radiogenic heat production in the mantle, heat flux from the core, and secular cooling of the mantle. Other sources (tidal dissipation, gravitational settling, changes in gravitational potential energy due to thermal contraction) contribute less than 1 TW.

Energy Budget of the Earth, Table 2 Estimates of the continental and oceanic heat flux and global heat loss

	Continental (mW m^{-2})	Oceanic (mW m^{-2})	Total (TW)
Williams and von Herzen (1974)	61	93	43

Jaupart et al.[a] (2007)	65	94	46

[a]The average oceanic heat flux does not include the contribution of hot spots. The total heat loss estimate does include 3 TW from oceanic hot spots

Radiogenic heat production

Different approaches have been used to estimate the composition of the Earth's mantle and its radiogenic heat production. Earth was formed by accretion of planetesimals in the Solar nebula that have the same origin as the chondritic meteorites. However, the accretion process and the giant impact that formed the Moon have modified Earth's composition relative to the meteorites. Estimates of mantle composition rely on comparing elemental ratios on Earth and meteorites, to infer the composition of bulk silicate Earth (BSE), that is, the mantle and crust. Another method assumes that compositional trends in meteorites and mantle rocks record processes in the solar nebula and the mantle, and that they will intersect at the composition of their common source. Both methods yield a heat production of ≈20 TW for BSE. Accounting for the radioelements that have been stored in the continental lithosphere leaves 13 TW in the convecting mantle. It is useful to compare the mantle heat production to its heat loss: this ratio is referred to as the *Urey ratio* of the mantle. It estimated to be in the range 0.21–0.49 with a preferred value of 0.33.

A lower bound for mantle heat production can be obtained from the composition of the rocks that are extracted from the mantle to form the seafloor. This only gives a lower bound because it does not take into account a possible hidden reservoir that has not been tapped by the extraction of the MORBs. This estimate is 11 TW for the mantle; accounting for the heat production in the continental lithosphere gives a total heat production higher than 18 TW for BSE. These various estimates are summarized in Table 3.

Heat flux from the core

Some authors have assumed that the heat flux from the core is equal to the heat flux transported by the hot spots. There is no reason that it should be so. The heat carried away by hot spots originating at the core mantle boundary must be less than the core's output. This lower bound is 4 TW. A different bound can be obtained by calculating the minimum heat flux that would be conducted along an adiabat in the core. The core is thought to have a very high thermal conductivity and the heat flux conducted along the adiabat is 40 mW m^{-2}, that is, 5 TW. How much energy is required to power the geodynamo has been much debated. Present estimates vary within a wide range (5–14 TW) with an average value of 9 TW (Nimmo, 2007; Buffett, 2007).

Secular cooling

Table 4 compares different ways of breaking down the energy budget of the Earth. Stacey and Davis (2008) add the radioactivity in the continental crust to that of BSE and thus overestimate the total heat production. Both Stacey and Davis (2008) and Davies (1999) assumed that all the heat from the core is carried away by the hot spots, although the hot spots provide only a weak lower bound on core heat flow.

The difference between the total mantle energy loss and the inputs from the core, radioactivity, and other sources, $39 - 1 - 13 - 9 = 16$ TW, must be accounted for by the secular cooling of the mantle. This gives a mantle cooling rate of $\approx$100 K Gy^{-1}. Mantle temperatures can be calculated from the composition of the Mid Oceanic Ridge Basalts (MORB). Petrological studies on Archean (3.5–2.5 Gy old) MORB like rocks suggest a more modest cooling rate of 50 K Gy^{-1} (Figure 5). The range of temperatures found in these studies is too wide to rule out that the secular cooling rate is higher than 50 K Gy^{-1}, but the difference between the present and secular rates of cooling raises interesting questions about the present energy budget.

Energy Budget of the Earth, Table 4 Various estimates of the breakdown of the global budget in TW. Stacey and Davis (2008) have added heat production in the continental crust to that of bulk silicate earth. They also assume that gravitational potential energy released by thermal contraction produces heat rather than strain energy. Both Stacey and Davis (2008) and Davies (1999) assume that hot spots carry all the heat from the core

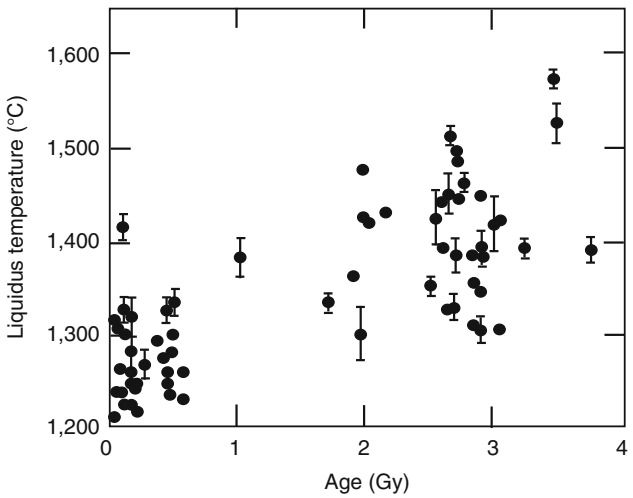
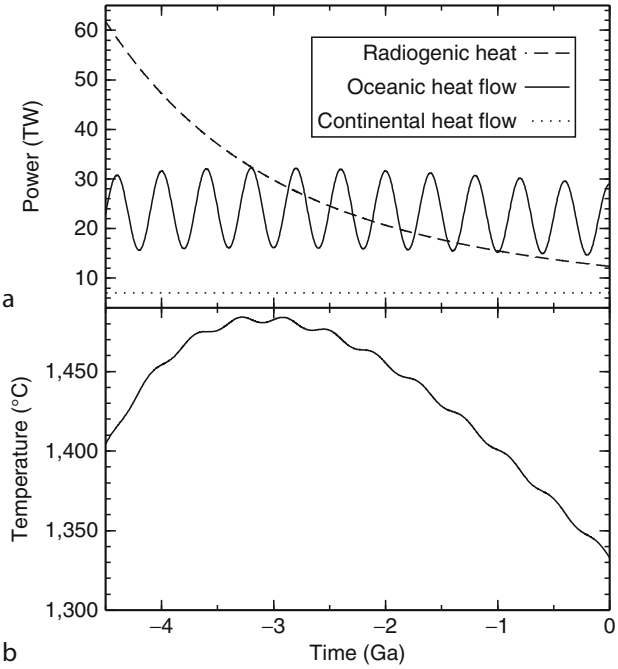
Present and long-term cooling rates

Is the present rate of energy loss equal to the long-term rate? The energy lost through the seafloor depends on the age distribution of the seafloor. It is likely that the energy lost through the seafloor fluctuates with the super continent cycle, and that the present energy loss is different from the long-term mean. The second point is that radioactive heat production in the mantle was higher in the past than now for two reasons: one reason is the run-down of radioelements and the other is the extraction of continental crust that removed radioelements from the mantle. Finally, the heat loss from the mantle depends on the total continental area as much more heat escapes through the seafloor than through the continental lithosphere. The energy flow from the core may also oscillate and have been different in the past, when the frequency of geomagnetic reversals was lower than in recent times.

The relative importance of these effects remains difficult to assess because we do not know exactly how the volume of continental crust changed with time, but Figure 6 presents one plausible thermal history of the mantle based on the assumption that the mantle heat loss oscillates by $\pm$7 TW over a period of 400 My corresponding to the supercontinent cycle.



Energy Budget of the Earth, Figure 5 Liquidus temperatures of basalts from ophiolites and greenstone belts with MORB characteristics as a function of age. Adapted from Abbott et al. (1994).



Energy Budget of the Earth, Figure 6 Effect of fluctuations of oceanic heat loss over a supercontinent timescale of τ_W = 400 My on the secular thermal evolution of the mantle, from Labrosse and Jaupart (2007). The model calculations rely on a simple parametrization of seafloor spreading that leads to a weak secular variation of oceanic heat loss. Heat loss fluctuations due to changes of seafloor spreading are superimposed on the secular trend. These changes occur on a timescale that is short compared to that of the secular trend and leave almost no trace on mantle temperatures. *Top panel* (a): the various contributions to the Earth's energy budget that are used in the calculation. *Bottom panel* (b): predicted evolution of the average mantle temperature through time.

Perspectives

The most promising avenue for improving our understanding of the energy budget is the recent development of neutrino observatories that can detect geo-neutrinos, that is, neutrinos from the decay of U and Th in the Earth (Fiorentini et al., 2005). With sufficient observations of geo-neutrinos, we might be able to determine more precisely the total heat production due to mantle radioactivity.

Summary

The Earth loses energy as heat flows out through its surface. The total energy loss of the Earth has been estimated at 46 $\pm$ 2 TW, of which 14 TW comes through the continents and 32 TW comes from the seafloor. After removing the heat production of radioactive elements in the continental lithosphere, the energy loss from the convecting mantle is 39 TW. Three main sources balance the mantle energy loss: Heat flow from the core, radiogenic heat production in the mantle, and the secular cooling of the mantle. The uncertainty on the exact contribution of each component is much larger than that on the total heat loss. The best estimate of the present cooling rate of the mantle (110 K Gy^{-1}) is higher than the secular cooling rate estimated from petrology. The present cooling rate may be different from its long-term average because of variations in seafloor spreading rates and higher mantle heat production in the past.

ENERGY PARTITIONING OF SEISMIC WAVES

Kalachand Sain
National Geophysical Research Institute, Council of Scientific & Industrial Research (CSIR), Hyderabad, India

Synonyms

Partitioning – conversion

Definition

When an incoming P wave strikes an interface between two isotropic homogeneous elastic media at some angle other than the vertical, some of the energy is converted into S wave which gets reflected and transmitted in the same way as the P wave. This is known as the energy partitioning of seismic wave.

Snell's Law: The angles of incidence, reflection and transmission as shown in Figure 1 are related by Snell's law, which says that the ratio of sines of angles of incidence, reflection, and transmission to velocities of respective media across the interface is a constant. In seismology, this constant is defined as the ray parameter, R_P as

$$\frac{\sin\theta_1}{V_{P1}} = \frac{\sin\theta_2}{V_{P2}} = \frac{\sin\varphi_1}{V_{S1}} = \frac{\sin\varphi_2}{V_{S2}} = R_P \quad (1)$$

where V_P, V_S and ρ are the P-wave velocity, S-wave velocity and density, and subscripts 1 and 2 represent the first and second layers respectively.

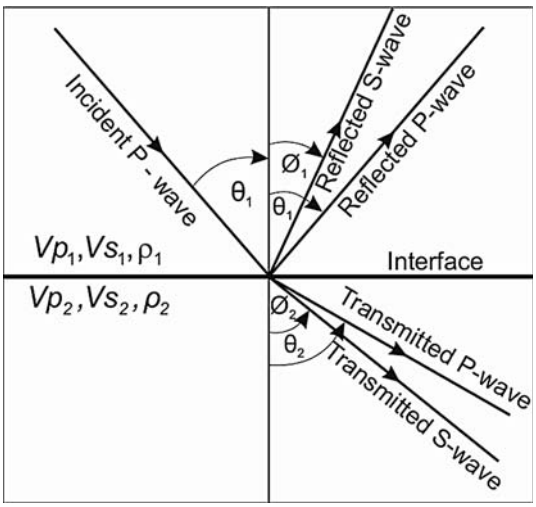
Reflection and transmission coefficients: A reflection coefficient describes either the amplitude or the energy of a reflected wave relative to an incident wave and similarly a transmission coefficient describes either the amplitude or the energy of a transmitted wave relative to an incident wave. When a plane wave strikes a horizontal interface vertically (i.e., at normal incidence), the reflection coefficient, R_C, and the transmission coefficient, T_C, are defined as

$$R_C = \frac{Z_2 - Z_1}{Z_2 + Z_1} \quad (2)$$

$$T_C = \frac{2Z_1}{Z_2 + Z_1} \quad (3)$$

Where Z_1 and Z_2 are the acoustic impedance (P-wave velocity multiplied by density) of the first and second media respectively.

Zoeppritz equation: When the seismic ray obliquely strikes the interface (Figure 1), separated by three elastic parameters (V_P, V_S, and ρ) on either side, the R_C and T_C as expressed by Equations 2 and 3 are not valid. The reflection and transmission coefficients or amplitudes of both P-P and mode converted P-S waves as a function of angle can be derived using the Zoeppritz equations (Zoeppritz, 1919) that can be easily expressed through a matrix (Waters, 1987) as



Energy Partitioning of Seismic Waves, Figure 1 Ray diagram for the partition of a plane wave energy at a horizontal interface.

$$Q = P^{-1}R \tag{4}$$

Where P is a 4 × 4 square matrix and, R and Q are 4 × 1 column matrices whose elements are shown as

$$\mathbf{P} = \begin{bmatrix} \sin\theta_1 & \cos\varphi_1 & -\sin\theta_2 & \cos\varphi_2 \\ -\cos\theta_1 & \sin\varphi_1 & -\cos\theta_2 & -\sin\varphi_2 \\ \sin 2\theta_1 & \frac{V_{P1}}{V_{S1}}\cos 2\varphi_1 & \frac{\rho_2}{\rho_1}\frac{V_{S2}^2}{V_{S1}^2} 2\sin\theta_1\cos\theta_2 & -\frac{\rho_2}{\rho_1}\frac{V_{P1}V_{S2}}{V_{S1}^2}\cos 2\varphi_2 \\ \cos 2\varphi_1 & -\frac{V_{S1}}{V_{P1}}\sin 2\varphi_1 & -\frac{\rho_2}{\rho_1}\frac{V_{P2}}{V_{P1}}\cos 2\varphi_2 & -\frac{\rho_2}{\rho_1}\frac{V_{S2}}{V_{P1}}\sin 2\varphi_2 \end{bmatrix} \tag{5}$$

$$Q = [\mathrm{R_{PPR}}\ \mathrm{R_{PSVR}}\ \mathrm{R_{PPT}}\ \mathrm{R_{PSVT}}]^{\mathrm{T}} \text{ and}$$
$$\mathrm{R} = [-\sin\theta_1 \ -\cos\theta_1 \sin 2\theta_1 \ -\cos 2\phi_1]^{\mathrm{T}} \tag{6}$$

$\mathrm{R_{PPR}}$ and $\mathrm{R_{PSVR}}$ are the reflection coefficients and, $\mathrm{R_{PPT}}$ and $\mathrm{R_{PSVT}}$ are the transmission coefficients of P-P and mode converted P-S waves respectively.

Figure 2a displays the coefficients of reflections and transmissions for P-P and converted P-S waves as a function of incident angles (θ) as per Equation 4 for the model as shown in the figure itself. At zero angle or offset, the R_C for P-P wave is mainly governed by the P-wave velocity but at large offsets its value depends on both the P and S wave velocities. The nature and amplitudes of curves vary with the elastic parameters across the interface (Figure 2b). These elastic parameters again depend on the lithology and fluids present within.

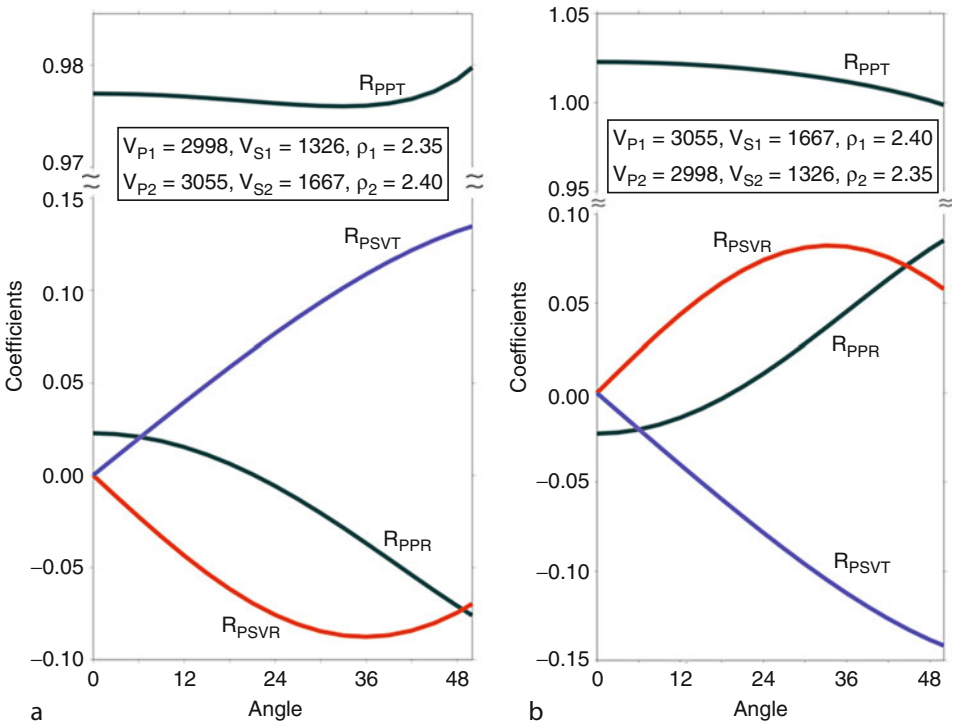
Approximation to the Zoeppritz equation led to an elegant method of reducing these curves to just two parameters. According to Shuey (1985), the P-wave reflection coefficient, $R_C(\theta)$ for an incidence angle (θ) up to ~30° can be expressed as

$$R_C(\theta) \approx A + B\ sin^2\theta \tag{7}$$

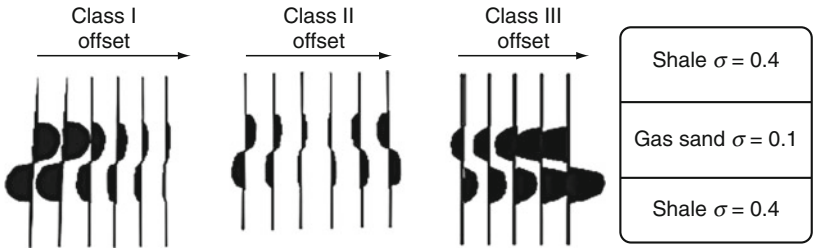
where,

$$A = \frac{1}{2}\left(\frac{\Delta V_P}{V_P} + \frac{\Delta\rho}{\rho}\right),\ B = AA_0 + \frac{\Delta\sigma}{(1-\sigma)^2} \tag{8}$$

$$A_0 = B_0 - 2(1+B_0)\frac{1-2\sigma}{1-\sigma}, B_0 = \frac{\Delta V_P/V_P}{\Delta V_P/V_P + \Delta\rho/\rho},$$
$$V_P = \frac{(V_{P2}+V_{P1})}{2}, V_S = \frac{(V_{S2}+V_{S1})}{2}, \rho = \frac{(\rho_2+\rho_1)}{2},$$
$$\Delta V_P = (V_{P2}-V_{P1}), \Delta V_S = (V_{S2}-V_{S1}),$$
$$\Delta\rho = (\rho_2-\rho_1), \Delta\sigma = (\sigma_2-\sigma_1), \sigma = \frac{(\sigma_2+\sigma_1)}{2},$$
$$\sigma_i = \frac{(.5V_{Pi}^2 - V_{Si}^2)}{(V_{Pi}^2 - V_{Si}^2)}$$



Energy Partitioning of Seismic Waves, Figure 2 (**a**) Reflection and transmission coefficients as a function of incidence angles for the model shown inside. (**b**) reflection and transmission coefficients as a function of incidence angles for the model shown inside in which the layer parameters are interchanged from the model in (**a**).



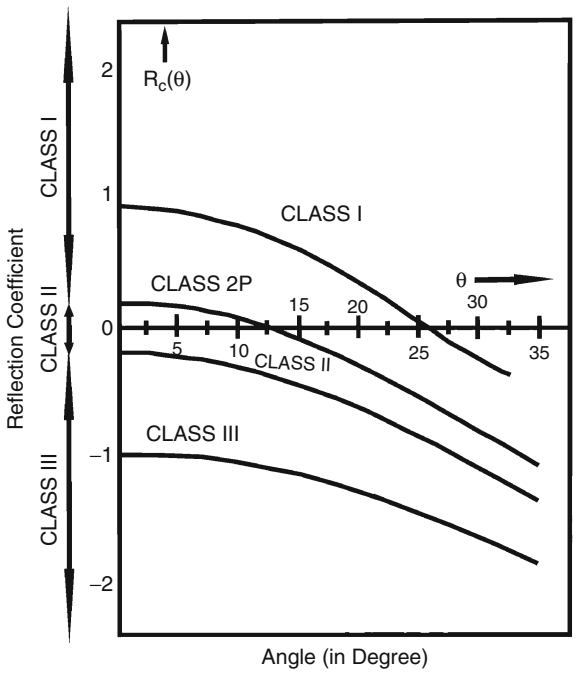
Energy Partitioning of Seismic Waves, Figure 3 Seismogram showing AVO response for three classes of gas sand anomalies, and a typical reservoir showing the Poisson ratio.

Equations 7 and 8 are valid up to high A for a negative impedance contrast across an interface, and to about $A = 0.2$ for a positive impedance contrast. Since 30° angle corresponds to the maximum angle that we generally encounter in normal seismic data acquisition, this approximation is widely used to determine the amplitude versus offset (AVO) attributes such as the intercept, A and the gradient, B for the interpretation of seismic data.

AVO response for a realistic earth model: The reflections from various subsurface interfaces exhibit a wide range of AVO characteristics that depend upon the rock types and fluid contents. From the field data, the amplitudes and offsets of reflected phases can be converted into reflection coefficients and angles, and by modeling using the Zoeppritz equation we can derive various elastic parameters (Ojha and Sain, 2007, 2008) or Poisson ratio (σ) that can be used as a direct indicator for hydrocarbons, as inclusion of oil or gas in the rock lowers the σ. Any overpressure in the trapped gas can also be known from AVO anomaly (Tinivella, 2002) that helps in avoiding drilling hazard. In oil industries, the AVO attributes have gained considerable popularity for lithology identification and reservoir characterizations (Castagna and Backus, 1993; Castagna et al., 1998) due to the fact that seismic amplitudes at interfaces are affected by the variations of physical properties just above and below the interfaces. In a recent paper, Ojha et al. (2010) have demonstrated through a field example that a plot of A versus B coupled with a rock physics can be used as a rapid tool for detecting free-gas below a bottom simulating reflector, and quantifying the amount of gas-hydrate and free-gas along a seismic reflection profile.

The gas-sand detection is the most promising application of AVO analysis. The characteristically low V_P/V_S ratio or σ of gas sand is expected to be differentiated from other low-impedance layers, such as coals and porous brine or oil sands. Rutherford and Williams (1989) have defined three distinct classes of gas-sand AVO anomalies (Figures 3 and 4) mainly based on the intercept, A (normal incidence reflection coefficient) and gradient, B attributes.

The Class I is a high impedance sand anomaly and occurs when the normal-incidence P-wave reflection coefficient is strongly positive and shows a strong amplitude decrease with offset and a possible phase change at far offset. The Class II anomaly occurs when the gas sand has similar impedance to the neighboring shale. For the gas



Energy Partitioning of Seismic Waves, Figure 4 AVO curves for three classes of gas sand anomalies.

sand scenario, the normal incidence reflection coefficient is close to zero and becomes negative at larger offsets. The Class III is the classic Gulf of Mexico AVO anomaly where gas sand has low impedance compared to shale. The normal incidence reflection coefficient is negative and becomes more negative as offset increases. The "bright spot" is associated with the Class III AVO anomaly and can be used as a direct indicator for hydrocarbons.

If the rock overlying the reservoir has a velocity appreciably lower than that of the reservoir itself (e.g., carbonate reservoir capped by shale), the effect of hydrocarbon is to decrease the impedance contrast and reduce the reflection coefficient producing a "dim spot." Class I and Class II AVO anomalies can produce the reverse effect. When the rock overlying the reservoir has a velocity slightly smaller than that of the reservoir rock, lowering the impedance of reservoir rock by hydrocarbons may invert the sign of the reflection, producing a polarity

reversal. The sand types and presence of gas can be identified from the classical A-B crossplot.

Summary

Because of energy partitioning, we can record both P- and S waves using multi-component sensors, and derive both P- and S-wave seismic velocities and their ratio (V_P/V_S), study of which provides more accurate information on lithology and fluid content than that obtained either by P- or S-wave velocity alone.

Acknowledgments

I am grateful to the Director, NGRI for his permission. The Ministry of Earth Sciences, Government of India is thankfully acknowledged for sponsoring the gas-hydrate research at NGRI.

EQUATORIAL ELECTROJET

Archana Bhattacharyya
Indian Institute of Geomagnetism, Navi Mumbai, India

The equatorial electrojet (EEJ) is a narrow band of intense electric current that flows along the dip equator in the day side ionospheric E region with peak current density at an altitude of around 105 km.

Cause

Electrical conductivity of the partially but significantly ionized upper atmosphere of the Earth is anisotropic due to the presence of Earth's magnetic field. In the ionospheric E region, movement of electrons in response to an electric field is influenced by the geomagnetic field, whereas for the heavier ions, collisions with neutral particles have much greater influence. This difference in the behavior of electrons and ions gives rise to a large Hall conductivity in the E region. Atmospheric tides, driven mainly by solar heating, cause the neutral atmosphere to undergo global-scale daily oscillations, which set the electrically conducting fluid in the ionosphere into motion thereby generating an electric field in the E region due to dynamo action in the presence of the geomagnetic field. At the dip equator, where the geomagnetic field is horizontal and northward directed, an eastward electric field in the magnetic east-west direction drives a downward Hall current, which is restricted due to the limited vertical extent of the E region. This causes charges to accumulate producing an upward polarization electric field much larger than the original eastward electric field in a region where the Hall conductivity is much larger than the Pedersen conductivity, and the upward electric field now drives an eastward Hall current that greatly exceeds the original eastward Pedersen current. Together these eastward currents constitute the normal equatorial electrojet (EEJ) (Forbes, 1981).

Observations

Comparison of geomagnetic field variations recorded at observatories located near the dip equator with data from low latitude observatories outside the influence of the EEJ but in the same longitude zone, show a typical enhancement of about 40–100 nT in the horizontal component of the geomagnetic field during daytime at the equatorial location, due to the EEJ. Figure 1a shows the location of the dip equator at different geographic longitudes computed from International Geomagnetic Reference Field model IGRF11. Figure 1b gives the locations of a chain of magnetic observatories in the Indian longitude region located at different latitudes, which extend northward from the dip equator to the focus of the solar quiet (Sq) current system that also flows in the day side E region of the ionosphere driven by E region dynamo electric fields generated by atmospheric tides, while Figure 1c depicts the average pattern of daily variation of the horizontal component of the geomagnetic field measured at these locations on magnetically quiet days of November 2001. The excess current that flows in the dip equatorial region of the ionspheric E layer as a consequence of the geometry of Earth's main magnetic field is the EEJ. In situ measurements by rockets have provided information about the current density and electric field profiles in the EEJ (Pfaff et al., 1997). Satellite

observations of magnetic field produced by the EEJ have yielded information about longitudinal variations in the spatial features and strength of the EEJ. For a normal EEJ, the same pattern of steep rise in current strength in the morning hours reaching a maximum between 10:30 and 12:00 LT, and then a gradual decrease to insignificant values around 18:00 LT is seen at all longitudes. Assuming the EEJ to flow in a thin sheet, on the average the current density estimated from CHAMP satellite observations is 0.19 A/m, while the latitudinal extent of the EEJ at noontime has been estimated to be about ±2 degrees around the dip equator, where the current peaks (Lühr et al., 2004). It is yet to be established how return currents close the EEJ. At a fixed longitude, the EEJ shows considerable day-to-day variation, and also seasonal and solar cycle dependence. On some days, the magnetic signatures recorded at observatories or by satellites indicate a daytime current flowing in the westward direction. This is called the counter electrojet, a phenomenon not yet understood (Rastogi, 1989).

Uses of EEJ observations

The electric field in the equatorial ionospheric E region plays a major role in determining the spatial distribution of ionospheric plasma throughout the low latitude ionosphere, which affects the operation of satellite-based communication and navigation systems such as the Global Positioning System (GPS). The EEJ is an indicator of the

state of this electric field during daytime. In the processing of data collected in magnetic surveys as a part of geophysical exploration for natural resources, it is necessary to remove the diurnal variation in the geomagnetic field due to the EEJ. The EEJ is also a natural source for electromagnetic induction studies. However, its latitudinal extent sets a limit on the depth within the Earth to which electrical conductivity can be determined using temporal variations of the EEJ.

Long-range dependence and disorder; Power law; Randomness; Scaling; Self-affine; Self-similar

Definition

Fractals. The objects having fractional dimension are termed as fractal. Also, such objects are self-similar in nature, thus their shape is independent of the scale and remains same under dilatation or contraction. The concept is extended to the time series analysis, and those time series in which power spectrum follows power law are termed as fractal time series.

Chaos. It is a state of extreme disorder. Behavior of chaotic systems is highly sensitive to initial conditions. Small change in initial conditions, even due to rounding off errors in computation can yield widely diverging outcomes for chaotic systems, rendering long-term prediction impossible in general. The chaos can be quantified by Lyapunov exponent if it is positive.

Introduction

The origin of fractals dates back to the eighteenth century in the study of non-differentiable functions by Karl Weierstras, Georg Cantor, and Felix Hausdorff, however, the term fractal was coined by Mandelbrot (1967, 1983) in a paper published in science "How long is the coast of Britain?" and later in his book *Geometry of Nature*. Fractals and Chaos are relatively new mathematical innovations, which find their applications in several branches of pure and applied sciences. Applications of fractals and chaos have been widely explored in solid earth geophysics and its successful applications are demonstrated in many areas of geophysics, namely: gravity, magnetic modeling (Turcotte, 1997; Dimri, 2005), seismic inversion, earthquake frequency–magnitude relationship (Ouchi and Uekawa, 1986; Dimri et al., 2005), analysis of reflectivity sequence (Painter et.al., 1995; Toverud et al., 2001), and fractal representation of soil structures to characterize soil water properties in terms of porosity and particle size distribution (Rieu and Sposito, 1991). Another important study is simulation of fractures using fractal method (Borodich, 2000; Tanaka et al., 2001). A new technique is proposed by Srivastava and Dimri (2007) that uses modified Voronoi tessellation to model the complex geological structures. Further, fractal or scaling behavior of time series has been widely used in analysis and modeling of geophysical time series (Todoeschuck and Jensen, 1988, 1989). Chaos has been used in studies related to atmosphere, climate, and earthquake studies (Grassberger and Procaccia, 1983; Srivastava, 2005).

Basic concepts

Power law (scaling behavior)

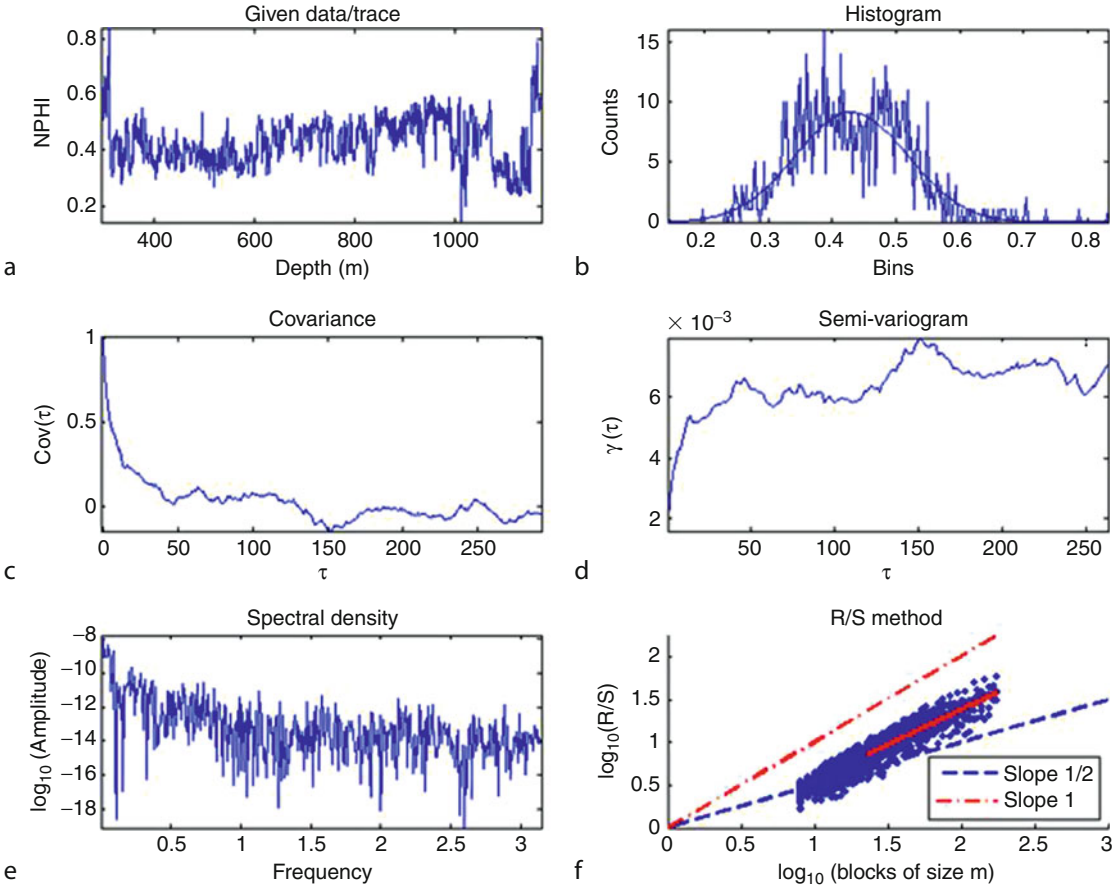
Spectral analysis of fractal time series shows that power (P) is proportional to frequency (f) raise to power a real exponent (β), termed as scaling exponent (Figure 1a, e). In mathematical form it is represented as:

$$p(f) \propto f^{-\beta} \tag{1}$$

This behavior is also known as scaling law.

The fractal analysis of time series is fundamentally based on the concept of fractional Brownian motion and fractional Gaussian noise. The fractal time series, also

Harsh K. Gupta (ed.), *Encyclopedia of Solid Earth Geophysics*, DOI 10.1007/978-90-481-8702-7,



Fractals and Chaos, Figure 1 Test of fractal behavior of the time series: (**a**) given Neutron porosity log, (**b**) histogram of the well log, (**c**) covariance showing power law behavior, (**d**) semi-variogram showing power law behavior, (**e**) log power spectrum showing power law, and (**f**) Hurst coefficient ($H = 0.80$) showing fractional Gaussian noise (fGn) characteristic of the well log.

known as time series having long memory are characterized by fractional Gaussian noise (fGn). A time series is said to follow fGn characteristic if (1) its histogram is fat tailed Gaussian, (2) covariance, semi-variogram, and power spectrum follow power law behavior, i.e., values of log power spectrum either decays or increases with lag and covariance behaves as a mirror image of semi-variogram, and (3) Hurst coefficient lies within (0.5–1) as shown in Figure 1. A popular method of Hurst coefficient estimation is Re-Scaled range analysis (R/S analysis). Below we discuss the definition and basic concepts of fractional Brownian motion and fractional Gaussian noise.

Fractional Brownian motion (fBm)

Fractional Brownian motion is generalization of classical Brownian motion (cBm). The fractal nature of fBm can be understood from the following mathematical definition. Assume that $f(t)$ is a single valued continuous function of time/space (t). Let the increments (or difference of adjacent values) $\delta f = f(t_2) - f(t_1)$ follow Gaussian distribution (Molz and Boman, 1993) with the following properties:

$$\begin{aligned} &\mathrm{E} < f(t_2) - f(t_1) \geq 0, \text{ and} \\ &\mathrm{E}[f(t_2) - f(t_1)]^2 \geq \alpha |t_2 - t_1|^{2H}, \end{aligned} \tag{2}$$

where, $\mathrm{E}<X>$ is the mean or expected value of X, α is constant of proportionality, and H is an exponent known as Hurst coefficient (Mandelbrot and Van Ness, 1968; Voss, 1985a, b) lying between 0 and 1 ($0 \leq H \leq 1$). The expected values are obtained by averaging over many increments of size $|t_2 - t_1|$. The Equation 2 holds for any value of time increment $\delta t = |t_2 - t_1|$. It is obvious from Equation 2 that for $H = 0.5$, $\mathrm{E}<[f(t_2) - f(t_1)]^2 \geq \alpha |t_2 - t_1|$, so the fractional Brownian motion reduces to classical Brownian motion (cBm).

Fractional Gaussian noise (fGn)

The concept of fractional Gaussian noise is intertwined with the fractional Brownian motion. The detailed discussion and criteria to distinguish between them are explained

in the paper by Hewett (1986) and Hardy and Beier (1994). Here we describe in brief the relationship between fBm and fGn.

Let, $x_1, x_2, x_3, \ldots x_n$ be the sequence of numbers separated by time interval δt that represents a fBm process, then one can generate a corresponding fGn or time derivative process by computing the sequence $[(x_2 - x_1), (x_3 - x_2), (x_4 - x_3), \ldots (x_n - x_{n-1})]/\ \delta t$. Conversely, if one starts with a fGn sequence of numbers given by $y_1, y_2, y_3, \ldots y_n$, then, numerical integration will yield the corresponding fBm sequence given by:

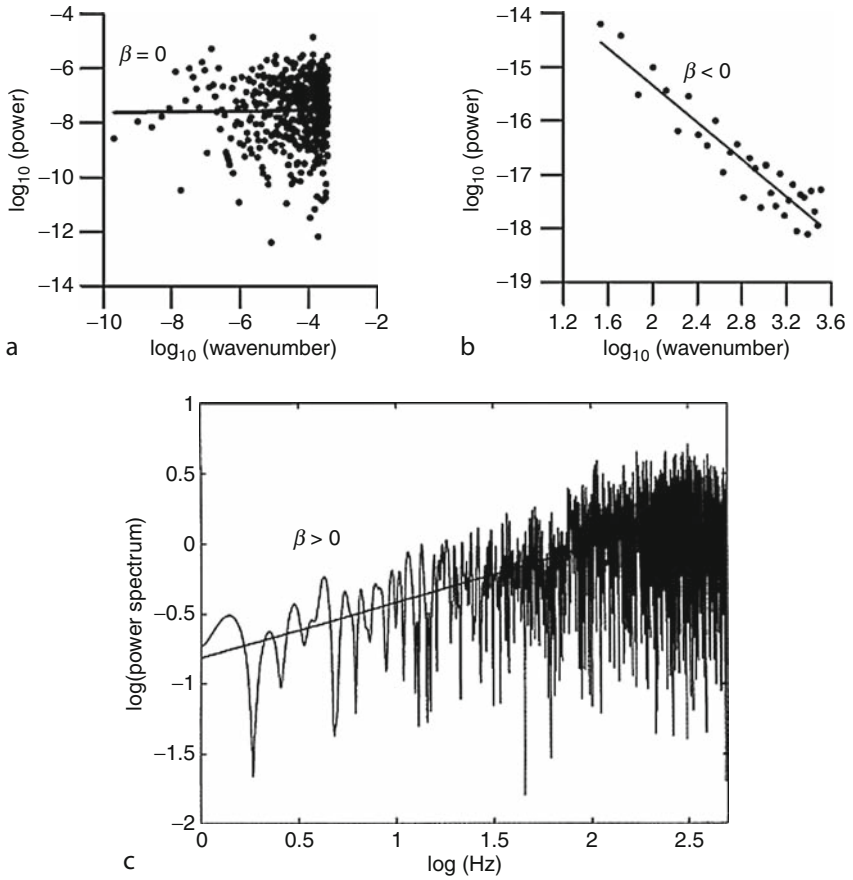
$$[y_1, (y_1 + y_2), (y_1 + y_2 + y_3), \ldots (y_1 + y_2 + y_3 \ldots + y_n)].$$

Fractal signal analysis

Geophysical signals are often in the form of time/space series that can be characterized by combination of stochastic component, trend component, and periodic component (Malamud and Turcotte, 1999). To quantify the stochastic component of the time series it is necessary to specify the statistical distribution of values and persistence. There exist a variety of techniques to quantify the strength of persistence, but the most commonly used is the spectral analysis, where the log-log plot of power spectrum of time series is plotted against frequency (or wave number in case of space series) and the value of slope, known as scaling exponent (say β), gives an estimation of persistence. Persistence study is useful to understand the nature of the phenomenon. Depending upon the value of scaling exponent, persistence can be characterized as weak or strong. Scaling exponent controls the balance of high and low frequencies and determines the degree of smoothness or correlation of the time series.

Analyzing geophysical time series

Persistence of the time series is a measure of correlation between adjacent values of the terms in time series. The uncorrelated or random data with zero persistence is the white noise. The case $\beta = 0$ (Figure 2a) has a power independent of frequency and is the familiar case of white noise. Values of such a time series are uncorrelated and completely independent of one another. The time series is anti-persistent if adjacent values are anti-correlated. When $\beta < 0$ (Figure 2b), the series is anti-correlated and each successive value tends to have the opposite sign. Noise with $\beta = -1$ is sometimes called flicker noise, while that with $\beta = -2$ is Brownian noise. The time series is persistent if adjacent values are positively correlated to



Fractals and Chaos, Figure 2 Power spectrum of (**a**) random data, (**b**) anti-persistent data, and (**c**) persistent data (after Dimri, 2005).

each other. For $\beta > 0$ (Figure 2c), the series is positively correlated, that is, persistent.

Fractal behavior of various physical properties

The Earth's inherent complexity makes it difficult to infer the location, distribution, and structure of rock types, grain size distribution, material strength, porosity, permeability, etc., from the geophysical observations; these characteristics are often inferred from the distribution of fundamental physical properties such as density, electrical conductivity, acoustic impedance, and many others. For geophysical study, the physical response of the Earth can be approximated by convolution model (Dimri, 1992). Extraction of useful information from the observations made over the surface needs advanced processing and interpretation techniques. Since physical properties of the earth system follow fractal (scaling) rather than hitherto assumed random distribution, the interpretation techniques of geophysical exploration are reformulated for fractal (scaling) geology (Dimri, 2005).

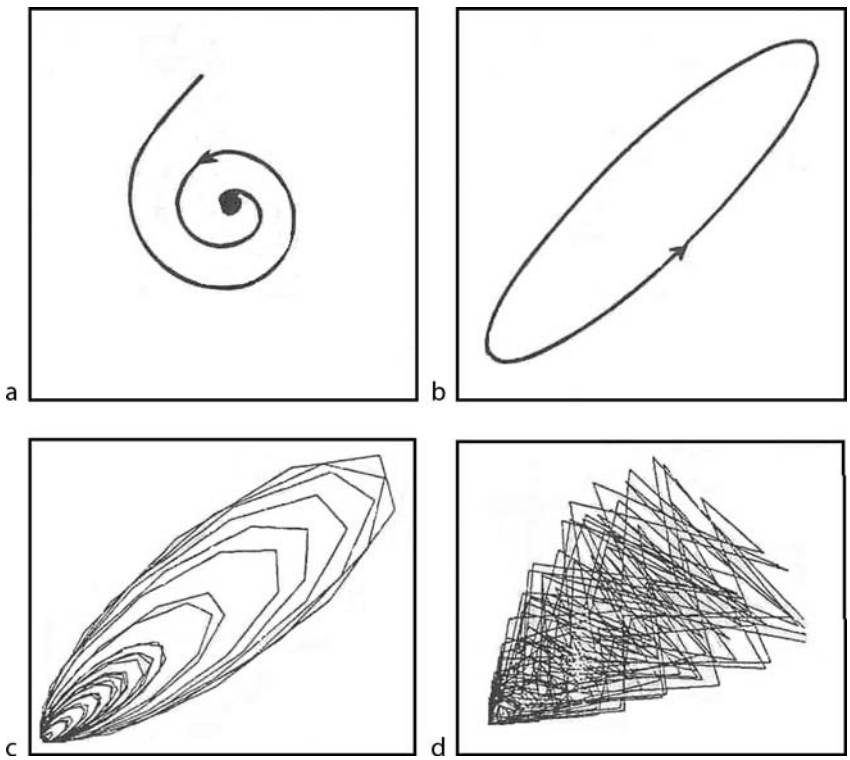
Fractal dimension and seismicity distribution

The fractal theory has led to the development of a wide variety of physical models of seismogenesis including nonlinear dynamics. Fractal concepts can be efficiently used to characterize the seismicity pattern of a region. The fractal nature of the spatial distribution of earthquakes was first demonstrated by Kagan and Knopoff (1980), Hirata and Imoto (1991), and Hirabayashi et al. (1992). The hypocenter distribution data suggests that the changes in fractal dimension could be a good precursor parameter for earthquakes as it is a measure of the degree of clustering of seismic events. A change in fractal dimension corresponds to the dynamic evolution of the states of the system. Generally the values of b-value (half of fractal dimension) cluster around 1 when the system is relatively stable and decreases to lower values around 0.3 prior to the failure. The decrease in value of fractal dimension before a big earthquake is observed by several authors (Ouchi and Uekawa, 1986, De Rubies et al., 1993). Hirata et al. (1987) showed that the change in fractal dimension with time is largely dependent on the crustal conditions of the study region.

Chaos

'And now a bubble bursts, and now a world'
An essay on Man, Alexander Pope

The concept of chaos was proposed by Lorenz, who advocated that a small perturbation in the coupled system can amplify to a great deal in some other part of the system. The chaotic systems are known to have finite fractal dimension (Moharir, 2000). The chaotic behavior of the system can be assessed by the quantitative estimate of



Fractals and Chaos, Figure 3 Trajectory of the types of attractors (**a**) point attractor (**b**) periodic limit cycle (**c**) quasi-periodic, and (**d**) chaotic attractor (after Tiwari, 2000).

Lyapunov exponent. The system is said to be chaotic, if Lyapunov exponent is positive (>0).

Various evolutionary fluctuations exhibit the features of a dissipative dynamical system with possible chaos/attractors in phase space (Tiwari, 2000). If all the trajectories of evolutionary processes converge towards a subset of phase space irrespective of their initial conditions, then the subset is called an "attractor" (Tsonis and Elsner, 1988). The nature of attractor is characterized by its fractal dimension. A "strange attractor" will have a non-integer (fractal) dimension and can be represented by a more complex form in a phase space. Also, such an attractor is characterized by the chaotic trajectories and a broadening of the frequency spectrum. Evidence of chaos/strange attractor has been reported in many global geophysical and planetary system dynamics. The shape of the attractor depends on the nature of the physical process. The shape of most common four kinds of attractors, namely, point attractor, periodic limit cycle, quasi-periodic, and chaotic attractors is shown in Figure 3. The fractal dimension of a chaotic system (strange attractor) indicates the number of ordinary differential equations needed to model the process, or in other words, it is indicative of the number of variables required for almost complete description of the dynamic system (Tsonis and Elsner, 1988).

Summary

Geophysical interpretation techniques have been reformulated after the findings from the analysis of physical properties recorded in different deep bore wells worldwide, which shows that physical properties of the earth system follow fractal instead of random distribution (Dimri, 2005). Recent research in solid earth geophysics employing fractals and chaos includes modeling of the earth's magnetic and gravity fields, where it has been shown that rocks have scaling stratification (Lovejoy et al., 2008; Lovejoy and Schertzer, 2007). Another, significant research includes simulation of fGn series, which helps to improve the inversion results by way of providing a suitable initial model (Srivastava and Sen, 2009, 2010). In atmospheric sciences, the interesting research is done to model the atmospheric dynamics, which repeats scales after scales and behaves like a cascade (Lovejoy et al., 2009). There are several interesting applications of chaos in climate and rainfall modeling (Hosking, 1984; Sivakumar, 2000).

Introduction

The seismological data can be analyzed and interpreted in terms of three basic concepts. The first is based on the geometrical ray theory of optics. Most of our knowledge about the interior of the Earth has come from the application of the ray-theoretic methods to seismological data. Ray theory is useful for periods shorter than a minute. Travel-times of seismic phases constitute an important component of the ray theory concept.

The second concept is that of surface waves. The study of the dispersion of surface waves helps us in determining the regional structure, e.g., low-velocity zones, oil-bearing structures, etc. The surface wave theory is useful in the period range 10–300 s.

The third concept is that of the normal-mode theory or free oscillations of the Earth. In here, the field is viewed as a sum of standing waves instead of traveling waves. The standing waves can be seen as peaks in the amplitude spectrum of a seismogram. Theoretical seismograms can be computed for spherically symmetric, nonrotating, elastic, isotropic (SNREI) Earth models by mode-summation techniques at low frequencies. At high frequencies, the number of modes required to represent the field becomes so large that the mode-summation technique is not practicable.

The Earth reacts to an earthquake or an explosion by vibrating as a whole in the same manner as does a bell when it is struck. The study of the Earth's free oscillations is based on the theory of vibrations of an elastic sphere. The problem increases in complexity as we proceed from an isotropic homogeneous sphere to models of the Earth which take into account its anelastcity, anisotropy, radial and lateral heterogeneity, rotation, gravity, and prestress.

The problem of the oscillations of an elastic sphere is an old one. It attracted many classical physicists of the nineteenth century, including S.D. Poisson, Lord Kelvin, G.H. Darwin, and H. Lamb. In a classic paper, Lamb (1882) discussed the various modes of oscillations of a uniform elastic sphere and calculated the important roots of the frequency equation. He classified the oscillations of a sphere

as of the "first class" and the "second class." In an oscillation of the first class, the dilatation and the radial component of the displacement vanish everywhere, so that there is no change of shape. In the case of the oscillations of the second class, the radial component of the vorticity vanishes. The oscillations of the first class are now known as toroidal or torsional oscillations and the oscillations of the second class as spheroidal or poloidal oscillations.

The Earth differs from a homogeneous elastic sphere in two important respects: self-gravitation and radial heterogeneity. Gravity does not affect the toroidal oscillations because these are divergence-free and have no radial component of the displacement, so that the density distribution remains unchanged. But gravity plays an important role in the case of the spheroidal oscillations. Bromwich (1898) investigated the effect of self-gravitation, simplifying his work by dealing only with an incompressible sphere. Love (1911) showed that a self-gravitating sphere of the size and mass of the Earth and of rigidity that of steel has a free period of oscillation of almost exactly 1 h for the mode ${}_0S_2$ (the fundamental mode of the spheroidal oscillation of the second order). Obviously, if this mode were to be observed, instruments would be needed that had sensitivity at periods very much longer than the periods of seismic motion then being routinely recorded.

Shida (1925) designed an electromagnetic seismograph with pendulum period 180 s and galvanometer period 1,200 s for observing Earth's free oscillations. However, the technology of that time was incapable of achieving the precision and sensitivity that were demanded. It was Hugo Benioff, who first constructed an electromagnetic strainmeter which was capable of recording free vibrations as long as 1 h. However, he had to wait for a big earthquake to make an appropriate use of the strainmeter developed by him, since the Earth will produce its deeper modes only when a large amount of kinetic energy is released by an earthquake or an explosion.

Benioff was able to record a ground motion of 57 min period for the Kamchatkan earthquake of November 4, 1952, on his strainmeter. He (Benioff, 1958) attributed it to the mode ${}_0S_2$ of the oscillations of the Earth. This was the first time that the natural oscillations of the whole Earth had been observed. It was but natural that several seismologists started investigating the problem of the free oscillations of the Earth theoretically and calculating the periods of the normal modes of real Earth models. Jobert (1956) applied Rayleigh's principle in calculating the period for the mode ${}_0T_2$ (the fundamental mode of the toroidal oscillation of the second order) as 43.54 min for the Bullen B model of the Earth. In the following year, Jobert (1957) applied the same method in obtaining the period for the mode ${}_0S_2$ as about 53 min. Pekeris and Jarosch (1958) applied variational methods in calculating the period of the mode ${}_0S_2$ as 53 min. Soon after, Alterman et al. (1959) integrated the equations of motion numerically and calculated the periods of various normal modes of the Earth. In particular, they showed that the period of the mode ${}_0S_2$ should be 53.7 min for Bullen B model of the Earth. A wide range of normal modes of the whole Earth were observed by several seismological groups in the USA for the great Chilean earthquake of May 22, 1960. The agreement between the observed periods and the periods calculated by Alterman et al. (1959) was excellent. This was the beginning of a new branch of seismology – the low frequency seismology. Impetus to research in this new field was provided by several factors: (1) availability of instruments capable of recording long-period oscillations of the Earth, (2) availability of high-speed electronic computers for Fourier analysis of the recorded data, and (3) availability of computer codes for numerical solution of differential equations efficiently. A network of low-noise accelerometers deployed all over the globe in 1970s permitted routine detection of normal-mode spectral peaks following earthquakes of relatively modest magnitude.

Observations of the 1960 Chilean earthquake indicated that the mode ${}_0S_2$ did not have a single spectral peak, but, instead, was composed of at least two lines with periods 53.1 and 54.7 min. Indeed, Backus and Gilbert (1961) and Pekeris et al. (1961) showed theoretically that for the mode ${}_0S_2$, five spectral lines exist if the rotation of the Earth is taken.

The work of Alterman et al. (1959) and their contemporaries did not include the effects of lateral heterogeneity, ellipticity, prestress, anisotropy, and anelasticity. Considerable progress has since been made in the direction of taking one or more of these features into account. Madariaga (1972) studied toroidal oscillations of a laterally heterogeneous Earth. Kanamori and Anderson (1977) and Woodhouse (1980) discussed the effect of the departure from perfect elasticity. Woodhouse and Dahlen (1978) investigated the effect of a general aspherical perturbation on the free oscillations of the Earth. Excellent reviews on the free oscillations of the Earth have been given by Stoneley (1961), Alterman et al. (1974), Lapwood and Usami (1981), Buland (1981), Dahlen and Tromp (1998), and others.

Toroidal oscillations of a uniform elastic sphere

On applying the method of separation of variables, the equation of motion for the toroidal oscillations of a homogeneous isotropic (uniform) elastic sphere of density ρ and Lamé's parameters λ and μ leads us to the following equation for the radial eigenfunction $W(r)$:

$$\frac{\mathrm{d}^2W}{\mathrm{d}r^2}+\frac{2}{r}\frac{\mathrm{d}W}{\mathrm{d}r}+\left[\frac{\rho\omega^2}{\mu}-\frac{l(l+1)}{r^2}\right]W=0, \tag{1}$$

where ω is the angular frequency and $l = 0, 1, 2, 3, \ldots$ is a separation variable. Equation 1 can be solved in terms of the spherical Bessel functions. Solution of Equation 1, which remains bounded as $r \to 0$, is of the form

$$W=A_0 j_l\left(\frac{\omega r}{\beta}\right), \tag{2}$$

where $j_l(\chi)$ is the spherical Bessel function of the first kind and $\beta = (\mu/\rho)^{1/2}$ is the shear wave velocity. The boundary condition that the surface $r = a$ of the sphere is traction-free yields the frequency equation:

$$\chi j_{l+1}(\chi) = (l-1) j_l(\chi), \tag{3}$$

where $\chi = \omega a/\beta$.

Since the frequency equation (3) is a transcendental equation, for each l, it possesses an infinite number of roots in χ. Let these roots be numbered in ascending order of magnitude and denoted by ${}_n\chi_l$ $(n = 0, 1, 2, \ldots)$. The corresponding frequencies and periods can be found through the relations.

$${}_n\omega_l = \left(\frac{\beta}{a}\right){}_n\chi_l, \quad {}_nT_l = \frac{2\pi}{{}_n\omega_l}. \tag{4}$$

Then ${}_n\omega_l$ are the eigenfrequencies and ${}_nT_l$ are the eigenperiods. Further, $n = 0$ is associated with the fundamental mode and $n = 1, 2$, etc., are associated with the first overtone, the second overtone, etc. For a given $l > 0$, there exists a family of n concentric nodal surfaces, i.e., interior surfaces at which the toroidal eigenfunction W vanishes. These nodal surfaces are given by

$$j_l\left(\frac{r}{a}\,{}_n\chi_l\right) = 0. \tag{5}$$

There are no toroidal oscillations associated with $l = 0$, since the corresponding displacement is identically zero. The value $l = 1$ yields a rigid rotation. The accompanying toroidal oscillations are known as rotatory vibrations. For $l = 1$, the frequency equation (3) becomes $j_2(\chi) = 0$, which may be expressed in the form

$$\frac{\tan\chi}{\chi} = \frac{3}{3-\chi^2}. \tag{6}$$

The lowest roots of Equation 6 are given, approximately, by

$$\chi = 5.763,\ 9.095,\ 12.322,\ 15.514\ldots \tag{7}$$

Equation 7 lists the first four overtones. For $l = 1$, the fundamental mode does not exist. For this mode $(l = 1,\ n = 0)$, every part of the sphere shows rotation around some axis in one direction. Such a motion could not be excited without the application of an external torque and so would not be a free oscillation. Consequently, the frequency equation has no root corresponding to this mode (Lapwood and Usami, 1981; p. 35).

For rotatory vibrations, the nodal spheres are given by

$$j_1\left(\frac{r}{a}\,{}_n\chi_1\right) = 0$$

which yields

$$\tan\left(\frac{r}{a}\,{}_n\chi_1\right) = \frac{r}{a}\,{}_n\chi_1. \tag{8}$$

Table 1 lists the dimensionless frequencies, periods, and nodal spheres for rotatory vibrations of a homogeneous sphere for the first four overtones.

From Equation 3, the frequency equation for the toroidal oscillations of the second order $(l = 2)$ is given by

$$\chi j_3(\chi) = j_2(\chi),$$

or, equivalently, by

$$\frac{\tan\chi}{\chi} = \frac{\chi^2 - 12}{5\chi^2 - 12}. \tag{9}$$

The corresponding dimensionless frequencies, periods, and nodal surfaces for the fundamental mode and the first four overtones are listed in Table 2.

Spheroidal oscillations of a uniform elastic sphere

Spheroidal modes corresponding to $l = 0$ are known as radial modes because the associated particle motion is purely radial. The frequency equation for the radial vibrations is (Ben-Menahem and Singh, 1981; p. 346)

$$\zeta\cot\zeta = 1 - \frac{1}{4}\left(\frac{\lambda + 2\mu}{\mu}\right)\zeta^2, \tag{10}$$

where

$$\zeta = \frac{\omega a}{\alpha}, \quad \alpha = \left[\frac{(\lambda + 2\mu)}{\rho}\right]^{1/2}. \tag{11}$$

Free Oscillations of the Earth, Table 1 Dimensionless frequency (χ), period (T in seconds), and nodal spheres (r_n) for the rotatory vibrations ($l = 1$) of a homogeneous sphere

n	χ	T[a]	r_1/a	r_2/a	r_3/a	r_4/a
1	5.763	1113	0.780			
2	9.095	705	0.494	0.849		
3	12.322	521	0.365	0.627	0.885	
4	15.514	414	0.290	0.498	0.703	0.907

[a]Assuming $a = 6371$ km, $\beta = 6.24$ km/s

Free Oscillations of the Earth, Table 2 Dimensionless frequency (χ), period (T in seconds) and nodal spheres (r_n) for the toroidal oscillations of the second order ($l = 2$) of a homogeneous sphere

n	χ	T[a]	r_1/a	r_2/a	r_3/a	r_4/a
0	2.501	2565				
1	7.136	899	0.808			
2	10.514	610	0.548	0.865		
3	13.771	466	0.419	0.660	0.895	
4	16.983	378	0.339	0.535	0.725	0.914

[a]Assuming $a = 6371$ km, $\beta = 6.24$ km/s

It may be noted that the frequency equation for the spheroidal oscillations is a function of the ratio λ/μ. For the Poissonian case ($\lambda = \mu$), the lowest roots of Equation 10 are given, approximately, by

$$\frac{\zeta}{\pi} = 0.816, 1.929, 2.936, 3.966, \ldots. \tag{12}$$

Assuming $a = 6371$ km, $\alpha = 9$km/s, the corresponding periods (in seconds) are found to be

$$T = 1735, 734, 482, 357, \ldots. \tag{13}$$

The fundamental radial mode ${}_0S_0$ corresponds to an expansion and contraction of the whole sphere without its form changing. For the nth overtone ${}_nS_0$, there are n concentric nodal surfaces inside the sphere at which the displacement vanishes identically.

For $l = 1$, the fundamental mode ${}_0S_1$ does not exist, since it represents a rigid-body translation. Even though the geometric center of the sphere is displaced, its center of mass does not move (Lapwood and Usami, 1981; p. 37). Thus the movement of the center does not contradict the physical requirement that the center of mass stays unmoved. The roots of the frequency equation representing the first four overtones ($l = 1$, $n = 1, 2, 3, 4$) are given, approximately, by

$$\chi = 3.424, 6.771, 7.444, 10.695, \tag{14}$$

assuming $\lambda = \mu$.

In the case of the spheroidal oscillations of the second order ($l = 2$), the oscillating sphere assumes alternatively the forms of a prolate and an oblate spheroid. Therefore, this mode of oscillation is known as the football mode.

Oscillations of an SNREI Earth model

In the last two sections, we have discussed oscillations of a homogeneous, isotropic, elastic, non-gravitating, spherical Earth model. This relieves the free oscillation problem of its mathematical intricacies while retaining its important features.

The equations of motion of a spherically symmetric, nonrotating, elastic, isotropic (SNREI) Earth model may be written in the form (Aki and Richards, 1980; Ben-Menahem and Singh, 1981)

$$\text{div}\ \vec{T} + \rho[\text{grad}(\Psi - gu_r) + \boldsymbol{e}_r g\ \text{div}\ \boldsymbol{u}] = \frac{\rho\,\partial^2 \boldsymbol{u}}{\partial t^2}, \tag{15}$$

$$\nabla^2\Psi = 4\pi G\,\text{div}(\rho\boldsymbol{u}), \tag{16}$$

where

$\boldsymbol{u}$ = displacement vector
$\vec{T} = \lambda\vec{I}\text{div}\boldsymbol{u} + \boldsymbol{\mu}(\nabla\boldsymbol{u} + \boldsymbol{u}\nabla)$ = stress tensor
g = acceleration due to gravity
G = gravitational constant
Ψ = perturbation in the gravitational potential

Equations 15 and 16 are to be solved subject to suitable boundary conditions. Thus, $\boldsymbol{u}$, $\boldsymbol{e}_r \cdot \vec{T}$, Ψ and $\partial\Psi/\partial r - 4\pi G\rho u_r$ must be continuous everywhere. However, at a boundary between a solid and a fluid or between two fluids, u_r rather than $\boldsymbol{u}$ must be continuous.

In the absence of external body force, the motion of the Earth consists of a superposition of free simple harmonic oscillations of the form

$$\boldsymbol{u}(\boldsymbol{r}, t) = \boldsymbol{u}(\boldsymbol{r})\exp(i\omega t).$$

Therefore, the equation which governs the free oscillations of the Earth is obtained from Equation 15 by making the substitution $\partial/\partial t \to i\omega$. This yields

$$\mathcal{L}\boldsymbol{u} + \rho\omega^2\boldsymbol{u} = 0, \tag{17}$$

where $\mathcal{L}$ is a self-adjoint linear operator. Equations 16 and 17 together with boundary conditions define an eigenvalue problem. Every model of the Earth will possess an infinite number of eigenfrequencies ω_i and a corresponding infinite number of eigenfunctions $\boldsymbol{u}_i(\boldsymbol{r})$.

As mentioned in the Introduction, the oscillations of the Earth are of two types: toroidal and spheroidal. At high frequencies, the toroidal oscillations correspond to the Love surface waves and *SH* body waves. Toroidal eigenfunctions are of the form

$$\boldsymbol{u}(\boldsymbol{r}) = W(r)[-\boldsymbol{e}_r \times \text{grad}\ Y_{ml}], \tag{18}$$

where

$$Y_{ml} = P_l^m(\cos\theta)\exp(im\varphi)$$

is a surface spherical harmonic. For every value of l except zero, there is a fundamental toroidal mode ${}_0T_l$ and an infinite number of overtones ${}_nT_l (n = 1, 2, \ldots)$. From Equation 18 it is seen that, for toroidal oscillations, $u_r = \text{div}\ \boldsymbol{u} = 0$.

At high frequencies, the spheroidal oscillations correspond to the Rayleigh surface waves and $P - SV$ body waves. The spheroidal eigenfunctions are of the form

$$\boldsymbol{u}(\boldsymbol{r}) = \boldsymbol{e}_r U(r) Y_{ml} + V(r)\text{grad}\ Y_{ml}. \tag{19}$$

For every value of l, there is a fundamental spheroidal mode ${}_0S_l$ and an infinite number of overtones ${}_nS_l (n = 1, 2, \ldots)$. From Equation 19, it can be verified that $(\text{curl}\ \boldsymbol{u})_r = 0$. On putting $\Psi(\boldsymbol{r}) = P(r)\,Y_{ml}$, and using Equations 18 and 19, Equations 16 and 17 can be transformed into a set of four ordinary differential equations of the second order in U, V, W, and P. One of these is an equation in W alone and corresponds to the toroidal oscillations. The remaining three equations are coupled in U, V, and P, and correspond to the spheroidal oscillations. These equations are awkward for numerical integration, because one needs to evaluate the derivatives of empirically determined quantities $\lambda(r), \mu(r)$, and $\rho(r)$ in order to obtain the coefficients. This can be formally obviated by converting these equations into an equivalent

set of eight linear differential equations of the first order which are free from the derivatives of λ, μ, and ρ. Out of these eight equations, two correspond to the toroidal oscillations and the remaining six to the spheroidal oscillations. We can thus express the equations governing the free oscillations of an SNREI Earth model in the form (Singh, 1992)

$$\frac{dY}{dr} = A(r)Y, \tag{20}$$

where Y is an $(N \times 1)$ column matrix and $A(r)$ is an $(N \times N)$ square matrix. The number N depends upon the kind of oscillations and the nature of the medium (Table 3).

From Equations 17 and 18, we have the following radial equation for the toroidal oscillations

$$\mu\left(\frac{d^2W}{dr^2} + \frac{2}{r}\frac{dW}{dr}\right) + \frac{d\mu}{dr}\left(\frac{dW}{dr} - \frac{W}{r}\right) + \left\{\rho\omega^2 - \frac{l(l+1)}{r^2}\mu\right\}W(r) = 0. \tag{21}$$

This equation involves $d\mu/dr$. Numerical evaluation of the derivative of the empirically determined $\mu(r)$ can be avoided by defining $y_1 = W, \quad y_2 = \mu\left(\frac{d}{dr} - \frac{1}{r}\right)y_1$.

The differential equation of the second order (21) is equivalent to two differential equations of the first order:

$$\begin{aligned}\frac{dy_1}{dr} &= \frac{y_1}{r} + \frac{y_2}{\mu},\\ \frac{dy_2}{dr} &= \left[\left(l^2 + l - 2\right)\frac{\mu}{r^2} - \rho\omega^2\right]y_1 - \frac{3}{r}y_2.\end{aligned} \tag{22}$$

For spheroidal oscillations, the set of six linear differential equations of the first order is obtained by defining

$$\begin{aligned}&y_1 = U, \quad y_2 = (\lambda + 2\mu)\frac{dU}{dr} + \frac{2\lambda}{r}U - \lambda\frac{l(l+1)}{r}V,\\ &y_3 = V, \quad y_4 = \mu\left[\frac{1}{r}(U - V) + \frac{dV}{dr}\right],\\ &y_5 = P, \quad y_6 = \frac{dP}{dr} - 4\pi G\rho U.\end{aligned} \tag{23}$$

In the case of the liquid core, $\mu = y_4 = 0$ and

$$y_3 = \frac{1}{r\omega^2}\left(gy_1 - \frac{y_2}{\rho} - y_5\right). \tag{24}$$

Explicit expressions for the elements of the matrix $A(r)$ have been given by Singh (1992).

Equation 20 subject to an appropriate set of homogeneous boundary conditions can be integrated by the Runge–Kutta method. For a given SNREI Earth model $\lambda(r), \mu(r)$ and $\rho(r)$ and given l, there is a discrete set of values of ω for which the boundary conditions are satisfied. We denote this set by ω_i (eigenfrequencies) and the corresponding displacements by $\boldsymbol{u}_i$. The index i signifies the normal mode. Each i stands for a triplet (l, m, n) of numbers; l being the colatitudinal mode number, also known as the angular order ($l \geq 0$); m, the azimuthal mode number ($-l \leq m \leq l$); and n, the radial mode number ($n \geq 0$). The numbers l, m, n describe the manner in which the displacement field depends upon the colatitude, the azimuth, and the radial distance, respectively. However, because of the spherical symmetry, the eigenfrequencies are degenerate in m (i.e., ω_i are independent of m). This degeneracy is removed when the rotation of the Earth, its ellipticity or lateral heterogeneity is taken into account.

The spherical harmonic

$$P_l^m(\cos\theta)\,(\cos m\phi,\ \sin m\phi)$$

from which the eigenfunctions are derived has (l-$|m|$) nodal latitude lines and $2|m|$ nodal longitude lines on the surface of the Earth. The value of m depends upon the source exciting the oscillations.

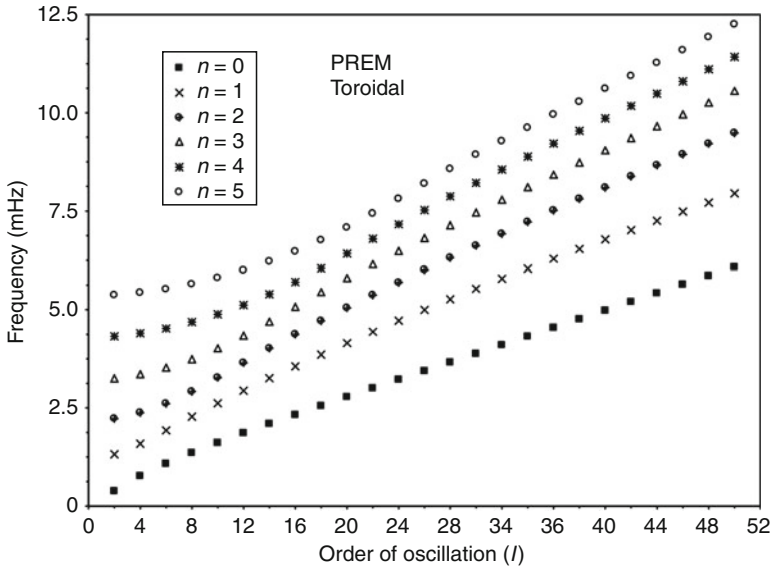
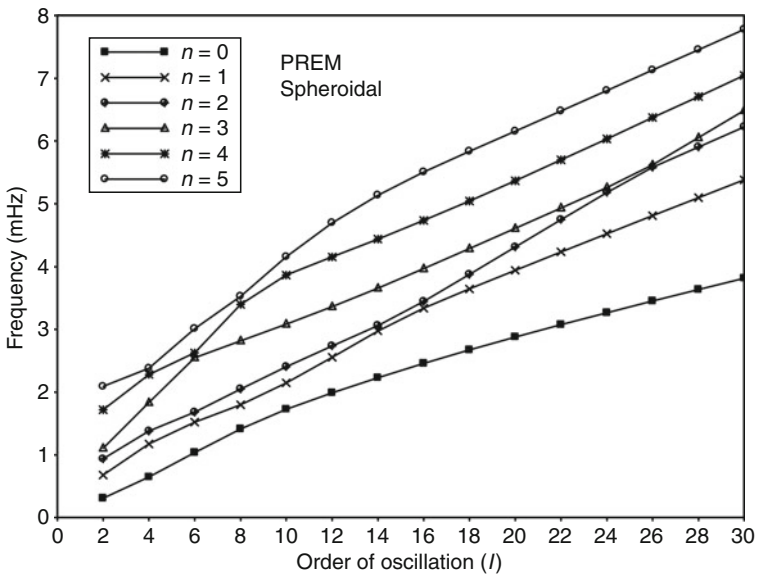
and Anderson, 1981)) with mean observed frequencies. The computed eigenfrequencies are obtained from the website (http://stuplots.geophys.uni-stuttgart.de/~plots/Modes/modes.html). In this website, the eigenfrequencies and eigenfunctions can be computed for PREM and three other Earth models for $0 \leq n < 50$, $0 \leq l < 200$, using the FORTRAN program MINOS written by Drs. Freeman Gilbert and Guy Masters. The mean observed frequencies are taken from the website (http://igppweb.ucsd.edu/~gabi/rem.dir/surface/rem.surf.html). The agreement between the computed and observed values is excellent.

The eigenfrequencies of the toroidal oscillations computed for PREM are shown in Figure 1 as functions of the angular order l for the fundamental mode $n = 0$ and the first five overtones $n = 1$–5. The corresponding eigenfrequencies of the spheroidal oscillations are shown in Figure 2.



Free Oscillations of the Earth, Figure 1 Eigenfrequency $f = 1/T = \omega/2\pi$ of the toroidal oscillations for PREM.



Free Oscillations of the Earth, Figure 2 Eigenfrequency of the spheroidal oscillations for PREM. Only points corresponding to even values of $l = 2, 4, \ldots, 30$ have been plotted. For the sake of clarity, points representing the eigenfrequencies for even values of l have been joined by continuous curves. However, the intervening curves do not represent any physical reality.

Effect of the rotation of the Earth

As mentioned earlier, the eigenfrequencies of a spherically symmetric, nonrotating, elastic, isotropic Earth model are degenerate in the azimuthal mode number m. The introduction of the rotation removes this degeneracy. The effect of the diurnal rotation of the Earth can be calculated by carrying out a first-order perturbation calculation. Let $\mathbf{\Omega}$ denote the uniform angular velocity of the Earth about its center. Assume that the observer is referred to a non-inertial frame, which, for all times, maintains a state of uniform rotation with angular velocity $\mathbf{\Omega}$. Let (x_1, x_2, x_3) be a Cartesian coordinate system in this uniformly rotating frame of reference, let the origin of the system coincide with the center of the Earth, and let $\boldsymbol{e}_3$ be aligned along the axis of rotation, so that $\mathbf{\Omega} = \Omega \boldsymbol{e}_3$.

The rotation of the Earth introduces two body forces. One of them is the centrifugal force $r \sin\theta\, \Omega^2$ perpendicular to and away from the axis of rotation. The other force introduced by the rotation is the Coriolis force, which, per unit mass, is equal to $2\Omega(\partial \boldsymbol{u}/\partial t) \times \boldsymbol{e}_3$.

Assuming $\Omega/{}_n\omega_l << 1$ (the highest value of $\Omega/{}_n\omega_l \simeq 1/27$) and carrying out a first-order perturbation calculation, it can be shown that (Ben-Menahem and Singh, 1981; p. 390)

$$ {}_n\omega_l^m = {}_n\omega_l + m\tau\,\Omega, -l \le m \le l, \tag{25} $$

where

${}_n\omega_l$ = eigenfrequencies of a nonrotating Earth model
${}_n\omega_l^m$= eigenfrequencies of the corresponding rotating Earth model.

The splitting parameter

$$ \tau = \frac{1}{l(l+1)} \tag{26} $$

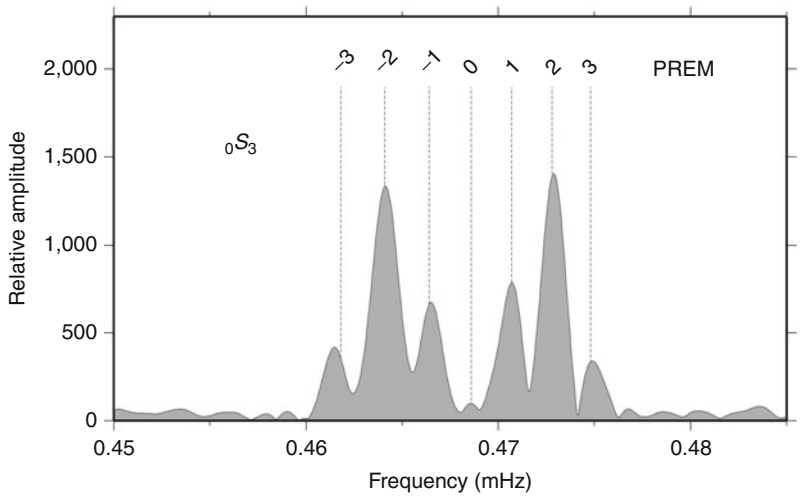
for the toroidal oscillations, and

$$ \tau = \frac{\int_0^a (2U + V) V \rho r^2 \mathrm{d}r}{\int_0^a [U^2 + l(l+1)V^2] \rho r^2 \mathrm{d}r} \tag{27} $$

for the spheroidal oscillations, where a is the radius of the Earth; U and V are defined in Equation 19.

Therefore, for both toroidal and spheroidal oscillations, the degenerate eigenfrequency ${}_n\omega_l$ is resolved by a slow rotation of the Earth into $(2l + 1)$ frequencies ${}_n\omega_l^m (-l \le m \le l)$. The set of $(2l + 1)$ spectral lines for a given (l, n) is called a mode multiplet and each member of this set is called a singlet. For the toroidal oscillations the splitting parameter $[l(l+1)]^{-1}$ does not depend upon the Earth model. However, in the case of the spheroidal oscillations, τ depends upon the Earth model. The splitting of the terrestrial spectral lines is the elastodynamic analogy of the splitting of atomic spectral lines by a magnetic field discovered by Zeeman in 1896.

Figure 3 shows the Zeeman splitting of the fundamental spheroidal mode of the third order ${}_0S_3$ observed in the Fourier spectrum of the gravimeter record of the February 27, 2010, Maule (Chile) earthquake. The time series is 400-h long and the effect of local barometric fluctuations has been removed. The rotation of the Earth removes the degeneracy of the multiplet; six out of seven singlets



Free Oscillations of the Earth, Figure 3 Fourier spectrum of the February 27, 2010, Maule (Chile) earthquake (Mw = 8.8) record provided by the superconducting gravimeter at the Black Forest Observatory (BFO). The rotation removes the degeneracy and splits the ${}_0S_3$ multiplet into seven singlets. The vertical dashed lines indicate the theoretically predicted frequencies of the singlets for the spherically symmetric Earth model PREM, including the effect of the rotation of the Earth and hydrostatic flattening. (Figure made available by Dr. Rudolf Widmer-Schnidrig of BFO who holds the copyright.)

can be clearly identified. The singlet corresponding to the azimuthal mode number $m = 0$ is missing because either the source or the receiver is located on a nodal line of the mode.

The ellipticity of the Earth also removes the degeneracy giving (Dahlen, 1968)

$$ {}_n\omega_l^m = {}_n\omega_t\left[1 + e\left(b + m^2 c\right)\right] \tag{28} $$

to first order in ellipticity e, where $b = b\,(n, l)$, $c = c\,(n, l)$. Thus the ellipticity splits the degenerate eigenfrequency ${}_n\omega_l$ into $(l + 1)$ lines ${}_n\omega_l^m (0 \le m \le l)$.

Other departures from symmetry, e.g., lateral inhomogeneity, anisotropy and initial stress, have the same effect of removing the degeneracy.

Jeans' formula

The complete seismic field induced by a point source in an SNREI Earth model can be expressed as an infinite sum of normal modes. However, we know from seismogram analysis that most of the recorded Earth motion can be explained in terms of propagating waves. Therefore, there must exist a relationship between these two seemingly different aspects of seismic wave motion.

Consider a general term in the normal-mode solution expressed by Equations 18 and 19. The factor of this term which depends upon the time and the colatitude is derivable from

$$ P_l^m(\cos\,\theta)\exp(i\omega t), \tag{29} $$

where $\omega = {}_n\omega_l$ is an eigenfrequency. Replacing the Legendre function by its asymptotic approximation for large values of l, this factor becomes

$$ (-l)^m\left(\frac{1}{2\pi l \sin\,\theta}\right)^{1/2}\left[\exp\left\{i\left[\omega t - (l + 1/2)\theta + \frac{\pi}{4} - \frac{m\pi}{2}\right]\right\}\right. \\ \left. + \exp\left\{i\left[\omega t + (l + 1/2)\theta - \frac{\pi}{4} + \frac{m\pi}{2}\right]\right\}\right]. \tag{30} $$

The first term describes a wave motion of frequency ω diverging from the pole $\theta = 0$, whereas the second term describes a wave motion diverging from the antipode $\theta = \pi$.

In cylindrical coordinates, a wave diverging from the axis may be expressed in the form

$$ \exp[i(\omega t - k\Delta)], \tag{31} $$

where k is the wave number. Putting $\Delta = a\theta$ and comparing Equations 30 and 31, we get Jeans' formula (Jeans, 1923):

$$ l + \frac{1}{2} = ka \quad (l >> 1). $$

This formula tells us that, if l is large, every mode of oscillation can be interpreted as a traveling wave whose parameters are functions of l and n and are given by

$$ T = \frac{2\pi}{\omega}, c = \frac{a\omega}{l + \frac{1}{2}}, \Lambda = \frac{2\pi a}{l + \frac{1}{2}}, \tag{32} $$

where T is the period of the oscillation, c is the phase velocity, and Λ is the associated wavelength. These relations are found to yield a good approximation for $l \ge 7$. The connection between the free oscillations and traveling waves (mode-ray duality) has been studied by Jeans (1923), Ben-Menahem (1964), Brune (1964), and others.

Jeans' formula can be used to determine the eigenfrequencies from the observed dispersion data, and then the normal-mode formalism can be used to find the elastic properties of the Earth.

Conclusions

We have described how to compute the eigenperiods of an SNREI Earth model. Modifications due to lateral inhomogeneity, anisotropy, and initial stress can be found by perturbation methods (Woodhouse and Dahlen, 1978). The eigenperiods of different modes of vibration are increased by the anelasticity of the Earth. In addition, anelasticity results in the decay of the amplitudes of the free oscillations with time. Necessary allowance for anelasticity can be made while constructing Earth models using normal-mode theory (Dziewonski and Anderson, 1981).

The study of the free oscillations of the Earth played a leading role in the development of geophysical inverse theory in the late 1960s (Backus and Gilbert, 1967, 1968, 1970) and 1970s. This theory enables us optimal extraction of information regarding the internal constitution of the Earth from a finite set of gross Earth data (Wiggins, 1972). Comprehensive exposition of the inverse theory has been given, amongst others, by Tarantola (1987) and Parker (1994). Dahlen and Tromp (1998) gave a comprehensive treatment of the problem of computing synthetic seismograms for a realistic three-dimensional model of the Earth, using normal-mode summation technique.

Major discoveries based on the observations of the Earth's free oscillations are (in chronological order):

1. Finite rigidity of the inner core (Dziewonski and Gilbert, 1971)
2. 1D density distribution inside the Earth (Gilbert and Dziewonski, 1975; Masters and Gubbins, 2003)
3. Construction of PREM (preliminary reference Earth model) by Dziewonski and Anderson (1981)
4. Construction of first global 3D upper mantle velocity model (Masters et al., 1982)
5. Construction of 1D attenuation model (e.g., Masters and Gilbert, 1983)
6. Tight upper bound on the maximum differential super rotation of the inner core (e.g., Laske and Masters, 1999)

Free oscillations of the Earth are typically observed after a large earthquake. Recently, continuous free oscillations of the Earth (primarily fundamental spheroidal modes between 2 and 7 mHz) have been discovered (Suda et al., 1998; Tanimoto, 2001). Observational evidence points to the

atmosphere (e.g., Kobayashi and Nishada, 1998) and oceans (e.g., Rhie and Romanowicz, 2004) as possible sources of excitation of these oscillations. Stochastic excitation of normal modes by surface pressure variations, caused by atmospheric and/or oceanic turbulence, may explain the overall amplitudes of observed modes of the continuous free oscillations of the Earth.

Acknowledgments

The authors are thankful to the reviewer, Dr. Rudolf Widmer- Schnidrig of the Black Forest Observatory, for his useful suggestions and comments and for providing the Fourier spectrum of the 2010 Maule (Chile) earthquake gravimeter record shown in Figure 3.

GEODESY, FIGURE OF THE EARTH

Kusumita Arora
National Geophysical Research Institute, Council of Scientific & Industrial Research (CSIR), Hyderabad, India

Definition

Geodesy is the discipline that deals with the measurement and representation of the Earth, its gravity field, and geodynamic phenomena (polar motion, Earth tides, and crustal motion) in three-dimensional time-varying space.

"Figure of the Earth" in geodesy most commonly deals with the representation of the external geometry of the Earth, without going into the causal mechanisms.

Background

The shape of the Earth has always been speculated upon – historical accounts of sailors record that they feared falling off the edge of the Earth if they sailed too far. Early ideas about the Figure of the Earth held the Earth to be flat and the heavens a physical dome spanning over it. Two early arguments for a spherical Earth were that lunar eclipses were seen as circular shadows that could only be caused by a spherical Earth, and that the pole star is seen lower in the sky as one travels south.

The flat disk advocated by Homer (in the ninth century B.C.) later gave way to the spherical body postulated by Pythagoras (in the sixth century B.C.) – an idea supported 100 years later by Aristotle (384–322 B.C.). According to old texts, the first geodetic experiment took place around 250 B.C. by Eratosthenes (about 284–192 B.C.) in Egypt. Eratosthenes noted that the Sun on the summer solstice day at Syene (close today to Assouan) was at the zenith while its zenithal distance at Alexandria (approximately on the same meridian) was recorded as $7°12'$. By knowing the geometrical distance between Syene and Alexandria thanks to a cadastre performed by Ptolemy Soter (about 360–283 B.C.), he deduced, the length of the terrestrial circumference as 40,500 km. Later Hipparchus (in the second century B.C.) recommended the use of latitudes and longitudes for cartography (in agreement with its Greek etymology).

The great Indian mathematician Aryabhata (476–550 A.D.) described the Earth as being spherical and rotating on its axis. He estimated the circumference of the Earth, accurate to 1% of today's measurement. The medieval Persian geodesist Abu Rayhan Biruni (973–1048 A.D.) is sometimes regarded as the "father of geodesy" for his significant contributions to the field. He solved complex geodesic equations based on spherical trigonometry in order to accurately compute the Earth's circumference and radius, which are very close to modern values.

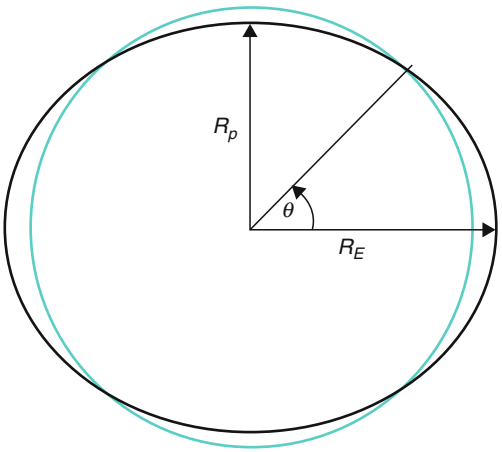
Mathematical Figures of the Earth

The actual shape of the Earth consisting of its topographic surface with its variety of landforms and water areas is not suitable for mathematical representations because the formulas that would be required to take these features into account would necessitate a prohibitive amount of computations. The Pythagorean concept of a spherical Earth offers a simple surface, which is mathematically easy to deal with. Many astronomical and navigational computations use it as a surface representing the Earth. While the sphere is a close approximation of the true Figure of the Earth and satisfactory for many purposes, to the geodesists interested in the measurement of long distances – spanning continents and oceans – a more exact figure is necessary. In the mid- to late twentieth century, research across the geosciences contributed to drastic improvements in the accuracy in the description of the Figure of the Earth.

The concept of a perfectly spherical Earth was eventually refined by Sir Isaac Newton based on his theory of

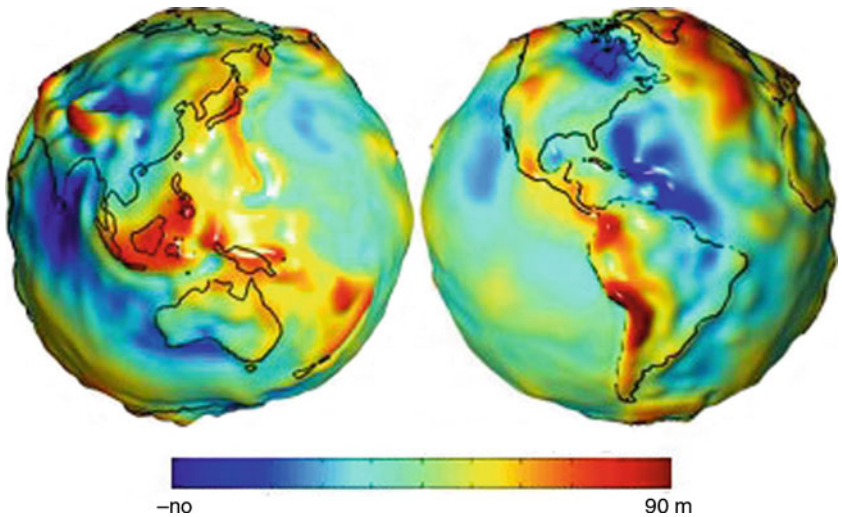
Harsh K. Gupta (ed.), *Encyclopedia of Solid Earth Geophysics*, DOI 10.1007/978-90-481-8702-7,

gravity, deriving that the Earth would not be perfectly spherical but slightly squashed at the poles and bulging at the Equator due to the forces acting upon it as it spins. Mathematically, this shape is described as an oblate spheroid or as an ellipsoid of revolution (Figure 1), an oval that revolves about its shortest dimension. This shape is most commonly used for exact measurements over long distances, across continents or oceans. Closer approximations utilize spherical harmonics for whole Earth shape or local approximations in terms of local reference ellipsoids. The idea of a planar or flat surface for Earth, however, is still acceptable for surveys of small areas where local topography is more important than the curvature. For such small areas, exact positions can be determined relative to each other without considering the size and shape of the whole Earth.



Geodesy, Figure of the Earth, Figure 1 An oblate spheroid (*black*) superimposed on sphere (*cyan*); R_P is the polar radius 6,357 km and R_E is the equatorial radius 6,378 km. θ is the latitudinal angle.

Another method estimates the Earth's surface using mean sea level of the ocean with all continents removed – this surface is equivalent to an equipotential surface and is called the Geoid. Due to variations in the Earth's mass distribution (oceans and land), the Geoid has an irregular shape that is described as "undulating." The ellipsoid of revolution mentioned above, is a mathematical approximation of the Geoid. The Geoid, unlike the ellipsoid, is so far deemed to be too complicated to serve as the computational surface on which to solve geometrical problems like point position. The separations between the two, referred to as Geoid undulations, Geoid heights, or Geoid separations, are irregular. The Geoid undulations over a spherical Earth are shown in Figure 2, where the red colored areas indicate positive deviations of the Geoid from the ellipsoid and the blues indicate negative deviations of the Geoid from the ellipsoid. Many of these deviations have obvious spatial correlations with surface expressions of substantial topographic features, which in turn indicate significant geodynamic activity. However, there are also undulations that do not bear such relations and the causal mechanisms remain to be established. An equipotential ellipsoid or level ellipsoid is an ellipsoid that is defined to be an equipotential surface. When an ellipsoid of revolution (semimajor axis a, semiminor axis b, flattening (a−b)/a) is defined, it can be made an equipotential surface of normal gravity potential, determined by means of the ellipsoidal surface, the enclosed mass, and the angular velocity (independently of the internal density distribution). The equipotential



Geodesy, Figure of the Earth, Figure 2 Geoid undulations derived from observed gravitational satellite orbit perturbations [from http://upload.wikimedia.org/~]; the greatest departure of the Geoid from ellipsoidal form is a 105-m low south of India. This is very small compared with undulations of the land surfaces or the 5-km mean difference in level between continents and ocean floors.

ellipsoid furnishes a simple, consistent, and uniform reference system for all purposes of geodesy and does not include an atmosphere.

The possibility that the Earth's equator is an ellipse rather than a circle and therefore the ellipsoid is triaxial has been a matter of scientific controversy for many years. Modern technological developments have furnished new and rapid methods for data collection and orbital data from satellites have been used to investigate the theory of ellipticity. A second theory proposes that observed long period orbital variations of the early Earth satellites indicate an additional depression at the South Pole accompanied by a bulge of the same degree at the North Pole. It is also contended that the northern middle latitudes were slightly flattened and the southern middle latitudes bulged by a similar amount. This concept suggested a slightly pear-shaped Earth (Figure 3). Modern geodesy tends to retain the ellipsoid of revolution and treat triaxiality and pear shape as a part of the Geoid figure: They are represented by the spherical harmonic coefficients C22, S22, and C30, respectively, corresponding to degree and order numbers 2,2 for the triaxiality and 3,0 for the pear shape.

Apart from rotation, there are other motional forces, which affect the shape of the equipotential surface. Precession is the effect of external torque exerted on the Geoid causing the spin axis to describe a circular cone. This motion is caused by the gravitational attraction of other celestial masses, particularly the sun, moon, and planets. Precession arises because of the ellipticity of the Geoid, with torque exerting on the equatorial bulge, in combination with the obliquity of the axis of rotation in relation to the plane of revolution (the ecliptic and fixed, heliocentric space). The period of precession is presently about 25,780 years.

Geodesy, Figure of the Earth, Figure 3 Concept of a pear-shaped Earth, from www.icsm.gov.au/mapping/~.

Polar Motion is the change in the position of the axis of rotation in relation to the surface of the Geoid, which was observed by five stations near latitude 39.1333° N, which began observations in 1899. The Conventional International Origin is defined as the mean position of the instantaneous pole during the period 1900–1905. Secular Polar Motion is the drift in the pole position thought to be due to tectonic movement. Seasonal Polar Motion is a fluctuation with an annual period with considerable fluctuation in amplitude ranging from 1.3 to 3.7 m.

Determining the exact Figure of the Earth is not only a geodetic operation or a task of geometry, but is also related to geophysics. Without any idea of the Earth's interior, we can state a "constant density" of 5.515 g/cm³ and, according to theoretical arguments such a body rotating like the Earth would have a flattening of 1:230. In fact the measured flattening is 1:298.25, which is more similar to a sphere and a strong argument in favor of very compact Earth's core. Therefore the density must be a function of the depth, reaching from about 2.7 g/cm³ at the surface to approximately 15 g/cm³ within the inner core. With increasing accuracy of the measured global gravity field from dedicated satellite missions, it is observed that the true vertical generally does not correspond to the theoretical vertical (deflection ranges from 2″ to 50″) because topography and all geological masses disturb the gravitational field. Therefore the gross structure of the Earth's crust and mantle can be determined by geodetic–geophysical models of the subsurface.

Reference coordinate system

Description of the shape and size of the Earth as well as measurement of distances on its surfaces and definitions of position locations of any particular point inevitably depends upon the use of a Reference Coordinate System. Reference ellipsoids are customarily expressed by the size of the semimajor axis (a) and flattening (f). The quantity f is a purely mathematical one. The mechanical ellipticity of the Earth (dynamical flattening) is determined by observation and differs from the geometrical because the Earth is not of uniform density. The 1967 Geodetic Reference System posited a 6,378,160 m semimajor axis and 1:298.247 flattening. The 1980 Geodetic Reference System posited a 6,378,137 m semimajor axis and 1:298.257 flattening. This system was adopted at the XVII General Assembly of the International Union of Geodesy and Geophysics (IUGG).

The World Geodetic System 84 (WGS 84) is the standard for use in cartography, geodesy, and navigation. It comprises a standard coordinate frame for the Earth, a standard spheroidal reference surface (the *datum* or *reference ellipsoid*) for raw altitude data, and a gravitational equipotential surface (the *Geoid*) that defines the *nominal sea level*. Presently WGS 84 uses the 1996 Earth Gravitational Model (EGM96) Geoid, revised in 2004. This Geoid defines the nominal sea-level surface by means of a spherical harmonics series of degree

360 (which provides about 100-km horizontal resolution). The deviations of the EGM96 Geoid from the WGS 84 reference ellipsoid range from about −105 m to about +85 m.

International Terrestrial Reference System (ITRS) was defined by the IUGG in 1991 as a geocentric nonrotating system identical to the International Astronomical Union (IAU) defined Geocentric Reference System with Geocentric Coordinate Time (TCG). Conventional Terrestrial System (CT) is geocentric and references north to the 1900–1905 mean pole and 0° longitude to Greenwich Observatory. Terrestrial coordinate systems are earth-fixed and spin and revolve with the Earth. Terrestrial Reference System (TRS) is a spatial reference system corotating with the Earth in space, with positions of points attached to the solid surface of the Earth having coordinates that undergo only small variations with time, due to geophysical, tectonic, or tidal deformations.

Nowadays the realizations of the fundamental reference system supported by the International Association of Geodesy, the ITRF, (International Terrestrial Reference Frame with the year of realization, at present the ITRF 2008) are very strongly recommended to be used in precise geodesy, for geosciences applications and for navigation satellite systems. Fortunately, the choice of fundamental parameters of WGS 84 was made in the beginning (in the 1980s) as close as possible to the ITRF (at this time defined by the BIH – the Bureau International de l'Heure). As a result, within 1 m there is no difference between what is defined as WGS 84 and the ITRF 2008, the latest international realization with a centimeter level of accuracy.

Datum

A datum is a framework that enables us to define coordinate systems. Definition of datum has improved considerably with advancements in measurement techniques through technology.

Traditional Geodetic Datum: To describe positions on the Earth accurately, traditionally two datum were required: a horizontal datum and a vertical datum.

Horizontal Datum: A horizontal datum is used to fix a position in the X and Y directions. A horizontal datum was traditionally defined using an ellipsoid and an origin. The ellipsoid was generally chosen for a best fit of the Geoid locally.

Vertical Datum: A Vertical Datum is used to fix a position in the vertical direction, up and down the Z-axis. A vertical datum is a line, value, or set of values from which heights are measured.

The International Terrestrial Reference Frame (ITRF) is defined by the International Terrestrial Reference System and the Datum consistent with it and is based on a number of very accurate observations all over the Earth, employing Very Long Baseline Interferometry (VLBI), Satellite Laser Ranging (SLR), Lunar Laser Ranging (LLR), and the Global Positioning System (GPS) techniques. The measurements relate to a 3D Earth-centered Cartesian coordinate system. In changing to this Geocentric Datum, the Global Positioning System [GPS] can be most effectively used.

Summary

Geodesy, Figure of the Earth outlines the basic parameters by which the shape of the Earth is defined. The Earth being a system in dynamic equilibrium, is under the influence of many forces, all of which contribute to its final structure and thereby its detailed shape. The subject of Geodesy has evolved sufficiently technologically and mathematically to take into account the details of the Earth's shape as well as the physics of the causal mechanisms.

Synonyms

Height determination; Terrestrial positioning

Definition

Geodesy. Science for the determination and representation of the figure, shape, size of the Earth and of other celestial bodies along with their external gravity field as a function of time.
Positioning. Determination of coordinates for points on earth, sea, or space with respect to a reference system.
Ground positioning. Determination of terrestrial coordinates.
Leveling. The determination of heights of points with respect to a reference surface.

Introduction

Geodesy, along with Astronomy, is considered the oldest earth science, and dates back to the Sumerians of 5,000 years ago. The word "geodesy" is composite and is derived from the Greek noun «Γη = earth» and the verb «δαίω = divide». It is, literally, the science used to "divide, distribute, and measure the Earth." The roots of geodesy can be found in ancient Egypt and Babylon where "the geometry of the Earth" was used for the recovery of the land property boundaries, after, for example, the flooding of crops by the Nile River. The word "Geodesy" appeared, for the first time, in the fourth century BC in Aristotle's book *Metaphysika*. Before Aristotle, "geodesy" was called the "geometry of the Earth." Ancient Greeks and Romans were the first to invent geodetic or *surveying* instruments for constructing roads, buildings, and tunnels, laying water pipes, culverts, land surveying, etc. Great scientists such as Pythagoras, Aristotle, Eratosthenes, Poseidonius, W. Snellius, J. Picard, Newton, Gauss, Cassini, and many others contributed to geodesy, surveying, high precision leveling and mapping.

Today, *geodesy* is the science of accurately measuring and understanding (1) the geometric size, shape, and orientation of the Earth, (2) its gravitational field, and (3) the variations of these quantities over time (Torge, 2001; Herring, 2010). The development of geodesy goes together with spectacular achievements in the fields of astronomy, mathematics, probability and statistics, physics, map projections, fast computing, etc. As a first approximation, "geodesy" can be considered as the science of measuring distances or heights between terrestrial objects, or measuring angles between lines and determining directions of lines for the establishment of coordinates of points on or near the earth's surface. This is also called *ground positioning* or *surveying*.

One of the main tasks of geodesy is *positioning*. This is the accurate determination of coordinates of points on the earth's surface, at sea, or in space with respect to a reference system (McCarthy and Petit, 2003). Positioning can be divided into *absolute positioning*, where coordinates are determined with respect to an inertial reference system, and into *relative positioning* when coordinates are derived with respect to other reference points on Earth. Positioning constitutes essential information for mapping, cadastral surveys, highway and dam construction, earthquake and landslide monitoring, geodetic control networks, crustal and structural deformation, etc.

Ground positioning has traditionally been carried out using measurements of distances, and angles (and or directions) between terrestrial lines with theodolites and measuring tapes (Anderson and Mikhail, 1997). Later, distances have been measured by other equipment using the electromagnetic radiation. Over the last two decades, the methods and instruments for measuring, acquiring, storing, calculating, reducing, and portraying geodetic ground positioning data have changed dramatically. New types of geodetic measurements, along with the traditional ones, are now being made with total electronic geodetic stations, terrestrial laser systems, inertial systems, ground-based radar interferometers, terrestrial wireless positioning systems, precise underwater positioning systems, and finally with the space-based systems such as the Global Navigation Satellite Systems (Kaplan and Hegarty, 2005).

Geodetic leveling is the precise determination of height difference between two or more points on the earth's surface. It ultimately aims at the determination of the height above a reference surface, usually the mean sea surface. Again in leveling, the ancient Egyptians and the Babylonians were the first to employ it to connect the Nile River with the Red Sea and to apply leveling for irrigation. In the following sections, the geodetic ground positioning and leveling will be briefly elaborated.

Ground positioning

The primary purpose of ground positioning is to provide coordinates of points on the earth's surface based either on (1) the astronomic determination of latitude, longitude, and azimuth of a terrestrial line or (2) the observation of horizontal angles, distances, zenith angles, and height differences.

A *horizontal angle* is defined as that angle measured in the horizontal plane of the observer between two vertical planes. The *horizontal plane* is the tangent plane to the equipotential surface of the gravity field at the point of observation. In early geodetic surveys, painstaking efforts were employed to accurately measure angles and distances. Angles were – and are still to this day – measured using theodolites and the distances were measured using tapes made from metal having a low coefficient of thermal expansion. Later, electronic instruments were used for measuring angles and distances.

Electromagnetic distance measuring devices have been used to determine the distance between geodetic stations on the ground. Electromagnetic pulses are transmitted to a retroreflector (or even to the terrain target) and the emitted signal finally returns to the instrument. Intervisibility requirements and attenuation of the signal, mainly due to the atmosphere, allow measurements to be made at ranges up to about 50 km; but the best results are obtained at shorter distances with an accuracy even higher than 0.1–0.3 mm over 100 m.

Point coordinates have thus been established by a process of triangulation, trilateration or traverse surveys. *Triangulation* is the process of determining the relative

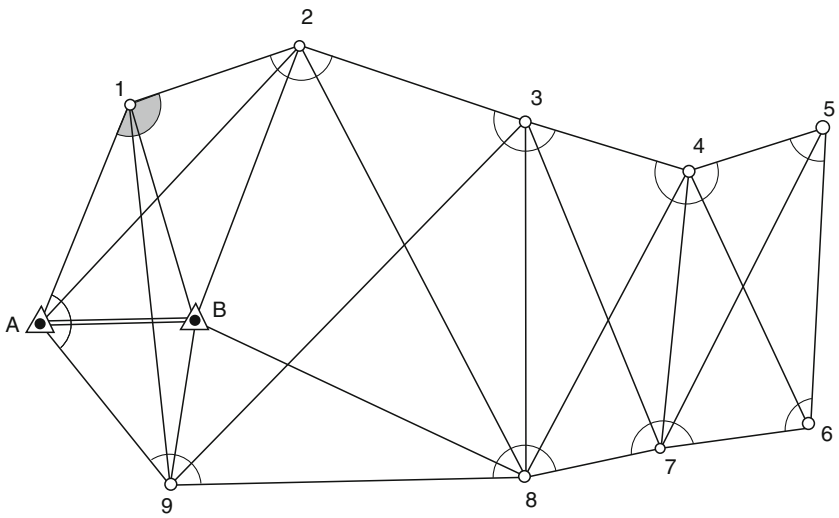
positions of a network of *control points* (Anderson and Mikhail, 1997) on the ground by theodolite measurements of directions or angles between intervisible stations (Figure 1). Angles have been more easily measured, as compared to distances, particularly when large distances over mountainous and rugged terrain were involved. As the name implies, triangulation employs horizontal angles and a limited number of lengths – called *geodetic baselines* – of connected triangles to determine trigonometrically the positions of stations (vertices of triangles). Triangles have been the simplest geometric figures that permit rigorous checks and adjustments of field observational errors. To compensate for the errors in the measurements, triangulation networks are adjusted mainly using the method of least squares. This method not only yields the final and adjusted coordinates of the vertices of the triangles but also gives their coordinate accuracies (Teunissen, 2000; Ghilani, 2010).

Trilateration is similar to triangulation process and again aims at the relative determination of positions using triangles, but now with their lengths measured by electromagnetic radiation with electronic instruments (Figure 2). Finally, *traverse surveys* consists of measurements of both horizontal (and vertical) angles at the traverse stations and distances along a series of connected lines on the ground. Unlike triangulation and trilateration, in which stations are commonly widely separated (e.g., 20–60 km), traverse surveys generally follow routes of highways, railways etc., with stations located close together (i.e., a few hundred of meters). The coordinates of these traverse stations are computed using basic trigonometric expressions as shown in Figure 3.

Astronomic azimuths are used to determine the orientation of the network with respect to the ellipsoid. The *astronomic azimuth* is the angle in the observer's local horizontal plane between the astronomic meridian and the vertical plane passing through the target point. Two coordinates, the geodetic latitude and longitude of each station of the network are then computed on this ellipsoid. The third coordinate of *height* above the reference ellipsoid is determined either from leveling and gravity data or from vertical angles.

All these geodetic measurements as well as other types (e.g., distance differences) are being made, today, by total geodetic stations, terrestrial laser systems, inertial systems, ground-based radar interferometry, wireless positioning, etc.

New kinds of theodolite measurement systems do not require a target and/or reflector to be monitored. They

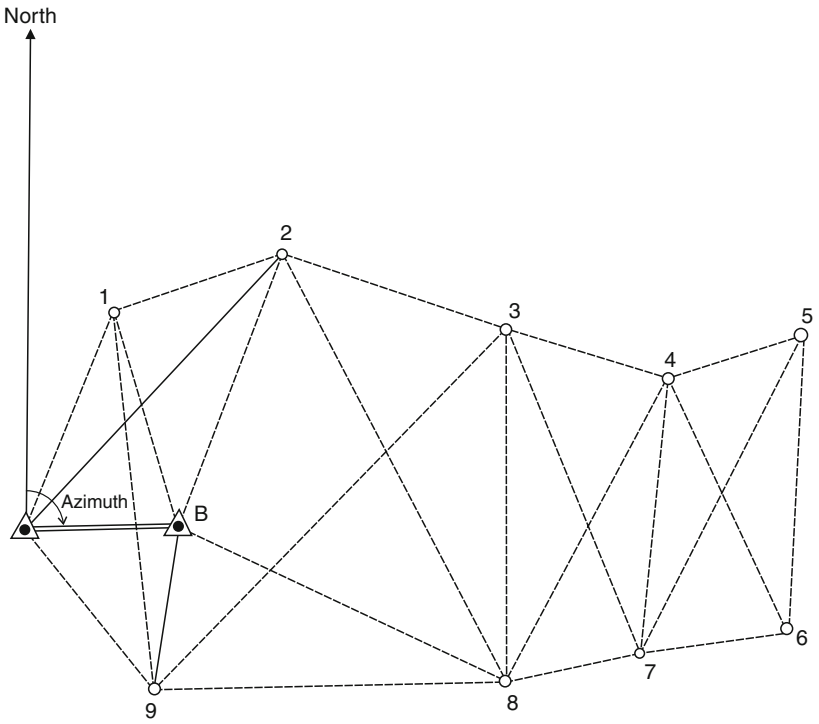


Known parameters:
1. Geodetic baseline AB (distance is known),
2. Latitude and Longitude of stations A and B,
3. Azimuth of length AB.

Measurements:
All horizontal angles to visible stations.

What is finally computed:
1. Distances to all control stations (triangle vertices),
2. Latitude and longitude of all stations,
3. Azimuth of all lines.

Geodesy, Ground Positioning and Leveling, Figure 1 An example of a triangulation network. The baseline AB is either known or measured, while all angles in the formed triangles are observed.



Known parameters:
1. Geodetic baseline AB,
2. Latitude and longitude of stations A and B,
3. Azimuth of line AB.

Measurements:
All distances to all inter-visible sites (stations).

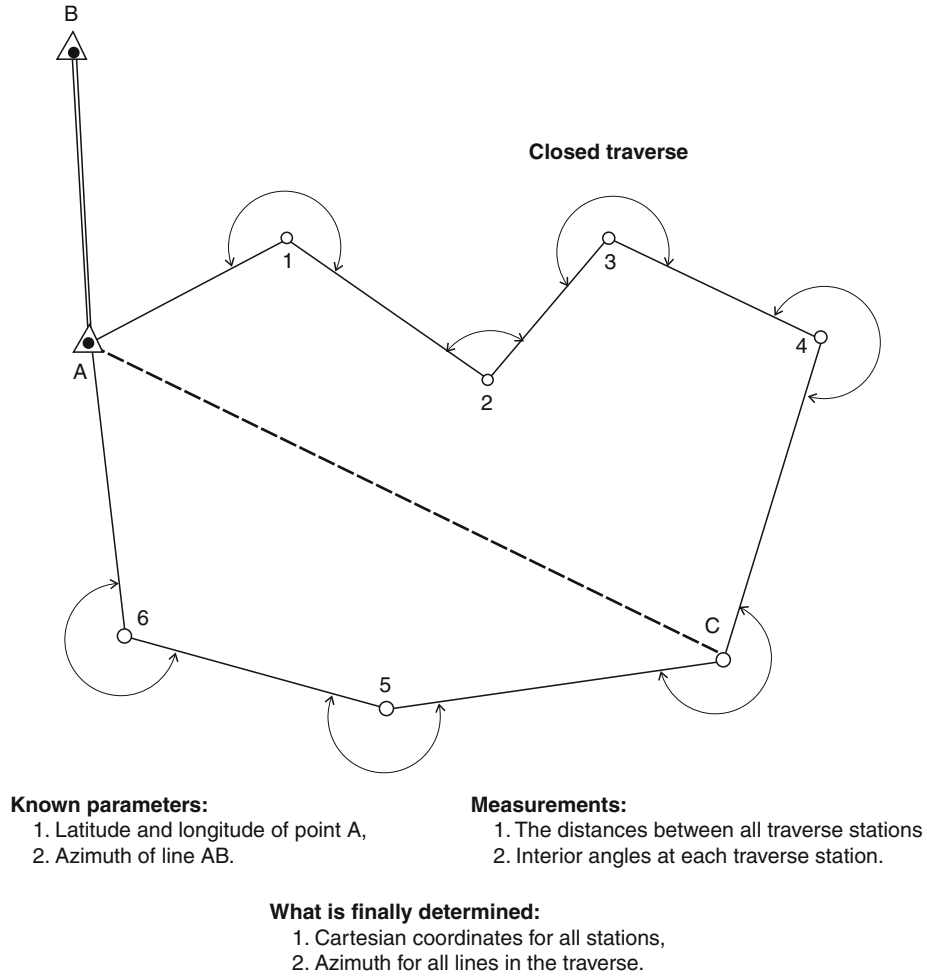
What is finally computed:
1. Angles and distances for all formed triangles,
2. Latitude and longitude for all stations,
3. Azimuth of all lines.

Geodesy, Ground Positioning and Leveling, Figure 2 A trilateration network where the azimuth of the baseline AB is determined to orient the network with respect to the north and all sides of the formed triangles are observed.

are able to measure point coordinates without targeting the object to be observed (Kahmen and Rieterer, 2004). Such systems use the texture on the terrestrial surface or of an object to locate "points of interest" to make angle and distance measurements. However, these new instruments require well-trained personnel to operate them.

Terrestrial laser scanners (Froehlich and Mettenleiter, 2004) can also provide detailed and highly accurate three-dimensional coordinates of terrestrial points rapidly and efficiently. Some scanners are suitable for indoor use and medium ranges (up to 100 m), while others are better for outdoor applications with longer ranges. Most systems use a laser beam, emitted by the instrument, which is directed into different directions, through a mechanical deflection mirror, to a number of reflective surfaces on the ground. The deflected laser light is detected and the instrument measures the time of flight for long ranges, and the phase measurement of the reflected signal, for medium ranges. For various scanning rates and/or a vertical scan angles up to 90°, the deflection mirror rotates continuously at adjustable speed and records target *range*, *angle*, signal *amplitude* and *time*. Some terrestrial laser scanners incorporate a camera to also capture a picture of an object being scanned. The accuracy of distance measurements is of the order of ± 1 cm, but this primarily depends on the intensity of the reflected laser light and on the reflectivity of the target surface. Terrestrial laser scanners have been used to characterize the kinematics of the landslide ground surface, by evaluating the involved displacement and deformation patterns. They have also been applied in surveying, mining, construction surveying, architecture, archaeology applications, as well as deformation monitoring, etc.

The standard wireless (i.e., Wi-Fi and the Ultra-Wide Band) networks employ a number of transmitters on the



Geodesy, Ground Positioning and Leveling, Figure 3 An example of a closed traverse. The geographic coordinates as well as the azimuth of the initial point A, with respect to point B, are known. Then the exterior (or interior) angles at each traverse station are observed along with the inter-station distances. The Cartesian coordinates for all stations of the traverse and the azimuths for all lines are determined using simple trigonometry.

ground and not only provide a way for finding the optimum communication relay routes in an ad hoc network of transmitters, but are also capable for ground positioning. The locations of the communication nodes (i.e., transmitters) of these networks are known. Positioning is achieved by measuring the *time of arrival* and the *time difference of arrival* for the communication signals. Thus, the positional accuracy of a network user depends on the ranging errors, the connectivity, and the available number of mobile nodes. The developed Ultra-Wide Band systems provide a dynamic three-dimensional accuracy of better than 5 mm (Kuhn et al., 2009). They are, at present, used for indoor wireless positioning, including robot tracking and monitoring but future uses to geophysical applications are soon to emerge.

Geodetic positioning techniques have also been extended to underwater applications using acoustic ranging to measure crustal deformation with centimeter level accuracies at several thousand of meters depths (Gagnon et al., 2005).

Another promising technique for geodetic positioning, height mapping, and deformation monitoring, such as tectonic seismic and volcanic deformation as well as ice and rock-glacier motion and ground subsidence, is provided by the *ground-based interferometric radar systems* (Werner et al., 2008). These instruments use real aperture radar antennas to illuminate a target area on the ground (Figure 4). The antennas are mounted in parallel on a rotational scanner. A radar image of the target area is formed, line by line, by rotating the antennas in azimuth and in the vertical axis. The range and the azimuth resolution of these radars are determined by the antenna beam width and the slant range. *Phase differences* (Cumming and Wong, 2005) between successive images, acquired from the same viewpoint, are used to determine line-of-sight displacements better than 1 mm. These instruments are

Geodesy, Ground Positioning and Leveling, Figure 4 A ground-based interferometric radar system to monitor deformation.

used for monitoring rapid moving landslides, and unstable mine slopes, as well as for terrain mapping. They can be used for short ranges from sensor to target (up to 1,000 m) to medium range applications (up to 4 km). The resulted accuracies are of the order of ± 1 mm and the entire observed area can reach up to thousands of square meters, while the radar system measures the displacements of all points in the area illuminated by the antenna.

Finally, space geodetic techniques are based on processing signals received from earth orbiting satellites to provide precise ground positioning and leveling (Herring, 2010). These systems, called Global Navigation Satellite Systems (GNSS), include the United States' Global Positioning System (GPS), the Russian Global Navigation System (Glonass), as well as the future ones such as the European Galileo, the Chinese Compass, the Indian Gagan, the Japanese Quasi-Zenith Satellite System, etc. Although originally developed for military and navigational purposes, new measuring and processing techniques (Hofmann-Wellenhof et al., 2007; Leick, 2003) were developed to improve the originally designed positioning accuracy of several meters. Today, these systems provide coordinates of ground locations at the millimeter level in the horizontal as well as in the vertical sense (Blewitt, 2010) over larger distances of several tens or hundreds of kilometers. In addition, they allow for three-dimensional positioning, do not require interstation visibility, their accuracy does not degrade with distance significantly, and provide continuous (e.g., every 1 or 20 Hz) positioning with respect to a global reference frame. In this vein, they have been applied for mapping, precise ground positioning to monitor plate tectonics, seismic and volcano ground deformation, etc.

The computational process, for all the above geodetic positioning techniques, requires their reduction on a reference surface, usually taken a flat horizontal surface or the *reference ellipsoid* (McCarthy and Petit, 2003) (Figure 5). In the flat horizontal surface the directions of the plumline (and thus gravity vector) are considered parallel. The ellipsoid is the curved surface approximating the size and shape of the earth and the Cartesian coordinate system is usually an earth-centered reference system for three-dimensional computations. Calculations involve solving equations derived from solid geometry, calculus, and statistics (Torge, 2001; Meyer, 2010).

The measured angles (directions) and distances are projected along normals onto the reference ellipsoid. The *geodetic datum* (McCarthy and Petit, 2003) is also defined as that which enables accurate location of features on earth through a mathematical model that describes the origin, orientation, and scale of coordinate systems.

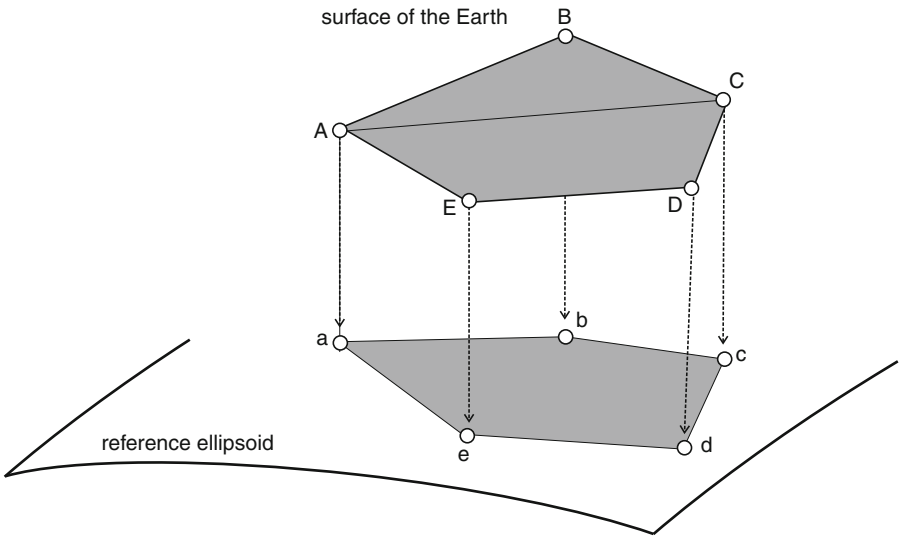
Leveling

Leveling is the general term applied to indicate the process by which elevations of points or differences in elevation between two or more points on the surface of the earth are determined. Differences in elevation are determined by taping, differential leveling, barometric leveling, and indirectly by trigonometric leveling. All height determinations require the establishment of a vertical datum (Ihde et al., 2008), usually taken as the mean sea level. This is realized by relative permanent objects on the ground, called *benchmarks*, whose elevation above an adopted geodetic datum is known.

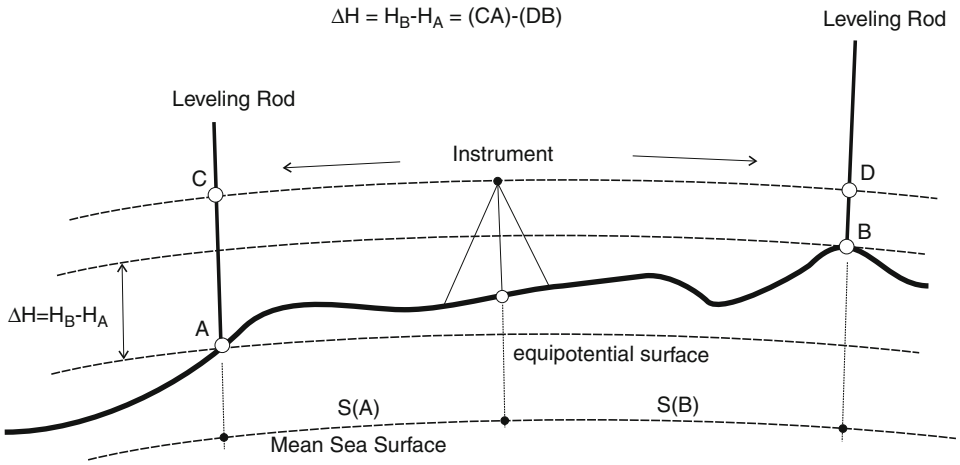
Differential leveling is accomplished by making measurements to two or more points through a telescope. The instrument's telescope, with suitable magnification, is regularly set horizontally with its line of sight being parallel to the equipotential surface of the local gravity field. A horizontal line of sight is established within the telescope

by a level vial or automatic compensator. The basic procedure is illustrated in Figure 6. A vertical measurement is made to the backsight of a graduated rod, held on fixed points, and is added to its height. Thus the height of the leveling instrument is determined. A second measurement is made to determine the height of the foresight rod. The instruments can then be moved forward and the leveling process is repeated until the elevation difference between the initial and the final point is established. Leveling procedures are limited by light of sight and to the distance between the level instrument and the rod. The readings on the rod can be taken either optically or electronically; the rod must be close enough to the level (about 40 m) to resolve the rod's readings in order to make accurate readings. Today, digital levels measure electronically to bar-coded rods, but can also measure optically to conventional rods. These are easy to use and because heights and distances are recorded electronically, reading and writing errors are avoided. They can be used for precise leveling of flat and sloping surfaces, and for establishing the vertical component of grade and ground profiles and for subsidence monitoring and control. The accuracy in height determination is of the order of less than ± 1 mm per km of distance in double leveling.

Differences in elevation are proportional to differences in the atmospheric pressure. Thus barometers, which are instruments to measure atmospheric pressure, can be used



Geodesy, Ground Positioning and Leveling, Figure 5 The observations of angles, distances, etc. measured on the earth's surface are reduced upon a reference ellipsoid and/or a flat horizontal surface.



Geodesy, Ground Positioning and Leveling, Figure 6 Differential leveling. Two leveling rods are placed vertically on points A and B, where the height difference is to be determined. The instrument is set up in the midway of A and B. A vertical measurement is made to the backsight of the graduated rod placed at A. A second measurement is also made to the foresight rod at B. The height difference is determined by subtracting the foresight from the backsight observation.

to determine relative elevations of points on the earth's surface. Elevations determined by barometric leveling probably are several meters in error even after they are corrected for the effects of temperature and humidity. Barometric measurements are made at a benchmark, while a second roving barometer is carried from point to point in the field.

The difference in elevation between two points, A and B, can also be established by measuring the vertical angle of the line from one point, A, to the other, B, as well as the slope distance, and then computing the difference in elevation using trigonometry. *Trigonometric leveling* is necessary when the elevations of inaccessible points must be determined. From two points of known position and elevation, the horizontal position of the unknown point is found by triangulation, and the vertical angles from the known points are measured. The technique is influenced by the atmosphere refraction (cloudy weather with good visibility with consistent temperature over measurement) and the earth curvature.

Summary

At present, the reference systems upon which all these geodetic positioning and leveling techniques are based, have been well defined with unprecedented accuracy and reliability (McCarthy and Petit, 2003; Ihde et al., 2008). The theory of errors for geodetic positioning and leveling has been well developed and applied in the measurements made. New data collection and processing technologies have emerged and matured. So, better results and reliable results are obtained, while the burden of adjustment computation and efficiency has further improved with fast computing and improved measurements and processing algorithms. All in all, Geodesy, ground positioning, and leveling have seen tremendous developments in recent years. New measurements (from optical to electronic) and new techniques (from angle measurement to phase and time and time-difference measurement of electromagnetic signals) and new instrumentation with increased accuracy (from meters to centimeters and millimeters at long distances) and capabilities (integration with Geographic Information Systems) have been emerged and matured for geophysical applications.

Definition

Geodesy. Scientific discipline dealing with the measuring and representing of Earth in the domains of time, space, and the gravitational field.

Networks. Set of materialized geodetic reference points as carriers of a specific reference frame tied to each other by geodetic measurements.

Reference system. A reference system is based on one definition of the reference. A geodetic reference system is a definition of a specific coordinate system.
Reference frame. A reference frame is one (among many possible) realizations of a reference system. It is characterized by a set of reference points from geodetic networks and a reference epoch.

Introduction

The historical definition of geodesy was given by F. R. Helmert (1880): "Geodesy is the science of measuring and mapping of Earth's surface." According to this definition, the task of geodesy is expressed in Torge (2003): "The task of geodesy is to determine the figure and the external gravity field of the Earth and other objects in space as functions of time by surface- or space-based observations."

Therefore, geodesy deals with measurements and representation of Earth's geometry, its gravitational field, and geodynamic phenomena (Earth rotation, Earth tides, and crustal motion) in three-dimensional and time-varying space. Metrology defines the physical units, which are needed in geodesy. The measurements are related to various geodetic instruments and different methods. Earth-bound instruments are mostly operated in global networks, while a space-borne instrument senses the entire Earth while in orbit. Earth models contain a mathematical description approximating the physical reality in which observation data are modeled. The description of Earth's figure and its external gravity field requires the definition of reference systems, which are constituted by measurements (Schneider, 1992).

As it is very difficult to fix a static and very precise global coordinate system to the continuously changing Earth, a permanent monitoring of reference positions in geodetic networks is necessary. These permanent observing networks, in which fundamental stations for geodesy have an indispensable role, are the base for global geodetic reference frames. Such reference frames are the backbone for a better understanding of the system Earth, for any kind of geoinformation systems, and for space exploration (Hase, 1999).

Geodetic reference systems

Theory of reference systems

In geodesy, the terms *reference system* and *reference frame* are different: A reference system is based on physical theories and reflects an ideal idea. A reference frame is one among many possible realizations of a reference system and based on geodetic observations and hence available to users (Kovalevsky and Mueller, 1981).

Example: A global reference system can be defined in such a way that the origin of the coordinate system coincides with the center of mass. The center of mass is an abstract physical model and not accessible as a reference point. However, geodetic observations of satellite orbits are useful to realize a corresponding reference frame because the center of mass of Earth coincides with one of the two foci of the elliptical orbit of the satellite. The used data set of observations delivers one particular reference frame with respect to the definition of the reference system.

Reference systems are standardized by the introduction of conventional reference systems that are based on the decisions of international committees. These conventional reference systems become available to users by conventional reference frames (Schneider, 1999). Reference frames are always based on observation data, which are processed with introduced hypotheses of the used reduction models. Due to the arbitrary settings in the processing of observation data, the defined ideal of a reference system can only be approximated with different analysis strategies. This circumstance and the need for comparison call for a standardization of reduction models in order to compare different reference frames. The IERS-Conventions are an example for the standardization of physical constants and models with respect to global reference frames (IERS Conventions, 2003).

Two reference systems are of importance in global geodesy: (a) the barycentric space-bound celestial reference system (CRS), and (b) the geocentric Earth-bound terrestrial reference system (TRS). While the first system is related to distant objects in space, the latter one is related to terrestrial reference points or to reference points in the near Earth space. Both systems are tied by the Earth Rotation Parameters (EOP).

The figure of Earth is approximated by Earth models. The geometric models are spherical or ellipsoidal while the geophysical models are based on expansion of the spherical harmonic functions in order to model the geoid as an equipotential reference surface. In an ideal situation, models of both categories coincide with their origins and have parallel main axes.

Metrology

Geodetic measurements in the domains of space, time, and gravity field refer to physical units of the SI (Sistéme International). In general, the modeling of space-geodetic measurements in Newtonian space-time shows deficiencies. The underlying physical model for the definition of physical units must be based on the theory of general relativity (Damour et al., 1991). This requires that the physical units are defined in infinitesimal small spatial areas with only local and not global validity. The question is whether physical units defined in local laboratory space can be used on the global scale for space geodesy.

The units for timescale, spatial-scale, and gravitational potential cannot be defined independently from the object to be measured. The metrological units are only defined as precisely as the measurements of the geodynamic phenomena interacting with the laboratory and vice versa (Hase, 1999).

The introduction of the constant of the speed of light, c = 299792458 m/s, enables the introduction of the physical

units *meter* and *second* and a method to measure space-time intervals if the synchronization of two local clocks fulfills the Einstein synchronization condition. Generally, this condition is not fulfilled on Earth. Therefore, the spatial distance of the clocks must be defined in relation to the desired resolution of the measurement in order to neglect the spatial curvature effects.

The global timescale is ideally related to the center of the mass of Earth as the effect of external gravitational bodies disappears. For practical reasons, timekeeping is not possible at the center of Earth's mass. Therefore, the timescale definition of *Temps Atomique International* (TAI) refers to a geocentric reference system with a definition of the second related to the equipotential surface of the rotating geoid. The world time is the *Coordinated Universal Time* (UTC), which is TAI corrected by an integer number of leap seconds realized by local clocks. The time second is realized by cesium frequency standards. Its SI-definition is as follows: The second is the duration of 9192631770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium atom ^{133}Cs (BIPM, 1998).

The metric scale is a secondary unit derived from the definition of the time second and the constant of the speed of light. The meter is defined as the distance travelled by light in vacuum in 1/299792458 s. Depending on the definitions for speed of light and time second, the metric scale is only valid in the vicinity of the time second-defining clock. That is why large distances should be seen as space-time intervals that are characterized by two-way measurements or one-way measurements with clock transportation.

The mass of Earth could be seen as constant if there were no exchange of radiation with the ambient universe. With respect to the terrestrial reference frames, the solar system with its gravitating bodies is seen as sufficiently isolated. The universal gravitational constant, $G = 6.67259 \times 10^{-11}$ m³/kg/s² $\pm$ 8.54×10^{-15} m³/kg/s², is imprecisely known with its relative accuracy of 10^{-4} (Bursa, 1992). G is the only link between the SI unit for mass and the gravitational phenomena. Given that only in the magnitude 10^{-17}, the tidal potential at the height of the geoid has an effect on the definition of the time second, the value of G may be applied in geocentric as well as in barycentric reference systems.

The product of the universal gravitational constant with the mass of Earth is called the geocentric gravitational constant, $GM = 398600.4418$ m^3/s^2 $\pm$ 0.0008 m^3/s^2, and can be determined with higher accuracy (2×10^{-9}) than the individual factors (10^{-4}). It is used for geodetic Earth models.

The IERS Conventions and IERS Standards mirror the actual status of parameters and models to be used in order to obtain a consistent TRF approximating the underlying physical theories with the best available models and constants (IERS Conventions, 2003).

Global geodetic reference systems

With the beginning of the satellite age, the need for an accurate global geodetic reference system became evident. Also spatial and geographical information datasets extending over national boundaries are calling for a common global reference frame for collection, storage, visualization, and exchanging of geoinformation.

Global geodetic reference systems have always been based on definitions and measurements with respect to the available scientific knowledge and technology. In former times, solid Earth models had been sufficient for global reference frames, scientific geodetic studies, and for mapping applications. Modern geodetic space techniques such as Very Long Baseline Interferometry (VLBI), Satellite Laser Ranging (SLR), Global Navigation Satellite Systems (GNSS), and modern instrumentation of local sensors such as absolute gravity meter (AG) and superconducting gravity meter (SG), much higher resolutions in the measurements showed the variability of the observables as a function of time. Consequently, the solid Earth models had to be replaced by viscoelastic Earth models.

For the purpose of reference frames, the viscoelastic Earth models must also contain models of plate-tectonic motion because reference points at different continental plates expose different directions and velocities of proper motion over time. The exhaustion of the kinematic motion of individual reference points is achieved in the coordinate estimation under the condition that the squared sum of the individual point motion is made to zero. This condition is commonly expressed as *no-net-rotation* (NNR).

As it appears to be an impossible task to fix a static and very precise global coordinate system on the continuously changing Earth, a permanent monitoring of reference positions in geodetic networks became necessary. These permanent observing networks, in which fundamental stations for geodesy have an indispensable role, are the base for global geodetic reference frames.

Currently, two global geodetic reference systems have a major importance: ITRS and WGS84.

International terrestrial reference system (ITRS)

The most important conventional terrestrial reference system (CTRS) is the International Terrestrial Reference System (ITRS). The ITRS is defined as a cartesic coordinate system in which (a) the origin coincides with the center of Earth's mass (including the masses of the hydrosphere and the atmosphere), (b) the metric scale is defined by the fixed velocity for the propagation of light in a gravitating environment and the physical definition for the unit of time according to SI, (c) the orientation is obtained by observation of Earth rotation relative to space-fixed objects of the celestial reference frame (ICRF), and (d) the system has no global residual rotation with respect to horizontal motions at the Earth's surface (NNR) (IUGG, 1991). The definition of origin, scale, and orientation is the *geodetic datum* of a reference

system. If a geographic coordinate system (latitude, longitude, ellipsoidal height) is chosen, the corresponding parameters of the desired reference ellipsoid must also be defined and becomes in general part of that datum. The GRS80-ellipsoid (Geodetic Reference System, 1980) is often used for the ITRS as best fitting the global figure of Earth's surface.

The ITRF is currently based on observation data of more than 3,800 reference points. International Services for VLBI, SLR, GNSS, DORIS, and the collection of local surveys at collocation sites with multiple techniques being operated provide the ITRF database.

The ITRF is published with respect to certain epochs, i.e., ITRF2005 and ITRF2008. The ITRF-coordinates and -velocities of the reference points are estimated in the processing of observational data. Each reference frame refers to a specific epoch and shall allow linear extrapolation of the coordinates to any desired epoch. However, long-term series and certain geographical regions partly expose nonlinear evolution of point positions and require frequently updated regional reference frames or nonlinear motion models.

The updating of the ITRF is necessary not only due to the continuously acting geodynamic forces on the global network and the need to update reference points, but also the introduction of improved models in the data reduction. For the generation of each new frame, the NNR condition is applied. The IERS Conventions contain the adopted constants, parameters, and models that shall be used for data processing (IERS Conventions, 2003).

World geodetic system 1984 (WGS84)

WGS84's geometrical base is comprised of (a) a global coordinate frame for the Earth and (b) a standard spheroidal reference surface (the *datum* or *reference ellipsoid*) for raw altitude data. In addition, the geophysical base is a gravitational equipotential surface model (the *geoid*) that defines the nominal sea level. The geophysical base was periodically updated as the underlying Earth Gravitational Model (EGM96, EGM2008) improved by its ground resolution from 200 km to 10 km.

The geometrical definition of WGS84 identifies Earth's center of mass as the origin of the coordinate system. The *zero-longitude* is identified with the IERS Reference Meridian, which lies 5.31 arcsec east of the Greenwich Prime Meridian for historical reasons related to the NNSS Doppler System.

The WGS84 is defined and maintained by the US Department of Defense. The GPS control segment consists of only a few globally distributed reference stations, whose coordinates together with the broadcast ephemerides are expressed in this datum. The control segment network is also called *zero-order network* as it fixes the reference frame.

Consequently, any GPS user who wants to determine a position in WGS84 is dependent on how accurately known the satellite orbits with respect to the control segment reference stations are. Due to orbit perturbations, the broadcast ephemerides are only approximations and need frequent updates. In absolute positioning mode, results are said to be in the WGS84 datum. In relative positioning model, a baseline vector between two stations can be determined with much higher accuracy. However, the datum is almost completely defined by the base station, which has a much higher uncertainty than the baseline vector. It is therefore desirable to tie GPS baseline vectors to ITRF reference stations using the precise orbit product of the International GNSS Service (which is obtained from hundreds of network stations) and express sets of estimated coordinates related to the most recent ITRF.

The *absolute accuracy* is defined by the true relationship of a position to the coordinate datum. The ITRF is multi-technique based and with a higher number of network stations, for which reason the ITRF provides a higher absolute accuracy than the WGS84 in its current configuration.

As it can be recognized by the defining parameters (Tables 1 and 2), the ITRS and WGS84 coincide within a few centimeters.

Geodesy, Networks and Reference Systems, Table 1 Defining geometrical and geophysical parameters of the Geodetic Reference System, 1980 (GRS80). The dynamical flattening expressed by the dynamical form factor J_2 and determined by satellite orbit perturbations was given preference in the definition. The geometrical flattening f = 1/298.257222101 became a derived parameter (Moritz, 1980)

Defining parameters of GRS80	Symbol	Value
Semimajor axis or equatorial radius	a	6,378,137.0 m
Dynamical form factor	J_2	0.001,082,63
Geocentric gravitational constant (incl. atmospheric mass)	GM	$398{,}600.5 \times 10^{+9}$ m^3/s^2
Angular velocity of Earth rotation	ω	$0.729{,}211{,}5 \times 10^{-4}$ rad/s

Geodesy, Networks and Reference Systems, Table 2 Defining geometrical and geophysical parameters of the World Geodetic System 1984. As opposed to the GRS80, the geometrical flattening f is the defining quantity and the dynamical flattening given by the dynamical form factor J_2 = 0,001081874 is a derived quantity

Defining parameters of WGS84	Symbol	Value
Semimajor axis or equatorial radius	a	6,378,137.0 m
Flattening $(a - c)/a$	f	1/298.257,223,560
Geocentric gravitational constant (incl. atmospheric mass)	GM	$398{,}600.441{,}8 \times 10^{+9}$ m^3/s^2
Angular velocity of Earth rotation	ω	$0.729{,}211{,}5 \times 10^{-4}$ rad/s

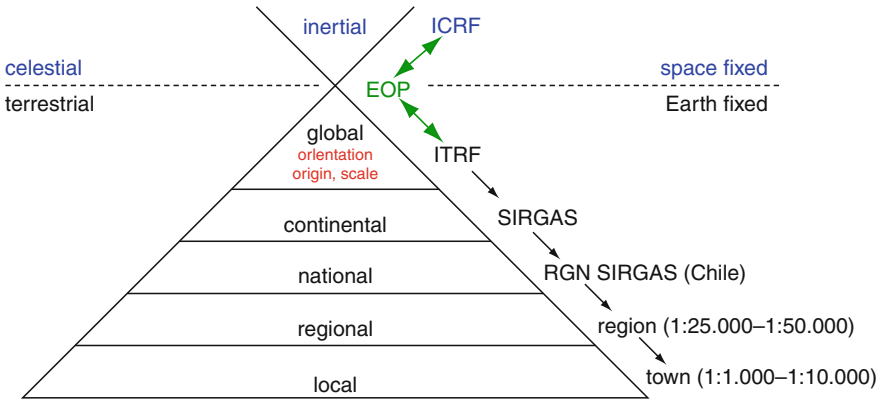
Continental reference systems

Like the surveying practice "working from the whole to the part," continental and national reference frames are established using subsets of reference points defining the global terrestrial reference frame. These frames can be ordered hierarchically beginning with the global terrestrial reference frame (TRF) in which the origin, orientation, and scale is defined. The continental reference network contains the corresponding subset of the global reference points providing the consistent frame and is densified by additional reference points. Consistency to the global reference frame is achieved by the network adjustment with the introduction of the global definition of origin, scale, and orientation represented by the subset of global reference points. National reference frames are established by composing the network of the corresponding global and continental reference points on national territory and additional densifying of national reference points. Thus, the densification of geodetic networks can be done in a consistent way to the most accurate global terrestrial reference frame, the ITRF. One example for consistency between hierarchical reference frames is the geocentric reference frame of the Americas, SIRGAS, and subsequent national reference frames in South-American countries (Figure 1) (SIRGAS). The GRS80 is mostly adopted as the reference ellipsoid for the continental reference frames for consistency reasons to the ITRF (Table 3).

Continental vertical reference systems have to overcome the national height system definitions and made consistent at the borders. Usually in continent-wide measuring campaigns at tide gauges and at national first-order reference points with leveling, GNSS and gravimetry are performed to resolve this task. An example is the European Vertical Reference System (EVRS) in its realization of the European Vertical Reference Frame 2007 (EVRF, 2007).

National geodetic reference systems

GNSS techniques turned the former particular national reference system into being part of a superior continental or global reference system. National geodetic networks are needed to provide a reliable common coordinate system for spatial datasets and geographical information data. At present, most national geodetic network infrastructures consist of continuously operating reference stations (CORS), which are linked to the ITRF. A GNSS CORS comprises a GNSS receiver with its antenna mounted on a stable monument at a safe and secure location equipped with a reliable power supply and a connection to the communication networks for data



Geodesy, Networks and Reference Systems, Figure 1 Hierarchical relationship between different reference frames. The International Terrestrial Reference Frame (ITRF) is tied to the space-fixed International Celestial Reference Frame (ICRF) via the Earth orientation parameters (EOP). The Earth-fixed ITRF defines the origin, orientation, and scale of this global reference frame. Subsequent frames on the continental, national, regional, or local level are consistent with each other if they are including reference points from the superior level (shown here is the example of Chile in South America). Therefore, the definition of the global reference frame is introduced. The shape of the triangle symbolizes the increasing number of reference points. On the top level, there are only a few global reference points (fundamental stations) necessary. On the bottom level, the maximum number of reference points is needed for small scale mapping and cadastre purposes.

Geodesy, Networks and Reference Systems, Table 3 Continental reference frames

Continental reference frames	Acronym	Meaning	Earth model
Africa	AFREF	African Geodetic Reference Frame	WGS84
Asia–Pacific	APRGP	Asia and Pacific Regional Geodetic Project	GRS80
Europe	EUREF	European Reference Frame	GRS80
North and South America	SIRGAS	Geodetic System for the Americas	GRS80

transmission. Different services make this infrastructure available to the users: (a) streaming real-time (raw) data over the Internet (NTRIP); (b) streaming real-time kinematic data (RTK) and differential GNSS data (DGNSS) for applications such as RTK-survey, GIS-data acquisition, and GNSS navigation; and (c) transfer of hourly or daily data files to an ftp-server.

The national coverage with CORS depends on the resources available and of the tectonic situation. A good example is the Japanese GPS Earth Observation Network System (GEONET) with about 1,200 CORS. This network with 30–50 km distance between each CORS is used not only for land survey but also for the monitoring of seismic and volcanic activities.

For historical reasons national geodetic systems may still refer to a best-fitting ellipsoid as a reference surface to the given national latitudes. With the introduction of the hierarchy of reference systems, the global Earth models are becoming more important especially for national reference systems due to consistency.

Vertical national reference systems are usually related to a tide gauge. The *zero-height* can be related to an average level of the seawater height (i.e., mean sea level). Some countries transferred the vertical reference from the tide gauge by spirit leveling to a distant benchmark at a secure location. Vertical reference systems are preferably related to the sea level as the accessible part of the geoid. Currently, vertical reference networks are measured not only by spirit leveling but also by GNSS combined with gravimetric measurements.

Historical reference systems

In the past, horizontal national reference systems were based originally on triangulation networks, when directions could be measured more precisely with theodolites than distances by rods. Triangulation networks had been oriented by astronomical azimuth measurements, setting the horizontal geodetic datum at the fundamental point. The scale was introduced by baseline enlargement networks.

The error in triangulation networks could reach 1–5 ppm with respect to the distance to the datum reference point. When electronics entered the geodetic instrumentation during the 1960s, electromagnetic signals (microwave, laser) allowed the measurement of distances more precisely than directions. Trilateration networks complemented or replaced the triangulation networks.

The introduction of space-geodetic methods in the 1980s, i.e., Navy Navigation Satellite System based on the Doppler effect and the follow-up GPS system, replaced most of the historical national reference systems based on classical triangulation or trilateration methods. The advantages are the global availability and the superior accuracy of the GNSS. The disadvantages are the dependency on the control segment of the GNSS and the availability of energy and communication in order to be able to use it.

The separation of horizontal and vertical reference networks is the consequence of the historical development of the geodetic methods. Modern geodetic space techniques such as VLBI, SLR, and GNSS are three-dimensional methods and can be used to overcome the classical separation. This becomes possible if the geometrical and geophysical properties of the geodetic observations are modeled correctly in the corresponding reference frame.

Global geodesy

International services

The task of global geodesy requires a global infrastructure of geodetic observatories. Currently, many institutions in various countries collaborate voluntarily to enable the production of terrestrial reference frames by sharing observational data, its processing, and geodetic products. Through the use of their human, technical, and financial resources, the contributing institutions are contributing to the products of the international services. This task is voluntarily organized by international services under the umbrella of the International Association of Geodesy (IAG). Even today, no country has been capable of reaching the same results on its own. This fact makes the nonprofit oriented work of international services indispensible to achieve the ITRF and the ICRF.

The international services can be classified according to their domains. In the space domain, the following are the services: International VLBI Service (IVS), International Laser Ranging Service (ILRS), International Global Navigation Satellite System Service (IGS), and International DORIS Service (IDS). In the time domain the Bureau International des Poids et Mesures (BIPM) in Paris hosts the office, which is generating the Universal Time (UT) scale as the time base. In the gravity field domain, the International Gravity Field Service (IGFS) forms the umbrella for the Bureau Gravimetrique International (BGI), International Geoid Service (IGeS), the International Center for Earth Tides (ICET), the International Center for Global Earth Models (ICGEM), and the International Digital Elevation Model Service (IDEMS).

The International Earth Rotation and Reference System Service (IERS) is primarily using the products of the IVS, ILRS, IGS, and IDS for the computation of the ICRF, ITRF, and EOP. All of the services mentioned above are part of the International Association of Geodesy (IAG).

With the development of the geodetic space techniques, it became obvious that an international coordination is beneficial for the users of geodetic products in navigation, land surveying, mapping, and scientific research. Therefore, most of the international services were created during the 1990s to continue previously existing collaborations related to projects.

The IAG introduced a project called Global Geodetic Observing System (GGOS) as its contribution to the Global Earth Observing System of Systems (GEOSS). GEOSS is an effort of the Group of Earth Observation (GEO), which unifies more than 80 countries and more

than 50 international organizations to improve the monitoring and hence the better understanding of global changes. The international services form the backbone for the realization of GGOS. The goal of GGOS is to provide a TRF with a global precision of 1 mm in position and 0.1 mm/year velocity determination (Plag and Pearlman, 2009). This ambitious goal can only be reached if more geodetic observatories with the characteristics of a fundamental station for geodesy will be implemented in a more homogeneous global distribution. The international services themselves try to improve their products so that they match the high precision demands of GGOS. This challenges the design of observing networks, improved observation schedules, new instruments and targets, improvements of the data acquisition and processing, and the homogenization and integration of the models of geodetic space techniques.

If the postulated precision can be achieved in the reference frames, trends in global changes will be resolved in shorter time periods. This compensates the lack of long-term monitoring data at many locations on Earth.

Fundamental station for geodesy

At fundamental reference points for global reference frames one encounters the necessary instrumentation for observing in the space domain, in the time domain and in the gravitational field domain of Earth. These domains correspond to the underlying physical model on which global geodetic reference systems need to be defined.

Each geodetic space method leads to a specific TRF, e.g., VLBI to a VLBI-TRF, SLR to a SLR-TRF or GNSS to one of the GNSS-TRF. Each one of the specific TRFs contains site positions and velocities of the specific instruments. Each one of the different techniques has some advantages, but also weaknesses regarding the realization of reference systems. Geodesists prefer to use all the techniques in a synergetic way in order to minimize the effect of otherwise undetectable systematic errors. Thus, the collocation of different geodetic space technique instruments at some sites is a must in order to achieve the best TRF. The space geodesy instruments also need to be complemented by local sensors in order to obtain a complete set of observables for the models used in data reduction.

A geodetic observatory in which all relevant space-geodetic observation methods are operated is called a fundamental station if it complies with the following characteristics: (a) *Permanency* of the operation by consideration of the timescales of geodynamic phenomena and therefore long-term assured production of geodetic data, (b) *Complementariness* of the operated geodetic space techniques for the best possible coverage of the System Earth affecting phenomena as to obtain the best possible realization of a precise global reference system, (c) *Redundancy* within the selected instruments for quality assurance of the observational data by independently obtained results of the same observables, (d) *Linking* of the technique-specific reference points by their corresponding space vectors, usually determined by a local survey within a local geodetic network, which is also used for the monitoring of the local site stability.

A fundamental station for geodesy enables the link and the transformation from one technique-specific reference frame (e.g., VLBI) to another (e.g., GNSS) by coordinate transformation. Fundamental stations are constitutive for the realization of the ITRF, which is based on observational data produced by VLBI, SLR, GNSS, and DORIS (Hase, 1999).

Instrumentation of a fundamental station

The Geodetic Observatory in Wettzell, Germany, and the Transportable Integrated Geodetic Observatory (TIGO) in Concepción, Chile (see Figure 2) are both examples of a fundamental station for geodesy. Both observatories operate radio telescopes for geodetic/astrometric VLBI, optical telescopes with a laser system for SLR, some GNSS receivers at the site plus an additional regional permanent network for monitoring the regional stability in the space domain. At both sites, *local geodetic networks* are installed that allow to tie the telescope reference points to the GNSS antenna reference points and hence the individual technique-specific reference frames.

As the geodetic space techniques basically measure time intervals, a fundamental station needs to be equipped with frequency standards defining the time unit: the second. The instrument for the time domain is a time and frequency laboratory, which operates at least three atomic clocks based on frequency standards. An issue in timekeeping is redundancy in instrumentation. Otherwise, drifts in time cannot be related to one specific clock. The geodetic observatories Wettzell and TIGO operate three cesium normals for long-term timescale generation and use one of the three available hydrogen masers for short-term time interval measurements.

Concerning the gravity field domain, a fundamental station must measure the gravity periodically with an absolute gravity meter and permanently with a superconducting gravity meter in order to determine the Earth tides. The daily gravitational deformations of Earth's crust reach several decimeter, which is therefore the largest time variable spatial parameter in intercontinental baseline measurements and needs to be considered in the analysis of geodetic space techniques.

Fundamental stations for geodesy produce observational data in the space, time, and gravitational field domain.

In order to perform the observations correctly or to interpret the measurements afterward, additional local sensors are necessary. Meteorological sensors deliver input data for the application of refraction corrections during observation with the telescopes and compute signal travel times through the atmosphere. Hydrological sensors are requested to model seasonal variations in the gravity data. Laser gyroscopes deliver local Earth rotation parameters (as opposed to global determined EOP by geodetic

Geodesy, Networks and Reference Systems, Figure 2 The Transportable Integrated Geodetic Observatory (TIGO) in Concepción, Chile. The foreground shows the Satellite Laser Ranging (SLR)-System, behind it a pillar with Global Navigation Satellite Systems (GNSS)-antennas, and on the right the Very Long Baseline Interferometry (VLBI) radio telescope. All geodetic space techniques are placed at one site to define reference points for the global reference frame ITRF. The space vectors between the different instruments can be measured by a local survey. Not visible are the gravity meter and atomic clocks that are part of TIGO.

space techniques) and seismometers deliver epochs of seismic events to model the nonlinearity of continental drift respective to the site motion.

Summary

The task of geodesy is to establish global geodetic reference systems. These reference systems are defined theoretically in context of the knowledge of physics. Global reference systems are realized by geodetic observatories and measuring reference stations that mark reference points in the space and time domain and in the gravitational field of Earth. Metrology provides the corresponding physical constants and units to be used in the measurements. The cooperative use of the same geodetic method at various measuring platforms creates a geodetic network. A set of observational data from a geodetic network defines a specific geodetic reference frame that relates usually to a specific epoch. Continuous changes of Earth's surface require a permanent monitoring. Different terrestrial reference frames can be tied together by collocating geodetic space techniques.

Fundamental stations for geodesy establish reference points in technique-specific TRF that are tied together by the knowledge of the local spatial vectors between the technique-specific reference points. The ITRF is based on observational data of various space-geodetic methods tied in a synergetic manner at collocated and fundamental stations. The WGS84 is based only on GPS-observations and coincides with the multi-technique-based ITRF within 1–2 cm. Global change studies drive the global precision of TRF to 1 mm in position and 0.1 mm in point velocity. The International Association of Geodesy undertakes an effort with the Global Geodetic Observing System to set up the necessary infrastructure.

The use of geodetic satellite methods in positioning requires a precise knowledge of orbital parameters. Two out of six parameters are dependent on the variable Earth's rotation. Monitoring Earth's rotation requires the creation of a Celestial Reference System. The ICRF is based on quasar positions measured by global VLBI networks. The transformation parameters from the space-fixed celestial reference frame to the Earth-bound terrestrial reference frame are given by the time variable Earth orientation parameters (EOP).

GEODESY, PHYSICAL

V. Chakravarthi
National Geophysical Research Institute, Hyderabad, Andra Pradesh, India

Geodesy is a branch of earth sciences that deals with the measurement and representation of the earth's shape and its gravitational field. Geodesy may be broadly divided into the areas of global (satellite) geodesy, geodetic surveys (national and supranational), and plane surveying (topographic surveying, cadastral surveying). Global geodesy includes the determination of the shape of the earth, its orientation in space and its external gravity field. A geodetic survey is for the determination of the earth's surface and gravity field over a region that typically spans a country or a group of countries. In plane surveying, the details of the earth's surface are determined on a local scale, and thus the curvature and gravity effects are generally ignored. A close relation exists between the above three areas of geodesy in the sense that geodetic surveys are linked to reference frames established by global geodesy, whereas plane surveys are generally referenced to control points established by geodetic surveys. Physical geodesy utilizes measurements and characteristics of the earth's gravity field as well as theories relating it to deduce the shape of the geoid (see *Geoid Determination, Theory and Principles*; *Geoid, Computational Method*) and thus the figure of the earth (Haffman and Moritz, 2005). With sufficient information regarding the earth's gravity field, it is possible to determine geoid undulations, gravimetric deflections, the earth's flattening and other broad characteristics of the earth, such as equatorial ellipticity – the C22, S22 terms of the spherical expansion of the gravity field, the C21, S21 terms related to the position of the rotation axis, etc., with a view to their application in geodesy.

Historical Development of Geodesy

Geodesy is one among the oldest sciences dealing with the planet earth. Superseding the use of sphere as a model for the earth, the oblate rotational ellipsoid became widely accepted as the model of choice in the early eighteenth century. The significance of the gravity field was recognized in the nineteenth century leading to the introduction of the geoid. Later in the second half of the twentieth century, satellite techniques paved the way for realization of the three-dimensional concept of geodesy. A drastic increase in the accuracy of geodetic observations required that time variations be taken into account, which in turn leads the development of four-dimensional geodesy. Extensive material on geodetic history can be found in Smith (1986).

Gravity field of the earth

A body rotating with the earth experiences the gravitational force of the masses of the earth, other celestial bodies, as well as the centrifugal force due to the earth's rotation (see *Earth Rotation*). The resultant is the force of gravity (see *Gravity Field of the Earth*). If the effects of centrifugal force and that of celestial bodies are removed from gravity, the left out component is gravitation. Newton's law of gravitation states that the force of attraction between two point masses m_1 and m_2 is directly proportional to the product of their masses and inversely to the square of the distance between the centers of respective masses and is given as

$$F = \frac{-Gm_1m_2}{r^2}\frac{k}{r}, \tag{1}$$

where, F is the force on m_2, r is the distance between m_1 and m_2, and G is the universal gravitational constant. The minus sign represents that the force is always attractive. By setting the mass at the attracted point to unity, the above equation transforms into the gravitational acceleration

$$g = \frac{-Gm}{r^2}\frac{k}{r}. \tag{2}$$

The vector k may be expressed by the position vectors r and r' in the Cartesian coordinate system as

$$k = r - r', r^T = (X, Y, Z), r'^T = (X', Y', Z'),$$

with the magnitude of

$$k = \sqrt{(X - X')^2 + (Y - Y')^2 + (Z - Z')^2}.$$

However, the earth is composed of an infinite number of differential mass elements, dm. The gravitation on the unit mass results from the integral over the individual contributions. The equation for gravitational acceleration then takes the form

$$g = -G \iiint \frac{r - r'}{|r - r'|^3} \mathrm{d}m. \tag{3}$$

The mass element dm can be expressed as

$$\mathrm{d}m = \rho \mathrm{d}u, \tag{4}$$

where, ρ is density of volume element du.

The representation of gravitational acceleration and related computations are simplified if the scalar quantity potential is used. Because the gravitational field is invariant to rotations

$$\mathrm{curl}\, g = 0 \tag{5}$$

The vector g may be represented as the gradient of a potential U (Sigl, 1985),

$$g = \mathrm{grad}\, U. \tag{6}$$

For a point mass m, we have

$$U = \frac{GM}{r}, \quad with \quad \lim_{r \to \infty} U = 0. \tag{7}$$

For the earth, we have

$$U = G \iiint \frac{\mathrm{d}m}{r} = G \iiint \frac{\rho}{r} \mathrm{d}u, \quad \lim_{r \to \infty} U = 0. \tag{8}$$

The potential indicates the work that must be done by gravitation in order to move the unit mass from infinity to the point under consideration.

From the above relations, it is clear that once the density function ρ was known for the earth, the gravitation can be calculated as a function of position. In reality, detailed density information is available for the upper layers of the earth only, while global models merely consider radial density changes (see *Earth, Density Distribution*). Consequently, gravity field observations have to be used in order to model the exterior gravity field (Torge, 2001).

Properties of the gravitational potential

Gravity potential U satisfies Laplace's equation (Murthy, 1998), i.e.,

$$\nabla^2 U = 0, \tag{9}$$

at all points unoccupied by matter. All the space derivatives of this potential also satisfy Laplace's equation. However, at points occupied by matter, gravity potential satisfy Poisson's equation

$$\nabla^2 U = -4\pi G d, \tag{10}$$

where d is the density at the point under consideration. Green's theorem connecting volume and surface integrations of potential fields has many important applications. If U and U' are two potential functions, whose first derivatives are finite, continuous, and single valued throughout a volume, v, bounded by a closed surface, s, then

$$\int_v (U \nabla^2 U' - U' \nabla^2 U) \mathrm{d}v = \int_s \left[U \frac{\partial U'}{\partial n} - U' \frac{\partial U}{\partial n} \right] \mathrm{d}s, \tag{11}$$

where n is the direction of the outward drawn normal to the surface. The theorem is independent of the size or shape of the surface or the nature of distribution of masses causing U and U'. If U' is assumed to be constant everywhere, and U is the Newtonian potential due to masses distributed both inside and outside the closed surface, s, then

$$\nabla^2 U' = 0, \quad \frac{\partial U'}{\partial n} = 0 \tag{12}$$

reducing equation to the form

$$\int_v \nabla^2 U \mathrm{d}v = \int_s \frac{\partial U}{\partial n} \mathrm{d}s. \tag{13}$$

If U_{in} and U_{out} are, respectively, the potentials due to masses inside and outside s, then U_{out} obeys Laplace's equation, while U_{in} satisfies Poisson's equation, i.e.,

$$\int_s \frac{\partial U}{\partial n} \mathrm{d}s = -4\pi GM. \tag{14}$$

This is called Gauss' law, which states that the total normal gravitational flux over a closed surface is $-4\pi G$ times the enclosed mass. This law holds good irrespective of the type of mass distribution in s. Basic relationships can therefore be established between the observations in the gravity field and the parameters describing the surface.

Disturbing potential

The difference between the actual (measured) gravity potential, W, and the normal gravity potential (constructed matching the known reference ellipsoid with an equipotential surface), U, is called the anomalous or disturbing potential, T (Hofmann and Moritz, 2005). The disturbing potential, T, is numerically smaller than U or W, and captures the detailed, complex variations of the true gravity field of the earth from point-to-point, as distinguished from the overall global trend captured by the smooth mathematical ellipsoid of the normal potential. The relation between the geoidal undulation, N, disturbing potential, T, and the force of gravity (F) computed from the normal gravity potential can be expressed by Bruns' formula as

$$N = \frac{T}{F}. \tag{15}$$

The Stoke's formula which enables one in determining the geoid from gravity data in physical geodesy can be expressed as

$$N = \frac{R}{4\pi F_0} \iint_{\sigma} \Delta g \; S(\Psi) \mathrm{d}\sigma. \tag{16}$$

Here, Δg stands for gravity anomalies, R is mean radius of the earth, F_0 is a mean gravity value over the earth, and $S(\Psi)$ is the Stokes function, a kernel function derived by Stokes in a closed analytical form. The symbol $\iint_{\sigma}$ signifies an integral extended over the whole unit sphere.

Geoid and reference ellipsoid

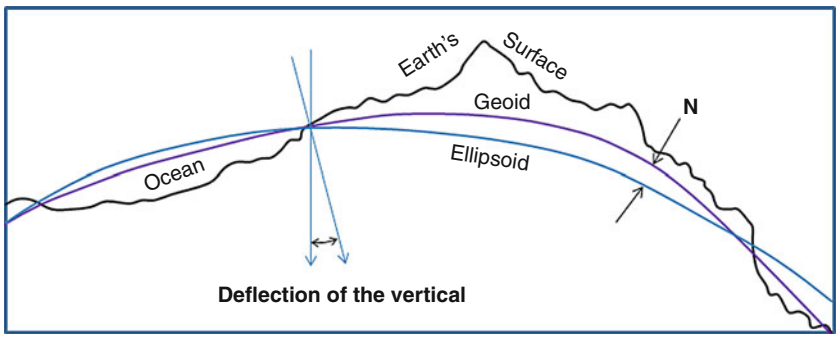
The equipotential surface of the earth's gravity field that coincides with the Mean Sea Level (MSL) in the absence of currents, air pressure variation, etc., is called the geoid. Most of the efforts in physical geodesy are concentrated on the geoid determination with steadily increasing accuracy (Heiskanen and Moritz, 1967). The geoid is important for understanding more about ocean currents and is also used as a reference for traditional height systems and monitoring sea-level change. However, as in the case of any other equipotential surface of the earth's gravity field, the geoidal surface is also an irregular surface and too complicated to serve as the computational surface. The mathematical surface that best fits the geoid is the reference ellipsoid. The relation between the geoid and the ellipsoid is shown in Figure 1. The ellipsoid lies below the geoidal surface in elevated regions and above the MSL over the oceans. The geometrical separation between the geoid and the reference ellipsoid is called the geoidal undulation, N (see *Geoid Undulation, Interpretation*), which generally varies globally between ±110 m.

Gravity measurements are used in physical geodesy to determine the figure of the earth (see *Geodesy, Figure of the Earth*). The earth shape can be equated to a sphere or an ellipsoid depending on the physical problem being dealt. The justification in equating the earth's shape to a model other than that of sphere can be found from two observations, namely, (1) for a rotating sphere having radius, R, and angular velocity, ω, the gravitational attraction at the equator and pole should differ by $R\omega^2$. For the values of R and ω relevant to the geoid, this figure works out to be 3.4 gal as against the observed one of 5.17 gal in gravity values at the equator and the pole. This discrepancy suggests an appreciable departure of the mean shape of the geoid from that of a sphere, also (2) arc measurements at the pole and equator showed that the meridian degree at the pole is longer than that at the equator. The centrifugal acceleration causes the Earth's surface to flatten at the poles and to bulge at the equator. These effects would adequately explain the observed discrepancy in difference of gravity at the equator and the pole. It is thus reasonable to equate the earth's shape to that of an oblate ellipsoid. The earth's gravity field on the ellipsoidal surface varies only with the geographic latitude, φ, and is defined by the International Gravity Formula (Wilcox, 1989, also see *International Gravity Formula*)

$$g(\varphi) = 978.0327(1 + 0.0053024 \sin^2\varphi - 0.0000058 \sin^2 2\varphi)$$

Methods of in situ measurements

Two distinctly different types of gravity measurements are made: absolute gravity measurements and relative gravity measurements. If the value of acceleration of gravity can be determined at the point of measurement directly from the data observed at that point, the gravity measurement is absolute (see *Gravity Measurements, Absolute*). If only the differences in the value of the acceleration of gravity are measured between two or more points, the measurements are relative (see *Gravity Method, Surface*). The most important gravity field quantities measured on the earth's surface are gravity potential differences determined by leveling in combination with gravity measurement; the modulus of the gravity vector determined by absolute and relative gravity measurements; the direction of the gravity vector determined by geodetic-astronomical observations; and the components of the second-order gravity gradient tensor determined by torsion balance measurements.



Geodesy, Physical, Figure 1 Relation between earth's topography, geoid and reference ellipsoid.

Satellite geodesy

Satellite geodesy utilizes artificial satellites and the moon as extraterrestrial targets or sensors. For a point mass earth model, the orbital motion of a satellite is described by Kepler's laws. The actual gravitational field and nongravitational forces create orbital perturbations. Satellites used for geodetic applications differ in design, equipment, and orbit according to the respective observation technique and the mission purpose. Classical measurement methods based on orbital perturbations, introduced and employed from 1960s to 1980s demonstrated the efficacy of satellite observations for establishing large region geodetic control networks and gravitational field determination (see *Gravity Method, Satellite*). Now the Global Positioning System (GPS) has become the most important method for a fast and precise determination of geodetic positions (see *Geodesy, Ground Positioning and Leveling*). Today, the GPS governs three-dimensional positioning at all scales, while laser distance measurements primarily contribute to global reference networks (see *Geodesy, Networks and Reference Systems*). By monitoring the ocean surface, satellite altimetry contributes to gravity field modeling, and high-resolution global gravity recovery is now possible from satellite-to-satellite tracking and gravity gradiometry missions (e.g., GRACE and GOCE missions). The theory of satellite orbits and measurement methods was described in detail by Seeber (1993) and Kaula (1966).

Determining the geoid

An intimate relationship exists between the height of the geoid, the earth's gravitational attraction, and the distribution of mass within the earth. The shape of the geoid does place important constraints on the mass distribution. Moreover, since the local vertical is defined as the direction of the gravitational attraction, which is always perpendicular to the geoid, geoidal anomalies cause deflections of the vertical, which are of vital practical importance for surveyors. Determining the geoid is therefore an important objective in geodesy and geophysics.

In the pre-satellite era, the geoid was determined from the gravity field, which entailed measuring gravitational attraction or deflections of the vertical (or both) at a large number of locations around the Earth. Accuracy and resolution were limited by the number and distribution of observations that were feasible. Since the advent of artificial satellites, geoid determinations have become easier, more accurate, and of higher resolution (see *Geoid, Computational Method*; *Geoid Determination, Theory and Principles*; *Gravity Method, Satellite*). Since the early 1980s, the mean sea level (or oceanic geoid) has been measured directly by a radar-altimeter mounted on a satellite. It is important to remove the effects of waves, storms, ocean currents, and other similar effects, but ultimately this method gives a precision of a few centimeters in geoid height. Although they cannot be used over land, such measurements have yielded unprecedented high-resolution coverage of the geoid over the sea (Rapp, 1982a, b; Sandwell and Schubert, 1982; Cazenave and Monnereau, 1987; Wunsch and Stammer, 1998; Fu and Cazenave, 2001). In recent past, under the NASA Earth System Science Pathfinder (ESSP) Program, the GRACE mission was launched to accurately map the variations in the Earth's gravity field. The mission has provided the scientists an efficient and cost-effective way to map the Earth's gravity fields with high accuracy. The results from this mission yielded crucial information about the distribution and flow of mass within the Earth and its surroundings. The gravity variations that GRACE study include changes due to surface and deep currents in the ocean, runoff and ground-water storage on land masses, and exchanges between ice sheets or glaciers and the oceans. More details on the mission can be found at http://www.csr.utexas.edu/grace. Further, satellite gradiometer mission (see *Gravity, Gradiometry*) named as Gravity field and steady-state Ocean Circulation Explorer (GOCE) was designed and launched by the European Space Agency (ESA) to determine gravity field anomalies with an accuracy of 1 mGal and geoid with an accuracy of 1–2 cm. The GOCE will be gathering data around 20 months to map the Earth's gravity field with unparalleled accuracy and spatial resolution. The final gravity map and model of the geoid will provide users worldwide with a well-defined data product that will lead to a better understanding of the physics of the Earth's interior to gain new insights into the geodynamics associated with the lithosphere, mantle composition and rheology, uplift and subduction processes, a better understanding of the ocean currents and heat transport, a global height-reference system, to serve as a reference surface to study topographic processes and sea-level change, better estimates of the thickness of polar ice sheets and their movement. Further details of the mission can be found at http://www.esa.int/esaLP/ ESAYEK 1VMOC_LP goce_0.html.

Gravity reduction

Gravity measurements provide values for the acceleration of gravity at points located on the physical surface of the earth. Before these measurements can be used for most geodetic purposes, they must be converted into gravity anomalies. Gravity measured on the physical surface of the earth must be distinguished from normal gravity referring to the surface of the reference ellipsoid. The measured gravity values show point-to-point variation on the earth's surface because the measured field depends on latitude and elevation of the station and also due to the effects of topographic masses above sea level (Murthy, 1998). The important corrections to the measured gravity data include latitude or normal correction, free-air correction, Bouguer correction, topographic correction, and isostatic correction (see *Gravity, Data to Anomalies*). The latitude correction calculates the normal gravity on the ellipsoidal surface, the free-air correction extrapolates it to the level of observation, the topographic and Bouguer

corrections account for the gravity effect of the material between the geoid and the ground surface. Isostatic correction removes long-wavelength variations in the gravity field inversely related to topography. The magnitudes of these corrections more often equal to the measured field itself and therefore should be evaluated carefully and precisely.

Gravity models

Two important models are in vogue: (1) effect models and (2) source models (Sünkel, 1989). Effect models deals with the calculation of four parameters to define the best fitting ellipsoid to the shape of the earth. These parameters are the product of the gravitational constant and the total mass of the earth, a dimensionless dynamical form parameter in terms of a second degree spectral coefficient of the earth's gravity field which is closely related to the flattening of the ellipsoid of revolution, the equatorial radius, and the angular velocity. However, the surface defined by the above parameters describes the global feature of the shape of the earth and its gravity field (see *Geoid, Computational Method*; *Gravity Method, Principles*). For more elaborate models, spherical harmonic coefficients have to be derived from surface and satellite data (Rapp and Cruz, 1986). Ditmar et al. (2003) discussed the regularization issues of the computation of spherical harmonic coefficients of the gravity gradiometric data acquired by the GOCE satellite. The effects of high-frequency temporal gravity field sources due to ocean tides, atmosphere, and hydrological mass variations on the GOCE satellite-to-satellite tracking and gradiometer measurements and on the corresponding geopotential model recovery are reported by Han et al. (2006) (see *Gravity Field, Temporal Variations from Space Techniques*). On the other hand, source models presume a density model having radially changing but laterally constant mass density. Such a density model can be described by a few parameters and can therefore be compared with an ellipsoidal model.

Conclusions

The gravity field of the earth, which forms the backbone for the studies relating to geometrical geodesy and physical geodesy, can be described in terms of potential, its derivatives both vertical and horizontal in several scales involving global, regional, and/or local information. The gradiometer missions will probably replace, even though not fully but to a large extent, the surface observations, thereby paving the way for more detailed information on geoid with unprecedented accuracy.

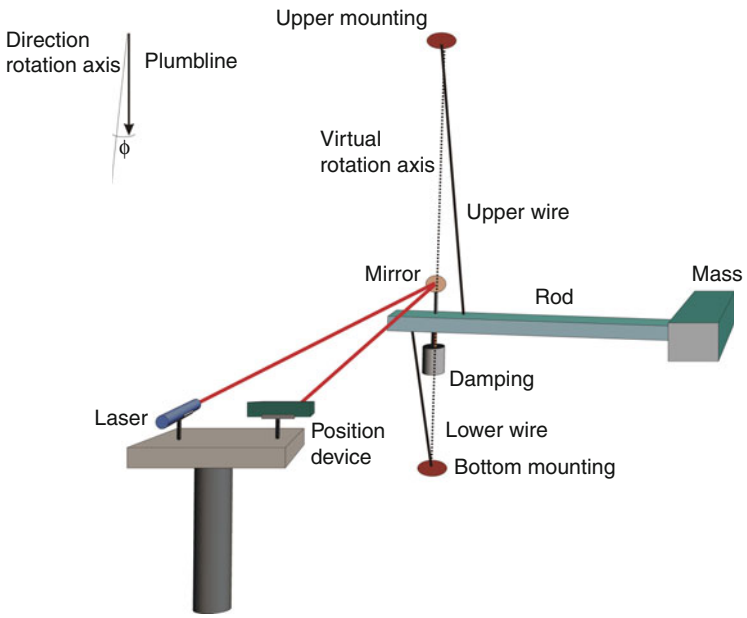
Definition

The ultra broad band horizontal geodetic pendulum is a device designed to measure the earth crustal movement in the range of periods typical of secular movements to seismic deformations. It measures the variation of the plumb line (vertical) with respect to the direction of two earth-fixed reference points (Zadro and Braitenberg, 1999).

Instrument description

The vertical pendulum is made of a mass suspended by a rod or wire that can oscillate in the vertical plane about a horizontal axis. For small amplitudes the oscillation period T depends on the moment of inertia K, the distance s of the center of mass from the rotation axis, the mass m, and the gravity acceleration g following the equation $T^2 = \frac{4\pi^2 K}{mgs}$. If the pendulum is allowed to oscillate about an inclined axis, the angle of the rotation axis with the vertical being φ, the period of oscillation is defined by $T^2 = \frac{4\pi^2 K}{\sin\varphi\, mgs}$. For small values of the angle φ, the rotation axis is near to vertical and the pendulum is called horizontal pendulum. Compared to the vertical pendulum of equal dimensions, the horizontal pendulum has an increased oscillation period. The first realizations of a horizontal pendulum were done in 1830 (Lorenz Hengler), and developed further by Zöllner (Zöllner, 1871, 1872). The construction of Zöllner is made of a horizontal rod on which at one end a mass is attached. At the other end and at a small distance from it the rod is connected by two wires to a housing structure (see Figure 1). The two wires are near to vertical above each other. Supposing the upper fixed point is shifted with respect to the lower fixed point along the Meridian, so that the line connecting the two fixed points makes an angle φ with the vertical, then the rod has its equilibrium position in the Meridian plane. If the direction of the vertical changes due to the influence of the gravitational attraction of the moon or sun toward east by a small angle α, the rod will rotate toward east by the angle $\frac{\alpha}{\sin\varphi}$. A similar rotation of the rod will be produced by the inclination of the housing structure or by a horizontal eastward movement of the housing structure as could be provoked by the passage of a seismic wave. In order to have an instrument sensitive in both NS and EW directions, usually a couple of orthogonally mounted pendulums is installed at one station. The movement of the rod is recorded by a space-sensitive device, as a magnetic induction coil mounted at the extreme of the rod or by an optical device that records the light ray reflected by a mirror mounted on the rod (e.g., Braitenberg et al., 2006).



Geodetic Pendulums, Horizontal Ultra Broad Band, Figure 1 Cartoon of a horizontal geodetic pendulum. The rod with the mass rotates in the horizontal plane about the virtual rotation axis. The angle φ of the virtual rotation axis with the plumb line is essential for the amplification factor of the pendulum.

Grotta Gigante horizontal pendulums

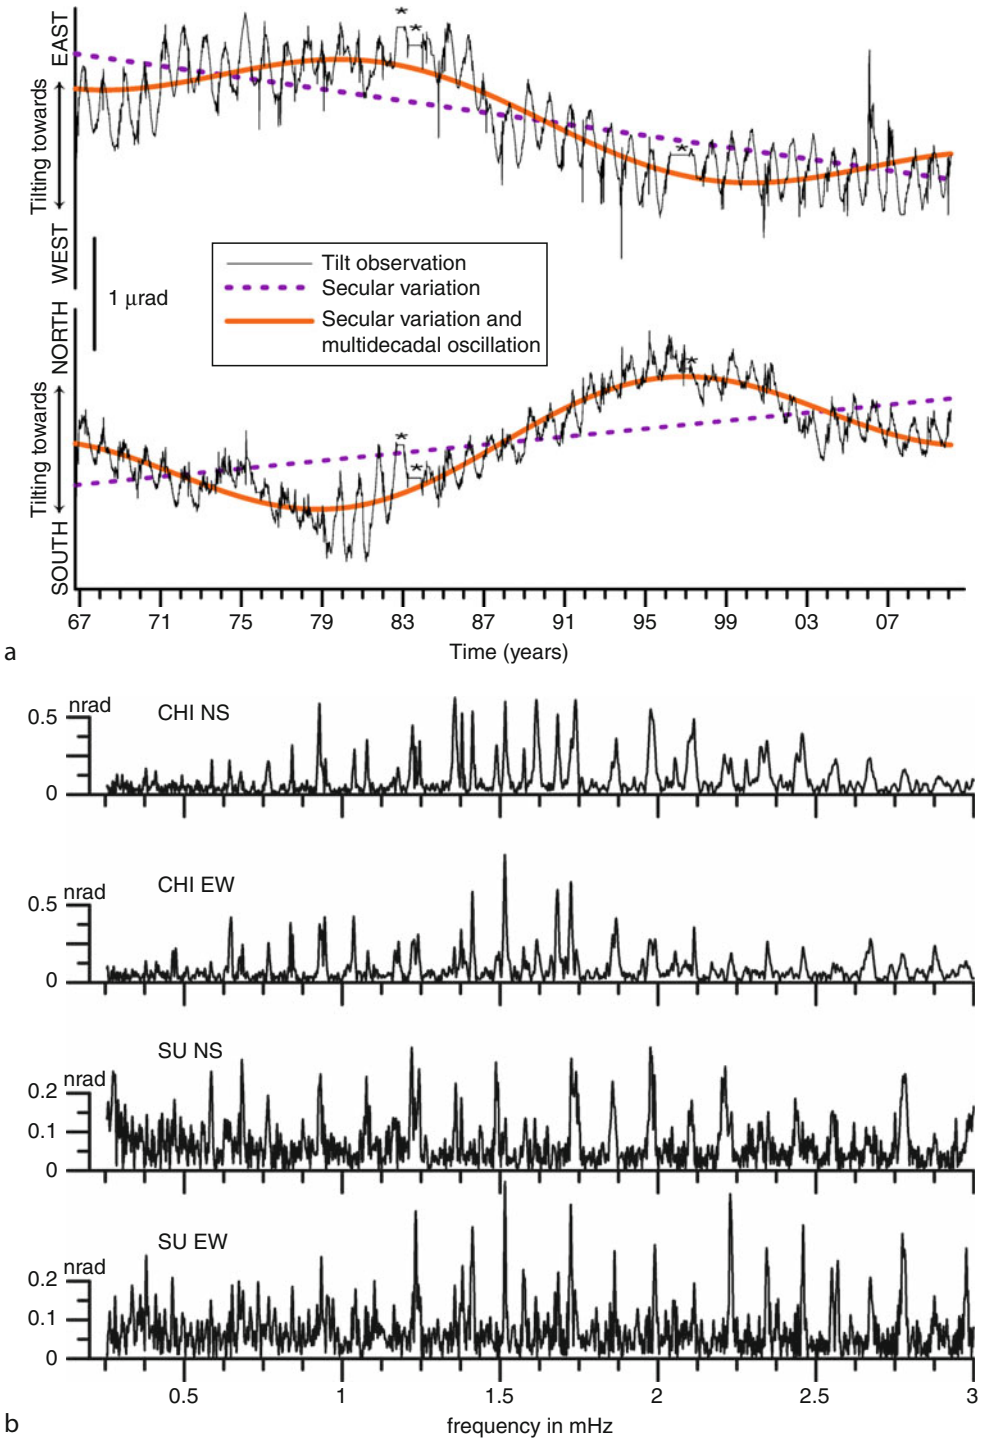
The largest prototype of a horizontal pendulum was built in 1959 by Antonio Marussi (Marussi, 1959) in a natural cave (Grotta Gigante) situated in the Italian Carst at 275 m above sea level near the town of Trieste, Italy. Trieste is a port on the Adriatic Sea, 150 km East of Venice. The upper and lower wires of the horizontal pendulum-rod are fixed directly into the rock, at a vertical distance of 95 m. The oscillation period of the pendulum is near to 6 min, and damping is critical. The original recording of the pendulum was on photographic paper, which was changed to a digital system in the year 2002. The instrument is very stable, and records multi-decennial crustal movements. The digital system has a sampling rate of 25 Hz, which makes it possible to observe fast movements of the pendulum caused by the passage of seismic waves. The smallest resolved tilt is 0.009 nrad (1 nrad = 10^{-9} rad).

The continuous record of tilt extends from 1966 to the present and demonstrates that the cave deforms continuously due to very different causes that act independently from each other. Each generates a characteristic signal contributing to the complex deformation of the cave. The graph in Figure 2a displaying the entire tilt sequence shows a secular drift that adds to an oscillation with a period of 33 years. The long-term movement is a tilt of the cave toward NW, parallel to the coastline, and is probably tied to a deformation of the Adria plate that is bent below the load of the sediments in front of the South Alpine mountain chain. The cause of the multi-annual oscillation is presently unknown, and could be tied to large-scale deformations imposed by the active deformation due to the collision of the Adria and the Eurasian plate, causing the seismicity at the contact between the sedimentary plain and the South Alpine mountains. The tilting of the cave with an annual period (mean period = 365.6 days and mean amplitude = 300 nrad for years 1966–2008; oscillation amplitude defined as half the peak-to-peak signal) has a characteristic orientation with extreme values in mid September and mid March. The annual tilting is due to the combined effect of the deformations due to the annual surface temperature variations (sinusoidal with an amplitude of 9.2°C) and to the variable loading of the Adriatic Sea.

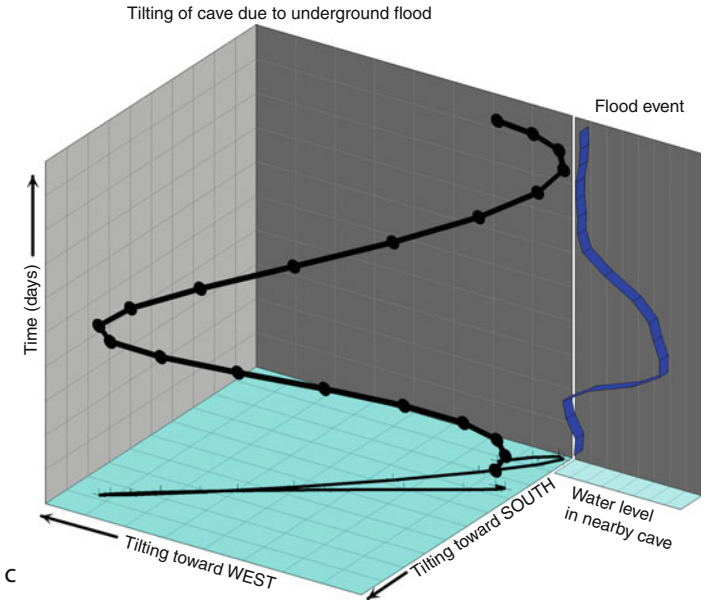
The earth tides generate a tilting that is due to the regular deformation of the earth in response to the gravitational attraction of moon and sun, with predominantly diurnal and semidiurnal periods. The amplitude of the earth tide tilting is 39 nrad, the gravitational attraction and the load of the ocean tide contribute to an additional tilt signal at the same tidal frequencies, but phase shifted with respect to the astronomical earth tide, leading to a total tidal tilting signal with a maximum amplitude of 90 nrad. The fault rupture of an earthquake leads to the generation of the well-known seismic waves that propagate along the earth surface and through earth's interior. Another movement caused by earthquakes is the oscillation of the earth at its resonance-frequencies, called the free oscillations. The crustal rupture causes the earth to pulsate in the spherical and torsional oscillation modes. The gravest spheroidal mode 0S2 where the earth deforms with an ellipsoidal pattern has a 54-min period, the more complicated modes having shorter periods. The gravest torsional mode 0T2 has a period of 43.9 min, one earth hemisphere rotating with respect to the other around a central axis (Bolt and Marussi, 1962). The geodetic pendulums of the Grotta Gigante station are the only instruments in the world that recorded the free oscillations generated by the greatest (M = 9.5, Chile, 1960; NEIC, 2010), third greatest (M = 9.1, Sumatra Andaman Islands, 2004; NEIC, 2010), and fifth greatest earthquake (M = 8.8; Chile, 2010; NEIC, 2010) ever recorded in instrumental seismology. The observations showed that the amplitude of the free oscillations of the Chile 1960 earthquake were up to four and a half times greater than those generated by the Sumatra-Andaman 2004 event (Braitenberg and Zadro, 2007), the greatest enhancement being found for the torsional modes (see spectrum in Figure 2b). The cave deforms not only due to periodic signals, similar to the ones we described before, but also due to transients, as pressure variations and underground water flow. The underground water flow is particularly interesting in carstic areas: The water from rainfall penetrates into the rock through pores and cracks until it finds an impermeable layer along which it flows downstream toward the sea. The Italian Carst is particular in this respect, as an entire surface river with an average flow of 9 m^3/s reaching peaks of 100 m^3/s during strong rainfalls, with extreme values up to 390 m^3/s, disappears after its passage through a natural cave (Skocjanske Jame, 2010). The underground river remains concealed for 33 km, until it emerges as a spring from the foot of the Carst and flows into the Adriatic Sea. The path of the flow is unknown, but its presence is identified by the geodetic pendulums. The cave responds in a characteristic direction to floods, with a signal that lasts in total between 4 and 8 days. The length of the deformation is indicative of the time the underground river takes to accommodate for the increased influx of water through the rainfall. The hydrologic-induced tilt signal is up to 300 nrad according to the existing records. Table 1 summarizes the different causes that generate a tilting of the cave together with the expected amplitude.

Besides the horizontal geodetic pendulums, other types of instruments exist with which tilt is observed. In the horizontal water tube, the differential water level at each end of the tube is measured by laser interferometry (e.g., Ferreira et al., 2006). The length of the tube extends over several tens of meters. Presently active instruments are found, e.g., at the Finnish Geodetic Institute, Metsähovi mine (Ruotsalainen, 2008) and in California (Piñon Flat Observatory, University of California, San Diego). Vertical pendulums are mounted in boreholes for measuring tilt and the displacement of the pendulum is detected by a capacitive transducer with resolution of 1 nrad; examples

are the tiltmeters of the Geodynamic Observatory Moxa, Thuringia, Germany. Application of a tilt array of this type to monitor pore pressure variations and minor earthquakes are given by Jahr et al. (2008). Portable short-base tiltmeters are used for volcanic monitoring, where the expected tilts are larger than for crustal deformation studies and therefore require less resolution and stability in time. The electronic tiltmeters record the movement of an air bubble in a conducting fluid. These instruments are used for volcanic monitoring of the USGS.



Geodetic Pendulums, Horizontal Ultra Broad Band, Figure 2 (Continued)



Geodetic Pendulums, Horizontal Ultra Broad Band, Figure 2 The graph shows the continuous time series of tilt recorded by the horizontal geodetic pendulum of Grotta Gigante. (**a**) *Black continuous line* are the NS and EW records with daily sampling. The regular oscillation is the annual tilting. The multi-decadal variation is the sum of an oscillation of 33 years (*thick line*) and a linear variation (*dashed line*). The spikes are due to tilting caused by floods of the underground carstic water flow. Asterisks mark data interruptions. (**b**) Spectral amplitudes in the frequency range of the free oscillations following the earthquakes of Chile 1960 (CHI-NS, CHI-EW) and Sumatra-Andaman 2004 (SU-NS, SU-EW). (**c**) The tilting of the cave due to the underground flooding: The *thick line* shows tilting of the cave during the flood and the z-axis is the time. The *thinner line* shows the tilting during the flooding in the EW and NS direction. Furthermore, the water level in a nearby cave during a flood is shown.

Geodetic Pendulums, Horizontal Ultra Broad Band, Table 1 Identified causes that deform the Grotta Gigante cave with characteristic periods and amplitudes

Cause of deformation	Characteristic period	Tilt maximum observed amplitude	Notes
Plate tectonics secular movement	Secular movement, near to static	31.4 nrad/year	
Plate tectonics multi-annual oscillation*	33 years	316 nrad	
Annual variation*	365.6 days	300 nrad	Orientation toward N60°E in mid March and toward N240°E in mid September
Earth tides*	Daily, half daily	39 nrad	
Ocean loading*	Daily, half daily	60 nrad	
Free oscillations* of the earth	54 min to a few minutes	Up to 0.7 nrad	
Underground water flow	A few days	Up to 300 nrad	

*Oscillation amplitude defined as half of the peak-to-peak excursion

Summary

The ultra broad band horizontal geodetic pendulum measures the inclination of a reference axis with respect to the vertical. The prototype installed in the Giant Cave in North-Eastern Italy has shown that the deformations that affect the upper crust are due to tectonic effects (seismic waves, free oscillations of the earth, coseismic deformation, tectonic plate deformation) and due to environmental effects (thermoelastic deformation, hydrologic water flow, ocean loading). The existing record of the greatest seismic event ever measured, the Chile 1960 earthquake, allows to make an absolute magnitude comparison with recent events due to the fact that amplitude factor, the instrumentational setup, and the location are perfectly known and controllable today.

GEODYNAMICS

Alessandro M. Forte
GEOTOP Département des Sciences de la Terre et de l'Atmosphère, Université du Québec à Montréal, Montréal, QC, Canada

Definition

Geodynamics (noun, functioning in the singular). A broad, multidisciplinary branch of geophysics that investigates the causes and consequences of the forces acting on and inside the solid Earth and the rock movements and deformations they produce.
Geodynamic, geodynamical (adjective). Relating or pertaining to the field of geodynamics.

The term geodynamics originates from two root words of Greek origin: *geo-*, relating to the Earth, and *dynamics*, the branch of physics that involves the study of forces acting on bodies and the changes in motion they produce. As the name therefore suggests, the focus of geodynamics is on the forces that act on the solid Earth and the motions and deformation they produce.

Historically, in the late nineteenth and early twentieth century, when geodynamics was emerging as a distinct field of study, it also included the earliest systematic investigations of earthquakes and propagating seismic waves. These studies later evolved into a separate branch of geophysics called seismology. Modern geodynamics investigates forces and movements over timescales that exceed the characteristic periods of propagating earthquake waves and corresponding Earth oscillations (i.e., approximately ranging from a second to an hour). On these longer timescales, for geodynamic processes ranging from Earth tides (hours to years) to postglacial rebound (thousands of years) and ultimately plate tectonics (millions of years), the deformation is sufficiently slow that the acceleration of the material is entirely negligible (i.e., the deformation is quasistatic).

The forces studied in geodynamics mainly originate from lateral changes in density $\Delta\rho$ on or within the Earth, thereby producing buoyancy or Archimedes forces $\Delta\rho\, g$ per unit volume, where g is Earth's gravitational field. For example, lateral density variations due to thermal plumes in the convecting mantle give rise to buoyancy forces $\Delta\rho\, g = \alpha\rho\Delta T\, g$, where α is the coefficient of thermal expansion and ΔT are the lateral temperature anomalies between the plumes and ambient mantle. These thermal buoyancy forces drive the convective circulation in the mantle and the corresponding surface motions of the tectonic plates. Similarly, the topographic depressions Δh at the Earth's surface left behind by the rapid melting of the massive ice sheets that once covered Canada and Scandinavia about 20,000 years ago, give rise to buoyancy forces $\Delta h\rho\, g$ per unit area that are focused at the surface (here ρ is the average density of the crust). Postglacial rebound is the slow viscous creep of the mantle and the resulting uplift of the crust produced by these surface forces.

There are also external forces $\rho\,\nabla\phi$ where, for example, $\nabla\phi$ is the gradient of the gravitational potential generated by the attraction of the Sun and Moon, or it may represent the centrifugal force due to Earth's diurnal rotation. For the former case, these forces produce the tidal deformations in the Earth or, for the latter case, they produce the oblate ellipsoidal shape of the Earth. These tidal and rotational forces change over an enormous range of timescales, from a few hours to hundreds of millions of years, and they produce globally distributed deformations throughout the Earth's interior and at the surface.

A major area of geodynamics research is the measurement and the quantitative modeling of forces and deformations in the crust, underlying lithosphere and deep mantle. An understanding of the relationship between force and deformation requires detailed knowledge of the rheology of the solid Earth that depends on the ambient temperature, pressure, and the timescales over which the forces are applied. For example, on timescales corresponding to the tides, the solid Earth behaves like an imperfectly elastic body. However, on the much longer timescales of mantle convection and plate tectonics, the solid mantle effectively behaves like a fluid medium with an extremely high viscosity.

The effective viscosity η of the mantle is one of the most important parameters in geodynamics because it controls the speed at which the mantle may flow and deform in response to buoyancy forces. The characteristic flow speed is $v = \Delta\rho g L D/\eta$ where L represents the lateral dimension (distance) of the density anomalies and D is the depth (typically that of the mantle) over which they exist. Flow velocities in the mantle are of the order of several centimeters per year, similar to those of the moving surface plates. This flow velocity determines the efficiency of convective heat transport across the mantle and hence governs the thermal (and chemical) evolution of the Earth. For this reason, a great deal of work in the second half of the twentieth century, and up to the present day, is dedicated to constraining the value and spatial variation of mantle viscosity from the analysis of various geodynamic data sets (e.g., from postglacial uplift rates, geoid anomalies, long-term sea level variations, plate motions).

The range of geophysical phenomena studied in geodynamics has increased greatly over the course of the twentieth century. For example, an early treatise on geodynamics by Love (1911) provided a detailed mathematical description of a range of problems that included the isostatic support of continents, the height of mountains chains and the forces required to maintain them, the Earth tides, the propagation of earthquake waves and the oscillations of the entire Earth produced by earthquakes. With the advent of plate tectonics and the acceptance that some form of thermal convection in the mantle is necessary to drive the plate motions, the scope of geodynamical investigations has been greatly enlarged.

Modern geodynamics research deals with a multitude of problems relating to plate tectonics and heat transfer in the Earth, as well as numerous studies of the rheology of the mantle and the crust-lithosphere system that bear directly on the efficiency of heat transport across these different structures. The very wide range of problems now included in contemporary geodynamics is well illustrated by Turcotte and Schubert (2002) and Schubert et al. (2004). Depending on the specific problem, it is difficult, if not impossible, to devise analog laboratory experiments that can properly incorporate the complex spatial variations of the physical properties of the solid Earth. This difficulty is further compounded when it is necessary to model geodynamic processes over extremely large spatial and temporal scales, as in the case of mantle convection and plate tectonics. To address these major challenges, the rapidly growing field of *computational geodynamics* has emerged, in which very complex problems in Earth dynamics are now routinely solved by numerical simulations on high-performance computers (e.g., Ismail-Zadeh and Tackley, 2010).

GEOELECTROMAGNETISM

Antal Ádám, László Szarka
Geodetic and Geophysical Research, Institute of the Hungarian Academy of Sciences, Sopron, Hungary

Definitions and scope

Geoelectromagnetism, in the broad sense, includes the application of classical electrodynamics to various interrelated regions of space (Sun, interplanetary field, magnetosphere, ionosphere, atmosphere), on and below the Earth surface (near-surface regions, crust, upper mantle [or lithosphere and asthenosphere using alternative nomenclature], lower mantle, and Earth's core). Over the Earth surface the dominant phenomena of geoelectromagnetism are electromagnetic waves, in a wide spectrum. The electromagnetic waves do not penetrate deep into the Earth. Instead, the propagation of the electromagnetic field inside the Earth is a diffusion process.

In a narrower sense, geoelectromagnetism means the application of time variations of natural electromagnetic fields to the study of the electric resistivity distribution

in the Earth's interior, which gives indispensable information about the structure, composition, and processes of the subsurface.

The term electromagnetic geophysics is also used, but electromagnetic geophysics in general includes all exploration techniques, which may employ not only natural sources, but various man-made sources as well. In order to investigate very deep structures, extremely large-size sources of natural electromagnetic field variations should be used. In the following, we restrict ourselves to those geoelectromagnetic methods that apply natural electromagnetic field variations as the source to study deeper (lithosphere, asthenosphere, and upper mantle) geological structures.

Introduction

Of three electromagnetic parameters (magnetic permeability, electrical resistivity, and permittivity) associated with the subsurface geology, only the magnetic permeability and the electrical resistivity are relevant because of the diffusive nature of the electromagnetic field propagation. The magnetic permeability is usually assumed to be constant, which – apart from some exceptional cases – has been seen to be a good assumption. The electrical conductivity σ of various earth materials varies over an extremely wide range; therefore, its spatial distribution reflects most structural/physical/petrological changes in the Earth. In practice, instead of the conductivity, the electrical resistivity ρ, where $\rho = 1/\sigma$, is often used. The ohm-meter (or Ωm) is the unit of measurement.

These methods are classified on the basis of the measured geoelectromagnetic field components. When only the electric field variations are measured, we speak about the *telluric* or *Earth current* technique, or *tellurics* (TT) for short. If only the geomagnetic field components are measured (usually as a function of the period of the time variations of the electromagnetic field), the method is known as "*Geomagnetic Deep Sounding*" (*GDS for short*), or by its other name: "*MagnetoVariation Sounding*" (MVS). Electrical conductivity anomalies (i.e., the zones of concentration of electric current) can be located by using the so-called "*Magneto-Variation Profiling*" (MVP), where the so-called induction vectors point to the current concentrations. A more sophisticated technique is the "*Magnetotelluric Sounding*" (MTS) or shortly "*magnetotellurics*" (MT), where both the electric and magnetic field variations are measured in a broad period range (see Skin Depth).

Although the Geomagnetic Deep Sounding (the MagnetoVariation Sounding) is more or less coeval with observatory records (see, e.g., Lamb, 1883), the history of almost all these variants dates back to about six decades. The MVP and its induction vectors were introduced in the second half of 1950s in studying the anomalous behavior of geomagnetic variations in North Germany (e.g., Schmucker, 1959; Wiese, 1965). The theoretical basis of the magnetotelluric (MT) method was laid by Tikhonov (1950) and Cagniard (1953). The first MT field measurements were carried out in the early 1960s. Application of the tellurics (i.e., the simplest technique) to investigate large sedimentary basins started in the middle of the twentieth century in Hungary (Kántás, 1954) and elsewhere.

In the following, the principles of these geoelectromagnetic methods will be presented. We summarize the governing equations of MVS, MVP, and MT techniques and illustrate their field application. The telluric measurements being the special case of the magnetotelluric method used in the so-called S-interval (see Figure 4) where the phase approximates zero, is not discussed here in detail.

Magnetovariational sounding (MVS) and magnetovariational profiling (MVP)

By simultaneously measuring the time variations of the horizontal and vertical geomagnetic field components at a site, it is possible to determine the subsurface electrical resistivity. Carrying out the measurements in a broad period interval, the depth-dependence of the electrical resistivity can be estimated (see Skin Depth).

For a spherical Earth, this technique is able to provide information about the Earth's conductivity down to the depths of 1,200–1,800 km in the mantle (Bailey, 1973; Rokityansky, 1982). For shallower studies (i.e., down to depths of less than approximately 100 km) the Earth's surface may be considered as plane.

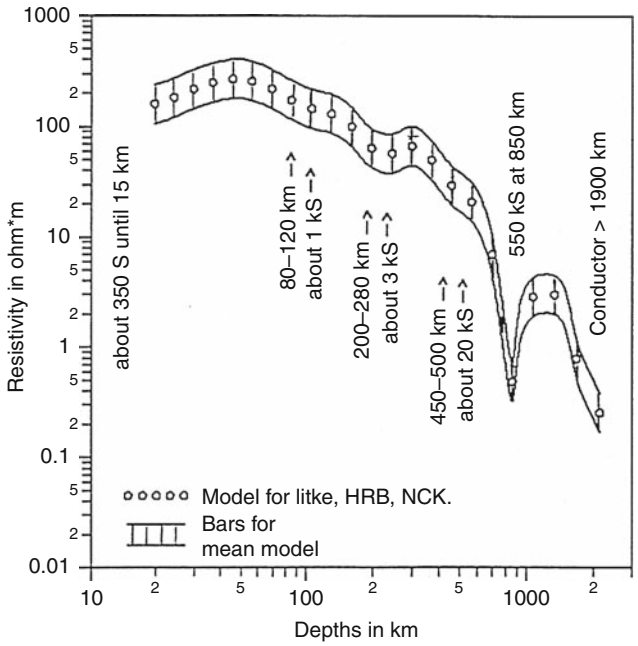
The magnetovariational profiling (MVP) aims at locating large lateral inhomogeneities of the Earth's crust and upper mantle. In the recent book by Berdichevsky and Dmitriev (2008), this theme is discussed in detail under the title "*Magnetovariation Studies*."

Deep mantle MVS studies

We follow Rokityansky (1982) nomenclature concerning the deep mantle studies. The field source of so-called Dst geomagnetic variations (used recently by Yu Semenov et al., 1997; Yu Semenov et al., 2008) is the ring current at the equator. When the vertical magnetic field of the ring current source is approximated by the first term in its spherical harmonic expansion, that is, $H_z \sim P_1^0(\cos\theta)$ where P_1^0 is the associated Legendre function in the first term of the expansion, the ratio of vertical (H_z) to horizontal $\left(\sqrt{H_x^2 + H_y^2}\right)$ field component can be converted into the complex apparent resistivity (Rokityansky, 1982). (In standard practice, x and y are the horizontal components, with the x-axis pointing northward, and the positive z-axis directed vertically downwards into the ground.) If the magnetic permeability (μ), the radius of the Earth (R), the geomagnetic colatitude of an observatory (Θ), and the angular frequency (ω) in the assumed time-dependence $e^{i\omega t}$ are known, then the apparent resistivity ρ is given as

$$\rho(\omega) = \frac{i\omega\mu}{4} R^2 \tan^2\Theta \left| \frac{H_z(\omega)}{\sqrt{H_x^2 + H_y^2}} \right|^2 .$$

Yu Semenov et al. (1997) used the daily mean values of geomagnetic observatories. Their first step in the analysis was a rotation of the observatory reference systems to determine the maximum Dst field (Schultz and Larsen, 1983). For the agreement between the horizontal Dst field and the first spherical harmonic model of the source, a coherence test was carried out. The period ranges, which were in contradiction with the source model, were excluded from further analysis. The transfer functions between the vertical (H_z) and horizontal $\sqrt{H_x^2 + H_y^2}$ components were computed only if the coherence values were greater than 0.7 between them. The transfer functions were converted into apparent resistivity. Yu Semenov et al. (1997) combined the magnetovariational data with the results of magnetotelluric sounding in observatories and estimated, by using a robust technique, the resistivity model below the observatories. The mean geoelectric structure of the mantle below the Pannonian Basin is shown in Figure 1 on the basis of data from Nagycenk, Litke (Hungary), and Hurbanovo (Slovakia). A more detailed combined MV + MT study in East-Central Europe pointed out a significant difference in the Precambrian and Phanerozoic mantle structures, separated by the Tornquist-Teisseyre Zone (TESZ line; Yu Semenov et al., 2008).



Geoelectromagnetism, Figure 1 The mean geoelectrical structure of the mantle in the Pannonian Basin using the magnetic records of Nagycenk, Litke (Hungary), and Hurbanovo (Slovakia) for magnetovariational soundings (Yu Semenov et al., 1997).

Schmucker (2003) proposal for the generalized horizontal spatial gradient method (gSHG) is promising for a reliable combination with the MT method as stated recently by Vozar and Semenov (2010) modeling. Kelbert et al. (2009) inverted long period geomagnetic response functions to derive a global-scale 3D model of electrical conductivity variations in the Earth's mantle. Their results – one order magnitude conductivity increase in the subduction zones – support the presence of at least some water in these transition zones.

Magnetovariational profiling

It is evident from the Biot–Savart law that on the surface, just over and near the center of a horizontal lineament of high electrical conductivity in the subsurface, in which the telluric currents are gathered, the measured vertical magnetic component H_z is zero. More precisely, H_z is changing sign along a profile, crossing the lineament. At the same time, the horizontal component $\sqrt{H_x^2 + H_y^2}$ has a maximum over the lineament, with a moderate decrease on both sides. Therefore, the $H_z \Big/ \sqrt{H_x^2 + H_y^2}$ ratio can be drawn as a vector, that is, a quantity having magnitude and direction. It is called "*induction vector*" or "*induction arrow*." Along a measuring profile crossing the lineament, the induction arrow will change sign. Induction arrow profiles at various periods provide useful depth information. The origin of the method goes back to the resolution of a paradox, namely when the vertical component of substorms in two German geomagnetic observatories (Wingst and Niemegk) proved to be of opposite sign. This paradox was attributed later to the North German anomaly (Schmucker, 1959).

The source of the method is the same as that of all other geoelectromagnetic methods and a similar time series analysis is needed to separate the variations of different periods (frequencies) for single station and array measurements too. Array and single site transfer functions are applied.

Array transfer function

The normal field is that which would exist in the presence of one-dimensional layered structure in which the inhomogeneity is embedded. The anomalous field is then most simply defined as the total measured field minus the normal field.

Due to the linearity of the Maxwell field equations, there exists a linear relationship between the anomalous and normal magnetic field components (Schmucker, 1970).

$$H_{xa} = T_{xx}H_{xn} + T_{xy}H_{yn} + T_{xz}H_{zn} + \varepsilon_x$$
$$H_{ya} = T_{yx}H_{xn} + T_{yy}H_{yn} + T_{yz}H_{zn} + \varepsilon_y$$
$$H_{za} = T_{zx}H_{xn} + T_{zy}H_{yn} + T_{zz}H_{zn} + \varepsilon_z$$

where H_x, H_y, and H_z are the field components and ε is the error of the relation. All these T quantities are period dependent and complex. Subscript "a" and "n" refer to anomalous and normal parts, respectively. The assumption that the source field is uniform, allows the normal part of the H_z component to be taken as zero. Accordingly, the third term on the right-hand side of equations can be neglected.

Single site transfer function
With the following condition

$$H_{zn} \ll H_{za},\ H_{xa} \ll H_{xn},\ H_{ya} \ll H_{yn}$$

the relation between the vertical and horizontal components is

$$H_{za} = T_{zx}H_x + T_{zy}H_y,$$

where T_{zx} and T_{zy} are complex values.

Induction vectors (arrows) are computed separately from the real and imaginary parts of the T values. In practice two variants are used (Wiese, 1965; Parkinson, 1959). The vector lengths in both cases are the same:

$$L_r = \sqrt{(\mathrm{Re}T_{zx})^2 + (\mathrm{Re}T_{zy})^2},$$

$$L_i = \sqrt{(\mathrm{Im}T_{zx})^2 + (\mathrm{Im}T_{zy})^2}.$$

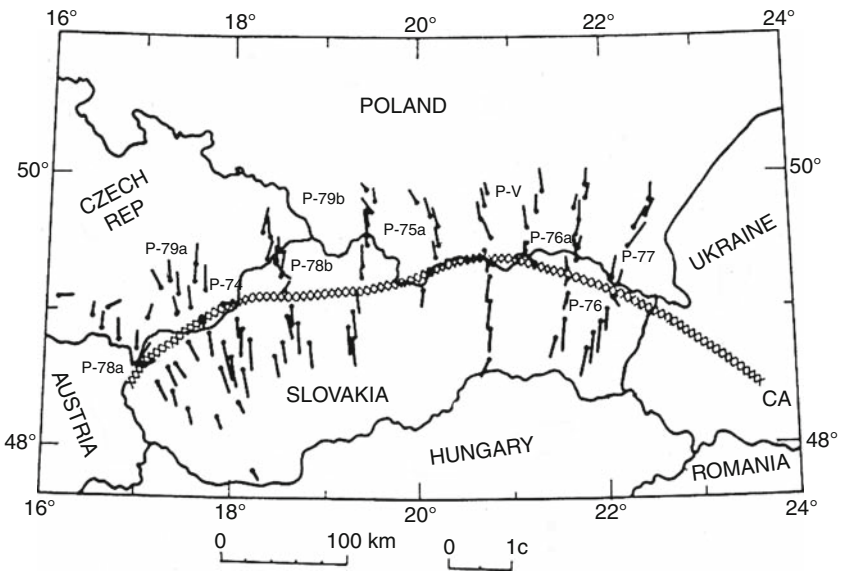
The azimuth of the Wiese vector (arrow)

$$\phi_w = \tan^{-1}\left(\frac{T_{zy}}{T_{zx}}\right)$$

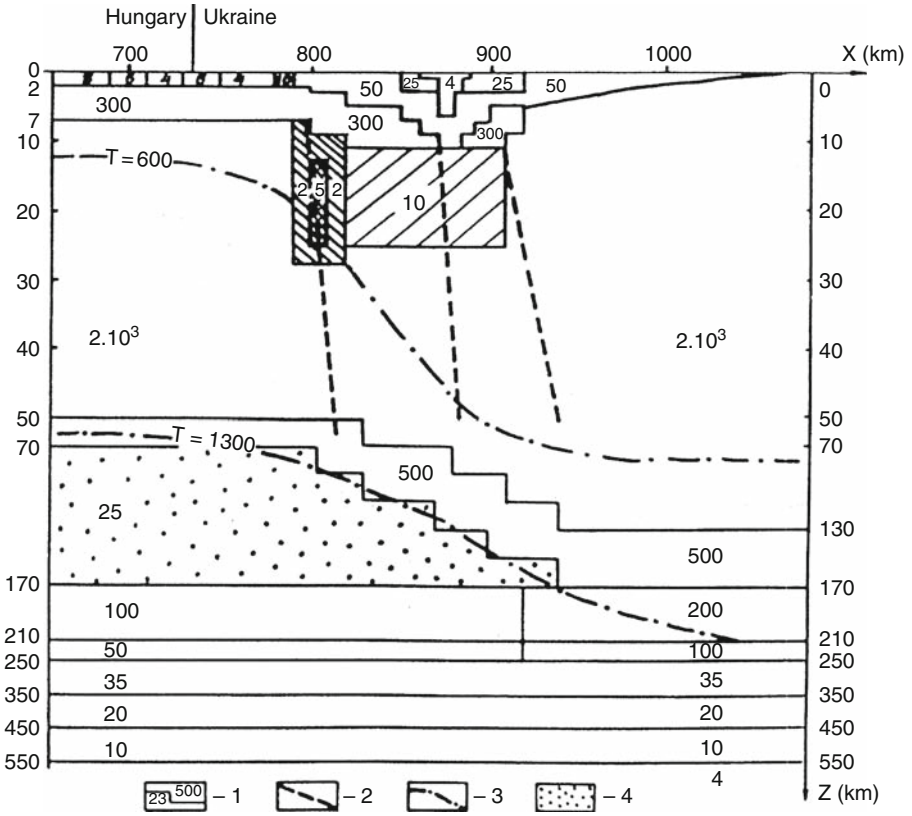
gives the direction of the maximum correlation between the upward *vertical* and horizontal field component. This definition of the azimuth implies that the x-axis is directed northwards. The magnitude (length) represents the ratio of vertical field amplitude to the amplitude of the horizontal component with which it correlates (Arora, 1997). The Wiese vectors point away from areas of higher conductivity. Conversely, the azimuth of the Parkinson arrow points towards the high electrical conductivity region. The induction arrows when displayed on the map clearly identify the location and trend of subsurface conductivity anomalies (Arora, 1997).

The MVP (induction vector) has an extended literature. Rokityansky (1982) provided a series of model studies. Arora (1997) published several alternative approximations, which might better determine the structure of the conductive bodies, for example, "perturbation arrows," "hypothetical event analysis," *Z/H* "pseudosection," and 2D modeling.

Among the field studies conducted in East-Central Europe in which induction vectors were plotted, it is the Carpathian conductivity anomaly (indicated at first by Wiese, 1965) that has received the greatest attention, attracting scientists from all neighboring countries. The distribution of the induction vectors is shown in Figure 2 (after Jankowski et al., 2005) and one of the best models is shown in Figure 3 (Zhdanov et al., 1986). For the assumed conductive region between 10 and 20 km there are two alternative hypotheses: (a) porous rocks saturated by mineralized water (ionic conduction), (b) conducting rock complex connected to graphite.



Geoelectromagnetism, Figure 2 Wiese induction vectors measured along the Carpathian conductivity anomaly (Modified after Jankowski et al., 2005).



Geoelectromagnetism, Figure 3 Geoelectric and geothermal model of the Carpathian conductivity anomaly and the deepening asthenosphere toward the East European Platform along a NE–SW profile (so-called KAPG geotraverse II) crossing the Transcarpathian region in Ukraina (After Zhdanov et al., 1986). Legend: 1, geoelectric boundaries and resistivity values of blocks in ohm.m; 2, deep faults; 3, isotherms; 4, conducting asthenosphere.

At present the induction vectors form an integral part of routine MT interpretation software (e.g., WinGlink) and the vertical magnetic components are also incorporated in MT inversion.

Magnetotelluric soundings

Basic formulas

Magnetotellurics (MT) means a joint measurement of the natural electric and magnetic field variations on the surface. Its energy source is partly the same as that of MVS and MVP. Namely, at frequencies $f < 5$ Hz the electromagnetic (EM) source field is generated by ionospheric as well as magnetospheric phenomena (micropulsations, substorms, etc.) and at frequencies $f > 5$ Hz the EM field is due to worldwide lightning. The source field penetrates into the Earth, where it is reflected from all resistivity interfaces. The measured field is the sum of the primary (source) and secondary (subsurface-dependent) fields. The signal propagation in the subsurface is diffusive. *Skin depth* δ is the depth at which a uniform field is attenuated to $1/e$ of its surface amplitude in a conductor of uniform conductivity:

$$\delta = \sqrt{2/\mu\sigma\omega},$$

where σ is the conductivity (Sm^{-1}), μ is the magnetic permeability (Hm^{-1}), and $\omega \equiv 2\pi f$ is the angular frequency with f denoting the frequency (Hz). The free-space value of magnetic permeability ($\mu = \mu_0 = 4\pi \times 10^{-7}\mathrm{Hm}^{-1}$) is generally assumed. As shown in the above equation, the lower the frequency is, the larger is the magnetotelluric depth of investigation.

The time variations of the two horizontal (E_x and E_y) components of the electric (or telluric) field are measured by using non-polarizable electrodes in a broad period range. The H_x and H_y horizontal geomagnetic field components are measured either with induction coils or fluxgates. From the time series of the horizontal electric and magnetic field components their frequency spectra are determined. In the simplest case, from $E_x(\omega)$ and $H_y(\omega)$ a complex impedance $Z(\omega)$ is computed as follows:

$$Z_{xy}(\omega) = \frac{E_x(\omega)}{H_y(\omega)}.$$

From Z the apparent resistivity ρ (i.e., the electrical resistivity of a fictitious homogeneous half-space) is defined as

$$\rho = \frac{1}{\omega\mu}\left|Z_{xy}\right|^2.$$

The phase difference between the electric and geomagnetic components is given as

$$\varphi = \arg Z_{xy} = \tan^{-1}\frac{\mathrm{Im}Z_{xy}}{\mathrm{Re}Z_{xy}}.$$

In the general case, the impedance is a period-dependent tensor:

$$\begin{vmatrix} E_x \\ E_y \end{vmatrix} = \begin{vmatrix} Z_{xx} & Z_{xy} \\ Z_{yx} & Z_{yy} \end{vmatrix} \begin{vmatrix} H_x \\ H_y \end{vmatrix}$$

where Z_{xy} and Z_{yx} are the antidiagonal or main impedance elements and Z_{xx} and Z_{yy} are the diagonal or additional elements.

For a 1D model (where the geoelectric structure varies exclusively with depth), the impedance elements are, theoretically, in the following relationships:

$$Z_{xy} = -Z_{yx} \text{ and } Z_{xx} = Z_{yy} = 0.$$

For a 2D model (where the resistivity section does not change in one of the horizontal direction named by strike direction), the apparent resistivity calculated from E_x and H_y components will differ from that derived from E_y and H_x, that is,

$$Z_{xy} \neq Z_{yx}$$

Furthermore, $Z_{xx} = Z_{yy} = 0$ is valid exclusively when the horizontal axes are aligned along and perpendicular to the strike direction.

One of the basic modes is called as *TE mode (or E-polarization),* where the electric field exists only in *strike direction. The other basic mode is called* as *TM mode (or H- or B-polarization),* where it is the magnetic field, which has one single component parallel to the strike direction. In the TE mode, there is also a measurable vertical magnetic component (H_z), which is usually also measured; in the TM mode, there is a measurable vertical electric component (which is not measured). The TE and TM mode apparent resistivities represent the geoelectric structure in two different ways. The TE mode is more sensitive to deep conductive anomalies, while the TM mode – due to the charge accumulation at the resistivity boundaries – is more sensitive to the inhomogeneity boundaries.

When the model is 3D, the complete impedance tensor has four nonzero complex elements.

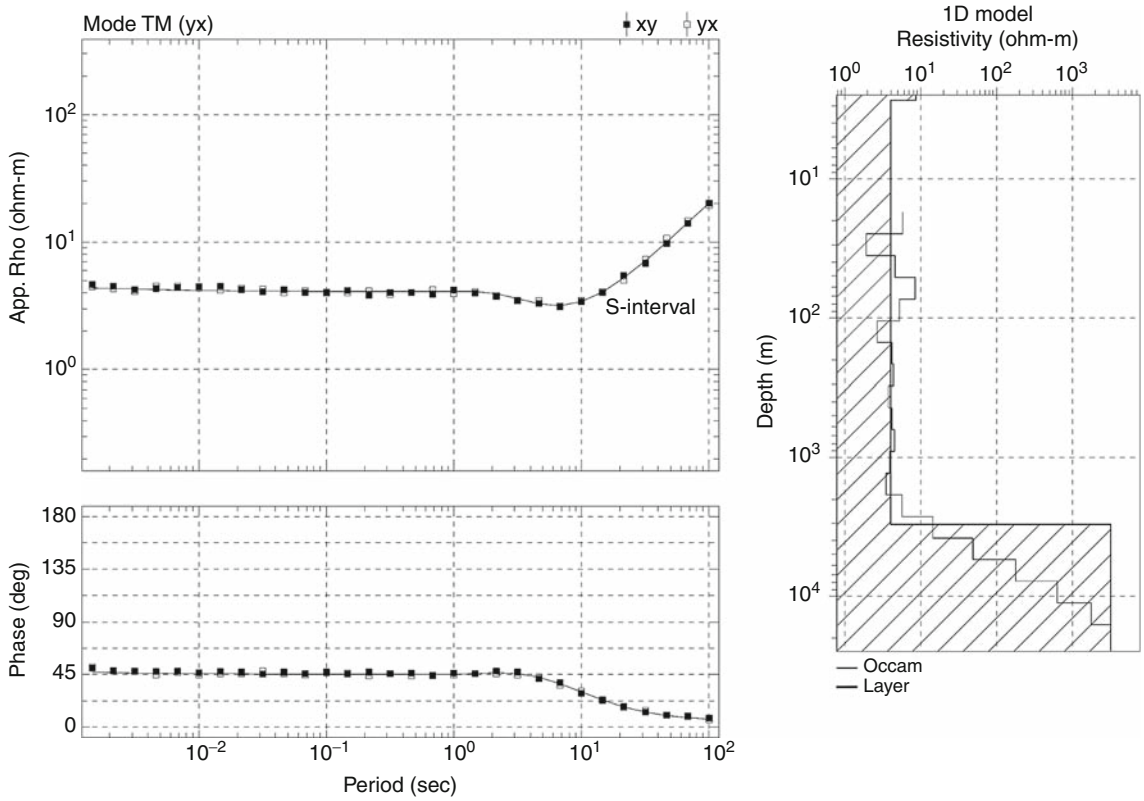
MT sounding curves are obtained by plotting apparent resistivity and impedance phase as functions of period (or square root of the period) over a wide period range. In Figure 4, a 2 layer 1D resistivity model is shown. Note that the resistivity curve is fully logarithmic while the phase curve is semi-logarithmic. $Z_{xy}(\omega)$ and $Z_{yx}(\omega)$ serve as the basis of the TE and TM mode $\rho(\omega)$ and $\varphi(\omega)$ sounding curves. Computing the impedance elements in rotated coordinate systems, one obtains so-called polar diagrams, which characterize the anisotropy of the resistivity distribution.

Interpretation

Complex impedance elements recorded over a range of periods and at many sites along a profile or over an area, can be used to estimate the true resistivity distribution of the subsurface. This procedure is called inversion. Before carrying out inversion, the impedance elements should be corrected from distortions of both technical and structural origin. The "remote reference" method – using the data of simultaneous measuring sites in the processing – reduces, for example, the effect of man-made electromagnetic noises (Gamble et al., 1979). Different *decomposition* techniques (e.g., (Larsen, 1977; Groom and Bailey, 1989; Bahr, 1991); corrected by Prácser and Szarka, 1999; Caldwell et al., 2004) enable suppression of the effect of a near-surface small 3D inhomogeneity causing the "*static shift*" of galvanic origin. At the same time they inform how well the impedance data correspond to a 2D resistivity model, and give an estimate for the strike direction, too. The papers by Bibby et al. (2005) and by Weaver et al. (2006) also explore the role of the phase tensor in determining dimensionality and strike direction. Due to the fact that the inversion is inherently nonunique, additional geophysical and geological information is needed in order to get a realistic model of the subsurface. The most frequently used 2D inversion algorithms in magnetotellurics are those by Rodi and Mackie (2001) and Siripunvaraporn and Egbert (2000) (see Figure 7). The fitness of the modeled and measured data is characterized by the root-mean-square (rms) values. Various EM imaging procedures, exploiting the whole information content of the impedance tensor, may also be useful, as proposed by Szarka et al. (2005) and Weaver et al. (2000). For this purpose, Szarka and Menvielle (1997) recommended the system of independent rotational invariants of the impedance tensor. The usefulness of this approach was demonstrated in detail by Novák (2009) using field data. In recent years, many papers have been published on 3D modeling and inversion and some have been presented at the biennial International Association of Geomagnetism and Aeronomy (IAGA) Workshops on Electromagnetic Induction in the Earth, including reviews of these topics, e.g., Avdeev (2005).

Application to geosciences and future directions

MVS, MVP, MT, and to a lesser extent tellurics have received a very wide application in studying the structure and physical processes of the Earth at various local, regional, and global scales. The development of field applications has been disseminated at the biennial IAGA electromagnetic induction workshops since 1972 (see MTNet website, http://www.dias.ie/mtnet/working group/wg_wsreviews.html) and at assemblies of IAGA. For example, at the last (11th) IAGA Assembly (Sopron,



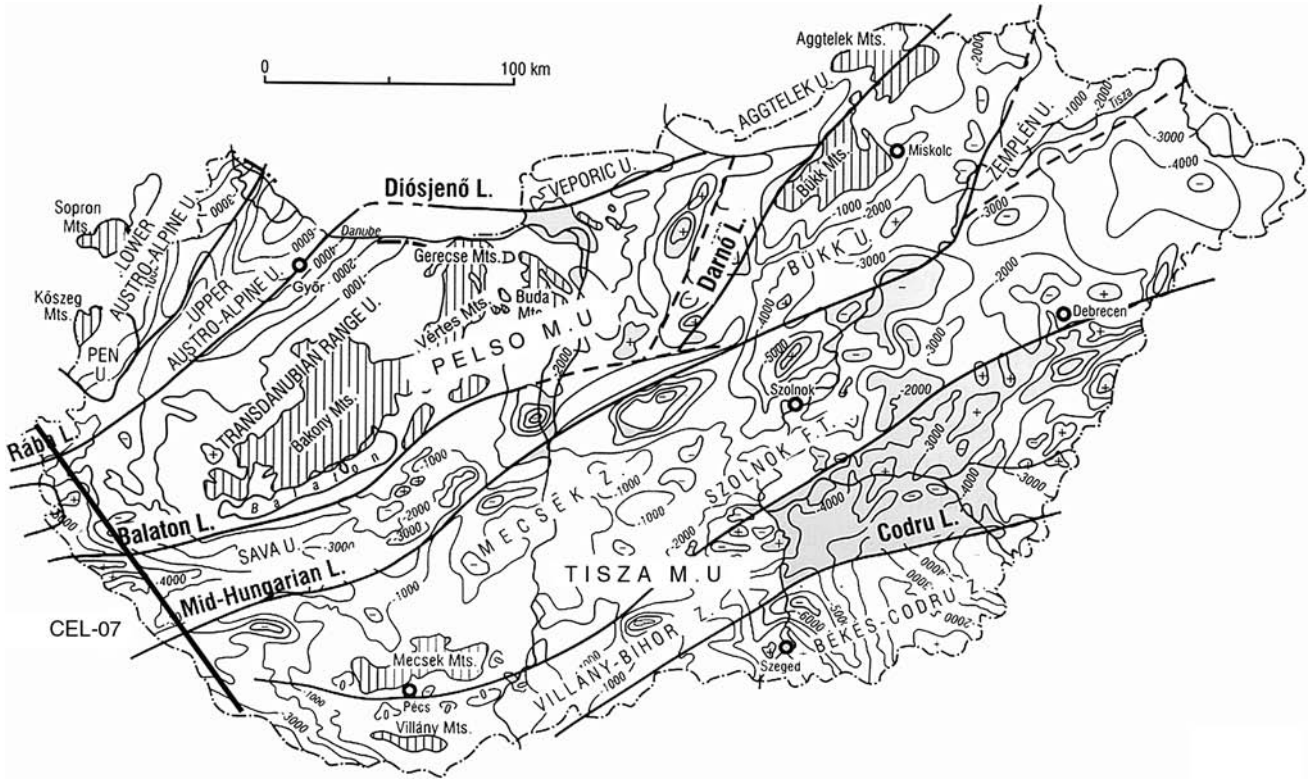
Geoelectromagnetism, Figure 4 Magnetotelluric sounding curves for a layer (1D) model with Rho1 = 4 Ω m, h_1 (thickness) = 3 km, Rho2 = 2,000 Ω m. According to the Occam and few-layer inversions the "S-interval" starts at a period of 10 s. At longer periods the telluric (Earth currents) method can be used to determine the thickness of the low resistivity sedimentary layer on a more resistive basement.

23–30 August 2009, www.iaga2009sopron.hu), a wide spectrum of geoelectromagnetic studies, from the surface to the middle of mantle, was presented: theoretical and practical aspects of near-surface and environmental problems, oceanic geophysical exploration, formation and deformation of the continental lithosphere, crustal tectonic processes, deep mantle structure, and data interpretation methods.

In order to illustrate the wealth of geoelectromagnetic applications, the authors present a selection from their own results from the Pannonian Basin, which is a very complex geological-geophysical unit of the Carpatho-Pannonian region. Such a summary cannot be done without mentioning other geoelectromagnetic investigations of the most well-known global geodynamic phenomena, such as the active plate tectonics in the Himalayas, Andes, San Andreas Fault, Afar region, etc. Earth being a "dynamic planet," great efforts have also been devoted to mitigate the geohazards: earthquakes, volcanoes (as accompanying phenomena of the plate tectonics), and landslides (Bedrosian, 2007; Korja, 2007).

Before discussing the electrical conductivity anomalies/structures in the Pannonian Basin, we give a short description about its geology from those aspects that constrain the spatial distribution of electrical resistivity in the subsurface. The Pannonian Basin has a fairly thick and relatively uniform low electrical resistivity sedimentary cover of Late Tertiary origin, which was investigated in detail by telluric/magnetotelluric soundings. According to Haas (2001), the Pre-Neogene basement "shows a mosaic pattern of heterogeneous structural elements, a collage of allochthonous terrains derived from different parts of the Tethyan realm" (Figure 5). In the basement there are two large Mega-units of composite terrains, which are separated by the ENE-WSW trending Mid-Hungarian Lineament. The South-Pannonian Mega-unit is the so-called TISIA (TISZA) Terrain and the North-Pannonian one is the so-called ALCAPA Mega-unit, which was formed from different smaller terrains. One of them is the PELSO in its southern part.

The evolution of the Pannonian Basin is significantly determined by the Miocene synrift, accompanied with a strong thermal heating, and leading to appraisal of crustal and mantle horizons and an extension of the basin by 10 to 30%, pre-dominantly in the NE–SW direction (Horváth and Berckhemer, 1982). These features are extremely dominant in the deep extensional sedimentary sub-basins (e.g., in the Békés basin).

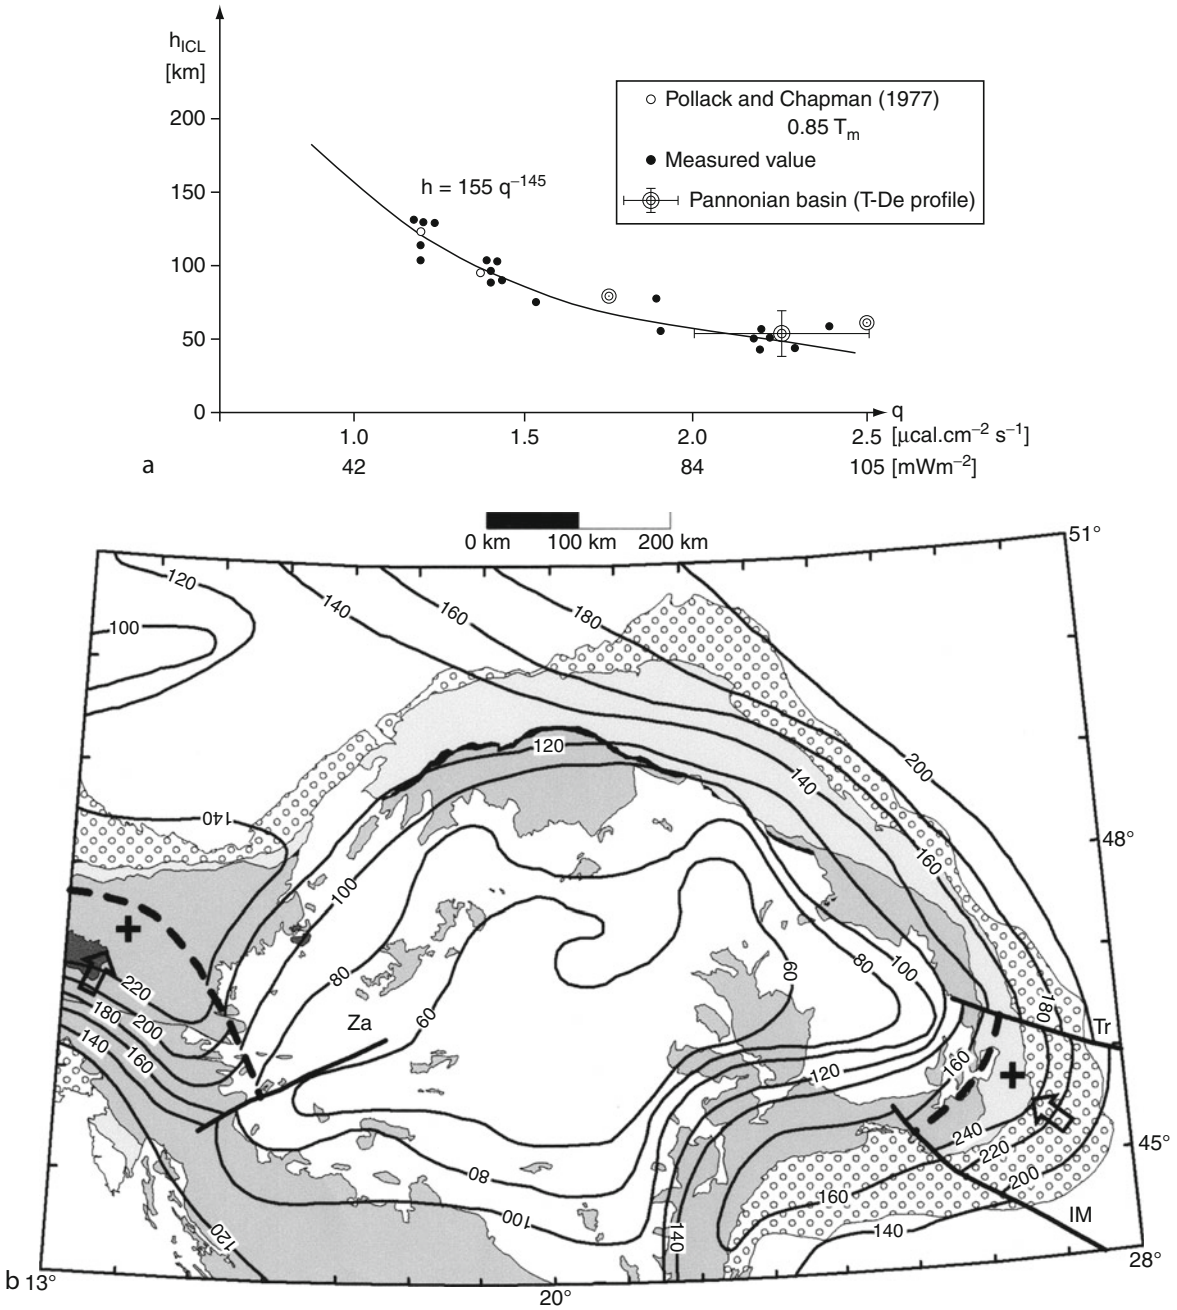


Geoelectromagnetism, Figure 5 Pre-Tertiary structural units of Hungary and depth of the pre-tertiary basement (Haas, 2001).

The spatial distribution of electrical resistivity/conductivity is influenced in the Pannonian Basin by the position, boundaries, and mosaic structure of the Mega-units and tectonic and thermal effects in the lithosphere, caused by synrift extension that has only been slowly compensated by the presently ongoing compression of the basin. The conductivity structures conserve the history of basin. Due to upheating of the Pannonian Basin – indicated by the high heat flow values at the surface of about 100 mW/m^2 – two geoelectric conductors are in an elevated position, in comparison to the surrounding mainly outer Carpathian: Paleozoic and Proterozoic regions.

Application of geoelectromagnetic methods is illustrated in five snapshots, representing various depth ranges: asthenosphere, mega-blocks, middle crust, upper crust, and near-surface.

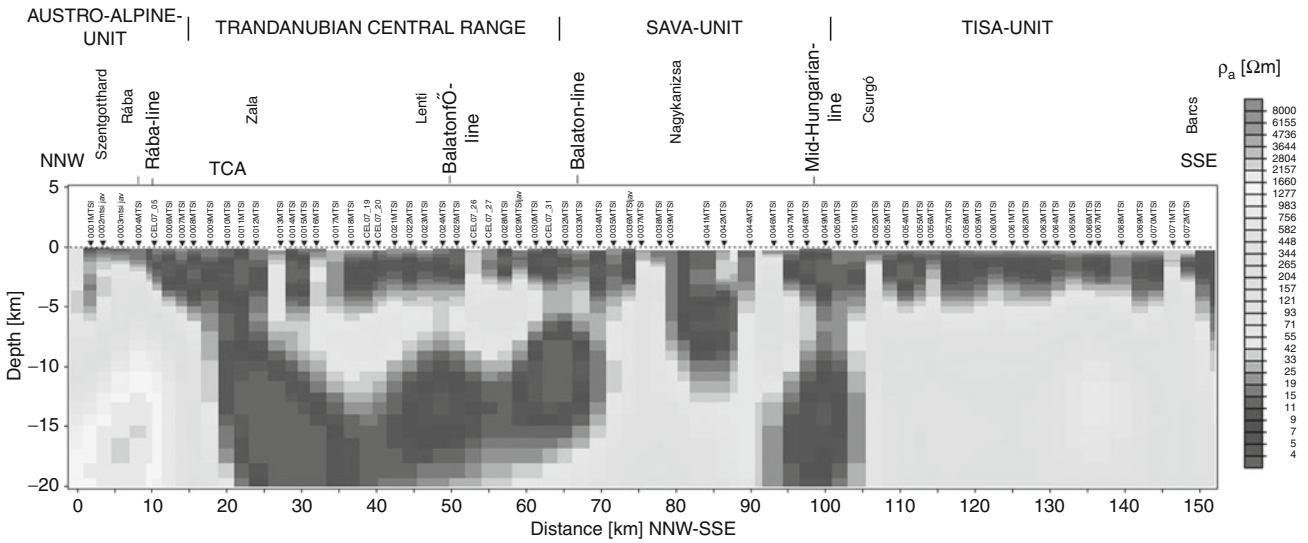
1. *Asthenosphere.* The depth of the high-conductivity asthenosphere – in which the temperature approximates the solidus of the mantle peridotite, so that a partial melting can start – is in the Pannonian Basin at about 60 km depth, indicated by Ádám (1965). In platforms and shield areas the asthenosphere is at much deeper position – if it exists at all. Its estimated value is about 250 km as concluded by extended projects such as BEAR in Finland (Korja and BEAR Working Group, 2003) and CEMES (Yu Semenov et al., 2008) in East-Central Europe (See also Figure 3). The MT indications of the conductive asthenosphere at an elevated position within Pannonian Basin were confirmed with reflection seismics (Posgay, 1975) and also with a thermobarographic diagram of well-equilibrated peridotite xenolith from the PELSO (Embey-Isztin et al., 2001). The elevated position is in close correlation with enhanced heat flow values (Figure 6a, Ádám, 1978). Its smallest depth of about 50 km was observed in the Békés extensional subbasin (Ádám et al., 1996). The map of asthenospheric depth in and around the Pannonian Basin is shown by Figure 6b as the result of seismic, seismological, and magnetotelluric measurements (See in Horváth et al., 2006, based partly on the MT data of Ádám and Wesztergom, 2001).
2. *Middle crust.* In the middle crust the transition between the brittle and ductile zone is also temperature dependent, which might be due to dehydration as proposed by Hyndman and Shearer (1989). Ádám (1978, 1987) found a relation between the mid-crustal conductivity increase and the regional heat flow values. In the Pannonian Basin there is only a weak indication of this anomaly at a depth of about 15–17 km, but this is supported by the lower limit of seismic focal depths and by strength decrease. The electrical conductivity of the lower crust was reviewed by Jones (1992).
3. *Boundaries of mega-units.* The boundaries of the Mega-units and their mosaics in the Pannonian Basin



Geoelectromagnetism, Figure 6 (**a**) Relation between the depth of the conductive asthenosphere and the regional heat flow (Ádám, 1978), (**b**) The map of the asthenospheric depth in and around the Pannonian Basin as results of seismic/seismological/magnetotelluric results (Horváth et al., 2006; Ádám and Wesztergom, 2001).

were studied among others along the deep seismic CEL-07 profile in SW Hungary with 72 deep MTS. The distance between neighboring magnetotelluric stations was in average only 2 km. The CEL-07 profile is shown together with the complicated basement tectonic structure in Figure 5.

The resistivity profile of the TE mode inversion along CEL-07 is shown in Figure 7 (the TM mode inversion profile is strongly distorted by charge accumulation at the boundary of electrical inhomogeneities falsifying the values of the resistivity distribution). The TE mode inversion clearly expresses the conductivity anomalies at the boundaries of the Mega-units: the Balaton + Balatonfő double lineaments at the southern border of the PELSO M.u. (mosaic of the ALCAPA M.u.) and the Mid-Hungarian Line at the northern

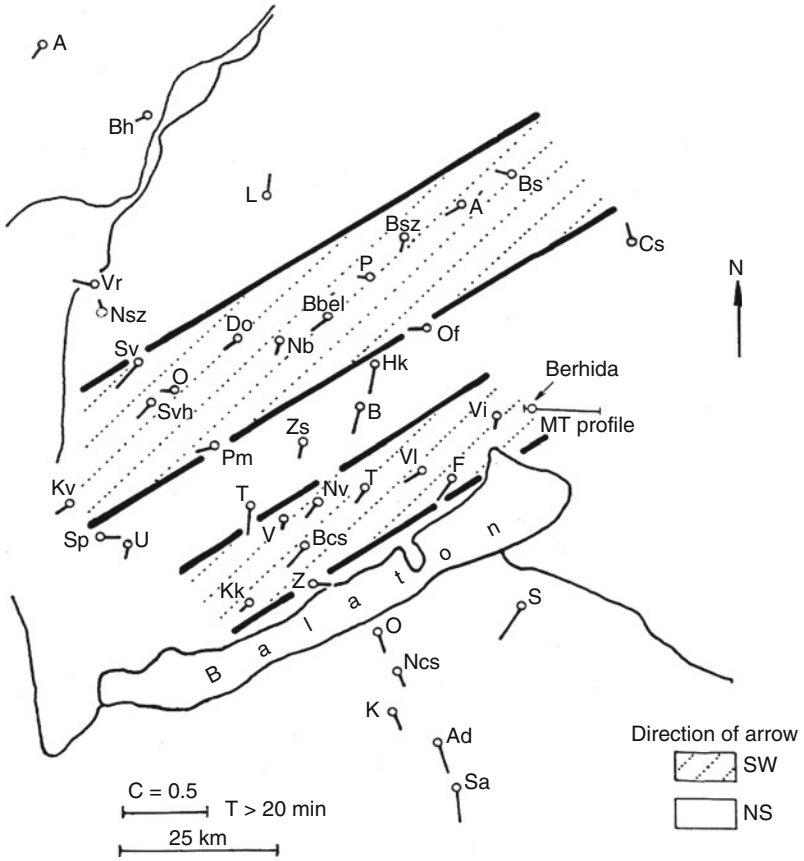


Geoelectromagnetism, Figure 7 The resistivity profile of the TE + Hz nonlinear conjugate gradient inversion of the magnetotelluric measurements along the CEL-07 profile (RMS = 1.344132). See the conductors corresponding to the deep boundary fractures (Ádám et al., 2005).

border of TISIA M.u. The horizontal electric conductance of the lineaments is about 2,500–3,000 S, starting at a depth of about 7 km. The source of the conductivity anomaly is certainly hot saline fluid containing also SiO_2 solution. Deep borehole data refer to accumulation of CO_2, increase of He concentration, etc. in the deep fractures. A high value of convective heat transfer, especially in volcanic eruption centers, also increases the electrical conductivity in these tectonic zones, which (e.g., the Balaton Line) is also indicated by the zero value of the induction vectors (Ádám et al., 2005).

4. *Crustal conductivity anomalies.* On the northern part of the CEL-07 resistivity profile there appears another conductivity anomaly that is assumed to be the continuation or ending of one of the extreme high fracture zones related to the Transdanubian Conductivity Anomaly (TCA) studied by 300 deep MT soundings (Ádám, 2001). The TCA consists of a conductive layer at about 5 km depth and of three significant fracture zones in the NE–SW direction. Their horizontal electric conductance value can reach 10,000 S. Such high conductance values make it probable that the sources of the anomaly are graphite/graphitic shists as well as fluid, which are partly within, and partly under the thick Mesozoic limestone sequence of the Bakony Mts. In this area there is significant seismic attenuation (Zsíros, 1985), and this must be due to an electrical conductor (Glover and Ádám, 2008). The large fractures as shown by the strongly reduced induction vectors (Figure 8) are connected to the hypocenters of the earthquakes (e.g., Mór in, 1809, Berhida in 1985, rarely exceeding a magnitude of 6 on Richter's scale). Glover and Ádám (2008) found a correlation between the depth to the zone of this high electrical conductivity anomaly and earthquake focal depths. According to Ogawa (2007) the earthquakes occur at the boundaries of the electric conductors, where only aseismic slip or elastic deformation can happen, rather than within the conductors themselves. In this way the energy can be transported towards the brittle zone, causing devastating earthquakes. In the presence of the hypothetical enhancement of magnetic permeability at the Curie depth (Kiss et al., 2005), MT interpretation of upper and middle crustal inhomogeneities should be carried out with a special care.
5. *Near-surface.* In order to study the near-surface depth range, either higher frequencies or local sources should be applied. Various high-frequency variants have been developed: instead of the classical MVP the so-called VLF; instead of the classical magnetotellurics: audiomagnetotellurics (AMT), radiomagnetotellurics (RMT), or VLF-EM. If the source is finite, we quickly arrive at various near-surface electromagnetic induction and direct current methods.

As a result of the various EM induction methods becoming increasingly important, the number of geoelectromagnetic papers published in international journals has shown an upward trend. Recently, Bedrosian (2007) reviewed MT measurements, which were carried out in the Himalayas (Lemonnier et al., 1999), in Southern Tibet (Li et al., 2003), in the Andean margin (Brasse et al., 2002), etc. In each of these dynamic areas the electrical conductivity anomalies appear at their most active segments, which has been also indicated by thermal activation (in forms of high heat flow), earthquakes, volcanoes, recent crustal movements, regional metamorphism



Geoelectromagnetism, Figure 8 Wiese induction vectors along the deep fractures of the TCA (Wallner, 1977).

(e.g., graphitization), partial melting, etc. Korja (2007) gives in his review a comprehensive description about the conductive anomalies in Europe. As Bedrosian (2007) stated, for a correct interpretation of MT (EM) data, due to the nonuniqueness of the geophysical inverse problems, independent geological and geophysical information is necessary. This conclusion is highly confirmed by our experiences with geoelectromagnetic results from the Pannonian Basin.

For further reading on various topics in geoelectromagnetism covered in this entry, both practical and theoretical, the reader is referred to the specialized monographs by Wait (1962), Berdichevsky and Zhdanov (1984), Weaver (1994), Simpson and Bahr (2005), and Zhdanov (2009) among others in sequence of the publication year.

Equipotential surface at mean sea level

Definition

Geoid. The gravitational equipotential surface of the earth that matches with the best approximation of the "mean sea level."

Tectonic forces. Forces originating from within the earth that alters surface configuration of the earth through uplift, movement, and deformation of the parts of the earth's crust.

Introduction

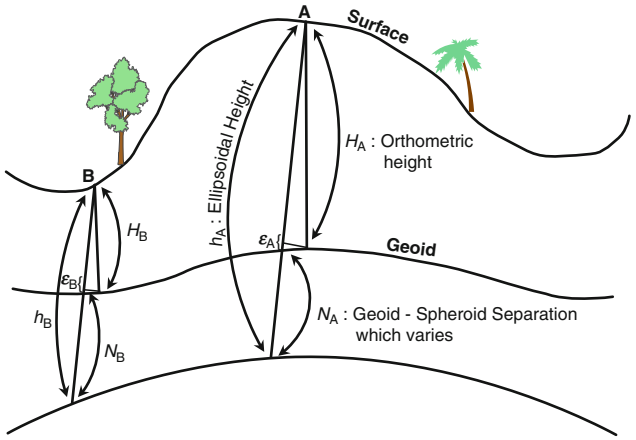
The earth does not have a perfect geometrical shape. Its shape matches very closely to that of an oblate spheroid. Topographical variations of several kilometers in the form of mountain ranges and oceanic trenches exist. Surface of the oceans, which conforms to a uniform gravitational potential, acts as an effective and useful way to define the shape of the earth. This oceanic surface serves as a reference surface for the earth.

Continuously changing configurations of the earth's surface are mostly engineered by the motion of the tectonic plates. The tectonic motion of a lithospheric plate and its deformation are responses to the force acting on it. Lateral density variation in the lithosphere produces both horizontal as well as vertical stress gradients. Gravitational Potential Energy gradient is thus directly proportional to the geoid height variation. Recent advances in space geodetic techniques make it now possible to map the geoid with unprecedented accuracy in both spatial and temporal domains, thus providing a new tool to study tectonics.

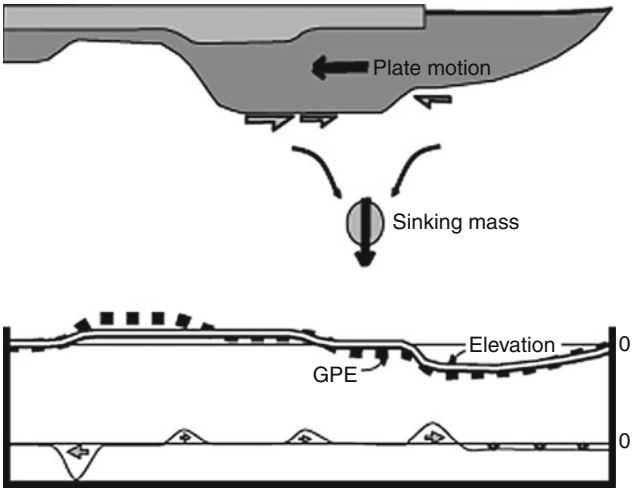
Geoid

Like any liquid in hydrostatic equilibrium, globally interlinked ocean water surface (without the effects of tides and waves), defines a gravity equipotential surface. Earth's gravity potential field contains infinite number of equipotential surfaces, almost parallel to each other (in case of an idealized earth). That particular equipotential surface which matches closest to the actual realization of the global mean sea level is the geoid. The Geoid surface is relatively smoother compared to the topographical surface of the earth. Whereas Earth's surface excursions range between +8,000 m at Mt Everest and −11,000 m at Maryana Trench, maximum geoid surface variation is about 200 m.

Over the oceans, realization of the geoid is easy as it is the "mean sea level". Geoid over the continents lies below the surface of the earth, and can be visualized as water level in the imaginary canals cutting across the continents and interconnecting the surrounding oceans. Because surveyor's spirit level or plumb bob follows the gravity equipotential, leveling traverse starting from the nearest tidal station running inside the continent, measures height above mean sea level or geoid, and is called orthometric height. All height measurements using conventional surveying techniques use geoid or "mean sea level" as the reference level. Though geoid is much smoother surface compared to the topographic surface of the earth, the geoid itself, because of inhomogeneous distribution of mass within the earth, undulates at much higher spatial wavelength domain. The undulation of the geoid is measured in reference to a "Reference spheroid" (Figure 1).



Geoid, Figure 1 A simplified cartoon showing geoid and spheroid levels both over the continents and oceans. Geoid anomaly is mostly positive over the continents and negative over the oceans.



Geoid, Figure 2 Different tectonic forces in play in a subduction zone where the subsiding slab sinks in weaker asthenosphere (slab pull), which excites mantle flow, thus creating a traction at the base of the plate (shown by small *gray arrows* at the base of the plate). Continental crust and oceanic crust are shown in *light gray* and *black* respectively, whereas mantle lithosphere is in *dark gray*. The lower figure shows surface topography, gravitational potential energy (GPE), and GPE gradient (lower line) across the plate. GPE gradient produced by the lateral variation of the lithospheric density/topography structure creates forces within lithosphere as shown by the *arrows*. Figure 1; Humphreys and Coblentz, 2007. Reproduced by permission of American Geophysical Union. Copyright [2007], American Geophysical Union.

Geoid anomaly at any point can be computed from gravity field measurements, but requires worldwide gravity data. Perturbations of the orbits of the artificial satellites have been used to model global gravitational field, covering both continents and oceans. Satellite and radar altimetry today provides the most refined technique of measuring the geoid over the oceans with an accuracy better than 10 cm. Starting with the first satellite by the then USSR in 1957, phenomenal improvement in measuring Earth's gravity field has been achieved. Important altimetric satellite missions contributing significantly in modeling ocean geoid include GEOS3(1975), SEASAT (1978), GEOSAT(1985), ERS-1(1991), TOPEX/POSEISDON(1992), ERS-2(1996), etc. Launching of twin-satellite system GRACE in 2002 was another significant event toward measuring Earth's gravity and geoid, both in temporal and spatial domains, covering land as well as oceans, with an unprecedented accuracy.

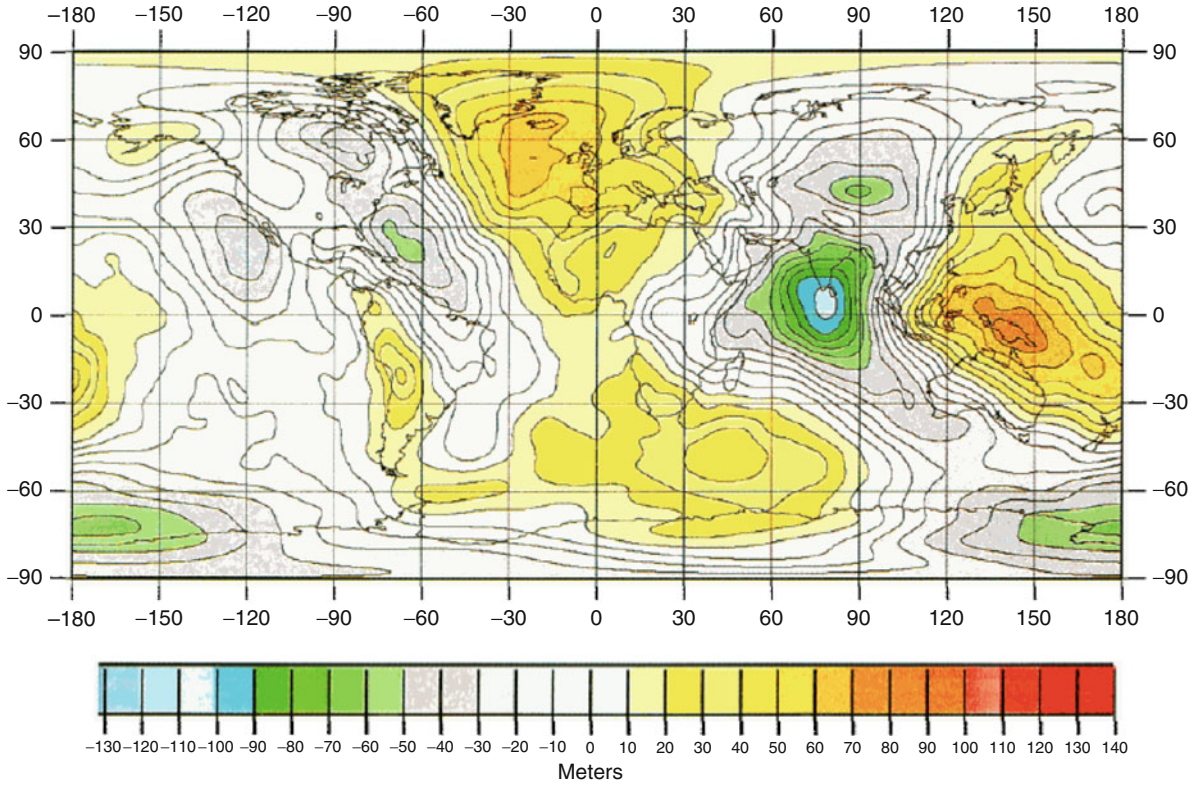
Tectonic forces

Tectonic forces acting on a lithospheric plate result in plate motion as well as accumulation of stresses, both in vertical and horizontal directions. Surface deformation and earthquakes are direct consequences of these stresses. Origin of the tectonic forces mostly lies in the flow in the asthenosphere which may either drive or resist the motion of the overlying plate. In the subduction zone, gravitational pull of the down going slab (slab pull) plays a more important role in driving the plate motion than the "ridge pushes" where slabs are driven away from the mid-oceanic ridges. Plate motion also creates traction on the base of the overlying continents (Humphrey and Coblentz, 2007). Another important source of force is generated by the lateral variation in density and thickness in the lithosphere which generates a gradient in gravitational potential energy (GPE). Figure 2 illustrates how a subducting slab generates GPE gradient and basal traction force. Tibetan plateau is an example of high GPE where continental collision produced high topography, thickened crust, extensional stresses on the plateau, and compression at the edges.

Geoid height variations are linearly proportional to the GPE gradients in an isostatically balanced lithosphere (Turcotte and Schubert, 2002). Geoid gradients can thus be used to study lithospheric stress gradients. Lithosphere-scale density inhomogeneities are reflected in shorter wavelength geoid anomalies. This, in combination with integrated density moment computed using a crustal density model at longer wavelength, can be used to produce GPE (Humphreys and Coblentz, 2007).

Geoid anomaly and tectonics

Deviation of the actual geoid surface from the reference spheroid is known as geoid anomaly. Figure 3 shows the global geoid height anomaly (Bowin, 2000). The largest geoid anomaly is a 100 m deep "hole" south of India, in



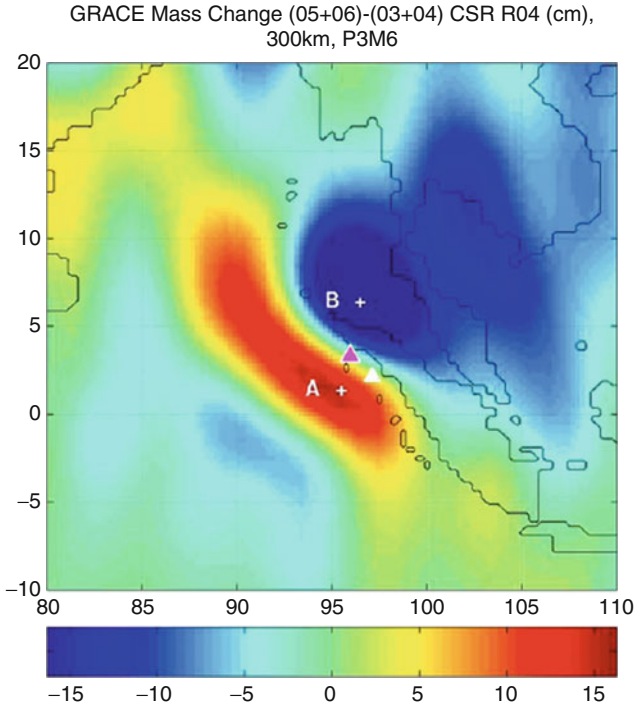
Geoid, Figure 3 The geoid height anomaly map of the world. The contour line interval is 10 m. Plate 1; Bowin, 2000. Reproduced by permission of American Geophysical Union. Copyright [2000], American Geophysical Union.

the Indian Ocean. This huge geoid "low" is caused by a mass deficiency in the mantle underneath the sea. Other short wavelength geoid anomalies exist along the oceanic trenches where one tectonic plate subsides underneath another plate, or along the mid-oceanic ridges where hot mantle material swells up to produce new oceanic crust. Geoid anomaly generally has a positive correlation with Free-air gravity anomaly. However, gravity anomaly is more sensitive to the shallower features whereas geoid anomaly is more sensitive to the deeper mass in homogeneities.

Study of the geoid anomaly helps to understand the distribution of large scale density inhomogeneity, the state of isostatic compensation, and also about the flexural property of the lithosphere. Global geoid anomaly data indicates that, when loaded (or unloaded) with a large dimension surface load (e.g., a mountain formation, or glaciation-deglaciation process) during a prolonged period, mantle flows and adjusts, and the surface load eventually attains hydrostatic equilibrium. In contrast, short-period or small-scale surface load is not isostatically compensated. These are explained by a viscoelastic lithosphere which is strong enough to support at a smaller spatial and temporal scale, but has a finite viscosity and flows like a fluid at a larger spatial and temporal domain. Study of spatial as well as temporal variation of the geoid anomaly can thus be a very useful tool to understand mechanical properties of the lithosphere. It may be noted that isostatically balanced mass distribution does not cause zero geoid anomaly. An isostatically compensated mountain range of 3 km height causes a positive geoid anomaly of ~16 m, where a 5 km deep ocean basin would result a negative geoid anomaly of about 9 m (Fowler, 1996). As geoid anomaly is more sensitive to lateral variation in lithospheric density structure, surface measurements of geoid anomaly can provide a very useful tool to study subcrustal configuration across a plate boundary (Banerjee et al., 1999).

GRACE and coseismic deformation

GRACE (Gravity Recovery and Climate Experiment) twin satellite system has made it possible to measure temporal variation of geoid height at a global scale with an accuracy of 2–3 mm (Tapley et al., 2004). The 2004 Sumatra-Andaman earthquake (Mw 9.2) provided an opportunity to measure coseismic as well as post-seismic gravity and mass variations using GRACE data (Han et al., 2006; Chen et al., 2007). Sudden change in lithospheric density structure as well as vertical movement could be detected in GRACE data (Figure 4). With this leap in space geodesy, remote sensing of Earth's Geoid provides another important tool to study tectonic processes.



Geoid, Figure 4 Temporal mass change in Sumatra-Andaman region during 2004 (Mw = 9.2) earthquake. Using GRACE data, it was possible to capture coseismic deformation of the December 26, 2004, Sumatra-Andaman event, as well as part of the coseismic deformation of the March 27, 2005, Nias earthquake. Summary

Geoid is the best available physical model of the earth. It is measurable using gravimetry and satellite altimetry data. Because geoid is a gravity equipotential surface, near-surface configuration of the earth's structure is reflected in geoid undulation. Tectonic forces that causes change in Earth's lithospheric configuration, are thus correlatable with the temporal and spatial changes of the geoid. Recent advances in satellite technology has enabled to measure and monitor geoid undulations with an unprecedented precision. As a result, many important Earth System processes like tectonic plate movement, surface deformation, sea level changes, etc are now being measured and monitored on a global scale. These have contributed significantly towards better understanding of the tectonics of the Earth.

Definition

The *geoid* is the equipotential surface of the Earth's gravity field, which best approximates the mean sea level at rest. Its determination requires (1) knowledge of the Earth's gravity potential and (2) a way of geometrically representing the geoidal surface, which is done via its deviations – called geoid undulations N – from the surface of a known reference ellipsoid. The geometric representation is of particular importance given that the geoid is the reference surface, or datum, for the physically meaningful orthometric heights, often called heights above mean sea level.

Basic principles: the gravity, normal, and disturbing potentials

The Earth's *gravity potential* W comprises the gravitational potential V and the centrifugal potential Φ:

$$W = V + \Phi = k \iiint_v \frac{\rho}{l} \mathrm{d}v + \frac{1}{2}\omega^2\left(x^2 + y^2\right) \tag{1}$$

V is a Newtonian potential due to the attraction of the masses, expressed as an integral of the mass density ρ over the volume v; l is the Cartesian distance between the computation point and the mass element $\rho \mathrm{d}v$, and k is Newton's gravitational constant. The centrifugal potential Φ is a function of the Earth's rotational velocity ω and the distance $p = (x^2 + y^2)^{1/2}$ from the rotation axis, namely, $\Phi = \omega^2 p^2/2$.

Due to our insufficient knowledge of the density distribution, Equation 1 cannot be used directly to compute V and W. Nevertheless, a solution can be obtained by utilizing the fact that V is a harmonic function outside the masses, that is (a) it satisfies Laplace's equation

$$\nabla^2 V = \frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} + \frac{\partial^2 V}{\partial z^2} = 0 \tag{2}$$

since the inverse distance in the integral of Equation 1 clearly satisfies $\nabla^2 l^{-1} = 0$ and (b) it vanishes as $l \to \infty$. *Stokes's theorem* postulates that V can be determined everywhere in free space from its values on the boundary surface that encloses all masses and thus knowledge of the interior density distribution is not necessary.

The above problem formulation is called *Dirichlet's problem*, or first boundary value problem (BVP) of potential theory (Hofmann-Wellenhof and Moritz, 2006). Its practical significance is rather limited since the potential is not a directly measurable quantity; it is important, however, for the expansion of V into a spherical harmonic series and for the relationship between V on the boundary surface and V in space (Poisson's integral). A more realistic BVP is *Neumann's problem*, or second BVP, in which the normal derivative $\partial V/\partial n$ is given on the boundary surface instead of V itself. This is because first-order derivatives of W constitute the *gravity vector*

$$\mathbf{g} = \nabla W = \left(\frac{\partial W}{\partial x}, \frac{\partial W}{\partial y}, \frac{\partial W}{\partial z}\right)^T \tag{3}$$

which is observable. It is, however, the third *BVP* that is particularly important in practice; it uses observables on the boundary surface that are a linear combination of V and $\partial V/\partial n$. We will see in the following that the determination of geoid undulations from gravity anomalies – which are derived from the measurements taken with a gravimeter – is such a problem.

The determination of W is a nonlinear problem and is further complicated by the fact that W itself is not harmonic since $\nabla^2 W = \nabla^2 \Phi = 2\omega^2$. Both limitations can be overcome by linearization and approximating the shape, size, and gravity field of the Earth by an equipotential ellipsoid of revolution with the same mass M and same rotational velocity ω as the Earth. In this case, the gravitational potential of the reference ellipsoid V_e can be computed analytically, and its centrifugal potential Φ_e is the same as Φ. Its gravity potential, termed *normal potential* U, is

$$U = V_e + \Phi_e = V_e + \Phi \tag{4}$$

and its gradient is the *normal gravity vector*

$$\boldsymbol{\gamma} = \nabla U = \left(\frac{\partial U}{\partial x}, \frac{\partial U}{\partial y}, \frac{\partial U}{\partial z}\right)^T \tag{5}$$

Both U and γ are analytical functions that can be computed from M, ω, and the semimajor and semiminor axes a, b of the reference ellipsoid. The difference between W and U at the same point is the *disturbing potential* T, which is obviously a harmonic function (since it is independent of the centrifugal potential, and since V_e, just like V, is harmonic being a function of the inverse distance):

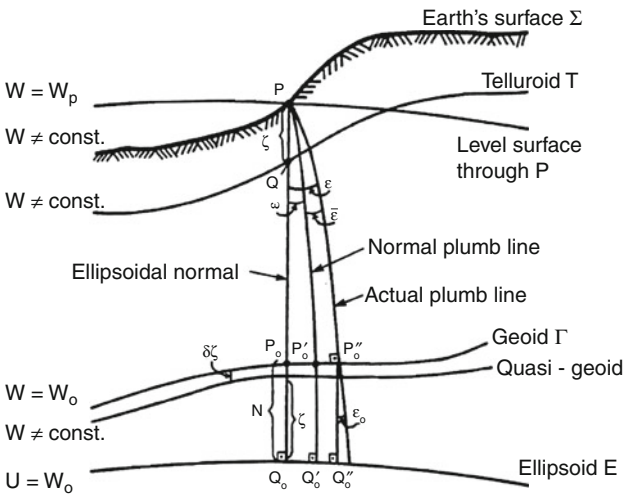
$$T = W - U = V - V_e \tag{6}$$

$$\nabla^2 T = 0 \tag{7}$$

Now since U is known, the problem of determining W has been reduced to the problem of determining T, which is a third BVP provided that an appropriate observable would be available on the boundary surface. This is indeed the case, as it will be shown in the following.

The Stokes and Molodensky geodetic BVPs

We select the geoidal surface Γ as the boundary surface that encloses all masses, we approximate Γ by the surface of the reference ellipsoid E, choose the normal potential U_o on E to be the same as the gravity potential W_o on the geoid, project a point P_o on the geoid on to a point Q_o on the ellipsoid along the ellipsoidal normal (see Figure 1), and define the geoid undulation N as the distance P_oQ_o and the *gravity anomaly* and *gravity disturbance* vectors



Geoid Determination, Theory and Principles,
Figure 1 Geometry of the Stokes BVP and the Molodensky BVP.

as $\mathbf{\Delta g} = \mathbf{g}_{P_o} - \boldsymbol{\gamma}_{Q_o}$ and $\mathbf{\delta g} = \mathbf{g}_{P_o} - \boldsymbol{\gamma}_{P_o} = \nabla T$, respectively, with magnitudes

$$\Delta g = g_{P_o} - \gamma_{Q_o} \tag{8}$$

$$\delta g = g_{P_o} - \gamma_{P_o} \tag{9}$$

We can now relate N to T, and Δg to T and its vertical derivative. Using Figure 1, only first-order terms in Taylor expansions, and assuming – because the vertical deflection angle ε is very small – that the vertical derivatives along the ellipsoidal normal, normal plumb line, and actual plumb line are all the same, we can write

$$\begin{aligned} T_{\mathrm{P_o}} = W_{\mathrm{P_o}} - U_{\mathrm{P_o}} &= W_{\mathrm{P_o}} - U_{\mathrm{Q_o}} - \left.\frac{\partial U}{\partial h}\right|_{\mathrm{Q_o}} N \\ &= W_{\mathrm{o}} - U_{\mathrm{o}} + \gamma N = \gamma N \end{aligned} \tag{10}$$

$$\begin{aligned} \delta g_{\mathrm{P_o}} = -\left.\frac{\partial T}{\partial h}\right|_{\mathrm{P_o}} &= g_{\mathrm{P_o}} - \gamma_{\mathrm{P_o}} = g_{\mathrm{P_o}} - \gamma_{\mathrm{Q_o}} - \left.\frac{\partial \gamma}{\partial h}\right|_{\mathrm{Q_o}} N \\ &= \Delta g - \frac{1}{\gamma}\left.\frac{\partial \gamma}{\partial h}\right|_{\mathrm{Q_o}} T \end{aligned} \tag{11}$$

Plumb lines are lines intersecting perpendicularly the surfaces of equal potential; that is, at every point, the gravity vector is tangent to the plumb line through that point.

The last two equations can now simply be written as

$$N = \frac{T}{\gamma} \tag{12}$$

$$\Delta g = \delta g + \frac{1}{\gamma}\frac{\partial \gamma}{\partial h} T = -\frac{\partial T}{\partial h} + \frac{1}{\gamma}\frac{\partial \gamma}{\partial h} T \tag{13}$$

Equation 12 is called *Bruns's equation* and provides N given T, while Equation 13 holds only on Γ and it is called the *fundamental equation of physical geodesy*. The normal gravity on an ellipsoid with semi-axes a, b and normal gravity values at the equator and pole γ_a, γ_b, respectively, can be computed from Somigliana's formula as a function of the point's latitude ϕ:

$$\gamma = \frac{a\gamma_a \cos^2\phi + b\gamma_b \sin^2\phi}{\left(a^2\cos^2\phi + b^2\sin^2\phi\right)^{1/2}} \tag{14}$$

Now *Stokes's BVP* can be defined as the problem of determining T, harmonic outside Γ, from measurements of Δg on the geoid that satisfy Equation 13. This is a third BVP of potential theory, mathematically described by the partial differential equation of Equation 7 with the boundary condition of Equation 13 and it provides T on and outside Γ. Because of the assumption that the geoid encloses all masses, the influence of masses outside Γ must be computed and removed mathematically from the measurements via various types of terrain reductions. These require knowledge of the density distribution of the topographic masses and are described in the section The Treatment of the Topography at the end of this chapter.

Since all gravity measurements are taken on the surface of the Earth $\sum$, a more realistic way of defining the problem is to select $\sum$ as the boundary surface rather than the geoid. This requires no terrain reductions but results in a mathematically more complicated BVP because $\sum$ is not an equipotential surface and the gravity vector is not perpendicular to it. The determination of the Earth's surface from gravity anomalies on it is an oblique derivative problem called Molodensky's problem (Molodensky et al., 1962).

In *Molodensky's BVP*, the Earth's surface is approximated by a surface called the *telluroid* T, W on $\sum$ is approximated by the normal potential U of T, and the gravity anomalies now are the difference between the gravity at the Earth's surface and the normal gravity at the telluroid, that is, $\Delta g = g_{\mathrm{P}} - \gamma_{\mathrm{Q}}$; see Figure 1. T is defined as the set of points Q above the ellipsoid that correspond to points P on $\sum$ having $U_{\mathrm{Q}} = W_{\mathrm{P}}$, $\phi_{\mathrm{Q}} = \phi_{\mathrm{P}}$, $\lambda_{\mathrm{Q}} = \lambda_{\mathrm{P}}$. This is called the Marussi telluroid and the ellipsoidal heights of its points are called normal heights H^*. The separation PQ between $\sum$ and T is called *height anomaly* ζ. The height anomaly is the solution to the Molodensky BVP, as defined by Equations 7 and 13, where now the boundary condition holds on the telluroid rather than the geoid and Δg refers to the Earth's surface rather than the geoid.

Analytical solutions to the geodetic BVPs

Since $\nabla^2 T = 0$, T and therefore N can be expressed as a spherical harmonic series (see *Gravity, Global Models*)

$$N = \frac{kM}{\gamma r}\sum_{n=2}^{\infty}\left(\frac{a}{r}\right)^n \sum_{m=0}^{n}\left[C_{nm}\cos m\lambda + S_{nm}\sin m\lambda\right]P_{nm}(\sin\phi) \tag{15}$$

the coefficients of which, S_{nm} and C_{nm}, can be determined from, for example, gravity anomalies on the geoid using the orthogonality property of spherical harmonics. P_{nm} are Legendre functions and r,ϕ,λ are the coordinates of the computation point. Applying Equation 15 to Equation 13, the spherical harmonic series for Δg is

$$\Delta g = -\frac{kM}{r^2}\sum_{n=2}^{\infty}\left(\frac{a}{r}\right)^n (n-1) \sum_{m=0}^{n}\left[C_{nm}\cos m\lambda + S_{nm}\sin m\lambda\right]P_{nm}(\sin\phi) \tag{16}$$

Another analytical solution of this problem is given by *Stokes's integral* (see *Gravity Field of the Earth*):

$$N = \frac{R}{4\pi\gamma}\iint_{\sigma}\Delta g S(\psi)\,d\sigma = \frac{1}{\gamma}\mathbf{S}\Delta g \tag{17}$$

where ψ is the spherical distance between data point and computation point, σ is the surface of a sphere of radius R (approximating the ellipsoid), and $\mathbf{S}$ is the Stokes integral operator. $S(\psi)$ is *Stokes's kernel function*

$$S(\psi) = \frac{1}{\sin(\psi/2)} - 6\sin\frac{\psi}{2} + 1 - 5\cos\psi - 3\cos\psi\ln\left(\sin\frac{\psi}{2} + \sin^2\frac{\psi}{2}\right) \tag{18}$$

$$\sin^2\frac{\psi}{2} = \sin^2\frac{\phi_P - \phi}{2} + \sin^2\frac{\lambda_P - \lambda}{2}\cos\phi_P\cos\phi \tag{19}$$

Molodensky's problem can be solved in various ways. We give here the final solution by the *method of analytical continuation to point level*; detailed derivations can be found in Moritz (1980). In this method, the gravity anomalies are reduced to the equipotential surface passing through the computation point P; see Figure 1. They are denoted by $\Delta g'$ and are obtained by the formula

$$\begin{aligned} \Delta g' &= \sum_{n=0}^{\infty} g_n, \\ g_n &= -\sum_{m=1}^{n} (h - h_P)^m \mathbf{L}_m g_{n-m}, \\ g_o &= \Delta g \end{aligned} \tag{20}$$

$\mathbf{L}$ is the *vertical derivative operator* expressed in terms of surface values as follows:

$$\begin{aligned} \mathbf{L}_m &= \frac{1}{m!}\mathbf{L}^m = \frac{1}{m!}\frac{\partial^m}{\partial h^m}, \\ \mathbf{Lf} &= -\frac{f}{R} + \frac{R^2}{2\pi}\iint_{\sigma}\frac{f - f_P}{l^3}\mathrm{d}\sigma \end{aligned} \tag{21}$$

where l is now the straight distance between the running point and the computational point P. Now, ζ at point P can be obtained by applying Stokes's integral operator $\mathbf{S}$ to $\Delta g'$:

$$\zeta = \frac{1}{\gamma}\mathbf{S}\Delta g' = \frac{1}{\gamma}\mathbf{S}\Delta g + \frac{1}{\gamma}\sum_{n=1}^{\infty}\mathbf{S}g_n = \sum_{n=0}^{\infty}\zeta_n \tag{22}$$

When the height anomaly is plotted above the ellipsoid, the resulting surface is called the *quasi-geoid*; see Figure 1. Since $h = H^* + \zeta \approx H + N$, the geoid undulation can be estimated from the height anomaly by the expression

$$\begin{aligned} N &= \zeta + \delta\zeta, \\ \delta\zeta &= H^* - H = \frac{\bar{g} - \bar{\gamma}}{\bar{\gamma}}H \approx \frac{\Delta g_B}{\gamma}H \end{aligned} \tag{23}$$

where $\bar{g}$ and $\bar{\gamma}$ are the mean values of gravity and normal gravity along the plumb line between the geoid and Earth surface and the normal plumb line between the ellipsoid and the telluroid, respectively, and $\Delta g_B = \Delta g - A_B + F$ is the Bouguer gravity anomaly at the computation point; the definitions of A_B and F are given after Equation 28. $H = \mathrm{PP''}_o$ and $H^* = \mathrm{QQ}_o$ are the *orthometric height* and *normal height*, respectively, of point P.

The operational solution to the geodetic BVPs

In contrast to the analytical solution which is model-driven, the operational solution is data-driven. It starts from the data and information about their noise and first and second moments (covariance functions) and estimates T as the "best" unbiased linear combination of the measurements. Besides being able to propagate the data noise into the results, it is also able to utilize as input, as well as predict, any functional of T. The harmonicity of T and the analytical relations between T and its functionals $f(T)$ are only used to derive the required covariance functions.

Mathematically, we want to estimate T, or more generally a signal vector $\mathbf{s}$ of functionals of T, from a vector of measurement $\mathbf{l}$, which can contain Δg or any other $f(T)$ such as, for example, deflections of the vertical, second-order gradients, geoid undulations, etc.

$$\hat{\mathbf{s}} = \mathbf{Hl} \tag{24}$$

In order to estimate the matrix $\mathbf{H}$, we require that the variances of the estimation errors $\mathbf{e} = \hat{\mathbf{s}} - \mathbf{s}$ be minimum or that the error covariance matrix $\mathbf{C}_{ee} = E\{\mathbf{ee}^T\}$ be minimum. By definition,

$$\begin{aligned} \mathbf{C}_{ee} &= E\{\mathbf{ee}^T\} \\ &= E\left\{(\mathbf{Hl} - \mathbf{s})(\mathbf{Hl} - \mathbf{s})^T\right\} \\ &= \mathbf{H}E\{\mathbf{ll}^T\}\mathbf{H}^T - E\{\mathbf{sl}^T\}\mathbf{H}^T - \mathbf{H}E\{\mathbf{ls}^T\} \\ &\quad + E\{\mathbf{ss}^T\} \\ &= \mathbf{HC}_{ll}\mathbf{H}^T - \mathbf{C}_{sl}\mathbf{H}^T - \mathbf{HC}_{ls} + \mathbf{C}_{ss} \\ &= \mathbf{C}_{ss} - \mathbf{C}_{sl}\mathbf{C}_{ll}{}^{-1}\mathbf{C}_{ls} \\ &\quad + \left(\mathbf{H} - \mathbf{C}_{sl}\mathbf{C}_{ll}{}^{-1}\right)\mathbf{C}_{ll}\left(\mathbf{H} - \mathbf{C}_{sl}\mathbf{C}_{ll}{}^{-1}\right)^T \end{aligned} \tag{25}$$

The last term in the right-hand side of the above equation is a nonnegative quadratic term and therefore $\mathbf{C}_{ee}$ can only be minimum when that term is zero, that is, when $\mathbf{H} = \mathbf{C}_{sl}\mathbf{C}_{ll}{}^{-1}$. Therefore,

$$\hat{\mathbf{s}} = \mathbf{C}_{sl}\mathbf{C}_{ll}^{-1}\mathbf{1} \tag{26}$$

$$\mathbf{C}_{ee} = \mathbf{C}_{ss} - \mathbf{C}_{sl}\mathbf{C}_{ll}^{-1}\mathbf{C}_{ls} \tag{27}$$

When the observations $\mathbf{l}$ contain noise $\mathbf{n}$, that is, consist of a signal component $\mathbf{t}$ and a noise component $\mathbf{n}$, then assuming that signal and noise are uncorrelated, the covariance matrices in the above equations become $\mathbf{C}_{ll} = \mathbf{C}_{tt} + \mathbf{C}_{nn}$, $\mathbf{C}_{ls} = \mathbf{C}_{ts}$, and $\mathbf{C}_{sl} = \mathbf{C}_{st} = \mathbf{C}_{ls}{}^T$. This method is generally known by the name of *least-squares collocation* (LSC). Knowledge of the covariance matrix of only one gravity field quantity is sufficient. From this, all other

covariance matrices can be derived by covariance propagation. A complete discussion of LSC can be found in Moritz (1980).

The treatment of the topography

The undulation of the geoid N can be obtained from the solution of Stokes's BVP provided that there are no masses outside the geoidal surface. There are many ways to mathematically account for the topographic masses, called *terrain reductions*, which preserve the total mass of the Earth but shift the masses above the geoid below it. *Helmert's second condensation reduction* will be briefly presented here as a representative from a number of possible terrain reductions. The masses above the geoid are basically condensed onto a layer on the geoid by (1) computing at point P and removing the attraction A_P of all masses above the geoid; (2) lowering station from P to P_o (see Figure 2) using the free-air reduction; and (3) restoring at P_o the attraction $A^c_{P_o}$ of the masses condensed on a layer on the geoid with density $\sigma = \rho H$. This procedure gives Δg on the geoid computed from the expression

$$\Delta g = \Delta g_P - A_P + F + A^c_{P_o} = \Delta g_P + F + \delta A \qquad (28)$$

where $F = -\partial g/\partial H \approx -\partial\gamma/\partial h$ is the free-air gravity gradient $\Delta(g_P + F)$ is the free-air gravity anomaly at P, and δA is the resulting attraction change.

The A and A^c terms in Equation 28 are obtained by applying Newton's integral in Equation 1 over the volume v of the relevant masses. For example, when the attraction A of all topographic masses above the geoid is computed, v is the volume of the masses between the geoidal surface and the surface of the topography. From Figure 2, it can be seen that $A = A_B - c$, where $A_B = 2\pi k\rho H$ (for ρ = constant) is the attraction of the infinite Bouguer plate through P called *Bugouer correction*, and c is the attraction of the residual topographic masses above and below the Bouguer plate, called the classical *terrain correction*.

δA is not the only change associated with this reduction. Due to the shifting of masses, the potential changes as well by an amount δT called the *indirect effect on the potential*:

$$\delta T = T_{P_o} - T^c_{P_o} \qquad (29)$$

where T_{P_o} is the potential of the topographic masses at P_o and $T^C_{P_o}$ is the potential of the condensed masses at P_o. The corresponding *indirect effect on the geoid* is $\delta N = \delta T/\gamma$. Due to this potential change, the use of Δg from Equation 28 into Equation 17 produces not the geoid but a surface called the *co-geoid*, depicted by the *co-geoidal height* N^c above the reference ellipsoid. Thus, before applying Stokes's equation, the gravity anomalies must be transformed from the geoid to the co-geoid by applying a small correction $\delta\Delta g$ called the *indirect effect on gravity*

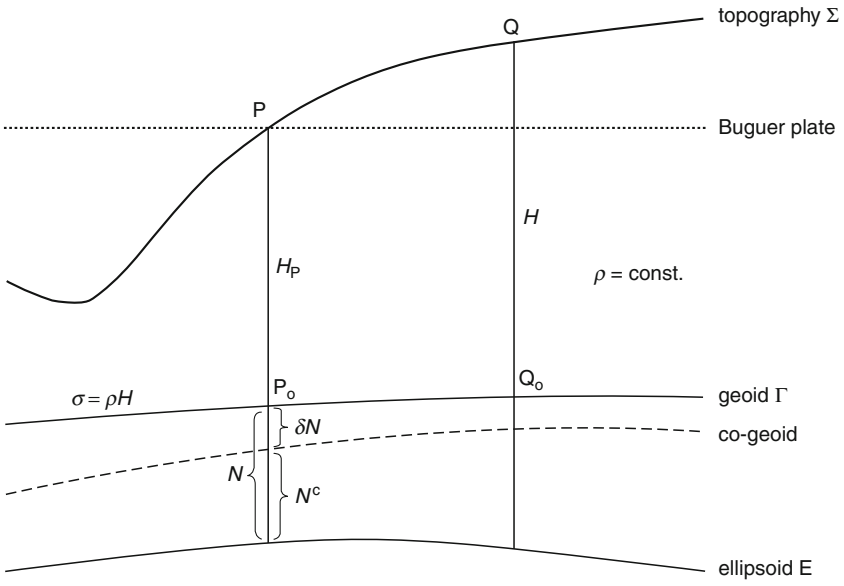
$$\delta\Delta g = -\frac{1}{\gamma}\frac{\partial\gamma}{\partial h}\delta T = -\frac{\partial\gamma}{\partial h}\delta N \qquad (30)$$

The final expression giving N can now be written as

$$N = \frac{1}{\gamma}\mathbf{S}(\Delta g + \delta A + \delta\Delta g) + \frac{1}{\gamma}\delta T = N^c + \delta N \qquad (31)$$

where N^c is the co-geoidal height and δN is the indirect effect on the geoid; see Figure 2.

Following Sideris (1990), δT and δA can formally be expressed using the planar approximation of the vertical derivative operator $\mathbf{L}$ of Equation 21, that is, without the



Geoid Determination, Theory and Principles, Figure 2 Actual and condensed topography.

term $-f/R$, which then becomes zero since $R \to \infty$ when the spherical surface is approximated by the tangent plane. The potential change is

$$\delta T = -\pi k \rho H_P^2 - 2\pi k \times \sum_{r=1}^{\infty} \frac{1}{(2r+1)!} \mathbf{L}^{2r-1}\left(\rho H^{2r+1}\right) \tag{32}$$

and the attraction change is equal to the classical terrain correction c:

$$\delta A = c = 2\pi k \sum_{r=1}^{\infty} \frac{1}{(2r)!} \mathbf{L}^{2r-1}\left[\rho (H - H_P)^{2r}\right] \tag{33}$$

These series expansions are valid for low slopes of the terrain, namely, for $(H - H_P)/l_o \leq 1$, where l_o denotes the planar distance between running and computational point.

Another commonly used terrain reduction is the *residual terrain model* (RTM) *reduction* (Forsberg and Tscherning, 1981). It computes at point P and removes only the high-frequency contributions of the topographic masses to gravity by, for example, computing the attraction of the masses between the actual topography and a very smooth "average topography" surface. The residual "geoid" produced by such reduced gravity anomalies is finally corrected by restoring the effect of the topographic masses that were removed. The RTM reduction yields a quasi-geoid rather than the geoid and, therefore, a final correction like the one in Equation 23 must be applied in the end in order to recover the actual geoid undulation.

The oceanic geoid and gravity from satellite altimetry

The only areas on Earth where, by definition, the geoid is almost directly observable are the oceans. From the difference between the ellipsoidal heights of altimetry satellites and the radar measurements to the surface of the sea, the ellipsoidal height h_s of the sea surface can be derived. h_s consists of the geoid undulation N and the sea surface topography (SST) H_s above the geoid. Thus, in principle, the geoid in the oceans can be derived from the expression

$$N = h_s - H_s \tag{34}$$

provided that a good model for the SST is available from oceanographic information. In addition, to minimize possible long-wavelength data biases, the *deflections of the vertical* are often derived numerically over the oceans as the slopes of the altimetry-derived geoid:

$$\xi = -\frac{\partial N}{r \partial \phi}, \eta = -\frac{\partial N}{r \cos\phi \partial \lambda} \tag{35}$$

Although theory exists for the solution of overdetermined and altimetry-gravimetry BVPs, where given are gravity anomalies on the continents and geoid from altimetry and/or gravity anomalies in the oceans, often in practice the oceanic geoid is also computed simply from Stokes's formula or from LSC using gravity data. Therefore, there is a need to obtain gravity anomalies in the oceans using as data altimetry-derived N and/or ξ,η.

Naturally, knowing N, one can use the following *inverse Stokes formula* to derive gravity anomalies in the oceans:

$$\Delta g_P = \frac{\gamma N_P}{R} - \frac{\gamma}{16\pi R} \iint_{\sigma} \frac{N - N_P}{\sin^3(\psi/2)} d\sigma \tag{36}$$

and then combine these gravity anomalies with the ones over land to produce a global set of gravity anomaly data which could be used in Stokes or LSC formulas to compute the global geoid. Note that the above equation has basically the form of the **L** operator acting on N, which, as expected, indicates that **L** and **S** are inverse operators. This can be proven easily, though rigorously, in planar approximation in the frequency domain; see details in *Geoid, Computational Method*.

Gravity anomalies in the oceans can also be computed from the deflections of the vertical, using the *inverse Vening Meinesz formula*

$$\Delta g_P = \frac{\gamma}{4\pi} \iint_{\sigma} (\xi \cos\alpha + \eta \sin\alpha) H(\psi) d\sigma \tag{37}$$

$$H(\psi) = \frac{\cos(\psi/2)}{2\sin(\psi/2)} \left(-\frac{1}{\sin(\psi/2)} + \frac{3 + 2\sin(\psi/2)}{1 + \sin(\psi/2)} \right) \tag{38}$$

where α is the azimuth of the line between the computation and the data point. A similar formula, termed the *deflection-geoid formula* (Hwang, 1998), also exists that gives N from ξ,η:

$$N_P = \frac{R}{4\pi} \iint_{\sigma} (\xi \cos\alpha + \eta \sin\alpha) C'(\psi) d\sigma \tag{39}$$

$$C'(\psi) = -\cot(\psi/2) + \frac{3}{2}\sin\psi \tag{40}$$

Another often used formula is the one that relates the vertical derivative of Δg to the horizontal derivatives of ξ and η. The spherical form of Laplace's equation is

$$\nabla^2 T = \frac{\partial^2 T}{\partial r^2} + \frac{2}{r}\frac{\partial T}{\partial r} + \frac{1}{r^2}\frac{\partial^2 T}{\partial \phi^2} - \frac{\tan\phi}{r^2}\frac{\partial T}{\partial \phi} + \frac{1}{r^2 \cos^2\phi}\frac{\partial^2 T}{\partial \lambda^2} = \frac{\partial \Delta g}{\partial r} + \gamma \frac{\partial \xi}{r \partial \phi} - \frac{\tan\phi}{r}\gamma\xi + \gamma \frac{1}{r\cos\phi}\frac{\partial \eta}{\partial \lambda} = 0 \tag{41}$$

If we neglect the third term on the right-hand side, we get

$$\frac{\partial \Delta g}{\partial r} = -\gamma\left(\frac{\partial \xi}{r\partial \phi} + \frac{1}{r\cos\phi}\frac{\partial \eta}{\partial \lambda}\right) \quad (42)$$

It is clear that since Δg, ξ, η, N, and their various derivatives are all functionals of T, they could all be used as input in LSC to predict both Δg and N in the oceans. Therefore, collocation could be used to either predict directly undulations and anomalies in the oceans from any gravity field quantity, or to densify or interpolate data necessary for the efficient evaluation of integrals like inverse Stokes or inverse Vening Meinesz. Details can be found in *Geoid, Computational Method*.

Summary

We have discussed briefly how the geoid is defined and how it can be estimated either analytically as the solution of the third BVP (or Molodensky's BVP) from gravity anomalies all over the Earth or as a "best" unbiased linear combination of all available gravimetric data using least-squares collocation. In either case, data have to be reduced to the geoid via an appropriate terrain reduction. The methodology used in the numerical determination of geoid undulations is described in the Chapter on the *Geoid, Computational Method*. The reader interested in obtaining a more comprehensive view of gravity field approximation is encouraged to also read the other chapters on geoid and gravity included in this volume. Finally, with dedicated gravity satellites like GRACE, the computation of temporal variations of the geoid and its application to other geosciences is now possible. This, however, is beyond the scope of this short entry and will not be discussed here.

Synonyms

Geoidal height, aka geoid undulation; Direct gravimetric problem, aka forward modeling; Moho surface, aka compensation level for the Airy-Heiskanen isostatic hypothesis; Depth of Moho surface is the same as the thickness of the lithosphere; Schiaparelli's body, aka body of nil external potential; Stokes's integral truncated to the spherical distance of ψ_0, aka inner zone contribution to Stokes's integral; Spectral transfer function, aka admittance; Sea surface topography (SST), aka dynamic topography; Ocean bottom depth, aka bathymetry

Definition

Direct gravimetric problem is defined as follows: "Given the distribution of density within the Earth, derive the (external) gravity field the density generates."

The *inverse gravimetric problem* (GIP) reads: "Given the external gravity field of the Earth, derive the distribution of density implied by the field."

Introduction

The main goal of geophysics is to learn about the physical processes as well as properties of the material within the Earth. These are studied by means of measurements (data) collected on the surface of the Earth and above it and, to a very limited degree, also in very shallow probes inside the Earth. The discussion of the data to be collected and the techniques to be used to study the physical processes and material properties within the earth are what this book is all about.

The focus of this section is on gravity field, the geoid in particular, to the exclusion of all other, such as seismological, magnetic, electrical, heat flow data. The only attribute of the Earth that can be studied by means of gravity is the mass density variations as gravity is the acceleration caused by mass attraction. Three aspects of gravity field can be used for these studies: gravity acceleration, the deflection of the vertical, and gravity potential. Gravity acceleration, in the guise of gravity anomalies, are discussed in *Gravity Anomalies, Interpretation*, the

deflections of the vertical are introduced in *Geodesy, Physical* and for an in-depth view of the definition of geoid the reader is advised to consult *Geoid*.

One of the general properties of the gravity filed is that deep-seeded density anomalies have long wavelength signature in the gravity field while shallow density anomalies have short wavelength signature. Consequently, if one wishes to study shallow density features, one looks at the short wavelength part of gravity field and if one wishes to study deep-seeded features, one looks at the longer wavelength part. This is, of course, true only as a general principle as there exist also shallow features of large lateral extent that have long wavelength signatures.

When it comes to the interpretation of gravity field, the data of choice by exploration geophysicists, that is, people looking for ore, hydrocarbon, and other deposits, are gravity anomalies. The reason for this is that these data are bountiful on land, relatively cheap, and they contain all the short wavelength information. Observed deflections of the vertical as supplied by national geodetic offices are less popular as a source of information as they are not very accurate, and they are few and far apart. But we may live to see this situation change with the advent of Digital Zenith Cameras (Hirt et al., 2010).

Gravity potential data, such as the values of disturbing potential – divided by the value of gravity to convert them to the geoid – are much smoother than the first two kinds. This means that the short wavelength content is missing. We know that all three descriptors of gravity field we discuss here are functionally related: gravity acceleration at a point is a total gradient of the potential at that point, the deflection of the vertical at a point is a horizontal gradient of the equipotential surface passing through that point. Thus, there is nothing to stop us from using the potential data, the geoid, in such a way as to evaluate either the gravity anomalies or the deflections of the vertical and use these for the interpretation, is there?

That can be done of course, but this procedure cannot reconstitute the high frequency content as it has not been there to begin with. Thus, the conversion would not help and it is better to use the geoid as is; this is the thesis of the book (Vaníček and Christou, 1993). The direct use of the geoid has caught an interest of interpreters as the marine geoid data from satellite altimetry became quite reliable and freely available in the past 25 years.

Direct problem

Suppose we know the density distribution $\rho(\mathbf{r})$ within the Earth. Then we can determine the potential $V(\mathbf{r})$ outside the earth in two different ways. We can use the well-known Newton's integral to get the gravitational potential in a spatial form at any point external to the Earth as (Vaníček and Krakiwsky, 1986, Equation 20.48)

$$V(r,\Omega) = G \int_{\Omega_0} \int_{r=0}^{r_t(\Omega')} \frac{\rho(r',\Omega')}{|\mathbf{r}-\mathbf{r}'|}(r')^2 \mathrm{d}r'\mathrm{d}\Omega', \qquad (1)$$

where G is Newton's gravitational constant, r is the radial distance from the center of the Earth, Ω is the geocentric direction composed of colatitude θ and longitude λ, Ω_0 is the full geocentric solid angle, r_t is the distance from the center of the Earth to the topographical surface of the Earth.

Alternatively, the reciprocal distance $\frac{1}{|\mathbf{r}-\mathbf{r}'|}$ can be developed into a series of fully normalized spherical harmonic complex functions Y_{jm} to yield

$$V(r,\Omega) = \frac{GM}{a}\sum_{j=0}^{\infty}\left(\frac{a}{r}\right)^{j+1}\sum_{m=-j}^{j} A_{jm}Y_{jm}(\Omega), \qquad (2)$$

where M is the mass of the Earth, a is the major semiaxis of the best fitting Earth ellipsoid, and A_{jm} are the gravity potential coefficients. The potential coefficients can be evaluated from the known density $\rho(\mathbf{r}) = \rho(r, \Omega) = \rho(r, \theta, \lambda)$ within the Earth as

$$A_{jm} = \int_{\Omega_0}\int_{r=0}^{r_t(\Omega)} \rho(r,\Omega)G_{jm}(r,\Omega)\mathrm{d}r\mathrm{d}\Omega, \qquad (3)$$

where the integration kernel G_{jm} is given by Martinec in Vaníček and Christou (1993, Chap. 7, Equations 13 and 14)

$$G_{jm}(r,\Omega) = \frac{4\pi}{Ma^j(2j+1)}r^{j+2}Y_{jm}*(\Omega). \qquad (4)$$

Here * denotes a complex conjugate. This is the spherical harmonic form of potential V, a dual form to the spatial form (Equation 1 above) – these two forms can be transformed into each other, back and forth any time. The relation between potential V and the geoid undulation N is explained in *Geodesy, Physical*.

The direct approach, also known as forward modeling, can be used for solving some geophysical problems. Notably, it can be used to determine the depth of Mohorovicic's surface, the surface that divides the astenosphere (density about 3.2 g cm^{-3}) from the lithosphere (density about 2.67 g cm^{-3}). The Moho surface is also the compensation level for the Airy-Heiskanen isostatic hypothesis. The depth of the Moho surface, or the lithospheric (crustal) thickness derived this way, assuming the most realistic astenospheric density and described by a spherical harmonic series of a limited degree and order is shown on a web page http://geology.com/articles/mohorovicic-discontinuity.shtml. The displayed map was compiled by US Geological Survey in 1999.

Inverse problem

The determination of density $\rho(\mathbf{r})$ as a function of position $\mathbf{r}$ from any of the gravity field attributes, that is, gravity anomaly $\Delta g(\mathbf{r})$, the components of the deflection of the vertical $(\xi(\mathbf{r}),\eta(\mathbf{r}))$, or the geoidal height $N(\mathrm{r})$, is known as the inverse gravity problem (GIP). The non-uniqueness of GIP was known already to Schiaparelli, who in

1875–1876 was speaking of "gravitationally transparent bodies," specific distributions of density that do not generate any gravitational attraction outside the Earth. A complete mathematical description of a Schiaparelli's body was formulated by Vaníček and Kleusberg (1985) as follows: for arbitrary values of coefficients $c^{(i)}_{\ell jk}$ the following "body":

$$\theta \in <-\frac{\pi}{2},\frac{\pi}{2}>, \lambda \in <0, 2\pi>, r \in <0, 1>:$$
$$\tilde{\rho}(\mathbf{r}) = \sum_{i=0}^{\infty} \sum_{\substack{\ell=0 \\ \ell \neq j}}^{i} \sum_{j=0}^{\infty} \sum_{k=0}^{j} c^{(i)}_{\ell jk} \phi_{ijk}(\mathbf{r}), \tag{5}$$

where

$$\forall i,j = 0, 1, ..., k \leq j : \phi_{ijk}(\mathbf{r}) = J_i(3, 3, r)[Y^c_{jk}(\Omega), Y^s_{jk}(\Omega)], \tag{6}$$

J_i are normalized Jacobi polynomials (Abramowitz and Stegun, 1964) and Y^c_{jk}, Y^s_{jk} are the cosine and sine parts of spherical harmonic functions, has a nil external potential outside the ball of radius 1. The consequence of this behavior is that if one tries to interpret the external gravity potential in terms of internal density distribution, any distribution that conforms to Equation 5 can be randomly and legitimately added to the solution.

If the GIP does not have a unique solution, does it make any sense to even think about using gravity in studying the density distribution? True, it is not possible to take the gravity field outside the Earth and invert it uniquely into the density distribution within the Earth. But the external gravity field, particularly the geoid in our context here, can be used together with other data to get useful information on density.

Truncated geoid

There is a variety of techniques used in geophysical exploration to interpret gravity information obtained on the surface of the Earth in terms of anomalous density. One interesting approach uses the truncated geoid to determine the depth of a spherical, i.e., ball-like, density anomaly, where by "truncated geoid" we understand the following integral:

$$N^{\psi_0}(P) = \frac{R}{4\pi\gamma} \int_{C_{\psi_0}} \Delta g(Q) S(P, Q) \mathrm{d}\sigma, \tag{7}$$

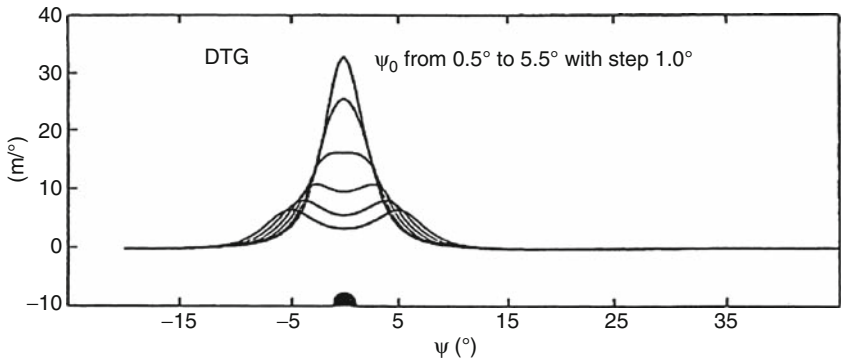
which represents the contribution of gravity to the geoid within the spherical cap C of a radius ψ_0. It can be viewed as the Stokes integral over the whole Earth, truncated to the spherical distance ψ_0, where P is the point of interest, Q is the dummy point in the integration, $S(P,Q) = S(\psi)$ is the Stokes spherical kernel and $\mathrm{d}\sigma$ is the surface element of the integration sphere of radius R.

It is the change of the truncated geoid with respect to the truncation parameter ψ_0,

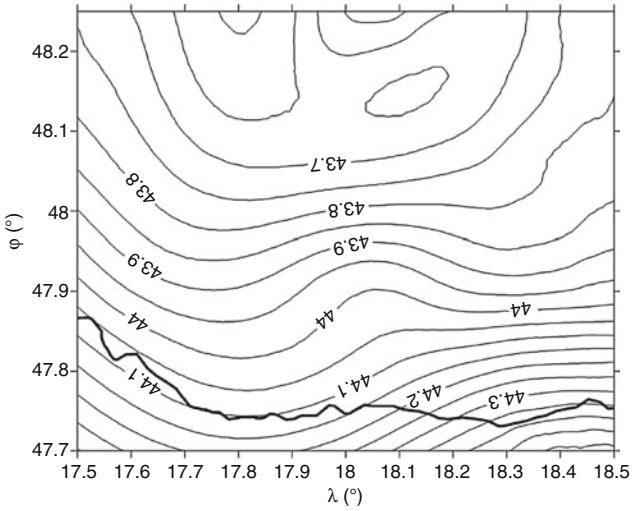
$$\frac{\mathrm{d}N^{\psi_0}}{\mathrm{d}\psi_0} = \lim_{\Delta\psi_0 \to 0} \frac{N^{\psi_0+\Delta\psi_0} - N^{\psi_0}}{\Delta\psi_0}, \tag{8}$$

that is of real interest. At the location of the density anomaly, the sequence of surfaces or profiles $\frac{\mathrm{d}N^{\psi_0}}{\mathrm{d}\psi_0}$ displays a dimple for a specific value of ψ_0 – see Figure 1 (from Vajda and Vaníček, 1999). This specific value of ψ_0 is almost linearly related to the depth of the anomaly.

In Figure 2, geoid from an area in Southern Slovakia is shown. Just northeast of the geographical center of the area, there is a local geoid low, known as "Kolarovo anomaly," that has been intriguing geophysicists for some time. It has been postulated by several authors that the center of mass of the density anomaly responsible for



Geoid Undulation, Interpretation, Figure 1 Sequence of profiles of the change of the truncated geoid with respect to the truncation parameter ψ_0 that shows the onset of the dimple for a value of $\psi_0 = 2.5°$.



Geoid Undulation, Interpretation, Figure 2 Geoid in the area of "Kolarovo anomaly" in Southern Slovakia (Courtesy of J. Janak, Slovak University of Technology).

the shown pattern is about 9.5 km bellow the Earth surface. The application of the truncated geoid technique shows an estimate of 8.7 km (Vajda et al., 2002).

Some other applications

In addition to the above-discussed applications, geoid can be used in many other ways; one of those applications is studying tectonic forces. Interested reader may read about the involved concepts in *Gravity, Global Models*. Bowin, in his earlier studies (1991), postulated that the 4–10° geoid undulations are consistent with the present zones of subducted tectonic slabs. His postulate has more recently been confirmed by Ricard et al. (2006). These authors also agree with Bowin's speculation (1983) that only the deepest Earth's mass anomalies cause geoid undulations of 2–10°.

Casenave in Vaníček and Christou (1993, Ch. 13) discusses the use of the geoid in studying different isostatic compensation models using the spectral transfer function, aka admittance in the "theory of systems" parlance. She studies the mechanical behavior of oceanic tectonic plates (flexure under seamount loading) and thermal evolution of oceanic lithosphere. Ricard et al. (2006) show that the elasticity of the lithosphere affects the geoid between 200° and 250°. Casenave also argues that the signatures of oceanic hot spots in the geoid are in the medium wavelength of $n \in (5, 20)$ and in 1–10 m in range.

It may be worth mentioning that meteorite craters are often clearly discernible in detailed geoid maps. The Manicouagan crater in Eastern Canada (location: N 51° 23′ and W 68° 42′) makes a very clear imprint on the geoidal map.

The last applications of the geoid we want to show here concern physical oceanography and the oceans in general. A very good overview of this topic by Nerem and Koblinsky is in Vaníček and Christou (1993, Chap. 16). Geoid, being an equipotential (level) surface, should be represented by the mean sea level if seawater were homogeneous, which, of course, it is not. As a result, the mean sea level is not in equilibrium and currents develop. Some time after the initiation of this motion, these currents reach a steady state, called geostrophic, and swirl around the globe in a perpetual motion attenuated only by friction.

The equation that describes the geostrophic motion is ascribed to Navier and Stokes, and it reads as follows:

$$\boldsymbol{V} + (\boldsymbol{V} \bullet \nabla)\boldsymbol{V} + 2\boldsymbol{\Omega} \times \boldsymbol{V} = \frac{-\nabla p}{\rho} + \boldsymbol{g} + \boldsymbol{F}, \qquad (9)$$

where $\boldsymbol{V}$ is the flow velocity vector, $\boldsymbol{\Omega}$ is the rotation vector of the Earth, p is the hydrostatic pressure, ρ is the seawater density, $\boldsymbol{g}$ is the gravitation vector, and $\boldsymbol{F}$ is the vector representing frictional forces (*ibid.* Equation 1). This equation, together with measurements taken at sea, is then used to derive the height of the sea surface above the geoid, which is called the "dynamic topography."

As discussed above, the instantaneous sea surface has been monitored by a technique called satellite altimetry for years. This surface represents, of course, the sum of the geoidal height and the dynamic topography. Subtracting the geoid from the measured sea surface yields the dynamic topography that can be easily converted into information about currents. Conversely, subtracting the dynamic topography from the measured surface yields the geoid. Interested reader can refer to following URL http://www.aviso.oceanobs.com/en/data/products/auxiliary-products/index.html for more detailed information.

Last but not least, the geoid obtained from satellite altimetry can be used to calculate the ocean bottom depth, aka bathymetry (Sandwell et al., 2006). The principle used in these calculations is the same as the one used in the determination of the Moho surface. Acknowledging that the ocean bottom is a surface that divides the crust (of an average density of 2.67 g cm^{-3}) from the layer of water (of an average density of 1.03 g cm^{-3}), forward modeling it then used to yield the ocean bottom surface.

Summary

The geoidal height (geoid undulation) is a quantity that can be quite readily interpreted in terms of density distribution within the Earth. The main application is in studying the processes that take place deep within the Earth, but even shallower density anomalies have an impact on a geoid map. Nowadays, when sea surface height

measured by satellite altimetry is freely available, marine geoid has become a particularly handy tool to use.

GEOID, COMPUTATIONAL METHOD

Michael G. Sideris
Department of Geomatics Engineering, University of Calgary, Calgary, AB, Canada

Introduction

In this entry, we are presenting numerical methods for estimating geoid undulations and other relevant quantities, based on the theory presented in the article on *Geoid Determination, Theory and Principles*. We will refer to formulas in that article by the equation number followed by Sideris (see *Geoid Determination, Theory and Principles*). For example, Stokes's equation will be referred to as Equation 17 of the article *Geoid Determination, Theory and Principles*.

The remove-compute-restore technique

In practice, we can evaluate Stokes's equation by numerical integration using only discrete data; therefore, short-wavelength information will not be properly represented in the solution (it will be aliased). In addition, we use data only in a certain region, and therefore the long-wavelength contributions of the gravity field will not be present in the results and must be computed in another way. These problems can be remedied by using a global geopotential model (GM) and heights, *H,* in a digital elevation model (DEM) to obtain the long and short wavelengths of the field, respectively. This leads to the standard *remove-compute-restore technique*, in which the long and short wavelengths are first removed from the gravity anomalies in a preprocessing step, then the residual anomalies Δg_r are used to compute residual undulations $N_{\Delta gr}$, and then the long- and short-wavelength contributions are restored in a post-processing step. The computation is based on the following formula:

$$N = N_{\mathrm{GM}} + N_{\Delta g_r} + N_{\mathrm{H}}, \quad \Delta g_r = \Delta g - \Delta g_{\mathrm{GM}} - \Delta g_{\mathrm{H}} \tag{1}$$

where Δg_{H} denotes the terrain contributions and N_{H} the corresponding indirect effect on the geoid; see Figure 1. It should also be noted that such residual anomalies are typically smaller and smoother, and therefore appropriate for use in interpolation and in the creation of gridded values by, e.g., least-squares collocation.

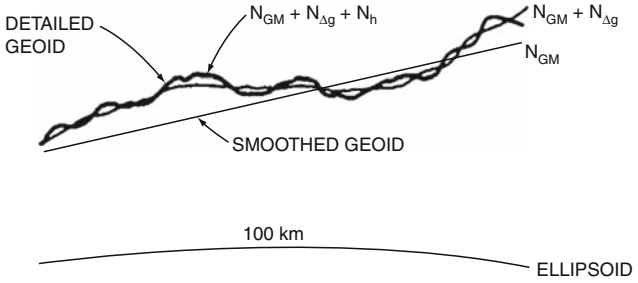
Computation of the GM-contributions

The geopotential model parts of Δg and N are usually computed by the spherical approximation of Equations 15 and 16 in Sideris, *Geoid Determination, Theory and Principles* from the coefficients of a GM of maximum degree $n_{\max}$, which is a function of the resolution of the data that were used to compute the coefficients C_{nm}, S_{nm}:

$$N_{\mathrm{GM_P}} = R \sum_{n=2}^{n_{\max}} \sum_{m=0}^{n} [C_{nm} \cos(m\lambda_{\mathrm{P}}) + S_{nm} \sin(m\lambda_{\mathrm{P}})] P_{nm}(\sin \phi_{\mathrm{P}}) \tag{2}$$

$$\Delta g_{\mathrm{GM_P}} = G \sum_{n=2}^{n_{\max}} (n-1) \sum_{m=0}^{n} [C_{nm} \cos(m\lambda_{\mathrm{P}}) + S_{nm} \sin(m\lambda_{\mathrm{P}})] P_{nm}(\sin \phi_{\mathrm{P}}) \tag{3}$$

G and R are the mean gravity and mean radius of the sphere, and ϕ_{P}, λ_{P} are the spherical latitude and longitude



Geoid, Computational Method, Figure 1 Contributions of different data to regional geoid determination.

of the computation point. This representation causes an omission or truncation error, but there is also a commission error because the data used to estimate the coefficients, and therefore also the coefficients themselves, do contain errors. Naturally, the spherical approximation itself causes an additional error, and therefore Equations 15 and 16 in Sideris, *Geoid Determination, Theory and Principles* are preferable to Equations 2 and 3.

A comprehensive discussion on the determination and proper use of GM coefficients can be found in *Spherical Harmonic Analysis Applied to Potential Fields*. Information on the high-resolution EGM08 model is given in Pavlis et al. (2008).

Computation of the Δ*g*-contribution

The contribution of gravity anomalies can be computed by use of either the Stokes integral or least-squares collocation (LSC). For simplicity in the notation, we will often write just N and Δg instead of $N_{\Delta g_r}$ and Δg_r in the equations, respectively.

Evaluation of Stokes's integral. The Stokes integral can be evaluated either on the sphere or on the plane by numerical integration using data on circular sectors (ring integration method) or on regular grids. Since gravity data are typically available on grids, and because Stokes's integral is a convolution integral on the plane and along parallels on the sphere, we will discuss here the integral's evaluation on regular grids by use of the very efficient *fast Fourier transform* (FFT) *technique* (Bracewell, 1978).

On the sphere, using Equations 17–19 in Sideris, *Geoid Determination, Theory and Principles*, we can write Stokes's integral explicitly as

$$N_P = \frac{R}{4\pi\gamma} \iint_{\sigma} \Delta g S(\phi_p, \phi, \lambda - \lambda_p) \cos\phi \, d\phi d\lambda \tag{4}$$

which is a convolution between $\Delta g \cos\phi$ and the Stokes kernel S only along parallels. For Δg_r given on $M \times N$ points on a spherical grid with spacings $\Delta\phi$, $\Delta\lambda$, Equation 4 can be written for every parallel of constant latitude ϕ_l as

$$\begin{aligned} N_{\Delta g_r}(\phi_l, \lambda_k) &= \frac{R}{4\pi\gamma} \sum_{j=0}^{N-1} \left[\sum_{i=0}^{M-1} \Delta g_r(\phi_j, \lambda_i) \cos\varphi_j \right. \\ &\quad \left. S(\phi_l, \phi_j, \lambda_k - \lambda_i) \Delta\lambda \right] \Delta\phi \\ &= \frac{R}{4\pi\gamma} \sum_{j=0}^{N-1} [(\Delta g_r(\phi_j, \lambda_k) \cos\phi_j) * \\ &\quad S(\phi_l, \phi_j, \lambda_k)] \Delta\phi, \\ &\quad \phi_l = \phi_1, \phi_2, \ldots, \phi_N \end{aligned} \tag{5}$$

The brackets in Equation 5 contain a one-dimensional (1D) discrete convolution with respect to l, i.e., along a parallel. Therefore, the above discrete convolution, denoted by $*$, can be evaluated by the 1D FFT (Starng Van Hees, 1990; Haagmans et al., 1993) as follows:

$$\begin{aligned} N_{\Delta g_r}(\phi_l, \lambda_k) = \frac{R}{4\pi\gamma} F^{-1} \left\{ \sum_{j=0}^{N-1} F\left\{ \Delta g_r(\phi_j, \lambda_k) \cos\phi_j \right\} \right. \\ \left. F\left\{ S(\phi_l, \phi_j, \lambda_k \right\} \right\}, \; \phi_l = \phi_1, \phi_2, \ldots, \phi_N \end{aligned} \tag{6}$$

where F denotes the direct Fourier transform and F^{-1} the inverse Fourier transform (Bracewell, 1978). Although Equation 6 is rigorous, its evaluation is not as efficient as it could be, as it still requires numerical summation along meridians. By employing various approximations for the Stokes kernel function, such as, e.g., $\cos\phi_P \cos\phi = \cos^2\bar{\phi}$, where $\bar{\phi}$ is the mean latitude of the computation area, it is possible to transform Equation 6 into a two-dimensional (2D) convolution. In this case, accuracy is traded for efficiency. Detailed formulas can be found in Forsberg and Sideris (1993).

In the planar approximation, which can be employed when the data is available in a limited area E with extent of no more than several degrees in each direction, the Stokes kernel can be approximated by its first term $1/\sin(\psi/2)$. Then the kernel and the differential areal can be converted to their planar equivalents, i.e., $S(\psi) \approx 1/\sin(\psi/2) \approx 2/\psi \approx 2R/l$, and $R d\sigma = dxdy$, yielding the following *planar form of Stokes's integral* (Schwarz et al., 1990):

$$N_P = \frac{1}{2\pi\gamma} \iint_E \frac{\Delta g}{l} dxdy = \frac{1}{2\pi\gamma} \Delta g_P * l_{N_P} \tag{7}$$

where l is the planar distance between data and computation point and l_N is the planar form of Stokes's kernel:

$$l_{\mathrm{N}} = \left(x^2 + y^2\right)^{-1/2} \tag{8}$$

On a grid with spacings Δx, Δy, the above 2D convolution integral takes the discrete form

$$\begin{aligned} N_{\Delta g_{\mathrm{r}}}(x_k, y_l) &= \frac{1}{2\pi\gamma} \sum_{i=0}^{M-1} \sum_{j=0}^{N-1} \Delta g_{\mathrm{r}}(x_i, y_j) \\ &\quad l_N(x_k - x_i, y_l - y_j) \Delta x \Delta y \\ &= \frac{1}{2\pi\gamma} \Delta g_{\mathrm{r}}(x_k, y_l) * \; l_N(x_k, y_l) \end{aligned} \tag{9}$$

$$\begin{aligned} & l_{\mathrm{N}}(x_k - x_i, y_l - y_j) \\ &= \begin{cases} [(x_k - x_i)^2 + (y_l - y_j)^2]^{-1/2}, & x_k \neq x_i \;\; or \;\; y_l \neq y_j \\ 0, & x_k = x_i \;\; and \;\; y_l = y_j \end{cases} \end{aligned} \tag{10}$$

Geoid undulations can then be evaluated by the 2D FFT as follows:

$$N_{\Delta g_{\mathrm{r}}}(x_k, y_l) = \frac{1}{2\pi\gamma} F^{-1}\left\{ F\{\Delta g_{\mathrm{r}}(x_k, y_l)\} F\{l_{\mathrm{N}}(x_k, y_l)\} \right\} \tag{11a}$$

or, in more compact form (which we will use for all convolutions from this point on),

$$N_{\mathrm{P}} = \frac{1}{2\pi\gamma} F^{-1}\left\{ F\{\Delta g_{\mathrm{P}}\} F\{l_{N_{\mathrm{P}}}\} \right\} \tag{11b}$$

Because $S(\psi)$ and l_{N} are singular at the origin, the contribution of the gravity anomaly of the computation point must be evaluated separately and added to the results of the convolutions. On the sphere, Hofmann-Wellenhof and Moritz (2006) give this contribution approximately as

$$\mathrm{d}N_{\Delta g_{\mathrm{r}}}(\varphi_{\mathrm{P}}, \lambda_{\mathrm{P}}) \approx \gamma^{-1} s_{\mathrm{o}} \Delta g_{\mathrm{r}}(\varphi_{\mathrm{P}}, \lambda_{\mathrm{P}}) \tag{12}$$

where s_{o} denotes the radius of a small area around the computation point in which Δg_{r} can be considered constant. On the plane, the corresponding equation would be

$$\mathrm{d}N_{\Delta g_{\mathrm{r}}}(x_{\mathrm{P}}, y_{\mathrm{P}}) \approx \gamma^{-1} \sqrt{\frac{\Delta x \Delta y}{\pi}} \Delta g_{\mathrm{r}}(x_{\mathrm{P}}, y_{\mathrm{P}}) \tag{13}$$

Equation 11 employs the numerical evaluation of the spectrum of Stokes's kernel and is the one that should be used in practice (with proper zero padding of the data) if we want the results from FFT to be identical to those from numerical integration; see Li and Sideris (1993). This is in fact true for any of the other convolution integrals that we are discussing here. Nevertheless, it is well known from Fourier theory that the inverse distance function l_{N} has an analytical spectrum, which is the inverse frequency q^{-1} in the frequency domain. Using u,v,w to denote the frequencies corresponding to x,y,z, this spectrum is

$$\begin{aligned} F\{l_{\mathrm{N}}(x, y)\} &= F\left\{ \left(x^2 + y^2\right)^{-1/2} \right\} \\ &= \left(u^2 + v^2\right)^{-1/2} = q^{-1} \end{aligned} \tag{14}$$

and therefore Equation 7 can be evaluated as follows:

$$N_{\mathrm{P}} = \frac{1}{2\pi\gamma} F^{-1}\left\{ F\{\Delta g_{\mathrm{P}}\} q^{-1} \right\} \tag{15}$$

This representation clearly shows that Stokes's integral is a smoothing, mainly low-frequency-dependent operator, and therefore geoid undulations are more sensitive to the long wavelengths of the gravity field.

The FFT method can use either mean or point data on a grid and computes simultaneously the geoidal heights at all grid points; see Sideris and Tziavos (1988) for the formulas with mean data. A large area can thus be covered very fast and with minimum cost. An interpolation technique such as LSC must be employed for predicting geoidal heights at points not on the grid and/or to grid irregular gravity anomalies. With gridded data, the FFT technique is by far the fastest of all available methods. Criticism that only the FFT suffers from leakage and aliasing effects are not valid since these effects depend on data density and coverage and thus affect all methods.

Given gridded gravity and topography data, the Molodensky solution of Equations 20–22 in Sideris, *Geoid Determination, Theory and Principles* can also be efficiently evaluated by FFT. Details can be found in Sideris (1987) and Schwarz et al. (1990).

Computation by least-squares collocation. A solution can also be obtained using least-squares collocation (LSC). For example, in the simple case that we only want to predict residual geoid undulations from residual gravity anomalies, the Equations 26 and 27 in Sideris, *Geoid Determination, Theory and Principles* reduce to

$$\hat{\mathbf{N}}_{\Delta g} = \mathbf{C}_{\mathrm{N}\Delta g}\left(\mathbf{C}_{\Delta g \Delta g} + \mathbf{C}_{nn}\right)^{-1} \mathbf{\Delta g} \tag{16}$$

$$\mathbf{C}_{ee} = \mathbf{C}_{NN} - \mathbf{C}_{N\Delta g}\left(\mathbf{C}_{\Delta g \Delta g} + \mathbf{C}_{nn}\right)^{-1} \mathbf{C}_{\Delta g N} \tag{17}$$

Given the covariance matrix for T, $\mathbf{C}_{\mathrm{TT}}$, the other covariance matrices can be derived by covariance propagation using Equations 12 and 13 in Sideris, *Geoid Determination, Theory and Principles* as follows:

$$\begin{aligned} \mathbf{C}_{NN} &= \frac{1}{\gamma^2} \mathbf{C}_{TT}, \\ \mathbf{C}_{N\Delta g} &= \frac{1}{\gamma}\left(-\frac{\partial \mathbf{C}_{TT}}{\partial h} + \frac{1}{\gamma}\frac{\partial \gamma}{\partial h} \mathbf{C}_{TT} \right), \\ \mathbf{C}_{\Delta g \Delta g} &= \left(-\frac{\partial}{\partial h} + \frac{1}{\gamma}\frac{\partial \gamma}{\partial h} \right)\left(-\frac{\partial \mathbf{C}_{TT}}{\partial h} + \frac{1}{\gamma}\frac{\partial \gamma}{\partial h} \mathbf{C}_{TT} \right) \end{aligned} \tag{18}$$

LSC's drawback is the need for inverting large covariance matrices or simply solving large systems of linear equations, which in practice often prevents the utilization of all given data, and thus prevents the application of LSC over large regions. To circumvent this problem, if gridded data are available, LSC can be applied in the frequency domain. This is actually related directly to the use of FFT formulas with noisy, heterogeneous data. It will in fact be shown below that the FFT method can use heterogeneous data, provided that they are given on a grid, and can produce error estimates, provided that the power spectral density (PSD) functions, which are the Fourier transform of the covariance functions, of the data and their noise are known. In this case, the technique is equivalent to frequency-domain collocation.

Computation by frequency-domain collocation. To illustrate how error propagation can be used with Stokes's integral, assume that the anomalies have errors n with known PSD P_{nn}. In this case, Stokes's convolution of, e.g., Equation 7, becomes

$$N = (\Delta g + n) * s + e \tag{19}$$

where $s = l_N/(2\pi\gamma)$ and e is the error of the estimated undulations.

Making use of the definition of the PSD function P_{xy} for two signals x and y as

$$P_{xy} = F\{x\}F\{y\}^* \tag{20}$$

where the superscript $*$ denotes complex conjugate, and assuming no correlation between the signal and noise, the PSD of N and the cross-PSD of Δg and N can be derived as follows:

$$P_{NN} = P_{ee} + S(P_{\Delta g\Delta g} + P_{nn})S^* \tag{21}$$

$$P_{\Delta gN} = P_{\mathrm{ee}} + S(P_{\Delta g\Delta g} + P_{nn}) \tag{22}$$

where $S = F\{s\}$ and $P_{\Delta g\Delta g}$ is the PSD of the gravity anomalies. From the above equations, the spectrum of Stokes's kernel and the output-noise PSD can be obtained as

$$S = \frac{P_{N\Delta g}}{P_{\Delta g\Delta g} + P_{nn}} \tag{23}$$

$$P_{\mathrm{ee}} = P_{NN} - P_{N\Delta g}(P_{\Delta g\Delta g} + P_{nn})^{-1}P_{N\Delta g} \tag{24}$$

Now Equation 19 can be evaluated in the frequency domain as follows:

$$F\{N\} = P_{N\Delta g}(P_{\Delta g\Delta g} + P_{nn})^{-1}F\{\Delta g\} \tag{25}$$

One can see immediately that Equations 24 and 25 are, formally, the frequency-domain equivalents of the LSC Equations 16 and 17. In fact, they can also be obtained starting from the general form of the equation for P_{ee} and estimating that $S = F\{s\}$ which makes P_{ee} minimum; such a derivation can be found in Sideris (1996). What makes them much more efficient, though, is that they require no matrix inversion as the -1 superscript in Equations 24 and 25 implies straightforward division at each frequency. Notice also that for noiseless data ($P_{nn} = 0$), Equation 24 yields to $P_{\mathrm{ee}} = 0$, and Equation 23 becomes $S = P_{N\Delta g} / P_{\Delta g\Delta g} = F\{N\}/F\{\Delta g\} = (2\pi\gamma q)^{-1}$. Note, however, that for the PSDs to be the Fourier transform of the covariance functions (CVs) used in collocation, these CVs have to be stationary, which is not the case in practice with the noise CVs. Thus, the FFT method, although it is much more efficient than LSC, has to approximate nonstationary noise covariance functions (which are easily handled by LSC) by stationary ones; for details, see Sansò and Sideris (1997), Kotsakis and Sideris (2001).

Computation of the terrain contributions

The terrain effect on Δg and the indirect effect on N are computed from approximations to Equations 32 and 33 in Sideris, *Geoid Determination, Theory and Principles*. Keeping only the terms for $r = 1$, these equations take the following form:

$$\begin{aligned} -\Delta g_{H_P} = c_P &= \pi k \mathbf{L}(\rho H - \rho H_P)^2 \\ &= \pi k\left[\mathbf{L}(\rho H^2) - 2H_P\mathbf{L}(\rho H)\right] \end{aligned} \tag{26}$$

$$\delta N_{H_P} = -\frac{\pi k\rho}{\gamma}H_P^2 - \frac{\pi k}{3\gamma}\mathbf{L}(\rho H^3) \tag{27}$$

With height data given in small area E around the computation point P, the planar approximation of the $\mathbf{L}$ operator can be used. In this case, the above equation becomes (Sideris, 1990)

$$\begin{aligned} c_P &= \frac{1}{2}k\iint_E \frac{\rho H^2 - \rho H_P^2}{l^3}\mathrm{d}x\mathrm{d}y \\ &\quad - H_P k\iint_E \frac{\rho H - \rho H_P}{l^3}\mathrm{d}x\mathrm{d}y \\ &= \frac{1}{2}k\left[(\rho_P H_P^2) * l_P^{-3} - H_P^2(\rho_P * l_P^{-3})\right] \\ &\quad - H_P k[(\rho_P H_P) * l_P^{-3} - H_P(\rho_P * l_P^{-3})] \end{aligned} \tag{28}$$

$$\begin{aligned} \delta N_{H_P} &= -\frac{\pi k\rho}{\gamma}H_P^2 - \frac{k}{6\gamma}\iint_E \frac{\rho H^3 - \rho H_P^3}{l^3}\mathrm{d}x\mathrm{d}y \\ &= -\frac{\pi k\rho}{\gamma}H_P^2 - \frac{k}{6\gamma}[(\rho_P H_P^3) * l_P^{-3} - H_P^3(\rho_P * l_P^{-3})] \end{aligned} \tag{29}$$

where $l_P^{-3} = (x_P^2 + y_P^2)^{-3/2}$. The above convolutions can be evaluated by FFT as follows:

$$\begin{aligned} c_P = &\frac{1}{2}k[F^{-1}\{F\{\rho_P H_P^2\}F\{l_P^{-3}\}\} \\ &-H_P^2 F^{-1}\{F\{\rho_P\}F\{l_P^{-3}\}\}] \\ &-H_P k[F^{-1}\{F\{\rho_P H_P\}F\{l_P^{-3}\}\} \\ &-H_P F^{-1}\{F\{\rho_P\}F\{l_P^{-3}\}] \end{aligned} \tag{30}$$

$$\begin{aligned} \delta N_{H_P} = &-\frac{\pi k\rho}{\gamma}H_P^2 - \frac{k}{6\gamma}\left[F^{-1}\left\{F\{\rho_P H_P^3\}F\{l_P^{-3}\}\right\}\right. \\ &\left.-H_P^3 F^{-1}\left\{F\{\rho_P\}F\{l_P^{-3}\}\right\}\right] \end{aligned} \tag{31}$$

From the definition of the vertical derivative operator **L** in Equation 21 in Sideris, *Geoid Determination, Theory and Principles* and the derivative property of the Fourier transform (Bracewell, 1978), we can see that

$$F\{\mathbf{L}f\} = F\left\{\frac{\partial f}{\partial z}\right\} = 2\pi i w F\{f\} = -2\pi q F\{f\} \tag{32}$$

where i is the imaginary unit. We have also used the relationship $iw = -q$, which is a straightforward result of Laplace's equation in the frequency domain:

$$\begin{aligned} F\{\nabla^2 f\} = &[(i2\pi u)^2 + (i2\pi v)^2 \\ &+ (i2\pi v)^2]F\{f\} = 0 \end{aligned} \tag{33}$$

Now Equations 26 and 27 can also be evaluated by FFT using the analytical spectrum of the **L** operator as follows:

$$\begin{aligned} c_P = &\pi k(F^{-1}\{-2\pi q F\{\rho_P H_P^2\}\} \\ &-2H_P F^{-1}\{-2\pi q F\{\rho_P H_P\}\}) \end{aligned} \tag{34}$$

$$\delta N_{H_P} = -\frac{\pi k}{\gamma}\rho_P H_P^2 - \frac{\pi k}{3\gamma}F^{-1}\{-2\pi q F\{\rho_P H_P^3\}\} \tag{35}$$

Such analytical representations of kernel functions, though not recommended for use in limited areas (Li and Sideris, 1993), are often used in satellite altimetry applications, as discussed in the section that follows.

Evaluation of satellite altimetry contributions

Like Stokes's formula, the inverse Stokes, inverse Vening Meinesz and deflection-geoid formulas employ kernels that are functions of the spherical distance ψ between the data and computation points; see Equation 19 in Sideris, *Geoid Determination, Theory and Principles*. Therefore, when gridded data is available, they can be efficiently evaluated on the sphere by either the rigorous 1D FFT or the approximate 2D FFT formulas, completely analogous to Equations 4–9 used for Stokes's integral. They will not be discussed further here, and the interested reader is referred to Hwang (1998) for detailed equations. Instead, we will concentrate here on the planar approximations with analytical kernel spectra.

On the plane, employing the same approximation for the sine and cosine of ψ as we did for Stokes's formula, Equations 36–40 in Sideris, *Geoid Determination, Theory and Principles* simplify to

$$\Delta g_P = -\frac{\gamma}{2\pi}\iint_E \frac{N - N_P}{l^3}\mathrm{d}x\mathrm{d}y = -\gamma \mathbf{L}N = -\gamma\frac{\partial N}{\partial z} \tag{36}$$

$$\begin{aligned} \Delta g_P &= -\frac{\gamma}{2\pi}\iint_E \left(\xi\frac{y - y_P}{l^3} + \eta\frac{x - x_P}{l^3}\right)\mathrm{d}x\mathrm{d}y \\ &= -\frac{\gamma}{2\pi}\left(\xi_P * l_{\xi_P} + \eta_P * l_{\eta_P}\right) \end{aligned} \tag{37}$$

$$\begin{aligned} l_\xi &= y/(x^2 + y^2)^{3/2} = -\partial l_N/\partial y \\ l_\eta &= x/(x^2 + y^2)^{3/2} = -\partial l_N/\partial x \end{aligned} \tag{38}$$

$$\begin{aligned} N_P &= -\frac{1}{2\pi}\iint_E (\xi\frac{y - y_P}{l^2} + \eta\frac{x - x_P}{l^2})\mathrm{d}x\mathrm{d}x \\ &= -\frac{1}{2\pi}(\xi_P * l_{x_P} + \eta_P * l_{y_P}) \end{aligned} \tag{39}$$

$$\begin{aligned} l_y &= y/(x^2 + y^2) \\ l_x &= x/(x^2 + y^2) \end{aligned} \tag{40}$$

By making use of the derivative property of the Fourier transform, their evaluation by FFT is done as follows:

$$\Delta g_P = -\gamma F^{-1}\left\{2\pi q F\{N_P\}\right\} \tag{41}$$

$$\Delta g_P = \gamma F^{-1}\left\{\frac{i}{q}\left(vF\{\xi_P\} + uF\{\eta_P\}\right)\right\} \tag{42}$$

$$N_P = F^{-1}\left\{\frac{i}{2\pi q^2}\left(vF\{\xi_P\} + uF\{\eta_P\}\right)\right\} \tag{43}$$

The planar form of Equation 42 in Sideris, *Geoid Determination, Theory and Principles*, namely

$$\frac{\partial \Delta g}{\partial z} = -\gamma\left(\frac{\partial \xi}{\partial y} + \frac{\partial \eta}{\partial x}\right) \tag{44}$$

also reduces to Equation 42 in the frequency domain, unless one is interested not in Δg but in its vertical derivative, which then can be computed from the expression

$$\left.\frac{\partial \Delta g}{\partial \xi}\right|_P = 2\pi\gamma F^{-1}\{ivF\{\xi_P\} + iuF\{\eta_P\}\} \tag{45}$$

Finally, Equation 35 in Sideris, *Geoid Determination, Theory and Principles* that gives the deflections from altimetry-derived undulations is in planar approximation

$$\xi = -\frac{\partial N}{\partial y}, \quad \eta = -\frac{\partial N}{\partial x} \tag{46}$$

and therefore its FFT-evaluation can be done via the expression

$$\begin{aligned} \xi_P &= -2\pi F^{-1}\{ivF\{N_P\}\}, \\ \eta_P &= -2\pi F^{-1}\{iuF\{N_P\}\} \end{aligned} \tag{47}$$

Summary

In this entry, we have outlined the steps in the remove-compute-restore technique that is employed in the numerical computations of geoid undulations. We have shown that most of the equations expressing the terrain and gravity effects on the geoid are convolution integrals, and have described in detail how they can be efficiently evaluated by FFT given gridded data on the sphere or on the plane. In addition, computations by least-squares collocation have been outlined both in the space and in the frequency domain, in which the formula is equivalent to Wiener filtering and provides both noise filtering and accuracy estimates of the geoid through propagation of the data noise to the results. The entry closes with the evaluation of various formulas used in gravity and geoid determination in the oceans using data from satellite altimetry.

GEOMAGNETIC EXCURSIONS

Martha Schwartz
Department of Earth Sciences, University of Southern California, Los Angeles, CA, USA

Synonyms

Excursions were initially observed as "tiny wiggles" in marine magnetic anomalies (LaBreque et al., 1977) and were termed "cryptochrons" by Cande and Kent (1992a, b).

Definition

Geomagnetic Excursions are periods of unusually high-amplitude secular variation (see *Geomagnetic Field, Secular Variation*). They are usually defined as short-term deviations of the Virtual Geomagnetic Dipole (VGP) more than 40–45° from the geographic poles (see *Geomagnetic Field, Global Pattern*).

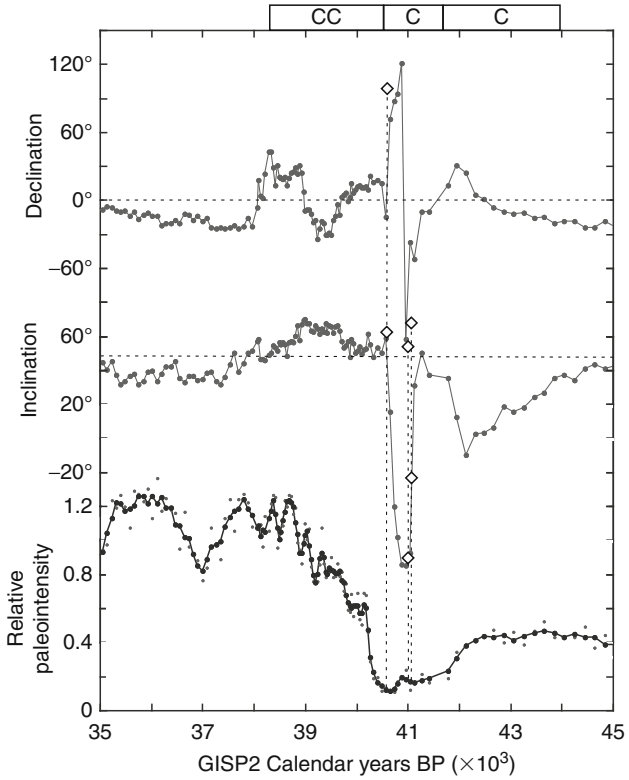
Geographical and temporal extent

Excursions last for up to a few thousand years during times of otherwise stable field polarity. The unusual directions, which sometimes represent regionally complete reversals (see *Geomagnetic Field, Polarity Reversals*),

are always accompanied by globally correlative low levels of field intensity (see *Paleomagnetic Field Intensity*). Low intensity starts earlier than the anomalous directions and outlasts them. There is some emerging evidence that excursions are global in extent. However, uncertainties in age control limit the ability to establish synchronicity among directional records recovered from different regions. Inadequate paleomagnetic recording may also cause excursions to be missed at certain localities. Lava flows do not provide a continuous record of field behavior, and sediment records of short-term directional field behavior may be smeared due to low sedimentation rates (see *Geomagnetic Field, Measurement Techniques*).

The frequency and duration of geomagnetic excursions are also open issues. Answers depend on recovering further high-quality replicated records, as well as better understanding of their regional versus global extent. There is reproducible evidence for 17 time intervals within the Brunhes Chron with at least regionally verifiable magnetic field excursions (Lund et al., 2006). Two well-recorded examples of excursions are the Laschamp Excursion, first noted in French lavas (Bonhommet and Babkine, 1967) which occurred about 40 ka, and the Blake Event (first observed by Smith and Foster [1969]) from about 120 ka.

The Figure 1, reproduced from Lund et al. (2005), is a high-resolution record of the Laschamp Excursion, as recovered from the Blake Outer Ridge in the North Atlantic Ocean.



Geomagnetic Excursions, Figure 1 Paleomagnetic secular variation and relative paleointensity (small dots are original data, large dots are 3-pt running average) records from Blake Outer Ridge core JPC14 for the time interval of the Laschamp Excursion. NRM after 20 mT demagnetization was used outside the excursion interval and NRM characteristic remanences were used in the excursion interval. These records show the same distinctive interval of low paleointensity seen in other cores (Figures 2, 3). But it contains a much more dramatic pattern of directional variability that we consider to be a more accurate and high-resolution record of the Laschamp Excursion as seen on the Blake Outer Ridge. The dashed lines indicate three time intervals where directions in this record are almost identical to the Laschamp Excursion directions seen in Europe (open diamonds). These three intervals also have similar paleointensity lows. Boxes at top indicate intervals of clockwise (C) or counterclockwise (CC) looping (circularity) in the directional data.

Field configuration during excursions

Complete understanding of the mechanism causing excursions depends on improved mapping of the global field geometry during excursional intervals. Roberts (2008) summarized three suggested excursionary field configurations. (1) The field remains largely dipolar but wanders away from the rotational axis. In this case VGP's would be consistent regardless of sampling site. (2) The ratio of non-dipole and dipole field components becomes very high. In this case VGPs would depend strongly on the sampling site. (3) Relatively localized sources in the outer-core produce regional excursions (see *Geomagnetic Field, Theory*).

Several numerical dynamo models are able to simulate magnetic field excursions for certain choices of boundary conditions. But model numerical simulations are limited in spatial or temporal resolution due to presently limited computer technology (Glatzmaier, 1999).

Origin

The most widely accepted explanation for the origin of geomagnetic excursions comes from Gubbins (1999). According to this theory, the outer core reverses briefly but the solid inner core, which has a magnetic diffusion time on the order of 3,000 years, does not reverse. In the case in which the inner core did have time to turn around, the event would be recorded as a full field reversal (see *Geomagnetic Field, Polarity Reversals*).

Summary

Geomagnetic excursions are brief periods of anomalous directions coupled with low field intensity. Their spatial extent, duration, and causative mechanism are under study. A review paper by Laj and Channel (see bibliography) provides an excellent summary of the research to date.

Introduction

The geomagnetic field is generated in the fluid outer core region of the Earth by electrical currents flowing in the slowly moving molten iron. In addition to sources in the Earth's core, the geomagnetic field observable on the Earth's surface has sources in the crust and in the ionosphere and magnetosphere. The signal from the core dominates, accounting for over 95% of the field at the Earth's surface. The geomagnetic field varies on a range of scales, both temporal and spatial; the description of the variations made here concentrates on the recent spatial and temporal variations of the field with origins in the Earth's core that can be surmised from observations made over the last four centuries.

Observations

The geomagnetic field is a vector quantity, having magnitude as well as direction. The direction of the geomagnetic field has been directly observed and recorded for at least 400 years beginning with observations of the angle in the horizontal plane between true north and the magnetic field vector, known as declination or magnetic variation. In 1634, it was realized by Henry Gellibrand that declination in London was changing with time when he compared his observations with those made by Edmund Gunter 12 years earlier. Since then, this important discovery of secular variation has ensured regular observations of the magnetic field through time. Measurements of declination were important for navigation across the oceans, and a source of early observations is ships' logbooks (Jackson et al., 2000). Before long it was also realized that other elements of the geomagnetic field were of interest, in particular the angle of dip of the magnetic field vector from the horizontal known as inclination, and this was also measured. However, it was not till 1832 when Carl Freidrich Gauss established his technique for measuring absolute intensity did we have accurate measurements of the magnitude of the geomagnetic field.

As demands on accuracy and interest in the geomagnetic field increased, permanent observatories began to be established. Since the 1840s the number of observatories around the world has slowly increased but has now dropped to about 160 in recent times. The advent of the proton precession magnetometer and the fluxgate magnetometer in the twentieth century considerably eased the automation of observatories during this time. However, regular manual absolute observations, nowadays of declination and inclination using a fluxgate theodolite, are necessary to maintain accurate baseline control over long periods of time. There are also networks of repeat stations providing data over extensive areas from which country-wide magnetic charts can be derived. More recently, magnetic measurements made by satellites have become important in determining the pattern of the geomagnetic field. In particular, vector data from Magsat (1979–1980), Ørsted (1999-current), and CHAMP (2000–2010) have all been utilized in the production of recent spherical harmonic models of the geomagnetic field.

Spherical harmonic analysis

Till the 1950s, magnetic charts at a given epoch for use in navigation depended on manually drawing contours through the observations (Malin, 1971). Although spherical harmonic analysis had been developed in 1839 by Carl Freidrich Gauss, it was not routinely used to fit mathematical models to the observations till the advent of computers. Before computers spherical harmonic

analysis required that the data be in the form of values of one or more of the orthogonal components X, Y, and Z of the geomagnetic field (magnetic intensities in the northerly, easterly, and vertically down directions) at points regularly spaced in latitude and longitude (Barraclough, 1978). This involved the intermediate stage of interpolating values from manually drawn contour charts.

The mathematical and physical basis for spherical harmonic analysis is now given. In a source-free region, the Earth's magnetic field B is the negative gradient of a magnetic potential V that satisfies Laplace's equation:

$$B = -\nabla V \quad \text{where} \quad \nabla^2 V = 0$$

A solution to Laplace's equation for the magnetic potential arising from sources inside the Earth at a given epoch is given by:

$$V(r,\theta,\lambda) = a\sum_{n=1}^{n_{max}} \left(\frac{a}{r}\right)^{n+1} \sum_{m=0}^{n} \left(g_n^m \cos m\lambda + h_n^m \sin m\lambda\right) P_n^m(\theta)$$

In this equation, r, θ, λ are geocentric coordinates (r is the distance from the center of the Earth, θ is the colatitude, i.e., 90° - latitude, and λ is the longitude), a is a reference radius for the Earth (6371.2 km), g_n^m and h_n^m are the spherical harmonic Gauss coefficients of degree n and order m, $P_n^m(\theta)$ are the Schmidt semi-normalized Legendre functions and n_{max} is the maximum degree of the spherical harmonic expansion. If the observations of the magnetic field are spread over time, the magnetic potential and corresponding Gauss coefficients are also dependent on time with splines being commonly used.

Maps of the geomagnetic field

It is worth noting here that the first published map of the geomagnetic field is that of declination made in 1701 by Edmond Halley. It was based on declination observations made during a magnetic survey expedition under naval command and covered the Atlantic Ocean (Clark and Barraclough, 2001).

The maps that we show here are based on spherical harmonic models. Nowadays, there are many such models of the geomagnetic field and here we look at two examples. One is the *gufm1* model which is derived from four centuries of magnetic field observations (Jackson et al., 2000) and extends to spherical harmonic degree 14 with B-splines being used to fit the variations in time from 1590 to 1990. It has smoothness imposed in both the spatial and temporal domains. The other model is the International Geomagnetic Reference Field (Macmillan and Finlay, 2011) produced under the auspices of the International Association of Geomagnetism and Aeronomy (IAGA). It extends to spherical harmonic degree 10 till 1995 and thereafter extends to degree 13. The variations in time from 1900 to 2015 in the IGRF are assumed to be piecewise linear and there is effectively no smoothness imposed in either the spatial or temporal domains. The final IGRF coefficients are made up of weighted averages of candidate sets of coefficients from (mostly) unregularized models.

Using the *gufm1* model, plots of declination and inclination at 1600, declination, inclination, and total intensity at 1950 are shown in Figures 1 and 2. Using the eleventh generation IGRF, plots of the magnetic elements at 2010 and their rates of change are shown in Figures 3–9. The rates of change plots are derived from a predictive secular variation model which extends to spherical harmonic degree 8. Up-to-date maps, and on-line calculators are available from a number of websites, for example, http://www.geomag.bgs.ac.uk/navigation.html and http://www.ngdc.noaa.gov/geomag/WMM/DoDWMM.shtml.

Features of note on these maps are the dip equator and dip poles in the maps of inclination (Figures 1, 2 and 8), and the area of weak magnetic field in the South Atlantic, and strong magnetic field near the poles in Figures 2 and 9. The dip equator is where the magnetic field is horizontal (inclination = 0°) and a current system is set up in the upper atmosphere called the equatorial electrojet. The dip poles (also called magnetic poles) are locations where the magnetic field is, on average, vertical. Another set of poles is the dipole poles or geomagnetic poles. Their positions can be derived from the degree 1 spherical harmonic coefficients (g_1^0, g_1^1, and h_1^1). Associated with the

geomagnetic poles, in approximately oval-shaped loci, are the auroral electrojets in the upper atmosphere. The electrojets, particularly the auroral electrojets, generate rapid time-varying magnetic fields of significant amplitude.

Recent changes in the geomagnetic field

From a comparison of the declination maps in Figures 2 and 7 it can be seen that the zero contour (the agonic line) is moving slowly westwards with time. This westwards movement of the magnetic field pattern at the Earth's surface, particularly prevalent in the Atlantic hemisphere, is related to the motion of fluid at the core surface slowly westwards, dragging with it the magnetic field lines.

Using IGRF-11 to compute the root mean square magnetic field vector at the Earth's surface arising from all spherical harmonic terms ($n \leq 10$), the centred dipole terms ($n = 1$) and the non-dipole terms ($1 < n \leq 10$), it can be seen in Figure 10 that since 1900, the geomagnetic

field is weakening overall by becoming less dipolar. However the non-dipolar part is strengthening. This may have consequences for the trajectories of energetic charged particles that enter the Earth's magnetosphere. One manifestation of this is the deepening, and westwards movement, of the South Atlantic Anomaly, the region where the geomagnetic field is weaker than elsewhere (see Figures 2 and 9). Energetic charged particles are able to penetrate closer to the Earth and cause a radiation hazard for satellites passing through this region.

Geomagnetic Field, Global Pattern, Figure 6 Horizontal intensity (nT) at 2010.0 and its rate of change (nT/year) for 2010.0–2015.0 computed from IGRF-11.

Superimposed on these gradual changes of the magnetic field are the so-called geomagnetic jerks. They are relatively abrupt (duration of months) changes in the second time derivative, or secular acceleration, of the magnetic field. The first observed geomagnetic jerk was that around 1969, and since the late nineteenth century when direct and continuous measurements of the Earth's magnetic field have been available, geomagnetic jerks

Geomagnetic Field, Global Pattern, Figure 11 Geomagnetic jerks as seen in the secular variation of the east component of the geomagnetic field observed at European observatories (IAGA codes of the observatories used are LRV, DOB, NUR, LER, ESK, HAD, DOU, BDV, FUR, CLF). Times of jerks are shown by arrows.

have also been observed to occur around 1925, 1978, 1991, and 1999. These jerks are most readily observed in the first time derivative of the easterly intensity at European observatories (Figure 11).

Various analysis techniques have been applied to jerks to investigate specific aspects of their temporal and spatial characteristics. Using wavelets, the 1969 and 1978 jerks have been shown to have different arrival times at the Earth's surface, with the northern hemisphere leading the southern hemisphere by about 2 years (Alexandrescu et al., 1996).

Understanding their origin is important, not only because they result from interesting dynamical processes in the core and may help determine the conductivity of the mantle, but also for improving time-dependent models of the geomagnetic field and for the strictly practical purpose of forecasting its future behaviour, for example, as used in navigation.

Definition

The International Geomagnetic Reference Field (IGRF) is a series of mathematical models of the Earth's main field and its annual rate of change (secular variation).

Each generation of the IGRF comprises three constituent models:

1. The IGRF model that is a prediction of the state of the main field at an epoch t (considering that the epoch of IGRF model elaboration is approximately between [*t-3 years*] and [*t-1 years*]).
2. The secular variation model that is also a prediction of the annual variation rate of the main field between epoch t and ($t + 5$ *years*).
3. The Definitive Geomagnetic Reference Field model (DGRF), which is the revision of the previous generation IGRF model 5 years before the epoch (*t-5 years*).

The constituent models are designated provisional or definitive. Once a constituent model is designated definitive it is not revised in subsequent generations of the IGRF.

Datasets

As it can be seen in Table 1, the periodicity of IGRF's elaboration varies with time. In addition, upgrades are regularly incorporated. For example, the truncation degree/order of the main field spherical harmonic analysis was extended from 10 up to 13 after 1995 (IAGA, Division V, Working Group 8, 2003). Similarly, the precision of the coefficients was extended from 1 nT to 0.1 nT after 1995 (IAGA, Division V, Working Group 8, 2003) and then to 0.01 nT after 2000 (IAGA, Working Group V-MOD, 2010).

These two changes were made possible by technological advances. Indeed, before 1979, only near-surface data (permanent observatories, repeat stations, land, airborne and marine surveys; see *Geomagnetic Field, Measurement Techniques*; *Magnetic Methods, Airborne*) were used (Peddie, 1983; Zmuda, 1971) and, consequently, the spatial distribution of data over the globe remained poor. The International Decade of Geopotential Field Research allowed modelers to take advantage of the excellent spatial coverage and high quality of measurements made by near-polar satellites (see *Magnetic Methods, Satellite*). The POGO satellites (1965–1971), Magsat (1979–1980), POGS (1990–1993), Oersted (1999–), SAC-C (2000–), and CHAMP (2000–), have all been utilized in the production of the IGRF.

Today, data from permanent magnetic observatories are still the most important source of information about time-varying fields, especially for secular variation constituent models (see *Geomagnetic Field, Secular Variation*) while magnetic satellite missions allow the acquisition of homogeneously distributed data over the entire globe during a short period of time (as compared to magnetic observatories time series). The two datasets remain highly complementary.

Basic mathematical expression

Each mathematical model consists in a set of coefficients, called Gauss coefficients, associated to solid spherical harmonic functions.

Indeed, in source-free regions (the spherical shell bounded by the Earth's surface and the base of the ionosphere at an altitude around 100 km), the main field, generated by fluid motions in the Earth's electrically conducting liquid outer core, may be expressed as the negative gradient of a scalar potential V, which is represented by a truncated (up to degree N) series expansion (see *Geomagnetic Field, Theory*):

$$V(r,\theta,\varphi) = R\sum_{n=1}^{N}\left(\frac{R}{r}\right)^{n+1}\sum_{m=0}^{n}\left(g_n^m\cos(m\varphi) + h_n^m\sin(m\varphi)\right)P_n^m(\theta)$$

where r, θ, φ are geocentric coordinates according to a reference coordinate system.

Geomagnetic Field, IGRF, Table 1 Summary of IGRF history

Full name	Short name	Valid for	Definitive for
IGRF 11th generation (revised 2009)	IGRF-11	1900–2015	1945–2005
IGRF 10th generation (revised 2004)	IGRF-10	1900–2010	1945–2000

IGRF 8th generation (revised 1999)	IGRF-8	1900–2005	1945–1990
IGRF 7th generation (revised 1995)	IGRF-7	1900–2000	1945–1990
IGRF 6th generation (revised 1991)	IGRF-6	1945–1995	1945–1985
IGRF 5th generation (revised 1987)	IGRF-5	1945–1990	1945–1980
IGRF 4th generation (revised 1985)	IGRF-4	1945–1990	1965–1980
IGRF 3rd generation (revised 1981)	IGRF-3	1965–1985	1965–1975
IGRF 2nd generation (revised 1975)	IGRF-2	1955–1980	–
IGRF 1st generation (revised 1969)	IGRF-1	1955–1975	–

r is the distance from the center of the Earth, θ is the colatitude (i.e., 90° – latitude), and φ is the longitude, R is a reference radius (Earth mean radius) set to 6371.2 km; ${g^n}_m$ and h^n are the Gauss internal coefficients, and ${P^n}_m(\theta)$ are the Schmidt semi-normalized associated Legendre functions of degree n and order m.

The IGRF coefficients are time dependent. In the series of IGRF mathematical models, the variations are assumed to be linear on 5-year intervals. For the upcoming 5-year epoch, the rate of change is given by predictive secular variation coefficients (see *Geomagnetic Field, Secular Variation*).

IGRF evolving

One of the first suggestions to develop an International Geomagnetic Reference Field model was made in 1954 at the International Association of Geomagnetism and Aeronomy (IAGA) Scientific General Assembly in Toronto. The aim in developing such reference models was to have a common basis for calculating the main geomagnetic field in order to homogenize the results of academical/fundamental studies (on fields as diverse as the crustal and external fields) and to provide the industrial world (Meyers and Davis, 1990) with a well-identified description of the Earth's core magnetic field.

Thus, an internationally coordinated effort was carried out under the aegis of IAGA relying on cooperation between magnetic field modelers, institutes, and agencies responsible for collecting and publishing geomagnetic field data.

Since 1969, date of the first adoption of an IGRF (IGRF-1 valid for 1955–1975), the IGRF has evolved into a series of mathematical models of the Earth's main field (Langel, 1987) and its annual rate of change at 5-year intervals covering the period 1900–2015 (Table 1).

New candidate models are carefully produced and widely documented as are their evaluation procedures. The final decision is made by the IAGA Working Group-V Mod. Most of the time, the elected DGRF and IGRF models of the current generation are derived by taking means (sometimes weighted) of the coefficients of selected candidate models. Indeed, one particular selected candidate model cannot be chosen preferably to another as the various datasets, selection criteria of the data, applied corrections and even modeling methods have their own strengths and weakness. The robustness of IGRF lies in the fact that even if there are significant differences between the candidate models in every part of the development chain (datasets, data selections, algorithms, regularizations), the results are fairly consistent at the end.

General Information about the IGRF and coefficients of the 11th generation are available at: http://www.ngdc.noaa.gov/IAGA/vmod/igrf.html.

Additional figures and programs to compute the field components for a specific location and time are available at: http://wdc.kugi.kyoto-u.ac.jp/igrf/index.html.

Introduction

Continuous monitoring, modeling, and interpretation of the geomagnetic field and its spatial and temporal variations are the prerequisites to understand our magnetic planet. Based on geomagnetic models (see *Geomagnetic Field, Global Pattern*), covering very short to longer temporal scales, it makes it possible to understand core dynamics (see *Core Dynamo*), lithospheric magnetic signals (see *Magnetic, Global Anomaly Map*; *Magnetic Anomalies, Interpretation*), and the geomagnetic environment. This represents an important challenge in understanding the System Earth. Clearly, geomagnetic measurements from ground and space represent the main ingredient in modeling and understanding the Earth's magnetic field (Mandea and Purucker, 2005, *Geomagnetic Field, IGRF*). Furthermore, magnetic measurements are also used in connection with different geophysical surveys (ground and/or airborne) in detecting mineralization and/or geological and tectonic structures. They are also used to detect archeological sites, shipwrecks, and other buried or submerged objects. Moreover, magnetic techniques are used at drilling sites for navigating well-bores, or in monitoring the geomagnetically induced currents that can result in damage to transformers, a potentially major expense to power companies. Finally, prediction of space weather is crucial considering its potential impact on man-made technologies on Earth and in space (satellites and spacecraft, electricity power grids, pipelines, radio and telephone communications, geophysical exploration, etc.).

Two types of measurements are needed to characterize the geomagnetic field: scalar and vector. A scalar measurement gives a very accurate value of the total strength of the magnetic field, however, a full characterization of the magnetic field vector is not reached. A vector measurement has the capability to provide the components of the magnetic field in particular directions, relative to the spatial orientation of the sensors. These measurements are relative. Both kinds of measurements are needed for an accurate and full description of the magnetic field.

Scalar measurements are based on the transformation of a frequency – a very accurate measurement – into intensity of the magnetic field. In the spectral domain, the measurement is indeed the location of the center of the spectral line. The relative accuracy of this determination is very high, something as 10^{-12} being common in physics. For magnetic measurements a relative accuracy of order of 10^{-7} is reached, due to the rather broad spectral line. In a proton precession magnetometer the universal physical constant is the gyromagnetic ratio of the proton (42.58 MHz/T), and the basic unit is time (inverse of frequency). In a proton magnetometer, protons in a liquid (such as water or kerosene) are first polarized; when the polarizing field is switched off, the protons precess around the magnetic field direction with a frequency that is proportional to the magnetic field intensity. Overhauser magnetometers are typically installed at magnetic observatories, but they are also used for some other ground observations or on board of the Ørsted and CHAMP magnetic satellites.

In contrast, vector measurements made with a fluxgate magnetometer are based on the nonlinearity of the magnetization of soft magnetic materials. The very sensitive part of this instrument is an easily saturable core made of a material with high permeability. This core is wrapped by two windings: an excitation coil and a pick-up coil. An alternating excitation current is passed through the excitation coil, driving the core through an alternating cycle of magnetic saturation. This changing field induces an electrical current in the pick-up coil, and this output current can be accurately measured. If the core is exposed to an external magnetic field, it is more easily saturated in alignment with that field and less easily saturated in opposition to it. The signal in the pick-up coil has not only the excitation frequency, but also the other harmonics. The second harmonic is particularly sensitive to the background magnetic field. Often, the current in the pick-up coil is integrated, yielding an output analog voltage, proportional to the magnetic field. The fluxgate magnetometers are subject to an instrument drift. To minimize these drift contributions in the final data different approaches are used to calibrate the fluxgate magnetometers, on one hand for the ground measurements and on the other hand for the satellite measurements.

The instruments used to measure the magnetic field on ground or in space are based on the same physical concepts, and they are basically the same. Of course, for space missions constraints are imposed by weight and consuming energy. More details on magnetometers used in ground-based observations are given in the section Earth's Surface Magnetic Field Measurements. Considering the different and more complex approaches in processing data provided by satellite missions, we review them in the section Near-Earth Magnetic Field Measurements. Finally, in the section Summary we offer a perspective on promising avenues in measuring the magnetic field.

Earth's surface magnetic field measurements

Historically, magnetic observatories were established to monitor the secular change of the Earth's magnetic field, and this remains one of their major functions (see *Geomagnetic Field, Secular Variation*). This generally involves *absolute measurements* that are sufficient in number to monitor instrumental drift of fluxgate magnetometers giving *variation measurements* of the three field components, in arbitrary units (see *Magnetometers*).

A scalar measurement of the field intensity obtained commonly by a proton magnetometer is absolute: as noticed before, it depends only upon our knowledge of a physical constant and a measurement of frequency. The measurements achieved with such an instrument have a great accuracy (in excess of 10 ppm). Figure 1a shows an Overhauser magnetometer.

Scalar magnetometers make measurements of the strength of the magnetic field only, and provide no information about its direction. It is also possible to make an absolute measurement of direction of the geomagnetic field, by measuring the angle I (*inclination*) with respect to the horizontal plane, and the angle D (*declination*) in the horizontal plane between the magnetic North and true North (the last one determined by reference to a fixed mark of known azimuth, obtained astronomically or by using a gyro). A fluxgate-theodolite (DI-flux), as shown in Figure 1b, used commonly to measured D and I, requires manual operation. The DI-flux consists of a nonmagnetic theodolite and a single-axis fluxgate sensor mounted on top of a telescope. The DI-flux is considered to be an absolute instrument, which means that the angles measured by the instrument do not deviate from the true values D and I. This is achieved by using an observation procedure that eliminates unknown parameters such as sensor offset, collimation angles, and theodolite errors. For example, collimation errors between the fluxgate sensor and the optical axis of the theodolite, and within the theodolite, are minimized by taking readings from four telescope positions. With the fluxgate sensor operating in the null-field mode, the stability and sensitivity of the sensor and its electronics are maximized. In a land-based observatory, such absolute measurements are typically performed once/twice a week, manually, and are used to monitor the drift of the fluxgate variometers.

A vector measurement is made with a fluxgate magnetometer that operates with minimal manual intervention. These instruments require temperature-controlled environments and installation on extremely stable platforms (however, some modern systems are suspended and

Geomagnetic Field, Measurement Techniques, Figure 1 Geomagnetic observatory sensor package: proton magnetometer (**a**), fluxgate magnetometer (**b**), theodolite with fluxgate coupled to the telescope (**c**). The new prototype of Geomagnetic AUtomated SyStem (GAUSS) is also shown (**d**).

therefore compensate for platform tilt). Even with these precautions they can still be drifting subject to sources from both within the instrument (temperature effects) and also the stability of the instrument mounting. Because these measurements are not absolute, they are referred to as variation measurements, they have to be calibrated against standard instruments, and then the instruments are known as *variometers*. One of the most widely used variometers is the FGE fluxgate manufactured by the Danish Meteorological Institute, Denmark (see Figure 1c). The sensor unit consists of three orthogonally mounted sensors on a marble cube. In order to improve long-term stability, these sensors have compensation coils wound on quartz tubes, resulting in a sensor drift of only a few nT per year. The marble cube is suspended by two strips of crossed phosphor-bronze working as a cardanic suspension to compensate for pillar tilting that might cause baseline drift. The box containing the electronics is almost magnetic free, and is placed several meters from the sensor to further minimize its effect on the readings. The magnitude and directional response of these instruments needs to be calibrated against accurately known sources.

All modern land-based magnetic observatories use similar instrumentation and process the data in a comparable way to produce similar data products. For a full description, see the INTERMAGNET Web site (www.intermagnet.org). The fundamental measurements recorded are on average 1-min values of the vector components and of scalar intensity. From the 1-min data, hourly, daily, monthly, and annual mean values are produced.

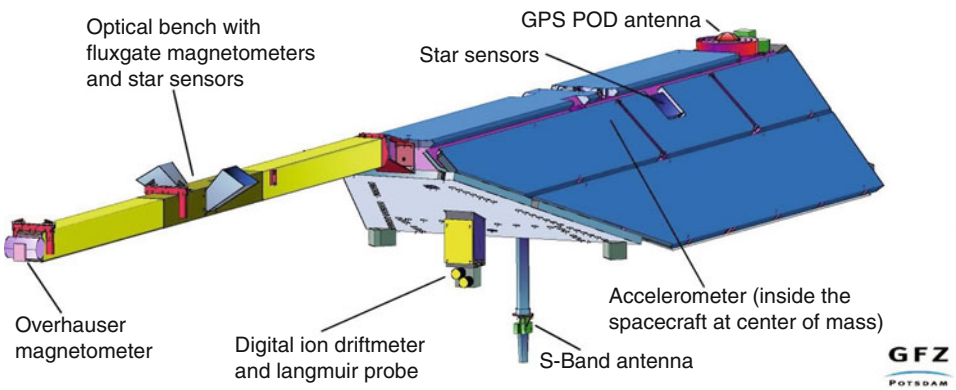
Finally, let us note that data processing consists in a weekly determination of baseline values from absolute measurements. The processing has to include the determination of all systematic errors, and the quality of measurements depends strongly on the experience and accuracy of the observer. Because of this subjective parameter in the final data products and because regular absolute measurements lack in remote areas, several attempts have been made to operate absolute vector field instruments automatically. Among them, one can note a DI-theodolite automatization (van Loo and Rasson, 2006) or a proton vector magnetometer (Auster et al., 2006) for discrete absolute measurements. Efforts have been done to develop a Geomagnetic AUtomated SyStem (GAUSS), instrument-based on rotating a three-component fluxgate magnetometer about well-known axes (Auster et al., 2007). Figure 1d shows this instrument, as mounted in Niemegk magnetic observatory (Germany). Only low mechanical requirements are necessary compared to the standard method with a DI-flux theodolite, but all demands on an absolute measurement are satisfied. The new system aims to be a reliable working automated absolute geomagnetic instrument worldwide.

Near-Earth magnetic field measurements

As stated previously, instruments used in measuring the magnetic field from space are based on the same techniques as the ones on ground, however, the approach to process the magnetic satellite measurements is more complex and different from the one used for magnetic observatories. For this reason, the main part of this contribution is dedicated to measurements processing from Overhauser and fluxgate magnetometers, and the examples refer mainly to the CHAMP satellite (www.gfz-potsdam.de) (Mandea et al., 2010). The instruments on board the CHAMP satellite are shown in Figure 2; those needed to measure the magnetic field are situated on the 4-m boom, far from the satellite body and its magnetic disturbances (see also *Magnetic Methods, Satellite*).

Overhauser magnetometer data processing

An Overhauser magnetometer (OVM), as the one that has been used on Ørsted or CHAMP satellites, is regarded as the magnetic reference instrument. Its output frequency is directly proportional, through the gyromagnetic ratio, to the ambient magnetic field magnitude. Generally, this instrument samples the magnetic field at a rate of 1 Hz



Geomagnetic Field, Measurement Techniques, Figure 2 The CHAMP satellite. The main magnetic instruments are installed on the 4-m boom, the Overhauser magnetometer (at the very end), and the two fluxgate magnetometers and the star cameras (on the optical bench).

with a resolution of 0.1 nT. In order to make the readings a traceable standard, the output frequency is compared to a reference oscillator.

Although the OVM readings are highly accurate, they do not simply reflect the Earth's magnetic field. There are magnetic influences from the spacecraft and the instruments that have to be accounted for. The major processing steps for correcting the data provided by such an instrument are (1) time correction, (2) correction of internal oscillation, (3) correction of additive fields, and (4) correction of multiplicative effects.

1. The input data come with a time stamp, accounting for the time of transmission from the instrument to the onboard data handling system. For the data interpretation it is important to know precisely the epoch at which the reading is valid. Since the satellite is a fast moving platform, readings have to be time-tagged with millisecond precision. The relevant time difference has been determined in ground tests. The epoch of the OVM readings is defined as the reference time to which the next level data of all the other instruments, relevant for the magnetic field products, are resampled.
2. During the next processing step the applied scale factor to the magnetic field readings is checked and corrected. For determining the actual frequency of the internal oscillator the cycles are counted within a gate of 60-GPS s. To convert the Larmor frequency into magnetic field strength, the gyro-magnetic ratio is applied, as recommended by the International Association of Geomagnetism and Aeronomy (IAGA), during the IUGG General Assembly in Vienna, 1991. With this convention, for example, the CHAMP scalar magnetic field readings can be traced back uniquely to the two internationally maintained standards, GPS-second and gyro-magnetic ratio.
3. The remaining corrections concern the disturbances produced by the satellite, and all fields adding to the true ambient are considered together. Contributions come from the remanent magnetization of the spacecraft, from electric currents in the systems, and also from the directional anisotropy of the sensor. These extra fields cannot be simply subtracted. Their influence on the field magnitude has to be determined by finding the projection of the disturbance on the total field vector. For example, the remanent magnetic field of the spacecraft has to be determined in a preflight system test. Since the OVM is mounted at the tip of a long boom, the remaining effect is only of the order of 0.5 nT. There are some stray fields, generated by electric currents, for example, in the solar panels that make effects of less than 0.5 nT. Current readings from the housekeeping data are also needed for this correction. Comparably large are the contributions from the three orthogonal magneto-torquers, which are used for controlling the spacecraft attitude. This contribution can be predicted quite reliably when the currents through the torquer coils are measured.
4. In the last step corrections associated with perturbations proportional to the ambient magnetic field are considered. For CHAMP, these are the permeability of the spacecraft and the cross-talk from the fluxgate magnetometers onto the Overhauser magnetometer. Based on the fairly small sizes of the various correction terms described above one can conclude that the field magnitudes provided are rather reliable, with an absolute accuracy of better than 0.5 nT.

Fluxgate magnetometer data processing

A fluxgate magnetometer (FGM) measures the three components of the magnetic field. These vector field measurements are performed at a rate of 50 Hz with a resolution of 0.1 nT. This higher rate is justified by the significantly larger variability of vector components compared to the fluctuations of the field magnitude. The FGM characteristics are expected to change in response to environmental influences or with time. In order to ensure reliable readings of the vector field components from a multiyear mission, the calibration parameters have to be updated at regular intervals (for CHAMP this is done every 15 days). The in-flight calibration is based on a direct comparison of the FGM readings with the OVM data. The main steps are: (1) time correction, (2) preliminary scaling of data, (3) correction for sensor temperature, (4) correction for torque fields, (5) rescaling of data with actual calibration parameters, and (6) decimation to 1 Hz data.

1. The FGM calibration starts with a proper dating of readings where the delay of the time stamp with regard to the exact epoch of measurement is considered.
2. In the following step the raw data are converted to physical units with the help of a preliminary set of parameters. The measurements are expected to have a bias and need to be scaled. Firstly, the offset vector is subtracted from the FGM readings, measured in engineering units. Thereafter, the results are scaled into nT. For CHAMP, linear, quadratic, and cubic terms are taken into account.
3. Corrections of the environmental influences are crucial. The sensor changes its geometry with the ambient temperature. This has an influence on the scaling factor. Other parameters, bias and sensor orientation, are not affected by temperature. In preflight test the temperature coefficients have been determined, and they amount to about 30 ppm/K for all axes. This effect is corrected using the temperature measurements at the sensor place.
4. During the next step the magnetic fields produced by the spacecraft are considered. For the FGM, there is no need to correct for constant or slowly varying influences, such as the remanent and induced magnetic field of the spacecraft: these effects are accounted for in the FGM calibration parameters. However, disturbances varying over short time have to be corrected directly. An example for that is the magnetic field generated by the current flowing through the torquer coils.

5. FGM data corrected to this level are used for the scalar calibration. This calibration against OVM data results in an improvement of the nine FGM processing parameters (three scale factors, three offset values, three angles between sensors).
6. The processing scheme is applied to the full 50 Hz data set. In order to make vector data consistent with the scalar data, they are resampled to 1 Hz. This resampling is not accomplished by a simple average over the FGM reading within a second. A linear fit to the 100 values centered on the target time is preferred. The new value is then computed from the derived function at the epoch of the related OVM reading. This procedure is performed individually for all three components.

The new data sets are accessible to users. These fully calibrated vector data useful for certain applications, are given in the FGM sensor frame. A transformation is needed to obtain data into the commonly used NEC frame (a local Cartesian frame having its origin at the position of the satellite with the three components pointing to geographic north, east, and to the center of the Earth). A number of rotations have to be performed for this coordinate transformation. The rotation angles from the FGM sensor system to the star camera (ASC) are determined before launch. The rotation into the celestial frame, ICRF, is based on the attitude data. For the rotation from the ICRF into the Earth-fixed, ITRF frame, the Earth's current rotation parameters are used (as provided by the IERS service), where the satellite position is taken from the precise orbit determination. The final rotation into the NEC frame requires just the satellite position. Magnetic field vector data in the NEC frame are the prime data source for all modeling efforts and for various other applications.

In-flight scalar calibration

When processing the FGM magnetic field readings for a multiyear mission, in-flight calibration plays an important role. For that reason the approach used for CHAMP is summarized here.

During the calibration process the readings of the OVM are used as a reference. By comparing field magnitude values with those from FGM, the nine principle parameters of the vector instrument can be determined in a nonlinear inversion. The basic idea is that the OVM and FGM should provide the same values for the magnetic field strength, and any difference can be explained by an improvement of the nine basic FGM parameters. These parameters are expected to be constant over at least one day. A linear expression relates the processed OVM data to the magnetic field components from the FGM through the nine unknowns. In practice, a system of equations is set up making use of all 86,400 daily measurements, from which the nine FGM parameters are determined by least squares. Averages over 15 days are used in the FGM processing for the final scaling of the vector data. After this last processing step the root mean square (rms) value of the difference between OVM and FGM varies from 0.1 to 0.2 nT. This can be regarded as a verification of the used calibration approach.

After more than 10 years of being in orbit, CHAMP satellite gives an interesting example about how the prime FGM parameters have varied over the mission period. There are systematic differences between the variations of the scale factors and the other parameters. The scale values show a monotonic increase over time. The trend is the same for all three components and it can reasonably well be approximated by a logarithmic function. Over the mission time life, the scale factor has changed by seven parts in 10.000, corresponding to an error in magnetic field of some 40 nT. The other parameters show no significant long-term trend, but exhibit periodic variations in phase with the orbit local time. Amplitudes of the offset variations are generally smaller than 0.5 nT. Regarding the sensor stability, variations are confined to angles of 0.001°, which correspond to 3.6 arc s. For these six parameters the in-flight calibration confirms the high stability of the FGM instrument on CHAMP. The synchronization of the deduced variations with the orbital local time suggests that other, not corrected perturbations of the measurements leak into these parameters. However, this does not affect the validity of the final data.

Summary

Here, we concentrate primarily, but not exclusively, on geomagnetic instruments and techniques used in a magnetic observatory settings or in a near-Earth magnetic observation. We have briefly described the basic instruments, their mode of operation, their relative and/or absolute accuracy, and the related sources of error. Currently, the magnetometry is a mature discipline, so something equivalent to the invention of the proton magnetometer would not be achieved very soon. It is more likely that some instrumental advances will be made toward the aim to stabilize vector magnetometers. Advances will be made in power reduction, data storage, and telemetry with the goals of increased automation and cutting costs. The coming age of the automated absolute instruments makes it possible to consider once again the possibility of a true underwater observatory.

The future needs of the scientific and commercial users will include ground- and space-based measurements. Increasing resolution and timing accuracy will be crucial. However, to achieve these requirements will demand more efforts from instrument makers and spacecraft designers.

The Earth's magnetic field will remain under observation with the ESA's forthcoming Swarm mission (Friis-Christensen et al., 2009). Three satellites will be launched in 2011 and will measure the magnetic field and its variations far more accurately than ever before. However, a comprehensive separation and understanding of the internal and external processes contributing to the Earth's magnetic fields is possible only by joint analysis of

satellite and ground-based data, with all difficulties arising in combining such different datasets. Continuous space-borne and ground-based monitoring of the magnetic field aims to address such needs.

Introduction: The discovery of geomagnetic reversals

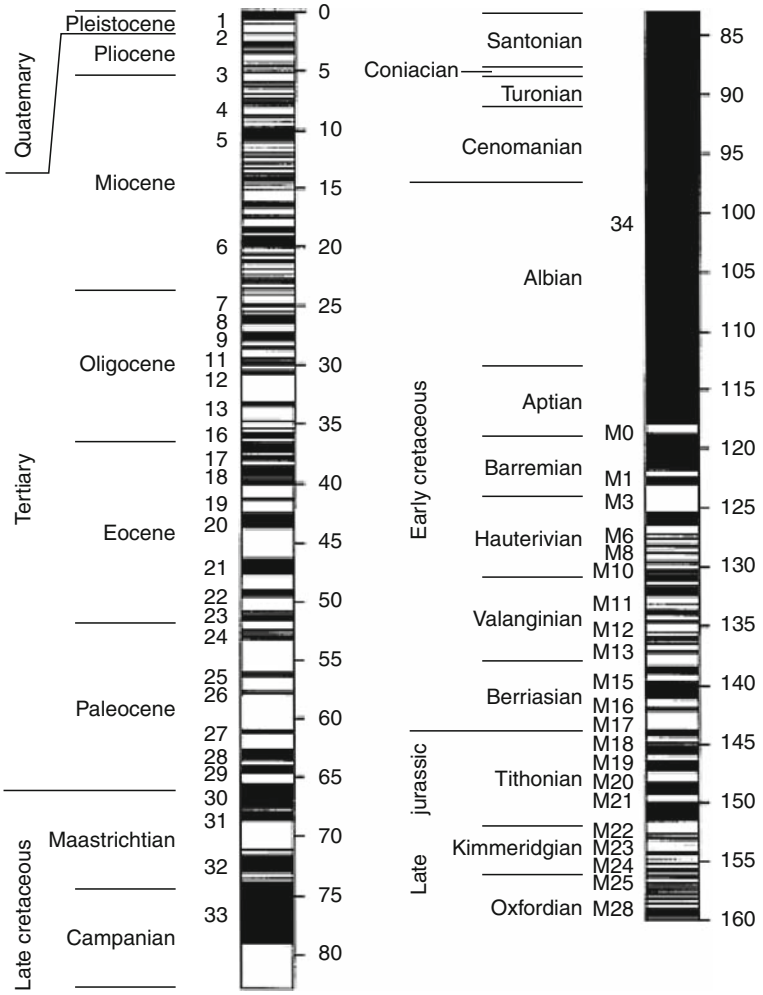
Bernard Brunhes (1906) was the first to measure magnetization directions in rocks that were approximately antiparallel to the present Earth's field. Brunhes (1906) recorded magnetizations in baked sedimentary rocks that were aligned with reverse magnetization directions in overlying Miocene lavas from central France (Puy de Dome). In so doing, Brunhes (1906) made first use of a field test for primary thermal remanent magnetization (TRM) that is now referred to as the "baked contact" test. Matuyama (1929) was the first to attribute reverse magnetizations in (volcanic) rocks from Japan and China to reversal of geomagnetic polarity, and to differentiate mainly Pleistocene lavas from mainly Pliocene lavas based on the polarity of the magnetization. In this respect, Matuyama (1929) was the first person to use the sequence of geomagnetic reversals as a means of ordering rock sequences.

The reality of geomagnetic reversals was then progressively established with the studies of Hospers (1951, 1953) in Iceland, and Roche (1950, 1951, 1956) in the Massif Central of France. The work of Hospers on Icelandic lavas was augmented by Rutten and Wensink (1960) and Wensink (1966) who subdivided Pliocene-Pleistocene lavas in Iceland into three polarity zones from young to old: N-R-N. Magnetic remanence measurements on basaltic lavas combined with K/Ar dating, pioneered by Cox et al. (1963) and McDougall and Tarling (1963a, 1963b, 1964), resulted in the beginning of development of the modern geomagnetic polarity timescale (GPTS). These studies, and those that followed in the mid-1960s, established that rocks of the same age carry the same magnetization polarity, at least for the last few million years. The basalt sampling sites were scattered over the globe. Polarity zones were linked by their K/Ar ages, and were usually not in stratigraphic superposition. Doell and Dalrymple (1966) designated the long intervals of geomagnetic polarity of the last 5 Myrs as magnetic epochs, and named them after pioneers of geomagnetism (Brunhes, Matuyama, Gauss, and Gilbert).

Then, the discovery of marine magnetic anomalies confirmed seafloor spreading (Vine and Matthews, 1963), and the GPTS was extended to older times (Vine, 1966; Heirtzler et al., 1968; Lowrie and Alvarez, 1981). Since then, the succession of polarity intervals has been extensively studied and used to construct magnetostratigraphic timescales linking biostratigraphies, isotope stratigraphies, and absolute ages (see Opdyke and Channell, 1996,"Magnetic stratigraphy", for a review).

The geomagnetic polarity timescale

The fit of the land-derived polarity timescale, from paleomagnetic and K/Ar studies of exposed basalts, with the polarity record emerging from marine magnetic anomalies (MMA) (Vine and Matthews, 1963; Vine, 1966; Pitman and Heirtzler, 1966; Heirtzler et al., 1968) resulted in a convincing argument for synchronous global geomagnetic polarity reversals, thereby attributing them to the main axial dipole. This intense research effort has culminated with the work of Cande and Kent (1995) based on the Marine Magnetic Anomalies record, using the South Atlantic as the fundamental template with inserts from faster spreading centers in the Indian and Pacific oceans. Cande and Kent (1995) adopted the astrochronological age estimates for the Pliocene-Pleistocene polarity reversals and fixed the age tie-point at the Cretaceous-Tertiary boundary at 65 Ma (Figure 1).



Geomagnetic Field, Polarity Reversals, Figure 1 The geomagnetic polarity timescale for the last 160 My. Numbers indicate the marine magnetic anomalies.

The changing frequency over time and the duration of geomagnetic reversals

Examination of the geomagnetic polarity timescale reveals some of the major characteristics of geomagnetic reversals. First, a clear characteristic is the widely different duration of periods of stable polarity separating geomagnetic reversals. Long periods of time during which there were no reversals have been clearly identified, such as the Cretaceous Long Normal Chron (also called the Cretaceous Superchron, about 118–183 million years ago) or the Kiaman Superchron, which lasted approximately from the late Carboniferous to the end of the Permian.

The frequency of reversals decreased prior to the Cretaceous Superchron, and slowly increased over the 80 million years from the end of this Superchron to the present. It has been suggested (Mazaud et al., 1983; Mazaud and Laj, 1991) that in this last period the frequency does not increase randomly but presents a dominant frequency corresponding to a period of approximately 15 million years. This suggestion has, however, been received with some skepticism (McFadden, 1987). The most recent analyses seem to converge toward a nonstationary Poisson process or at least a gamma process with k only slightly greater than 1 (Lowrie and Kent, 2004).

Another characteristic, revealed from the very beginning by the studies of reversals, is that the Earth's magnetic field strength drops to low levels during polarity reversals. There has been some debate on whether this drop is symmetrical or not on each side of the reversal. Valet and Meynadier (1993) suggested that the dipole intensity slowly decreases over a long period of time preceding a reversal and rapidly increases immediately after (the so-called sawtooth hypothesis). These authors also suggested that there is a positive correlation between the magnitude of the increase in intensity and the length of the subsequent polarity interval.

The sawtooth pattern, however, is not present in many sedimentary records (Tauxe and Shackleton, 1994; Tauxe

and Hartl, 1997; Laj et al., 1996; Channell and Kleiven, 2000; Channell et al., 2009). Interpretations of the sawtooth pattern, other than true geomagnetic behavior, have been given, either assuming sedimentary postdepositional artifacts (Mazaud, 1996) or the presence of a cumulative viscous component not removed by alternating field demagnetization (Kok and Tauxe, 1996a, b). Moreover, McFadden and Merrill (1998) have strongly questioned the suggestion that the duration of polarity intervals could be determined by the amplitude of the field recovery after the reversal. The fast recovery of the field intensity after the reversal does not appear either in a recent reconstruction of the Brunhes–Matuyama transition, based on four independent records, where the pre- and post-transitional intensity records appear symmetric about the reversal (Leonhardt and Fabian, 2007). In summary, the experimental evidence for the sawtooth hypothesis is controversial.

Also clearly apparent from the geomagnetic polarity timescale is the extremely short duration of polarity reversals compared to periods of stable polarity. The time it takes for the reversal to happen has been roughly estimated from the early works (Harrison and Somayajulu, 1966; Cox et al., 1963, 1964; Cox, 1969) to be between 10^3 and 10^4 years, with some estimates up to 28,000 years. In a recent article, Clement (2004) presents an analysis of available sedimentary records and shows that these records yield an average estimate of 7,000 years for the duration of a reversal. Moreover, the duration varies with site latitude, with a shorter duration observed at low-latitude sites. This short duration has been one of the most delicate factors to overcome in studying the detailed structure of reversals.

The morphology of geomagnetic reversals

Because of its importance to dynamo theory, the morphology of the geomagnetic field during reversals and whether or not it displays statistical asymmetries has been a subject of continuous research for many years. Records of geomagnetic field changes during a polarity transition have, however, been difficult to obtain, not only because of their short duration mentioned above, but also because the magnetizations of the rocks is weak due to the low intensity of the transitional field. It is only with the advent of sensitive magnetometers that the number of published transitional records has rapidly increased.

In probably the most famous of the early records, Hillhouse and Cox (1976) showed that the Virtual Geomagnetic Pole (VGP) (The Virtual Geomagnetic Pole is defined as the pole of the geocentered axial dipolar field that would give the observed direction of the field at the observation site. If the VGPs observed at several sites at a given time coincide, then the field has a dipolar structure.) path for the Brunhes–Matuyama transition recorded in sediments from Lake Tecopa (California) was different from the one previously obtained by Niitsuma (1971) from the Boso Peninsula in Japan, thereby providing evidence that the transitional field is not dipolar. Although in a more recent article Valet et al. (1988a) showed that the AF demagnetization used by Hillhouse and Cox (1976) did not completely remove a strong overprint, the conclusion that the transitional field was not dipolar was maintained.

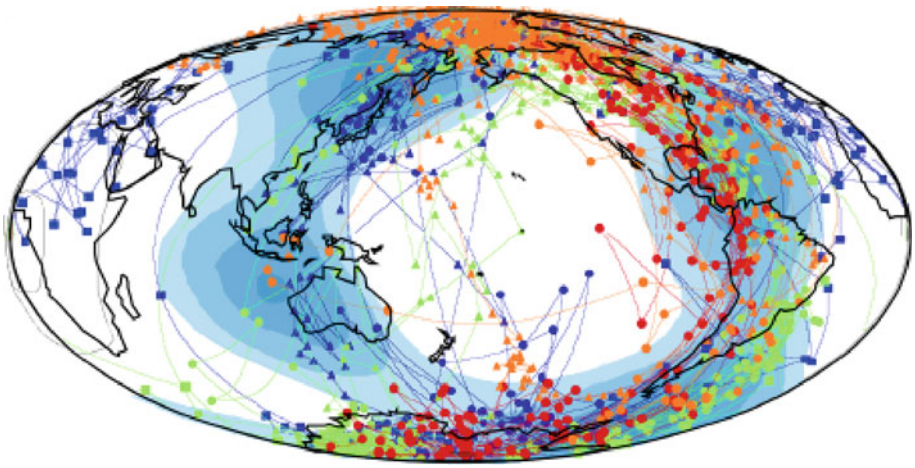
Another famous record was obtained from a Miocene lava sequence at the Steens Mountain (Mankinen et al., 1985; Prévot et al., 1985). The record displays several phases with large swings, one of which occurring at the extremely rapid rate of $50 \pm 21^\circ$ per year, while the intensity change was $6{,}700 \pm 2{,}700$ μT per year, about 10–50 times larger than the maximum rate of change observed for the non-dipole field in historical records. These amazing rates of change are still a matter of discussion among geophysicists.

Other transitional records were obtained from lava sequences in French Polynesia (Roperch and Chauvin, 1987; Roperch and Duncan, 1990; Chauvin et al., 1990). These records appear to indicate that a zonal field dominates the beginning of the transition, then non-dipolar terms emerge without any preferred axisymmetry, consistent with an earlier suggestion by Hoffman (1982).

Transitional records from sequences of relatively high accumulation rate marls in Western Crete (Greece), were reported in a series of papers by Valet and Laj (1981, 1984) and by Valet et al. (1983, 1986, 1988b). The results from multiple records indicated that the reversal process observed for four sequential transitions remained unchanged for about 1.3 Ma. In one record, obtained from a particularly high sedimentation rate section, fast directional fluctuations, reminiscent of the Steens Mountain record, were observed whose amplitude significantly increases during the transition. Slight smoothing of the data reveals that almost periodic fluctuations occurred on a longer timescale during the transition (Valet et al., 1986).

Two landmark papers were published almost simultaneously and independently in 1991. Clement (1991) examined records of the Brunhes–Matuyama transition obtained from the northern, equatorial, and southern latitudes in the Atlantic sector. The VGP paths from the mid-latitudes in the northern and southern hemispheres are nearly coincident and extend over the Americas. Paths from the equatorial site track almost antipodal to the other paths. These results suggest that during the reversal VGPs tend to fall along two longitudinal bands.

From a compilation of all the available sedimentary records from several sites and spanning about 12 million years, Laj et al. (1991) suggested that reversals and excursions exhibit geometric regularity: the VGP paths of these transitions tend to fall along either American or Asian-Australian longitudes, that is, the same as for the Brunhes–Matuyama reversal (Figure 2). As remarked by the authors a persistent geometry over 12 Ma has important geomagnetic consequences : since the duration



Geomagnetic Field, Polarity Reversals, Figure 2 The compilation of sedimentary records for the last 12 My (Laj et al., 1991) indicating the existence of preferred longitudinal bands for transitional VGPs. The blue shaded zones are characterized by fast seismic velocities in the lower mantle.

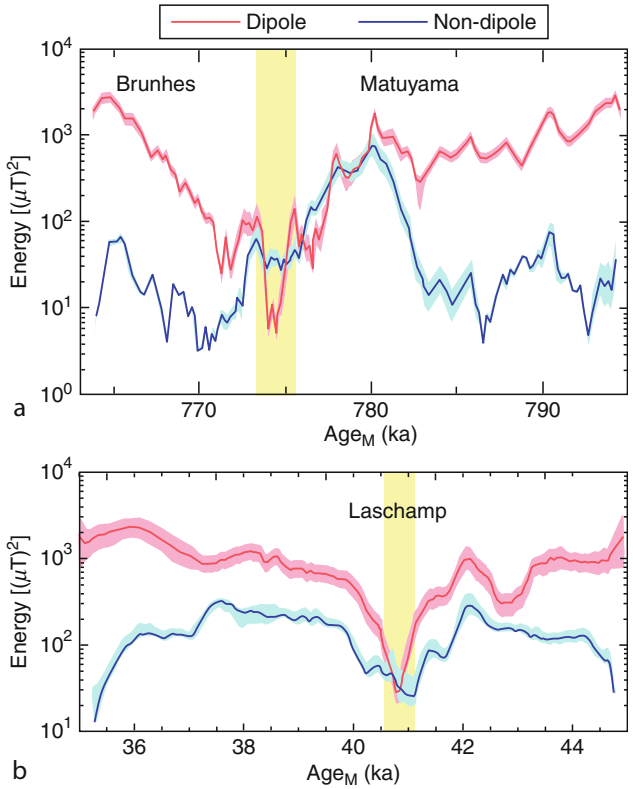
between transitions is longer than both the core's convective and magnetic diffusion timescales, the most plausible mechanism by which the core could retain a memory of previous transitions, particularly preferred longitudinal bands, is through some form of core-mantle coupling. This argument was reinforced by Laj et al. (1991) who noted the apparent correlation between preferred longitudes and lower mantle seismic velocity variations, possibly arising from thermal heterogeneities.

The suggestion of preferred longitudinal bands for transitional VGPs has, however, been met with some skepticism, some authors questioning the adequacy of the geographical distribution of the sites (Valet et al., 1992), or the reliability of transitional records from sediments (Langereis et al., 1992; Barton and McFadden, 1996). Statistical analyses of the distribution of path have not given a clear answer (Weeks et al., 1992; McFadden et al., 1993; Quidelleur and Valet, 1994). An initial analysis of transitional records from lavas (which are devoid of many of the problems of sedimentary magnetizations) appeared to indicate that transitional VGPs are statistically axi-symmetric (Prévot and Camps, 1993). However, a more recent analysis by Love (1998, 2000) using a mathematical approach in which the records are normalized taking into account differences in recording density of the paleomagnetic directions, has concluded that the volcanic transitional VGPs indeed show a significant tendency to fall along American and Asian-Australian longitudes, consistent with the sedimentary data. The existence of preferred longitudinal bands for transitional VGPs must, therefore, be considered as a realistic suggestion.

Alongside with the observations of records of geomagnetic reversals, phenomenological models have been developed to account for at least the main characteristics of the records. As early as 1976, Hillhouse and Cox (1976) suggested that if the usual non-dipole drift remained unchanged during the reversal, then one should observe large longitudinal swings in the reversal PGV paths. As this was not observed, these authors proposed that an invariant component dominates the field when the usual dipole has vanished (the so-called standing field hypothesis). Subsequently, Hoffman and Fuller (1978) and Hoffman (1979) proposed a model in which reversals originate in particular regions of the core and progressively extend to other regions (the so-called flooding model). None of these models was, however, capable of predicting VGP paths from particular sites on the Earth.

A significant step forward has been made recently, with the development by Leonhardt and Fabian (2007) of a Bayesian inversion method devised to reconstruct the spherical harmonic contents of the geomagnetic field during a reversal from paleomagnetic data. The validity of this inversion technique is proven, in particular, by iteratively combining four geographically distributed high quality paleomagnetic records of the Brunhes–Matuyama reversal into a single scenario without assuming an a priori common age model. The obtained results successfully describe most independent Brunhes–Matuyama transitional records.

Leonhardt and Fabian (2007) were able to discuss many questions about the transitional field, which had been controversially discussed (see, e.g., Merrill et al. (1996)) so far: primarily the question of contribution of dipole versus non-dipole fields during the reversal process. The results of their modeling indicates a strong increase of non-dipolar energy a few kyrs before the reversal. The non-dipole energy prevails on the dipole some 5 kyrs before the dipole minimum, after which both the non-dipole and dipolar energies decrease. Following the minimum in dipolar energy, the non-dipolar energy



Geomagnetic Field, Polarity Reversals, Figure 3 (**a**) Evolution of the dipole and non-dipole energies during the Matuyama–Brunhes polarity transition. (**b**) Evolution of the dipole and non-dipole energies during the Laschamp excursion.

drops further, while the dipolar energy increases first sharply then progressively recovers (Figure 3a). The model also shows that, during the reversal, the inverse flux penetrates the tangent cylinder (the imaginary cylinder aligned with the Earth's rotation axis and tangent to the inner core).

Dynamo mechanisms and reversals

For many years, scientific opinion has been divided on what causes geomagnetic reversals. Initial suggestions have been made that geomagnetic reversals are not due to spontaneous processes in the Earth's dynamo, but rather that they are triggered by external factors (such as arrival of continental slabs near the core-mantle boundary as a result of plate tectonics, or even mantle-core shear forces linked to external impacts).

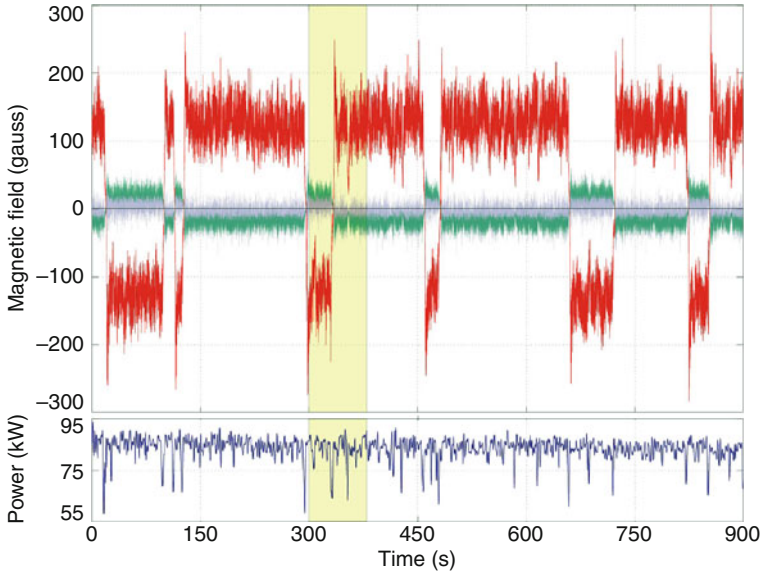
Today, most geophysicists believe that reversals are inherent aspects of the dynamo, which generates the geomagnetic field. Recent developments in numerical dynamo models, which take advantage of modern supercomputers, and also an experiment with a laboratory dynamo, point strongly that this is the only sustainable mechanism. In these models the equations describing the time-dependent thermal, compositional, velocity and magnetic field are solved simultaneously in the three-dimensional spherical geometry appropriate to the core. There is no a priori prescription for reversals, so, if they happen, they are an intrinsic property of the mechanisms of the geodynamo.

The first of these numerical models aiming to simulate Earth-like characteristics was published by Glatzmaier and Roberts (1995). This three-dimensional, self-consistent model was able to maintain a magnetic field for over 40,000 years. The model, considers a finitely conducting solid inner core, in agreement with findings by Hollerbach and Jones (1993) that a solid inner core tends to stabilize the geodynamo. Over the period of 40,000 year the model undergoes several polarity excursions and finally a reversal is observed. The model, therefore, shares some similarities with real reversals of the geomagnetic field, and therefore may provide insight into the mechanisms of geomagnetic reversals.

In this respect, Glatzmaier et al. (1999) and Coe et al. (2000) have run numerical simulations of the Glatzmaier–Roberts dynamo using a variety of thermal boundary conditions. The model displays a range of behavior that resembles records of real reversals of the Earth's magnetic field. Reversals occurred during both the homogeneous and tomographic simulation (in this last case the heat flux at the Core-Mantle Boundary is patterned after a seismic velocity model from tomographic investigation of the lower mantle). All reversals appear spontaneously, with no external triggering required. The tomographic model of Glatzmaier et al. (1999) also appears to offer some support for the hypothesis that VGPs during reversals correlate with areas of higher than average heat flux.

The question of how well the geodynamo model represents the Earth's field is of course fundamental. Indeed, if the Earth's values for the radius and the rotation of the core are used, then, owing to computation limitations, viscous diffusivity values at least three to four orders of magnitude larger than those of the Earth must be used. So, while some modelers have argued that the field produced by models should be fairly realistic, other modelers are less confident that the results can be directly extrapolated to the Earth, even at the large scales. In the author's opinion, numerical models have very largely improved our understanding of the mechanisms inherent to the production of the Earth's magnetic field.

Finally, a benchmark experiment showing how magnetic field reversals can be generated without any external triggering in a turbulent conducting field has been obtained recently in a laboratory environment, the so-called VKS experiment (this acronym stands for Von Karman Sodium) (Berhanu et al. (2007)). In 2000 experiments in Riga (Gailitis et al., 2001) and Karlsruhe (Stieglitz and Müller, 2001) showed that fluid dynamo could be generated by fluid sodium flows, when a favorable geometry is imposed to the flow. In the more recent VKS experiment, a turbulent flow is produced in a copper cylinder filled with liquid sodium whose flow



Geomagnetic Field, Polarity Reversals, Figure 4 Evolution of the magnetic field measured inside the flow vessel during the VKS experiment. The main component (red) is the azimuthal one. Note that all components decay to zero at a reversal. The bottom graph shows the evolution of the power driving the flow (Adapted from Berhanu et al., 2007).

is created by two counter-rotating impellers. When the speed of the impellers exceeds a critical value, the flow spontaneously generates a magnetic field that is self-sustained by the flow itself. This field undergoes large fluctuations, originating from the high level of turbulence. The most spectacular result was observed when the two impellers were counter-rotated at different speeds: in this case the temporal evolution of the field is characterized by a series of erratic reversals of polarity. These reveal remarkable similarities with the Earth's magnetic field, in the sense that the duration of the transitions is very short compared to the periods of stable polarity. In addition, excursions are also present, during which the field decays to very low values before growing again without a change in polarity (Figure 4). Although similarity to the Earth's magnetic field should not be overstressed, this laboratory experiment clearly shows that reversals can appear spontaneously, as a consequence of the complexity of the fluid flow, without any necessity for an external triggering.

Outlook: The future of geomagnetic reversals

The geomagnetic dipole has decreased in recent historical times at a rate of 5% per century, which is about 10–12 times the rate of free Ohmic decay of the geomagnetic dipole field in the core. Additional evidence for this rapid decrease is the poleward migration of large patches of reverse magnetic field at the core-mantle boundary that have largely contributed to the historical dipole field drop (Olson and Amit, 2006). Therefore, this is a very rapid change for the geodynamo, which has led to speculations about the possibility of an impending field reversal (Constable and Korte (2006); Olson and Amit (2006)). Because an intensity drop is also associated with excursions this second possibility should also be considered.

The inverse model of Leonhardt and Fabian (2007) may allow to have a deeper insight on this scenario. Indeed, when applied to the study of the Laschamp excursion (Leonhardt et al., 2009) the model indicates that both dipolar and non-dipolar energies at the Earth's surface decrease at approximately the same time with similar rates. The dipolar energy reaches its minimum slightly later than the non-dipolar energy. Then, for a brief interval the non-dipolar energy prevails, contrary to the Brunhes–Matuyama reversal discussed above where the non-dipole energy prevails on the dipole some 5 kyrs before the dipole minimum, after which both the non-dipole and dipolar energies decrease (Figure 3b). The time evolution of the dipole versus non-dipole fields is different for a reversal or an excursion and could, therefore, be an indicator for an incoming reversal or excursion.

At present, however, the non-dipole field energy is about one order of magnitude smaller than the dipolar term. This latter is still larger than the dipole energy calculated before either a reversal or an excursion using the Leonhardt and Fabian approach. So despite the decreasing trend of dipole energy, there is no indication in the present field that would point toward either type of instability. Together with Olson and Amit (2006), Leonhardt et al. (2009) therefore consider that it is not justified to consider the present decrease in dipole energy and an indication of an imminent reversal. We will have to wait some more time to know whether we are heading toward a reversal, an excursion, or whether we are simply undergoing an intensity fluctuation.

Acknowledgments

I thank Alain Mazaud for helpful discussions during the writing of the manuscript.

Geomagnetic field: secular variation

The geomagnetic field observed at and above the Earth's surface varies on a broad range of timescales, from less than seconds to millions of years. In general, fast variations with periods less than a year originate from sources external to the Earth. Secular variation is the continuous variation of the geomagnetic core field, associated to changes of fluid flow in the outer core (e.g., Wardinski, 2007). The name originates from the Latin "seculum," referring to a time interval of about a century. Secular variation describes the velocity of field change or the first temporal derivative of a time series of field observations.

Secular variation consists of mostly non-periodic, non-predictable field changes. The high-frequency end of the temporal secular variation spectrum is not well-understood. Very rapid variations that might occur in the core are damped and filtered out when passing through the mantle before being observed. The fastest known secular variation features, namely, geomagnetic jerks and rapid fluctuations, occur on timescales on the order of one year (Mandea and Olsen, 2009). It is difficult to discriminate between internal and external variations in observational data on these timescales. Long-term external field changes, e.g., the approximately 11-year sunspot cycle, are also reflected in the measured time series. Secular variation on several thousands to million year timescales includes excursions and complete polarity reversals of the geomagnetic core field.

Geomagnetic secular variation is not globally uniform. The geomagnetic dipole moment, a measure of the overall global field strength, has been decreasing at the rate of 5% per century since the beginning of systematic magnetic field intensity observations around 1840. The present spatial distribution of intensity secular variation is characterized by a large area of intensity decrease with two foci over North America and the southern Atlantic – south American region, and a smaller focus of intensity increase over the Indian Ocean (e.g., Lühr et al., 2009). Historical and paleomagnetic data indicate that secular variation has always been weak in the Pacific compared to the Atlantic hemisphere, which might be a consequence of lateral variations in lower mantle temperature (Gubbins and Gibbons, 2004).

Geomagnetic field. Nearly dipolar magnetic field emerging from the Earth's interior.
Dynamo process. Conversion of kinetic energy of motions into magnetic energy.
Geodynamo. Dynamo process operating in the Earth's liquid outer core.

Introduction

The forces exerted by magnetized rocks or lodestones have been known to mankind for many centuries before Christ, but the directivity of the lodestone appears to have been first observed by the Chinese in the first century B.C. It is known that at this time Chinese geomancers used a freely turnable spoon-like lodestone on a polished plate as a compass, not for navigational purposes, but probably for aligning tombs and houses. As navigational instrument the compass was introduced to European sailors by arabic merchants in the twelfth century A.C. A first systematic experimental study of the forces exerted by lodestones was published by Petrus Peregrinus in 1269. Some of his results are shown in Figure 1a. More refined experiments were carried out and described in his book *De Magnete* by William Gilbert (1600). He concludes that the Earth itself is a magnet like a lodestone.

In 1839 Carl-Friedrich Gauss introduced the representation in terms of spherical harmonics for the observed geomagnetic field. Through this representation it became possible to separate the magnetic fields of internal and external origin. The latter, being much smaller than the former and much more variable in time, is caused by ionospheric and magnetospheric currents. Only during magnetic storms can the externally generated magnetic field reach a significant fraction of the total strength of the

Upper configuration: "naturale," lower configuration: "non naturale." (**b**) A simple compass in the form of afloating lodestone. (After Stefani et al., 2008).

Earth's magnetic field (see *Magnetic Storms and Electromagnetic Pulsations*). Together with Alexander von Humboldt Gauss founded in 1836 the Göttinger Magnetischer Verein (Göttingen Magnetic Union) in order to create a worldwide network of observatories for the measurement of the magnetic field and its variations in time. Since that time the knowledge about the geomagnetic field and its time dependence has improved continuously (see *Geomagnetic Field, Global Pattern*).

The idea that the geomagnetic field originates from the ferromagnetism of the Earth's interior prevailed until the end of the nineteenth century even though the phenomenon of secular variation – known since the seventeenth century – was difficult to reconcile with the hypothesis of remanent magnetism. In early years of the twentieth century it became clear that the Curie temperature of ferromagnetic material is exceeded within the entire Earth except for the uppermost few tens of kilometers and that the magnetization of the Earth's crust is far to weak to act as a source of geomagnetism. Numerous other hypotheses have been proposed as origin of geomagnetism and rejected (Rikitake, 1966) except for the dynamo hypothesis. In the meantime magnetic fields had been observed on the sun and in 1919 Larmor proposed the dynamo mechanism for the origin of the magnetic field of sunspots.

According to the dynamo hypothesis motions within the outer liquid-iron core of the Earth can amplify a magnetic field from arbitrarily small amplitudes and sustain it at the observed finite strength against Ohmic dissipation. The feasibility of this mechanism in a simply connected region of nearly uniform electrical conductivity appeared to be doubtful for a long time, and the dynamo hypothesis experienced a setback when Cowling (1934) demonstrated that axisymmetric magnetic fields cannot be generated by the dynamo mechanism. Since the geomagnetic field is axisymmetric in first approximation, Cowling's theorem stimulated the search for alternative mechanisms. It was not until the late 1950s that Backus (1958) and Herzenberg (1958) demonstrated independently that dynamos are indeed possible in spheres of uniform conductivity.

Since that time dynamo theory has developed rapidly and it has become generally accepted that a geodynamo operates in the liquid outer core of the Earth. While in the 1960s and 1970s of the past century analytical models of the geodynamo have prevailed, the strong growth of computer capacities in recent decades has permitted numerical simulations with ever increasing details of convection driven dynamos in Earth's core-like rotating spherical shells. The principles of the dynamo process in such an environment are now reasonably well understood. The remaining uncertainties are caused by an insufficient knowledge of conditions in the Earth's core and lower mantle and the inability to model the dynamo process under the highly turbulent conditions of flow in the outer core.

Before outlining the concepts of dynamo theory we briefly mention the role of the crustal magnetic field which originates from ferromagnetic remanence of material below its Curie temperature in the lithosphere. When the observed magnetic field is represented in terms of spherical harmonics (see *Geomagnetic Field, IGRF*) it is found that crustal contributions dominate in coefficients of the degree 14 and higher. The crustal contributions to coefficients of lower degrees are still substantial, of course, but they do not exceed those originating from the core in general (see *Magnetic, Global Anomaly Map*). Crustal magnetic fields are often correlated with geological features and may indicate iron ore deposits such as the famous Kursk formation in the Ukraine. Other important crustal magnetic features are the magnetic stripes of the ocean floors extending parallel to the mid-oceanic ridges

which represent the most convincing evidence for the concept of plate tectonics (see *Magnetic Anomalies, Interpretation*).

The following sections are devoted to the dynamo theory of geomagnetism and its applications to the Earth's core. The current state of numerical models of the geodynamo will be described under the title Core dynamo.

Kinematic dynamo theory

The simplest description of a dynamo is obtained for a fixed velocity field, i.e., when the feedback of the generated magnetic field on the flow through the action of the Lorentz force is neglected. A single equation of magnetic induction describing the time dependence of the magnetic flux density $\vec{B}$ can be derived from Maxwell's equations in the magnetohydrodynamic approximation, in which the displacement current is neglected, and from Ohm's law which are given by

$$\nabla \cdot \vec{B} = 0, \qquad \frac{\partial \vec{B}}{\partial t} = \nabla \times \vec{E}, \qquad \nabla \times \vec{B} = \mu \vec{j}, \qquad \vec{j} = \sigma(\vec{E} + \vec{v} \times \vec{B}) \tag{1}$$

where $\vec{B}$ is the magnetic flux density, $\vec{E}$ is the electric field and $\vec{j}$ is the current density. σ, μ and $\vec{v}$ denote the electrical conductivity, the magnetic permeability and the velocity vector, respectively. Ohm's law has been written in the form valid for a moving conductor. Accordingly Equation 1 are invariant with respect to a Galilei transformation; in other words, the same Equations 1 hold in a system moving with constant velocity $\vec{V}$ with respect to the original system of reference when $\vec{v}$, $\vec{E}$ and $\vec{B}$ obey the relationships

$$\vec{v}' = \vec{v} - \vec{V}, \qquad \vec{B}' = \vec{B}, \qquad \vec{E}' = \vec{E} + \vec{V} \times \vec{B} \tag{2}$$

where the primed quantities refer to the new system. It is convenient to eliminate $\vec{E}$ and $\vec{j}$ from Equations 1 and to write

$$\frac{\partial \vec{B}}{\partial t} = \nabla \times (\lambda \nabla \times \vec{B}) = \nabla \times (\vec{v} \times \vec{B}) \tag{3}$$

where $\lambda \equiv 1/(\mu\sigma)$ is the magnetic diffusivity. Because of the absence of ferromagnetic effects in the Earth's core, the permeability is usually replaced by the permeability of the vacuum. From the form of Equation 3 it is obvious that $\nabla \cdot \vec{B} = 0$ remains satisfied if this equation is satisfied by the initial conditions. It is remarkable that Equation 3 is not only invariant with respect to Galileo transformations and thus compatible with the Navier–Stokes equations of motion, but is also invariant with respect to a transformation to a rotating system.

Since the Earth's outer core can be regarded as an incompressible fluid in first approximation, Equation 3 can be simplified further by the use of equations $\nabla \cdot \vec{v} = 0, \nabla \cdot \vec{B} = 0$,

$$\left(\frac{\partial}{\partial t} + \vec{v} \cdot \nabla\right)\vec{B} - \lambda \nabla^2 \vec{B} = \vec{B} \cdot \nabla \vec{v}, \tag{4}$$

where for simplicity $\lambda =$ const. has been assumed. This form of the equation of induction is revealing since it resembles the heat equation with the term $\vec{B} \cdot \nabla \vec{v}$ on the right hand side assuming the role of a heat source. This term tends to strengthen the magnetic field when a fluid particle is stretched in the direction of the local magnetic field line. Such an interpretation is especially useful for the dynamo problem. In order that a magnetic field $\vec{B}$ may grow, the term on the right hand side of Equation 4 must overcome the effect of the magnetic diffusion term on the left hand side. Using a typical velocity U and a typical length scale d, the ratio of the two terms can be described by the magnetic Reynolds number Rm,

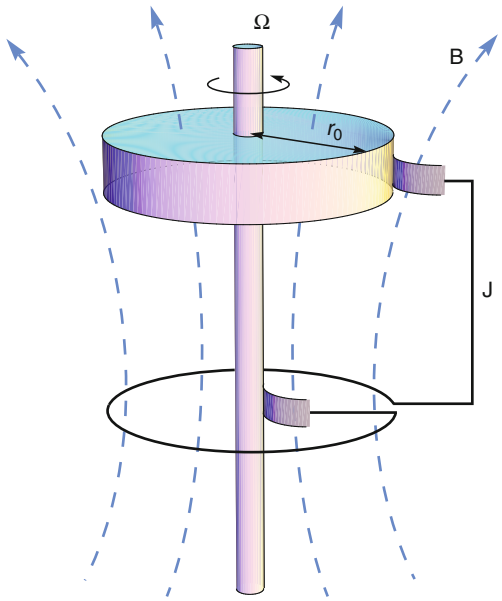
$$Rm \equiv Ud/\lambda. \tag{5}$$

Only when Rm is of the order of 1 or larger may growing magnetic fields become possible. Necessary conditions of this kind for a dynamo have been derived rigorously by Backus and Childress for a fluid sphere of constant magnetic diffusivity,

$$Rm \equiv Ur_o/\lambda > \pi, \tag{6}$$

where r_o is the radius of the sphere. In Childress's formulation U refers to the maximum velocity, whereas in Backus's formulation $U/\pi r_o$ is the maximum rate of strain of the velocity field.

The simplest dynamo is the disk dynamo originally invented by Faraday and shown in Figure 2. A metal disk is rotating about its axis with the angular velocity Ω. When the disk is permeated by an initial magnetic field $\vec{B}_0$



Geomagnetic Field, Theory, Figure 2 The disk dynamo.

parallel to the axis, an electromotive force U_e is generated between axis and rim of the disk,

$$U_e = \Omega \int_{r_1}^{r_0} \vec{B}_0 \, r dr \tag{7}$$

where r_1 and r_0 denote the radii of axis and disk. The electromotive force U_e can be used to drive an electric current J through the circuit indicated in the figure. Denoting by L and R the inductivity and the ohmic resistance of the circuit we obtain for the current J the equation

$$L\frac{dJ}{dt} + RJ = U_e \tag{8}$$

The current J flowing through the circuit is associated with a magnetic field $\vec{B}_1$ which may replace the initial field $\vec{B}_0$. The integral $2\pi \int_{r_1}^{r_0} \vec{B}_1 \, dr/J$ describes the mutual inductivity M between circuit and disk. Equation 8 for the self-excited disk dynamo can thus be written in the form

$$L\frac{dJ}{dt} = (\Omega M/2\pi - R)J \tag{9}$$

which allows for exponentially growing solutions once the dynamo condition

$$\Omega > 2\pi R/M \tag{10}$$

is satisfied. The exponential growth will be modified, of course, as soon as the Lorentz force $\vec{j} \times \vec{B}$ in the disk has grown sufficiently to affect the angular velocity Ω. A larger torque will then be needed to sustain the rotation speed.

The disk dynamo is an inhomogeneous dynamo since it depends on an inhomogeneous, multiply connected distribution of electrical conductivity as given by the wiring of the circuit. The dynamo would not work if the sense of wiring around the axis would be opposite to that shown in the figure or if it would be immersed in a highly conducting fluid. In this respect the disk dynamo differs from the homogeneous dynamo operating in the Earth's core in a singly connected finite domain of essentially homogeneous electrical conductivity. Velocity fields required for driving a homogeneous dynamo are necessarily more complex than the simple rotation velocity of the disk dynamo. It can even be proven that a simple form of motion, such as that of the disk dynamo, cannot drive a dynamo in a sphere if λ is a function of only the radial coordinate. More generally, the toroidal theorem states that growing solutions of Equation 3 do not exist if $\vec{v}$ and λ can be written in the form

$$\vec{v} = \nabla\Psi \times \vec{r}, \qquad \lambda = \lambda(|\vec{r}|). \tag{11}$$

Inspite of their differences homogeneous dynamos and the disk dynamo share a number of properties:

(i) For given external parameters there exists always a solution without magnetic field besides the dynamo solution, just as the disk of Figure 2 can rotate with $\Omega > \Omega_c$ in the absence of any initial field $\vec{B}_0$.

(ii) The existence of a dynamo solution requires that the magnetic Reynolds number Rm exceeds a critical value Rm_c which corresponds to the quantity $\Omega M/R$ in the case of the disk dynamo. The nonmagnetic solution exists, but it is unstable for $Rm > Rm_c$.

(iii) Magnetohydrodynamic dynamos always occur in two forms which are identical except for the sign of the magnetic field $\vec{B}$. This property reflects the fact the Lorentz force is given by an expression that is quadratic in $\vec{B}$.

Property (iii) is the basic reason that the geomagnetic field has often switched its polarity in the geologic past. These "reversals" have occurred nearly randomly about every 200,000 years in the time average. In contrast, the solar magnetic field reverses every 11 years in a surprisingly periodic fashion.

For the description of magnetic fields associated with a spherical system one often uses the general representation for a solenoidal vector field,

$$\vec{B} = \nabla \times (\nabla h \times \vec{r}) + \nabla g \times \vec{r} \tag{12}$$

in terms of a poloidal and a toroidal component each of which is decribed by a scalar function, the poloidal function h and the toroidal function g. Without loss of generality the averages of h and g over surfaces $|\mathrm{r}| = \text{const.}$ can be assumed to vanish. A homogeneous dynamo usually requires the interaction of both components. The functions h and g can be separated into their axisymmetric parts $\bar{h}$ and $\bar{g}$ and nonaxisymmetric parts, $\check{h} = h - \bar{h}$ and $\check{g} = g - \bar{g}$. Because of Cowling's theorem the latter parts play an essential role in the dynamo process. The component $\bar{g}$ can easily be generated in a spherical dynamo through a stretching of the axisymmetric poloidal field by a differential rotation. This process is known as the ω-effect. But the amplification of $\bar{h}$ requires the interaction of the nonaxisymmetric components of magnetic fields and velocity fields. This is often called the α-effect. This latter effect can also be used, of course, for the generation of $\bar{g}$ in the absence of a differential rotation. One thus distinguishes $\alpha\omega$- and α^2-dynamos. These concepts were originally introduced within the framework of mean-field magnetohydrodynamics for which we refer to the book of Krause and Raedler (1980).

Energetics of the geodynamo

For a prescribed stationary velocity field, Equation 3 admits solutions with an exponential time dependence, of which the growing ones are called dynamos. As the magnetic field grows, the action of the Lorentz force on the velocity field can no longer be neglected. The work done by the velocity field against the Lorentz force equals the energy consumed by ohmic heating. Thus, the

sustenance of a finite-amplitude magnetic field against ohmic dissipation requires a source of mechanical energy. A lower bound of about $10^8 W$ on the ohmic heating in the Earth's core can be obtained by a calculation of the minimum dissipation corresponding to the observed geornagnetic field, while an upper bound of about $10^{13} W$ is given by the observed geothermal heat flux. A realistic value is likely to be within the range 10^{11} to $10^{12} W$.

Numerous sources of energy for the geodynamo have been considered in the history of dynamo theory. The major ones that cannot be excluded right away are the precession of the Earth, thermal heat sources, and compositional buoyancy. The latter source first proposed by Braginsky in 1963 is probably the largest contributor, since the turbulence induced by precession appears to be marginal and since the Carnot efficiency of heat sources is relatively low (Gubbins et al., 2004). Compositional buoyancy is generated by the growing solid inner core. Iron and perhaps nickel crystallize at the inner core-outer core boundary while lighter elements stay in solution. The decrease in density caused by the increase in the concentration of light elements provides a source of potential energy that can drive convection in the outer core. Since the outer core contains about 10% light elements by weight, most likely silicon, sulfur and oxygen, the buoyancy provided by this process appears to be more than adequate to drive the geodynamo. The compositional buoyancy mechanism has the advantage that it could explain the apparent absence of a dynamo in the case of Venus (Stevenson et al., 1983; Nimmo, 2002). Since Venus resembles the Earth in most respects, the absence of a measurable magnetic field has posed a puzzle. The somewhat higher pressure at the Earth's center and the more efficient heat transport out of the planet because of plate tectonics seem to have allowed the inner core to form, whereas Venus will reach this stage of its thermal history much later. Estimates for the age of formation of the inner core of the Earth range from 1 to 2 b.y. Since evidence for geomagnetism exist for earlier times in the paleomagnetic record when the inner core had probably not yet nucleated, thermal buoyancy generated by cooling and possibly by radioactive elements is likely to have played a role in driving the geodynamo in the Earth's early history. In this respect the Earth resembles the major planets for which thermal buoyancy appears to be the only viable source of energy to drive the planetary dynamo.

The way in which compositional buoyancy drives convective motion in the outer core is not well understood. It is even possible that the outer part of the outer core is stably stratified. Another peculiar property of the solidification process at the inner core is the so-called mushy zone in which liquid and solid phases coexist (see *Earth's Structure, Core*). But those details have little influence on the theory of the geodynamo in its current state. Since the form of motion in the outer core is primarily determined by Coriolis and Lorentz forces the theory of geomagnetism has proceeded without distinguishing much between thermal and compositional buoyancy.

Geomagnetic Field, Theory, Table 1 Properties of the liquid outer core of the Earth

Property	Symbol	Value	Unit
Angular velocity of rotation	Ω	$7.27 \cdot 10^{-5}$	s^{-1}
Mean outer radius	r_o	3485 ± 3	km
Mean inner radius	r_i	1225 ± 15	km
Density	ρ	$9.9 - 12.2$	$10^3 kg/m^3$
Coefficient of thermal expansion	α	10^{-5}	K^{-1}
Thermal diffusivity	κ	$5 \cdot 10^{-6}$	m^2/s
Magnetic diffusivity	λ	2	m^2/s
Kinematic viscosity	ν	10^{-6}	m^2/s
Permeability of vacuum	μ_0	$4\pi \cdot 10^{-7}$	H/m

Some typical values of parameters used in the theory of the geodynamo are given in Table 1.

Magnetohydrodynamic theory of the geodynamo

The theory of the geodynamo requires the inclusion of the equations of motion for the rotating liquid core for several reasons. First of all, constraints on the velocity fields used in the dynamo equation are needed since rather arbitrary velocity fields are capable of generating fields that resemble the observed geomagnetic field. The velocity fields driven by geophysically realistic forces share special properties, such as the approximate alignment of the vorticity with the axis of rotation, that make them useful in the interpretation of certain features of the observed magnetic field. The second reason for including the equations of motion stems from the necessity of taking into account the Lorentz force without which an equilibrium amplitude of the magnetic field cannot be determined. Thirdly, the time dependence of the geomagnetic field can not be understood without a detailed knowledge of the dynamics of the velocity field in the core. The basic equations of motion for the velocity vector $\vec{v}$, the heat equation for the deviation Θ from the static temperature distribution, and the equation of induction for the magnetic flux density $\vec{B}$ are usually written in the following form:

$$\nabla \cdot \vec{v} = 0, \qquad \nabla \cdot \vec{B} = 0, \tag{13}$$

$$\begin{aligned}(\partial_t + \vec{v} \cdot \nabla)\vec{v} + 2\Omega\vec{k} \times \vec{v} \\ = -\nabla\pi + \alpha\Theta g\vec{r} + \nu\nabla^2\vec{v} + \vec{B} \cdot \nabla\vec{B}/\rho\mu,\end{aligned} \tag{14}$$

$$\partial_t\Theta + \vec{u} \cdot \nabla\Theta = \vec{v} \cdot \nabla T_s + \kappa\nabla^2\Theta, \tag{15}$$

$$\lambda\nabla^2\vec{B} = \partial_t\vec{B} + \vec{v} \cdot \nabla\vec{B} - \vec{B} \cdot \nabla\vec{v}, \tag{16}$$

where ∂_t denotes the partial derivative with respect to time t and where $-g\vec{r}$ denotes the force of gravity. ν is the kinematic viscosity, $\vec{k}$ is the unit vector of the axis of rotation and Ω is the angular velocity of rotation. The potential temperature distribution T_s describes the difference

between the temperature distribution for the static solution of the problem and the adiabatic temperature distribution with the same temperature at the inner core boundary. As mentioned before, Equation 15 remains essentially unchanged if T_s and Θ are interpreted a concentration of light elements. In that case the coefficient of thermal expansion α and the thermal diffusivity κ just need to be reinterpreted. All gradient terms in the equation of motion have been combined into $\nabla\pi$. In writing Equations 13–16 we have assumed the Boussinesq approximation implying constant material properties and a constant density ϱ except in the gravity term.

Using a dimensionless description the parameters of the problem can be reduced to four dimensionless groups, the Rayleigh number Ra, the Coriolis number τ, the Prandtl number Pr, and the magnetic Prandtl number Pm which are defined by

$$Ra = \frac{\alpha g \Delta T d^4}{\nu\kappa}, \quad \tau = \frac{2\Omega d^2}{\nu}, \quad Pr = \frac{\nu}{\kappa}, \quad Pm = \frac{\nu}{\lambda}, \quad (17)$$

where the thickness d of the spherical shell has been used as length scale and ΔT is the difference of the potential temperature between the inner core-outer core boundary and the core-mantle boundary. Instead of the Coriolis number often its inverse, the Ekman number $E = \tau^{-1}$, is used. Since λ/ν is roughly 10^6 in the Earth's core the main sink of mechanical energy is ohmic dissipation and it is generally believed that the term $\nu\nabla^2\vec{v}$ is unimportant except close to the rigid boundaries of the liquid core. Moreover, the magnetostrophic approximation is often applied in which the inertial term $(\partial_t + \vec{v}\cdot\nabla)\vec{v}$ is neglected in comparison to the Coriolis force. Without these terms the important Taylor constraint can be derived: After integrating the azimuthal component of Equation 14 over a coaxial cylindrical surface in the liquid core, one must conclude that an accelerating differential rotation occurs unless the condition

$$\iint [(\nabla \times \vec{B}) \times \vec{B}]_\varphi s d\varphi dz = 0 \quad (18)$$

is satisfied for every distance s from the axis. In deriving Equation 18 we used the fact that the inflow across the cylindrical surface is balanced by the outflow with the result that the contribution from the Coriolis force term vanishes. Different strategies have been designed to accommodate the Taylor constraint (Equation 18). In Braginsky's (1978) model Z the friction of the viscous Ekman layer at the solid surface of the sphere provides a balance on the right side of Equation 18. But this effect is small such that the constraint of Equation 18 becomes nearly satisfied by a poloidal field that is extended parallel to the axis of rotation except for the region close to the boundary.

In modern numerical simulations of convection driven dynamos in rotating spherical shells the Taylor constraint (Equation 18) is usually not approached because relatively high values of the kinematic viscosity must be assumed for numerical reasons and also because the inertial term $(\partial_t + \vec{v}\cdot\nabla)\vec{v}$ plays a larger role than it possibly plays in the geodynamo. Instead of an Earth-like ratio, values of the order unity for λ/ν are used to ensure numerical convergence. The high value of ν is interpreted as an eddy viscosity which is supposed to represent the dissipative action of small scale components of the velocity field which can not be resolved in the numerical simulations.

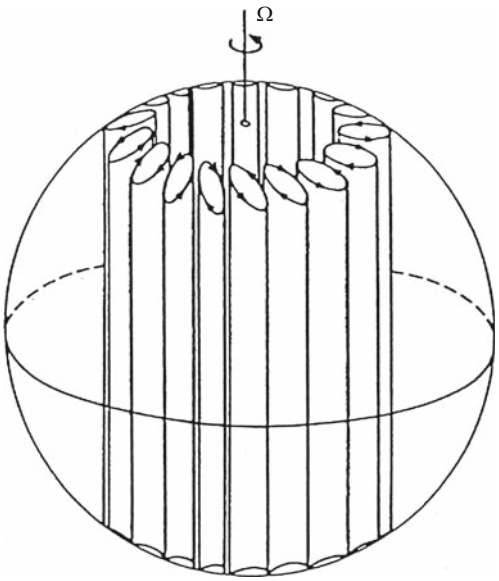
It is instructive to consider Equations 13–16 in the limit of a vanishing magnetic field. In that case the dominant terms are the Coriolis force and the pressure gradient, the balance of which,

$$2\Omega\vec{k} \times \vec{v} = -\nabla\pi \quad (19)$$

is called the geostrophic balance. The curl of Equation 14 together with $\nabla \cdot \vec{v} = 0$ gives rise to the Proudman–Taylor theorem

$$\Omega\vec{k} \cdot \nabla\vec{v} = 0 \quad (20)$$

which states that steady motion of a rotating inviscid fluid must not depend on the coordinate in the direction of the axis of rotation. Convection in a sphere requires, however, a finite radial velocity component and therefore cannot fully satisfy condition (20). As a result nonmagnetic solutions of Eqs. (13–16) exhibit a time dependence in the form of a drift in the prograde azimuthal direction. In addition they are characterized by small length scales in the directions perpendicular to the axis of rotation whereby viscous friction is increased. A sketch of the motion at the onset of convection in a homogeneously heated sphere is shown in Figure 3. For details on the dynamics of these



Geomagnetic Field, Theory, Figure 3 Sketch of convection columns in a rotating, internally heated sphere for Rayleigh numbers close to the critical value.

convection columns and their dynamo action we refer to the review article by Busse (2002).

Because of the small viscosity in the Earth's core, the Lorentz force offers a more effective release of the rotational constraint expressed by condition (20) than does viscous friction. The simplest approach to this problem is to consider the onset of convection in the presence of an azimuthal magnetic field of strength B_0 (Fearn, 1979). The analysis shows that the scale of the preferred mode of convection increases dramatically as B_0 is increased and the critical value of the Rayleigh number and the drift rate decrease. The dimensionless parameter governing this effect is the Elsasser number

$$\Lambda = \frac{B_0^2}{2\Omega\mu_0\rho\lambda} \tag{21}$$

which describes the ratio between Lorentz and Coriolis forces. When the magnetic field becomes very strong such that Λ exceeds unity it exerts an inhibiting influence on convection. It turns out that the minimum Rayleigh number for the onset of convection is achieved for $\Lambda \approx 1$. Eltayeb and Roberts suggested in 1970 that this condition is likely to determine the equilibrium strength of the magnetic field inside the Earth's core. While the condition $\Lambda \approx 1$ appears to fit the amplitude of the geomagnetic field reasonably well, numerical simulations of spherical dynamos do not provide much support for such a relationship. In fact, the dynamical effect of a magnetic field generated by dynamo action is quite different from that of an imposed magnetic field. In present geodynamo models it does not seem to affect the scale of convection significantly nor has it been found that it allows convection to exist at Rayleigh numbers below the critical value for onset of convection in the absence of a magnetic field.

There is still no general agreement about the relationship that governs the average strength of the magnetic field reached in the dynamo process. But it appears likely that the available energy for driving motions determines the average strength of the magnetic field as has been proposed by Christensen and Aubert (2006).

The velocity field displayed in Figure 3 is symmetric with respect to the equatorial plane. Even in its turbulent state the convection flow retains approximately this symmetry outside the tangent cylinder which touches the inner core at its equator. Because of this symmetry the solutions $\vec{B}$ of Equations 13–16 can be separated into two classes: a quadrupolar class that has the same symmetry with respect to the equatorial plane as the velocity field, and a dipolar class that exhibits the opposite symmetry. In both cases the Lorentz force is compatible with the symmetry of the velocity field. The observed geomagnetic field is primarily a dipolar field and so are most of the other planetary magnetic fields, but from a basic point of view quadrupolar dynamos are not less likely. The more complex structure of their poloidal field is balanced by the simpler form of their zonal component. The latter is symmetric with respect to the equatorial plane, where as it is antisymmetric in the dipolar case. The observed geomagnetic field includes a substantial contribution from quadrupolar terms which is not surprising, since the symmetry property exhibited in Figure 3 does not hold inside the tangent cylinder. Moreover, the thermal conditions at the core surface are not likely to be spherically homogeneous because of convection in the Earth's mantle.

The solution of Equations 13–16 becomes much simpler when the geometry of the spherical shell is replaced by that of a cylindrical annulus with a height decreasing with distance from the axis. An early analytical model (Busse, 1975) demonstrates that the dynamo action of convection columns such as those shown in Figure 3 depends on their helicity. The latter is defined as the azimuthal average over the vorticity multiplied by the velocity vector, $\vec{v} \cdot (\nabla \times \vec{v})$. The helicity is generated for example in the columns through the suction exerted by the Ekman layers at the upper and lower boundaries and by the finite change in height of the columns with distance from the axis. This helicity effect appears to dominate also in modern numerical simulations of the geodynamo.

Time dependence of the geodynamo

From observations of the secular variation and from the paleomagnetic evidence for reversals of the direction of the geomagnetic field, it is clear that the mechanism of the geodynamo is not steady. Since a complete model of the geodynamo does not yet exist, the various features that may lead to the observed time dependence cannot be derived from basic mechanisms. Thus, the theories of secular variation and of reversals rely on simplifying assumptions (see *Geomagnetic Field, Secular Variation*; *Geomagnetic Field, Polarity Reversals*). As simulations of the geodynamo become more refined, however, the observed secular variation and the increasing body of data on the process of excursions and reversals will be important for discriminating between different models of the geodynamo.

The time dependence of the nonaxisymmetric part of the magnetic field is a result of the basic dynamics discussed in the preceding section. Even without a magnetic field, the convection motion exhibits a time dependence in the form of a prograde or eastward drift at slightly supercritical Rayleigh numbers, to which a chaotic variability is added as convection becomes more vigorous. In the presence of a magnetic field, this drift is decreased substantially because the Lorentz force balances the ageostrophic part of the Coriolis force. The order of magnitude of the drift corresponds roughly to the observed westward drift of the nondipole part of the geomagnetic field. But since there is likely to be a zonal flow of the liquid core relative to the mantle of a similar order of magnitude, no direct comparison between theoretical and observed drift rates can be made without further knowledge about the velocity field in the core.

The geomagnetic time dependence of internal origin with the shortest duration is known as "geomagnetic jerk."

This term refers to rather abrupt changes in the second derivative with respect to time of the East-West component of the geomagnetic field over the time span of a year or so. Geomagnetic jerks are likely to be the result of magnetohydrodynamic waves in the outer core (Bloxham et al., 2002).

In contrast to the solar magnetic field, the geomagnetic field does not reverse in nearly periodic intervals. The time scale of reversals is an order of magnitude larger than the time scale of about 2×10^4 years for the diffusive decay of Earth's magnetic field. This may suggest the geodynamo is basically a steady dynamo. Recent evidence (Roberts, 2008) suggests, however, that geomagnetic excursions, in which the dipole moment of the Earth decreases to almost vanishing values for a time span of the order of a 1,000 years, occur much more frequently than reversals. No consensus about the origin of excursions and reversals has yet been achieved.

Outlook

In the past 2 decades the dynamo theory of geomagnetism has progressed enormously through increasing availability of computer resources; see *Core Dynamo*. This development will continue in the future with the main goal of reaching higher (and thus more realistic) values of the Coriolis number. Ultimately the lack of data on properties of the Earth's core and lower mantle will inhibit the progress in understanding the geodynamo.

For a more detailed exposition of the foundations dynamo theory and the associated fluid dynamical concepts, the reader is referred to the book edited by Dormy and Soward (2007).

Borehole geophysics

Definition

Borehole geophysics includes all methods that make continuous profiles or point measurements at discrete depth stations in a borehole. These measurements are made by lowering different types of probes into a borehole and by electrically transmitting data in the form of either analog or digital signals to the surface, where they are recorded as a function of depth. The measurements are related to the physical and chemical properties of the rocks surrounding the borehole, the properties of the fluid saturating the pore spaces in the formation, the properties of fluid in the borehole, the construction of the well, or some combination of these factors.

Introduction

The science of well logging was begun by Conrad Schlumberger in 1927 as an application of his work on resistivity measurements of the earth in surface exploration (see *Electrical Resistivity Surveys and Data Interpretation*). From the early measurement of electrical properties by means of normal and lateral resistivity curves, modern logging has progressed through such changes as the introduction of wall-contacting microspacing device, dipmeters, and conductive and inductive techniques. Parameters other than electrical have been utilized, such as radioactive properties of rocks both passive and forced as a result of bombardment by both gamma rays and neutrons; the measurement of acoustic properties, the measurements of other rock properties and auxiliary technique developments such as dielectric logging, temperature log, downhole viewers, remote sensors (dipmeter log, radar system, borehole gravimeter), etc.

The rapid advancement of well-logging techniques is observed in the 1980s and 1990s with the motivation of the petroleum industry to develop ever more cost-effective technology to evaluate thin-bed and nonconventional reservoirs. At the same time, geophysical technology also advanced rapidly with development of new techniques and improved mathematical methodology. The increased use of array tool design (multiple sources and receivers) provides improved vertical resolution, improved and multiple depths of investigations, and enables radial and azimuthal imaging by resistivity tools. Cased-hole resistivity logging may be realized, what could not be possible earlier. Acoustic-array designs, using either dipole or quadrupole sources, can acquire high-quality shear wave data in most types of reservoir rocks. A new generation of nuclear magnetic resonance (NMR) tools using pulse-echo technology provides an improved measurement without the operational restrictions of earlier tools. Nuclear tools have been improved by the use of new high-density gamma-ray detectors that allow higher logging speeds and better repeatability and permit a slimhole, through-tubing tool design. Renewed interest in neutron activation methods has produced new tools based on oxygen and silicon activation, like the pulsed-neutron source sensor. Improvements to existing resistivity and nuclear measurement-while-drilling (MWD) tools plus new caliper and acoustic porosity devices and measurement at the bit, ensure that MWD will continue to replace wireline logging in many situations. High angle, horizontal, and slimhole wells are now common as a result of advances in drilling technology. Wireline and MWD logging have been adapted for use in these wells; and new directionally focused resistivity tools have been developed; logging on coiled tubing is now routine. Improvements of downhole microprocessor-based technology and high-speed digital telemetry make possible the use of high data-rate array and imaging tools as well as increased possibilities of combinations of different tool types. Concurrent improvements in uphole computer processing combined with new visualization techniques made possible by the advent of powerful desktop computers enhance presentation and interpretation of the data acquired with these tools.

A chronological listing of these developmental steps is presented in literature (Johnson, 1962; Segesman, 1980; Prensky, 1994). The applications for geophysical well-logging methods continue to expand away from exploration for natural resources (oil and gas, water, minerals, geothermics) into the field of civil engineering, rock mechanics, disaster prevention, and environmental preservation. Information about recent and emerging developments and trends in well-logging and rock-characterization technology offer a lot of publications from meetings of geophysical societies (proceedings) and geophysical journals and books.

The main objective of borehole geophysics is to obtain more information than can be obtained from conventional drilling, sampling, and testing. Drilling a borehole or well is expensive, but the borehole provides access to the subsurface for geophysical probes. The most obvious log is a description of extracted cores, to provide information of lithology, microfossils, permeability, porosity, and fluids. These logs are used for geological correlation between different wells across an oil field and for the quantitative interpretation of the geophysical logs. The ideal would be to obtain continuous core, but this is very slow and thus expensive, therefore, it is done only for formations of special interest, usually potential oil-producing formations when they can be identified in advance. After drilling, samples may be obtained by sidewall sampling. Samples of fluids from surrounding rocks are also taken with a formation tester. Borehole logs provide continuous records that can be analyzed in real time at the well site. Thus, they can be used to guide completion or testing procedures. Log data are readily reproduced over long periods. Logs also aid the lateral and vertical extrapolation of geologic and fluid sampling data or hydraulic test data obtained from wells. In contrast, samples of rock or fluid from a borehole provide data only from sampled depth intervals and only after laboratory analysis. Data from some geophysical logs, such as acoustic velocity and resistivity, are also useful in interpreting surface geophysical surveys.

The manner in which a well is drilled affects the logging environment, through such factors as the resistivity of the fluid in the well bore, the diameter of the well, the roughness (rugosity) of the borehole wall, and the mud-filtrate invasion of porous formations surrounding the well. The thickness and composition of material between a logging probe and the borehole wall can have an effect on the data set. In general, the larger the borehole diameter, the poorer the quality of the geophysical logs obtained.

Wellbore environment

The physical properties of the geological formations in the vicinity of a borehole are often affected by the drilling process. Further, the temperature, lithostatic stress, and fluid

pressure increase with depth. Logging cable and tools must be constructed in such a way that can withstand the highest temperatures and pressures encountered in the well. Interpretation of well-log data may commonly require temperature correction.

Drilling is usually done using a rotating bit that grinds away the formations to produce cuttings from shales, sand from unconsolidated sandstones, or chips up to a few millimeters in size from solid rocks. The bit is fitted to the bottom of the drill stem, which typically consists of 10-m lengths of steel pipe screwed together. The bit may be turned by rotating the whole drill string of 10 m pipes from its top, but more commonly nowadays the bit is turned up by the mud being pumped through the turbine just behind the bit. Turbine drilling allows much greater control of drilling direction.

Down through the drill stem is pumped drilling fluid, commonly termed mud. It is a mixture of ingredients (liquid and solids) formulated to produce the required rheological properties such as density and viscosity. Drilling mud expedites the drilling operation by cooling, lubricating and cleaning the bit, reducing friction, and transporting cuttings from bit to the surface. Mud also serves to stabilize the wall of the hole, and - by its weight - to prevent any high-pressure gas encountered from blasting out of the hole, and also forms a mud cake, which is a layer made up of the solids in the mud deposited on the sides of hole opposite an intergranular permeable formation ensuring that the hydrostatic pressure of the drilling mud is higher than that of groundwater. The formation is invaded by the liquid of the mud, the mud filtrate, to a distance that depends on the porosity of the formation and properties of the mud. Nearest to the hole is the flush zone, in which the fluids are entirely mud filtrate (apart from some residual fluid that cannot be removed); next is the transition zone, with decreasing replacement until a sufficient distance is the uninvaded zone, quite unaffected by the drilling. In very permeable and porous formations, the mudcake builds up quickly and forms a barrier to further invasion. In less-permeable, low-porosity formations, the buildup is slow and invasion can be very deep. Thus, the resistivity of permeable rocks changes markedly because of the origin of these radial zones (Schlumberger, 1987). In pelitic formations (claystones, siltstones), the changes in elastic and mechanical (strength) properties occur along the borehole walls. Under the influence of drilling mud, the clay minerals swell and the cohesion of the rock is reduced; a low-velocity zone is formed along the borehole wall in the pelitic formations, being the more marked the longer the time interval between drilling and the moment of velocity measurement.

Calibration and standardization of logs

Standardization of logging measurements is the process of checking the response of logging probes in the field, using some type of portable field standard, usually before and after logging a well, to provide the basis for system drift correction in output with time. The Gamma-ray calibration pit and Neutron pit of the American Petroleum Institute (API) in the University of Houston are generally accepted over the world as a basic standard for nuclear logs because of definition of the API Gamma-ray unit and API Neutron unit.

Calibration is the process of converting measuring units of log response to units that represent rock characteristics. Calibration facilities should closely simulate the lithology and geometry to be logged. In many applications, it becomes difficult to utilize such calibration facility for several reasons (namely, the local lithologic environment substantially differs from lithology of calibrations blocks). Then, the calibration is performed by developing a regression between the measured geophysical property (the log) and the property of interest determined from laboratory tests using recovered core. The necessary condition is that the boreholes under study have been carefully cored. In principle, the quality of calibration is indicated by the correlation coefficient given from the regression. This calibration approach is also called "method of key beds."

Benefits and limitations of logging

Well logging differs from most other geophysical methods, not only in being carried out down a borehole, but in relating the physical quantities measured more specifically to geological properties of interest, such as lithology, porosity, and fluid composition. Their main advantage is greater detail, the measurements are made within formations of interest and can be compared with the geological information obtained from the same hole. Borehole logs usually provide continuous data that can be used to guide testing procedure and thus may reduce the number of samples needed and in this way the cost. The data are useful for interpreting surface geophysical surveys. Log data are repeatable over a long period. The repeatability and comparability provide the basis for measuring changes in exploitation wells. Changes in quality of casing, such as grade of corrosion, clogging, or changes in exploitation regime, may also be recorded.

Well logging cannot replace sampling completely. Background information is needed on each new geologic environment to aid log analysis. A log analysis cannot evaluate a set of logs properly without information on the local geology. Logs do not have a unique response, so it is necessary to combine more methods. And the limitation of logging measurements, which should be considered, is the borehole environment (diameter, mud, dimension of a probe, temperature, pressure, velocity of measurement). High technology and sophisticated interpretation procedures can overcome these limitations.

Principles

Well logging uses the principles of almost all methods in geophysical surface surveys: electrical, nuclear, seismic,

geothermal, gravity, magnetic, and electromagnetic and additionally some procedures particular to drilling activity. The latter involve measurement of borehole diameter, bearing and deviation of the borehole from vertical, the strike and dip of beds, and the direction and velocity of fluid moving within a borehole. The instruments and measurements have to be adapted for the special conditions of the subsurface, particularly the confined space of a borehole, where they also have to overcome the alterations produced in the surrounding formation by the drilling. The drilled holes occur from a few meters depth for engineering purposes, to over 10 km for the crust at depth investigation. Most important are those for hydrocarbon exploration and extraction, which commonly reach depths of a few kilometers. The boreholes can be vertical, oblique, even horizontal and geophysical measurement can be also carried out between holes or between hole and the surface: nearwell and crosswell reflection imaging and tomography.

The variation of a property down a borehole is recorded against depth as a log. Most logs are run by lowering the tool (measuring device) on a cable, often called wireline. In some situations, especially if the borehole is deviated far from the vertical, or may be unstable, the tool is placed in a modified section of drill pipe, called a collar, and lowered into a hole at or near the end of the drilling string.

Many geophysical logging techniques were developed in the petroleum industry, which is the most important application in the exploration, evaluation, and production of oil and gas, by providing information on porosity, permeability, fluid content, and saturation of the formations penetrated by a borehole, but logging methods have also been applied in holes drilled for other purposes. Logging for uranium and coal is routinely used because it is relatively easy to identify and evaluate uranium and coal beds for their quality and thickness. Evergrowing applications of logs can observed in water wells for evaluation of porosity and/or fractures, hydraulic parameters and water quality and groundwater dynamics. Shallow holes drilled for the characterization and remediation of contaminants has attracted some new logging techniques. Metal-mining applications continue to rely on the acquisition of core because borehole elemental assay methods have only been developed for a few specific cases. Core is also required for civil engineering (geotechnical) investigations: holes are generally shallow and core makes use of mechanical testing, whereas logging determines rock quality, namely, fractures under in situ conditions. Subsurface temperature measurements serve as critical input to many fields of engineering, exploration, and research such as gas and fluid production engineering, in well completions, in the exploration for hydrocarbons and ore minerals and for high-temperature geothermal resources as well, for testing hypotheses concerning the evolution of the Earth's crust and tectonic processes and for corrections of many temperature-sensitive borehole measurements. Various deep boreholes have been drilled for scientific purposes. Logging technology facilitates data generation for special geological studies concerning sedimentology and stratigraphic correlation, physical properties, mineralogy and geochemistry, fracture and stress, etc.

Instrumentation

Geophysical logging equipment appears complex, and the variety of instruments in use is very large. Any basic measuring system (measuring a natural physical field) consists of a sensor, signal conditioners, and recorders. Logging probes, also called sondes or tools, enclose the sensors, electronics for transmitting and receiving signals, and power supplies. Often there is an isolated artificial signal source in the lower part of the probe, which prevents the direct flow of the signal between source and sensor(s), so that the signal has to go through the rock surrounding the well. The probes (must be watertight and resistant to a high pressure and temperature) are connected to a cable by a cable head screwed onto the top of the probe. Some electric- and acoustic-logging devices are flexible; most are rigid. Probes vary in diameter from 25 mm to 150 mm. The probes are either axially symmetric (centralized) or use bowsprings or springloaded arms to force the probe sensors pad or pads against the borehole wall (side collimation). Some tool arms may be hydraulically driven. All producers publish temperature, pressure, and diameter specifications for their sondes. Because the diameter is limited and much components must be installed in the sonde, in some cases sondes are very long (some meters) even if a large distance between a source and detector is not required. Usually, in deep holes, the probes are stacked to obtain multiple measurements for economical reasons. Measurements are usually made with the probe pulled upward by a winch fitted with a depth counter to insure steady tension on the logging cable when data are recorded. This results in more uniform speed and more accurate depth determination.

The most recent logging systems are fully digital, with control of the logging equipment implemented from a computer keyboard. Logs are displayed by the computer, and a field record is obtained from a printer. In logging of oil or gas wells, the measured data are telemetered to a computation center where they are promptly evaluated automatically.

The well-log equipments are mounted on vehicle chassis, lighter ones (with cable length $\leq$ 500 m) on minibus chassis, while the larger ones (with cable length 1,000–3,000 m) are truck-mounted and those for logging deep wells (to a depth over a 5,000 m) are mounted on heavy-duty trucks. In equipments of medium and large size, the winches are driven by the vehicle motors, in light equipments by separate electric motors or hydraulically. Portable devices are used for logging mine and engineering-geological boreholes of difficult access. They are provided with a logging cable up to 300 m long. The devices for logging in coal mines must be sealed to prevent electrically detonated explosions.

The most widely utilized logging methods are summarized in Table 1. The principles and applications of quoted methods in the Table 1 are explained at length in literature (Serra, 2007; Serra and Serra, 2004; Hearst et al., 2000; Asquith and Gibbon, 1982; Keys, 1997; Chapellier, 1992; Schlumberger, 1987, 1989; Serra, 1986; Rider, 1986; Desbrandes, 1985; Serra, 1984; Pirson, 1977, etc.)

Geophysical Well Logging, Table 1 The most commonly used logs

Type of log	Potential uses	Borehole conditions required	Limitations
Spontaneous potential SP	Lithology, correlation, water quality	Uncased, mud filled only	Needs contrast in solutes in borehole versus formation
Normal and/or lateral resistivity logs (non focused log), Ra	Lithology, correlation, water quality	Uncased, fluid filled only	Influenced by fluid resistivity and bed boundaries
Conductively focused-current logs, LL Micro-focused logs, MLL	Lithology, correlation, water quality, monitoring formation fluid conductivity	Uncased, fluid filled only	Removes some but not all fluid and bed boundary effects
Inductively focused-current logs IL	Lithology, correlation, water quality, monitoring formation fluid conductivity	Uncased or cased with PVC or fiberglass, air or fluid filled	Poor response in massive resistive formations
Gamma-ray log GR Spectral GR	Lithology, correlation	Most conditions	Unusual lithology interpretations in glauconite, arkose and phosphate sands
Gamma–gamma log GGL-D	Bulk density, porosity, moisture, lithology, correlation, well construction	Wide range	Mineralogy may influence calibration through Z effect
X-ray fluorescence log XRF	Elemental composition of ores	Slim uncased holes, constant diameter, pure water or dry	Very short radius of investigation, mineralogy affects the sensibility and accuracy
Neutron log NNL Pulsed neutron porosity logging	Saturated porosity, moisture, lithology, correlation	Wide range, preferably in slim holes, fresh or brackish fluid filled	Ineffective porosity if clay minerals are included in total porosity
Spectroscopy of neutron-induced γ-rays	Mineralogy from elemental analysis	Wide range	Mineralogy may influence calibration
Nuclear magnetic resonance logging NMR	Amount of free fluids in the reservoir rocks	Uncased	Occurrence of magnetic minerals
Elastic wave propagation log (Acoustic log) AL	Saturated porosity, lithology, correlation	Uncased, fluid filled only	Measures primary or matrix porosity rather than total porosity, soft formations
Cement bond log CBL	Fluid content differentiation, bonding of casing	Uncased or cased, fluid filled only	Response gives a circumferential average of bonding, may not detect channels
Acoustic televiewer AT	Character and orientation of fractures, solution openings, and bedding	Uncased, fluid filled, water or mud	Fracture interpretation may be affected by drilling damage to borehole wall
Borehole television BTV	Well construction, secondary porosity, lost objects	Uncased or cased, air or clear fluid	No information in opaque fluid, dark mineral bands mimic fractures
Caliper log CL	Borehole diameter, log correction, well construction, fractures, lithology	Most conditions	Probe performance often affected by borehole deviation
Temperature log TM	Fluid movement in the borehole and/or behind casing, gas inflow, heat flux determination	Water filled	Affected by disturbance to fluid column by probe motion
Fluid conductivity log FRL	Fluid movement in the borehole	Water filled	Affected by disturbance to fluid column by probe motion
Flowmeter FM	Vertical fluid movement	Fluid filled	Spurious results may be cause d by convection, or by movement of fluid in annulus behind screens
Dipmeter and Borehole image technologies	Dip of strata, features of structural geology	Uncased, fluid filled only	
Clinometer	Orientation of the Dip log tool, deviation of the hole from vertical	Non metal casing, wide range	
Well completion methods	Well construction, numerous techniques for checking casing and completion materials, borehole deviation, etc.	All conditions	Labor and equipment intensive; completions may be irreversible and often depend on the specific interpretation

Fundamentals of log analysis

The process of log analysis for a project can be simplified into several basic steps:

- Data processing, including depth matching and meeting all logs and other data from a single well and editing and smoothing the data set
- Correcting borehole effects and other errors
- Converting log measurements to geologic parameters of interest; this is best done with calibration data for each probe
- Combining logs and other data from all wells on a project, so that the data can be extrapolated laterally in cross sections or on maps
- Writing a report describing the analytical procedures and results from the logs

The analysis of log data by computer offers a number of time-saving advantages: a large mass of data can be collated and displayed; logs can be corrected and replotted; scales can be changed, smoothing and filtering operations can be carried out; cross plots can be made between different kinds of logs and core data and calibration curves; correlation functions and rations can be plotted, as well as cross sections and isopach maps. An excellent introduction into this matter is presented by Doveton (1994).

Cross plots

Because valuable quantities can only be deduced from two or more physical properties, a number of logs are run; often several that will function together are combined in a single tool. Frequently used interpretation technique for more reliable estimation of resulting data is called cross plots. Fertl (1981) gives a good overview of the crossplot technique. The basic procedure is to plot log data for a given depth interval in a space defined by two log parameters. That is, one plots all pairs of observed values of neutron versus acoustic or density parameters, or density versus acoustic. Often, at each point in the plane of coordinate system corresponding to a measured pair of values, one plots a digit representing the number of times that pairs of values occur in the interval. Sometimes, the value of a third variable, such as the gamma-ray log, is measured at the same depth interval as the pair of data being crossplotted or is indicated by a color at the point in space; that is called a z-plot. This is particularly convenient in more complex lithologies.

Applications of geophysical well logging

In the oil industry

The *spontaneous potential* (*SP*) *log* represents the measurements of the naturally occurring potential difference between two electrodes: one is movable in the well, the other is fixed (grounded) on the surface. It is measured in millivolts. Electric currents arising primarily from electrochemical factors within the borehole create the SP log response. These electrochemical factors are brought about by differences in salinities between mud filtrate (R_{mf}) and formation water resistivity (R_w) within permeable beds. Because a conductive fluid is needed in the borehole for the SP log to operate, it cannot be used in nonconductive (i.e., oil-based) drilling muds. The concept of static spontaneous potential (SSP) is important because SSP represents the maximum SP that a thick, shale-free, porous, and permeable formation can have for a given ratio between R_{mf}/R_w. SSP is determined by formula $SSP = -K.\log (R_{mf}/R_w)$ [here R_{mf} is derived from the resistivity of mud, which is measured in the laboratory on a sample, while K has a value that depends on the temperature, it is 71 at the typical temperature of 25°C] or chart and is a necessary element for determining accurate values of R_w and volume of shale. The record of SP shows permeable beds and their boundaries and determines formation water resistivity and also volume of shale in permeable beds.

The *resistivity log* is used to determine the fraction of pore space that is occupied by water, called the water saturation, S_w (the fraction that is hydrocarbons $S_{hc} = 1 - S_w$). Because the rock's matrix or grains are commonly nonconductive, the ability of the rock to transmit a current is almost entirely a function of water in pores. Hydrocarbons are also nonconductive; therefore, as the hydrocarbon saturation of the pores increases, the rock's resistivity also increases. The most simple (standard) form of resistivity logging requires three electrodes that are lowered into a borehole, usually two current electrodes (a pair) A, B, and one measuring electrode M. The measuring electrode N is placed on the surface. The electrodes that are lowered into the borehole consist of lead rings fastened to the lower part of the cable or bar. Such an arrangement of electrodes is known as the resistivity logging probe. The contact between electrodes and formation is made through mud, which therefore must be conducting. The resulting curve is called apparent resistivity R_a. The true resistivity R_t would be measured by this simple sonde only in ideal case of homogeneous isotropic rock environment, which case in the borehole does not exists. The shape of resistivity curves obtained by logging is largely controlled by the configuration of electrodes. There are two basic types of simple resistivity probes, that is, *normal and lateral probes*. Normal probes have a distance between unpaired electrodes far smaller than between paired electrodes and represent the classical way of measurement. Measuring a set of R_a curves with different spacing is required to obtain a plot of values of R_a versus probe spacing. Connecting them by a line, we can correlate in this way obtained curves with theoretical curves (master curves) and thus to determine the true resistivity of the layer investigated, the resistivity and the diameter of the invaded zone. Since this process is extremely laborious, a method was sought which would replace this classic resistivity measurement and enable the true resistivity of rocks to be determined in a simpler way.

Research led to the development of a combination tool, known as laterologs, which consist of a central electrode and symmetrical placed other (shielding) electrodes.

They have great advantage as the registered R_a values are closed to the true resistivity (Hearst et al., 2000; Schlumberger, 1989; Serra, 1986). Examples are the microlog, microlaterolog, proximity log, and induction log.

The *radioactivity logs* involve the use of radioactivity to identify lithologies and to help deduce density and porosity, particularly when a hole is cased because they will function with steel case in place. The simple *natural gamma ray-log* responds to total natural gamma ray activity of the surroundings rocks in the borehole, which is due mainly to potassium (K), thorium (Th), and uranium (U, resp. Ra). Of lithologies commonly present, usually shales have the highest activity; sands are intermediate; limestones, dolomite, and quartz are low; while anhydrite, salt, coal, and chert are least active. Occasionally, potash beds, and accumulations of radioactive ores or minerals with higher activity than shales may be encountered. Although the gamma ray activity of shales varies widely on worldwide basis, it tends to be constant in a particular field. It is therefore used to estimate shale content, assuming the maximum value on the log means 100% shale and the minimum value means no shale. The *spectral gamma ray log* records separately the activities of K, Th, and U, so allowing more precise identification of shales, for these differ from other rocks in their relative proportions of the three elements. The *gamma–gamma or formation density log* (GG-D) has a strong source of gamma rays (mostly 137 Cs) at one end of the probe, at the other is a detector of the gamma rays that is shielded so that it cannot receive rays directly from the source, so only gamma rays that results from scattering from the surrounding rock are counted. The *neutron–neutron log* (NNL) is a record of the neutron flux after its passing from a source in the probe through a formation continuous with the borehole to the detector(s). The tool is equipped with a radioactive source that emits fast neutrons. Neutrons travelling through the formation only slow down significantly when they collide with atoms of a similar mass, that is, hydrogen atoms. That is why the measured value of NNL corresponds to the content of hydrogen (not only as its part of water or oil, but independently in the form of hydrogen occurrence in some minerals), referred to as hydrogen index. Other varieties of neutron–neutron log can be used, interrelated with application of different i) sources such as plutonium/beryllium or americium/beryllium or californium sources using neutron accelerators working in pulse regime and ii) detectors besides neutron tubes for epithermal and thermal neutrons using spectral detection of gamma rays produced as a result of few usual interactions of neutrons with formation (nonelastic collisions, neutron absorption, activation).

The *sonic log* measures a record of the elastic waves velocity versus depth in a borehole (see *Seismic Properties of Rocks*). The most simple tool design is single-transmitter tool, which commonly has a radial piezometric, electrostrictive, or magnetostrictive transducer placed along the axis of an acoustic tool. Receivers are mounted in much the same way. The borehole fluid must be a liquid for most tools to function. Care must be taken to acoustically isolate the transmitter from the receiver so signals are not transmitted through the tool (compare with *Seismic instrumentation*). This measuring system fails if the tool is not parallel to the borehole wall or if there are increases in hole diameter. To solve those problems, the *compensated acoustic log* was developed. It has two transmitters at each end, and for each tramsmitter there are two receivers positioned far enough along the tool that the first arrivals at both are rays refracted from the wall of the borehole. The choice of tool frequency is critically important for the generation of useful acoustic logs. High frequency and short wavelength are characterized by detailed spatial resolution and strong attenuation. Low frequency and long wavelength are characterized by poor spatial resolution but low attenuation. Careful study of the effects of frequency on acoustic logging indicates that the most important requirement for logging tool performance is excitation of a single mode. Hearst et al. (2000) find that the most commonly used acoustic-logging frequencies (10–20 kHz) correspond with the source band most likely to excite the single fundamental pair of P and S peaks under typical logging conditions for 15–25 cm diameter boreholes. There are many variations of the continuous velocity log, but all rely more or less on the same principle, though the number and type of sources and receivers are variable. The advent of compact downhole electronics controlled by powerful computers in the logging truck has offered the collection of digital waveforms from logging tools consisting of many receivers. Thus, more information than just the first arrival can be presented, and several methods of presenting the information have been developed: the full-wave display, variable-intensity display. It is now common practice to record the entire waveform digitally for later processing (full-wave acoustic logging). Tool using this mode of acoustic propagation measure both the velocity and the amplitude of the various components of the full acoustic waveform, that is, compressional, shear, and tube (Stoneley) waves (Paillet et al., 1992; Chen, 1989). Advances in characterization of full-waveform data facilitate fracture detection and evaluation, permeability measurement, and well completion. The measured data by continuous velocity log can help identify lithologies although the main application is to estimate the porosity. Other developments in acoustic logging are depicted in publication of Prensky (1994): *reflexion (Pulse-echo) tool* which employs ultrasonic pulse-echo transducers (borehole-televiewer type) that measure signal velocity and amplitude and have application in both open and cased hole. Further advances in acoustic logging are improvements in techniques such as *Downhole seismic, Wellbore resonance, Behind-pipe flow*, etc.

The *temperature log* provides the values of temperature of fluids in a borehole (which is not necessarily in thermal equilibrium with the formation temperature) with depth (in °C) or the temperature increment over a constant distance, that is, the temperature gradient (in $^{\circ}C.m^{-1}$).

The instruments used are thermometers and differential thermometers. As a measuring element, temperature-dependent resistors are used. They are located in the probe so as to be in contact with the fluid with their entire surface, if possible, and to be simultaneously thermally insulated from the body of the measuring probe. The time constant of the device is thus reduced to a minimum. There are two types of temperature-dependent resistors: *thermally positive* (metal wires, e.g., platinum, copper, etc.) and *thermally negative* semiconductor materials (thermistors). These thermally negative materials exhibit substantially higher sensitivity (by as much as 10 times) than the thermally positive materials, but their drawback is that their resistance varies with temperature nonlinearly (in contrast to metals). The temperature sensor independent of its material is usually inserted in a Wheatstone bridge so that temperature-dependent resistor is located in one branch of the bridge, and remaining three branches consist of resistors independent of temperature. For calibration, the logging thermometers are put into a water bath whose temperature is changed gradually and measured as accurately as possible. Desired accuracy is of the order of 0.01°C, the effective accuracy of commercial temperature log is 0.5°C. Very often, the temperature is recorded during the lowering of the probe so as to meet a thermal field with the minimum possible disturbance. The application of borehole-temperature data can be grouped in two broad categories: engineering uses and scientific uses (Prensky, 1992). Engineering uses incorporate: (1) correction of resistivity logs because temperature normally increases with depth and resistivity is a function of temperature (and salinity); (2) reservoir engineering: temperature is required for calculations of hydrocarbon recovery factors, including pressure–volume–temperature relationships and gas–oil ratios; (3) well completion and production logging: this issue includes the production of hydrocarbons and geothermal energy, location of top of casing cement (owing an exothermic reaction of setting cement producing an obvious temperature anomaly), designing cement slurries, detecting channels in the cement, Fluid flow – temperature anomalies are used for identifying the depth of fluid and gas entry or exit, detection of casing leaks and intervals of lost circulation, fluid injection – the contrast in temperature between injected fluid and formation fluids can identify zones of fractures.

Scientific uses are based on heat-flow measurements in boreholes, which are made by combining sets of temperature measurements under a steady temperature regime and thermal conductivity data, following the formula $Q = K\,(dT/dz)$, where Q is heat flow, K is thermal conductivity (known from literature for a given lithology or measured in laboratory), and T is temperature at depth z (when the temperature of mud has equalized with the temperature of the formation). Temperature in a borehole also generally changes with time as it returns toward equilibrium after the disturbance caused by drilling, which can take long time and may range from a few days for a shallow (100–150 m) air-drilled hole to several months for deep mud-drilled oilwells. The heat-flow knowledge contributes to solving a lot of scientific work, such as study of the Earth's evolution, stratigraphic correlation (changes in thermal gradient may correspond to lithology variations), basin analysis and modeling, detection of zones of overpressuring, detecting of regional aquifer flow, exploration for geothermal reservoir, etc.

Borehole imaging technologies are based on three types of sensors: electrical, ultrasonic, and optical. The *dipmeter* can also be considered a form of imaging. The dipmeter is used to determine the dip angle and dip direction of planar features intercepted by the borehole.

Indirect-imaging technologies: *Acoustic and electrical*

The electrical scanning tools rely on a resistivity contrast in the formation to obtain an image and thus limited to holes with conductive mud. Acoustic-imaging tools use a rotating, focused, ultrasonic transducer to measure reflectivity times and amplitude of the pulse-echo from the borehole wall or from the casing. Acoustic amplitude is sensitive to borehole irregularities, thus enabling determination of borehole shape, that is, borehole caliper. Prensky (1994) gives an excellent summary of the literature as regards the possibilities of these borehole imaging tools for identification and analysis of natural and induced fractures; borehole breakouts; thin beds; geologic structure, such as strike, dip, and faults; identification of sedimentary features; interpretation of depositional environment; and evaluation of casing corrosion.

Direct Imaging Technology: *Borehole video* is a wireline tool containing a miniature television camera and light source to obtain high-resolution, real-time visual images of the borehole or tubulars, in both air- or fluid-filled boreholes. The recent introduction of fiber-optic-based systems offers reduction in tool diameter and operation in greater depths. Applications include inspection of casing, tubing and perforations, detection of produced fluid entry, fracture deification, etc.

The *caliper logs* facilitate measurement of the true size and shape of a drilled hole. Most caliper tools are mechanical. The mechanical tool consists of several arms, which are pushed out against the wall of the hole by springs or hydraulic pressure; their extent is converted by an electromechanical device into an electrical signal suitable for recording (proportional to real diameter). Most independent calipers have three or four arms; some have as many as six. The diameter of the borehole is necessary to be known to introduce corrections in quantitative interpretation in almost all methods measured in the boreholes; to calculate the amount of cement needed to fix the casing; to give lithologic information, because washouts are indicative of formation properties – weak formations will tend to wash out, strong ones will not. Caliper logs can also give evidence of the presence of fractures.

The simplest relation between electrical conductivity and formation properties is given by an empirical relation

between formation factor F, defined as the ratio of the resistivity of a rock fully saturated by water R_0 to the resistivity of the water R_w with which the rock medium is saturated, and porosity Φ of clean sands (known as Archie's law): $F = R_0/R_w = a/\Phi^m$, where the coefficient a 'and the exponent m' (cementation factor) can be determined independently from laboratory measurements on core samples and are usually consistent within a lithologic unit. The Archie's formula has some limitations dealing with conductivity of pore space, which is frequently discussed in literature, for example in Hearst et al., 2000. *Dielectric log* is an electromagnetic method using high frequencies, when dielectric properties begin to dominate the propagation characteristics of electromagnetic waves. The presence of water continues to govern the tool response in this high-frequency regime (100 kHz and greater) because the dielectric permittivity of water is significantly greater than that of most earth materials. *Pulsed neutron logging* measures the rate of decay of thermal neutrons in the interval between two pulses of a neutron generator. *Nuclear magnetic resonance logging* (NMR) has been available for many years, since 1960s, but the literature on the applications of borehole NMR has grown very rapidly in the 1990s, and is constantly increasing. Originally, the method is based on the measurement of nuclear spin and magnetic moment of a hydrogen nucleus providing data of the free fluid index – how large a volume of fluid can be obtained from the rock by pumping, and the character of the fluid at the selected depths. The total signal is proportional to the total number of protons present in both the free and bound fluid. NMR measures proton spin–lattice (longitudinal, T1) and spin–spin (transverse, T2) relaxation times; these relaxation times are proportional to pore size and to bound (clays) and free (pore) fluids. In petrophysical terms, these parameters provide information for quantitative determination of permeability, pore-size distribution lithology in reservoir rocks. Kenyon (1997) is an excellent summary of the application of NMR to petroleum industry.

Porosity derived from logs shows summary in the Table 2.

Hydrogeologic applications

Geophysical well logs in water wells can be used to determine lithologic parameters with the aim to evaluate quality and geometry of aquifer system, both with intergranular porosity and fracture and estimate the quality and amount of contained water in the surroundings rocks. In addition to the lithologic parameters, a second important category of information that can be derived from well logs includes data on the character and movement of water in the borehole and the formation. Characteristics of fluids in the well bore can be measured directly, but the data on formation fluids must be inferred from logs. *Logs of the conductivity and temperature* of fluid in the borehole can be related to formation-fluid characteristics, provided that the well has had time to attain chemical and thermal equilibrium with the groundwater reservoir, that an adequate hydraulic connection exists between the hole and the rocks penetrated, and that the inhole flow does not disturb these conditions. *Flowmeters* (Schlumberger, 1993) are probes designed to measure groundwater flow rates along boreholes under ambient and forced gradient (during pump-test) conditions. Impellor flowmeters (Hill, 1990; Keys and Sullivan, 1979) require a significant velocity to rotate impellor blades, so that this probe cannot measure velocities less than about 10^{-1} m/s. Heat pulse (Hess, 1986) and electromagnetic (Molz et al., 1994) flowmeters can detect velocities as low as 10^{-3} m/s.

Techniques based on *time sequence measurements of flow logs* are applied only in clean wells, where mud has been replaced by water and the filter cake does not affect aquifer permeability in the vicinity of the borehole. Under these conditions, changes in the physical properties of the borehole fluids under ambient or stressed conditions reflect the properties of the formation and the water contained in the formation. Various properties of water

Geophysical Well Logging, Table 2 Summary of porosity derived from logs

Log	Property measured	Response to the type of porosity	Extraneous effects	Borehole requirements
Gamma–gamma	Electron density	Total porosity, best for high porosity	Matrix, salinity, water saturation, well construction	Wet or dry, cased or open
Neutron	Hydrogen content	Total porosity, best for low porosity	Bound water, matrix chemistry, salinity, water saturation	Wet or dry, cased or open
Acoustic velocity	Average P-wave velocity	Total porosity, only primary and intergranular	Cycle skipping, poor in high-porosity sediments	Fluid filled and open, high pressure
Resistivity	Pore fluid and interconnected porosity	Effective porosity both primary and secondary	Pore shape, fluid chemistry, water saturation	Open or with perforated PVC casing
Gravity logging	Bulk density	Total porosity	Stationary measurement	Deep reading, >50 ft (18 m)
Nuclear magnetic resonance	Relaxation time of protons	Amount of fluid in pores larger than some minimum	Bound water, very small pores, clay and magnetic minerals	Open hole

in boreholes, such as the conductivity, temperature, transparency, and/or radioactivity (using tracers) as a function of depth, may be used in this fluid column logging method (Chapellier, 1992; Kobr et al., 2005). Many of these properties can be measured using conventional borehole logging equipment. Log-derived hydraulic parameters, such as hydraulic conductivities or transmissivities can be obtained from both flowmeter analysis and time sequence of fluid logs. The last named method is also used to study water flow in the rock medium. Movement of the groundwater flow in sandy aquifers is oriented in the direction of the hydraulic velocity, by the hydraulic conductivity and the azimuth (direction) of the flow. Properly interpreted borehole fluid log can be used to locate zones where water enters and/or leaves the well bore, to estimate the specific yields of these zones and all parameters cited above. Also, this methodology is advantageous in contamination studies, to check the quality of well completion and in shallow boreholes for engineering geology (Hess, 1986; Tsung et al., 1990; Kelly and Mareš, 1993; Mareš et al., 1994; Molz et al., 1994; Paillet and Crowder, 1996; Keys, 1997; Paillet, 2000).

Mineral exploration

Although boreholes are routinely cored to detect and quantify the presence of economic minerals, often the information is incomplete because of missing core, or misleading because of rapid lateral variation of the mineralization (hydrothermal veins). The depth of investigation may be increased by lowering down the hole closer to the ore bodies. The logging system is adapted to the conditions of a mineral exploration program (smaller holes as diameters – from 49–122 mm; as depths – often less than 100 m) using portable logging system with appropriate methodology. The physical properties of interest are density, average mass number, electrical conductivity, and magnetic susceptibility. For disseminated types of ores induced polarization method is useful. Sometimes, self potential method is also used. In this case, the spontaneous potential is of interest in connection with minerals that are electronic conductors, such as massive sulfides, magnetite, and graphite. If two boreholes are available at reasonable mutual distance a cross-hole tomographic survey can be carried out either with seismic or electromagnetic method. This later can map the conductivity distribution between boreholes in the exploration for minerals as well as in environmental and crustal studies (see *Instrumentation, EM*). The modern radioactive methods (X-ray fluorescence analysis, spectroscopy of neutron-induced γ-rays) enable implementation of elemental analysis of the rocks in situ conditions. Due to heavy expenses involved, these methods are not usually considered as the routine ones in mineral exploration. But in some special conditions they may be economic (for example, neutron activation in the borehole on fluorine can be used for calculation of reserves).

Civil engineering, rock mechanics, and environmental preservation

Other well-logging applications for various geological studies can be found in literature (Deltombe and Schepers, 2004; Hurst et al., 1992; Hurst et al., 1990). Almost all methods discussed earlier can be applied, some modifications have been introduced. The most important methods for this reason are the acoustic methods: *sonic log, vertical seismic profiling, seismic tomography.* The main goal of this application is direct (in situ) determination of dynamic elastic properties because sonic logging and waveform analysis provide the means for obtaining continuous measurements of compression and shear velocities. More information can be found in Takahashi et al. (2006).

Summary

Geophysical logs are made by instruments in sondes, or tools, suspended mostly on a wire, with readings usually taken as they are pulled to the surface. Sondes often contain several instruments that can operate without mutual interference. The records of the variation of various quantities down boreholes are called logs, and are of both geophysical and nongeophysical quantities. Geophysical logs are often more valuable when combined than when used singly. Geophysical logging is not only cheaper than continuous coring but it provides information that cannot be obtained on cores, partly because of the alterations produced by the dribbling, and reduces the need for sampling.

Measurements of geophysical parameters in boreholes present the follows characteristics:

- Instruments have to be adapted for the dimensions of a borehole and usually to operate submerged in drilling mud.
- Measurements have to take into account the conditions (pressure, temperature, and technical conditions of the borehole) resulting from the drilling.

The most important application of well logging in the exploration, evaluation, and production of oil and gas, as well as other uses in different geological and engineering branches has been discussed.
